Journal of Medical Internet Research

Journal Impact Factor (JIF) (2023): 5.8
Volume 28 (2026) ISSN 1438-8871 Editor in Chief: Gunther Eysenbach, MD, MPH

Contents

Reviews

Measuring Substance Use With Ecological Momentary Assessment: Scoping Review of Methods and Key Recommendations for a Methodological and Reporting Framework (e92751)
Zachary Bryant, Tim Slade, Kirsten Morley, Jillian Halladay, Katrina Prior, Gezelle Dali, Taylor Braund, Matthew Sunderland, Yannik Terhorst, Johanna Schuller, Lennart Seizer, Louise Thornton, An Nguyen, Jack Wilson, Emily Stockings. 114

Data-Driven Methods Supporting Mental Health and Well-Being Service Delivery: Umbrella Review (e106104)
Salman Ahmad, Raymond Bond, Zeeshan Tariq, Gillian Cameron, Maurice Mulvenna, Edel Ennis, Kristel Miller, Daniel Buckley. 137

Implementation Strategies for Digital Nursing Technologies in Home Care: Scoping Review (e94803)
Deliah Katzmarzyk-Sauerwald, Daniela Holle, Musa Dukuray, Ronny Klawunn, Regina Schmeer-Oetjen, Volker Amelung. 157

Economic Evaluations of Algorithm-Enabled Remote Monitoring of Cardiac Implantable Electronic Devices: Systematic Review (e106939)
Hanan Daghash, Rohan Pandey, Ryan P W Kenny, Cristina Fernandez-Garcia, Edward Meinert, Gurdeep S Sagoo. 184

Efficacy of Digital Health Interventions for Insomnia: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e90905)
Shan Gao, Baiting Zhang, Xiaobo Li. 212

Imaging-Based AI for Predicting Pathological Complete Response in Esophageal Cancer After Neoadjuvant Therapy: Systematic Review and Meta-Analysis (e98520)
Zhiwei Li, Xin Gao, Jing Zhou, Lei Wang, Fuqiang Ren. 251

Effectiveness of Digital Health Interventions on Rehabilitation Outcomes in Patients After Total Knee Arthroplasty: Systematic Review and Network Meta-Analysis (e101277)
Wenhua Zhang, Jingqi Mei, Xun Li, Jun Liu, Keliang Chen, Dianbo Zhang. 278

Cognitive Behavioral Therapy–Based Digital Interventions for Illicit Substance Use Disorders: Scoping Review of Intervention Design, Efficacy Indicators, and Methodological Gaps (e99718)
Sungmin Kim, Su-Ji Jung, Miju Kang, Younghoon Chon, Na-Rae Lee, Hwang Gyu Il, In-Young Choi, Dai Kim, Ji-Won Chun. 319

Applications, Technical Characteristics, and Evaluation Approaches of Retrieval-Augmented Generation in Nursing: Scoping Review (e98495)
Mengqi Chen, Anna Ma, Chengyun Wang, Chuanwu Lyu, Yonghui He, Zhongkang Xu, Xueyun Li, Danyang Cheng, Jie Li, Lina Wang. 350

Application of Digital Health Interventions for Cognitive Management in Children With Cancer: Scoping Review (e104881)
Tao Liu, Saad Saif, MaoTing Tang, Lin Mo. 368

XSL•FO
RenderX

Digital Health Technologies for Mobility Recovery Among Intensive Care Unit Survivors: Scoping Review (e105445)
Yuhang Yan, Jiayan Zhu, Sining Peng, Jin Qiu, Linghong Cheng, Xiaohua Ge. 390

Nurses' Attitudes and Experiences With Generative AI in Clinical Practice: Qualitative Systematic Review (e99489)
Mengmeng Wang, Chunyan Zhang, Naikuan Ye, Huan Li, Yue Bao. 409

Machine Learning Models for Glycemic Prediction in Type 1 and Type 2 Diabetes: Systematic Review and Meta-Analysis (e100653)
Haoran Yang, Diliyaer Abudukeremu, Yuhan Shi, Li Fang, Lei Li, Wenzheng Gu, Yunqi Jia, Rongfang He. 426

The Current Roles of AI in Public Health Practice: Scoping Review (e108250)
Sean Harrison, Claire Tatton, G Melendez-Torres, Joelle Kirby, Sophie Robinson, Daniel Mutanda, Alisha Davies, Jessica Armitage, Rabeea'h Aslam, Tom Arthur, Joht Chandan, Ruth Garside, Jo Thompson Coon, Rhiannon Evans. 450

Digital Health Interventions to Prevent Posttraumatic Arthritis After Traumatic Knee Injury: Scoping Review (e99607)
Josh Cosgrove, Rodrigo Rabello, Emma Dunphy, William Marsh, Dylan Morrissey. 464

Reporting Gaps and Challenges in Randomized Trials of Generative AI for Medical Use: Insights From a Systematic Review (e94543)
Jae Ko, Ji Hwang, Sung Kim, Ji Kwon. 484

The Impact of Telemedicine Interventions on Maternal and Fetal Outcomes in Women With Gestational Diabetes: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e103569)
Hongyue He, Juan Deng, Jingxian Liu, Xiaohong Xu, Jiao Chen, Lixin Liu, Haoyue Zhang, Fang Wang. 506

Technological Integration in Triage With AI and Machine Learning Compared With Conventional Triage and Narrative Synthesis of Telehealth for Patient Prioritization in Emergency and Acute Care Settings: Systematic Review and Meta-Analysis (e93931)
Faii Ashour, Waqas Sami, Intima Alrimawi, Moattar Rizvi, Majeda El-Banna. 527

AI-Based Clinical Decision Support Systems in Primary Care: Systematic Review of Clinical Implementation (e96882)
Florian Naye, Steven Ouellet, Farzaneh Yousefi, Chloé Cachinho, Frédéric Bergeron, Onil Bhattacharyya, Vess Stamenova, Maxime Sasseville.
5 5 4

Environmental Impact of Digital Health Care Technologies in Reducing Carbon Footprints: Scoping Review (e88341)
Sarath Rathnayake, Chinasa Odo, Natasha Alvarado, Hadiza Ismaila, Veronica Parisi, Joshua Pink, Ruth Agbakoba, Rebecca Randell. 591

A Typology of Moderator Practices and Community Guidelines in Online Mental Health Communities to Establish a Framework for Digital Safety: Systematized Review (e99367)
Ashleigh Charles, Stefan Rennick-Egglestone, Karen Fortuna, Neil Coulson, Stine Bjerrum Moeller, Matthew Geeleher, Julian Harrison, Mark Holden, Mike Slade, Fiona Ng. 611

The Forgotten Student—Generative AI Use in Medical Education and the Technology-Integrated Educational Design (TIED) Road Map: Scoping Review (e96099)
Anita Pienkowska, Olivia Ng, Jianlin Hou, Siew Han. 645

Blockchain for Digital Health Governance: Evidence Gap Map and Scoping Review (e96098)
Sarina Yaghobian, Nina Sulkowski, Gary Galambos, Linda Scarazzini, Nicolas Maloumian, Stephane Verhaeghe. 663

Effects of Digital Health Interventions in Chronic Musculoskeletal Pain: Systematic Review and Bayesian Network Meta-Analysis of Randomized Controlled Trials (e95903)
Xuxin Wang, Wen Jing, Yunxia Li, Hui Li, Jing Li, Yuanyuan Liu, Su'e Yuan. 682

Effect of Digital Technology–Based Interventions on Core Symptoms and Cognitive Function in Children With Attention-Deficit/Hyperactivity Disorder: Systematic Review and Meta-Analysis (e103353)
Aiwei Wang, Weijie Qin, Lu Chen, Wei Tuo. 706

Wearable Sensors in Gait Assessment for Parkinson Disease and Stroke in Real-World Environments: Systematic Review and Meta-Analysis (e93413)
Saskia Neumann, Jose Albites-Sanabria, Aileen Naef, Andreas Luft, Lorenzo Chiari, Chris Easthope Awai. 728

Evidence and Future Directions for Pediatric Health Care Chatbots: Systematic Review (e98432)
Seongwoo Yang, Ju Jin, Seng You, Min Kim, Kyung Kim. 750

The Use of Waivers of Guardian Permission in the United States for Pediatric Digital Health Intervention Research Since 2020: Systematic Review (e87047)
Colleen Stiles-Shields, Elyse Shenberger, Ann Bernica, Gabriella Bobadilla, Kandis Fletcher, Jasmine George, Sydney Gordon, Erika Gustafson, Crystal Hernandez, Taylor Hilderbrand, Sarah Kumi, Christine Lee, Sarah Lorduy, Meera Phanse, Lauren Potthoff, Naomi Quezada, Dale Smith, Holly Hudson, Emily Anderson. 767

Accuracy of Artificial Intelligence in Diagnosing Obstructive Sleep Apnea Using Photoplethysmography: Systematic Review and Meta-Analysis (e78718)
Brian Yeo, Esther Gao, Joan Tan, Jun Koo, Yi Lee, Nicole Tan, Adele Ng, Zhou Leong, Thun Ong, Leong Leow, Guang-Bin Huang, Benjamin Tan, Song Toh. 788

Conversational Agents for Asthma and Chronic Obstructive Pulmonary Disease Management: Scoping Review (e98338)
Nurfaizah Hassan, Tiang Teo, Mei Liew, Wee Tan, Wenjie Wu, Timotius Tan, Siti Mustafah, Deborah Poh, Hong-Gu He, Joanne Khor, Genevieve Tan, Si Yoong, Ying Jiang. 800

Assessing the Value for Money of AI-Assisted Technologies for Older Adults: Scoping Review of Economic Evaluations (e104019)
Qi Gao, Minji Hong, Yot Teerawattananon, Yi Wang. 825

Electroencephalography in Subjective Cognitive Decline and Mild Cognitive Impairment: Systematic Review of Biomarkers, Classification, and Prognostic Evidence (e92709)
Sifei Lu, Sheng Hu, Junxuan Huang, Yehua Shi, Dee Yu, Wenting Cao, Mingzhang Yin, Jindong Petersen, Binwen Huang. 843

Explainable Machine Learning Predictive Models for Surgical Site Infections: Scoping Review (e94617)
Rui Sun, Yao Liu, Shuya Lu, Ermira Tartari, Gabriel Birgand, Lin Yang, Lei Zhou. 864

Machine Learning and Deep Learning for the Diagnosis of Cervical Degenerative Diseases: Systematic Review and Meta-Analysis (e92008)
Hongwei Duan, Ruiyuan Chen, Minghui Liang, Liqian Wang, Tianyi Wang, Aobo Wang, Ziqian Ma, Yu Xi, Shuo Yuan, Ning Fan, Lei Zang. . . 8 9 1

AI-Based Measurement Tools for Intrinsic Capacity in Older Adults: Scoping Review (e90411)
Chengji Yu, Ping Lu, Ying Zhou, Juan Zhao, Xiaodie Yang, Dayu Tang, Liying Ying. 912

Clinical Surveillance Technologies in Nonintensive Care Unit Hospital Settings: Systematic Review and Bayesian Network Meta-Analysis of Randomized Trials (e98205)
Xinbo Yin, Xiangmin Li, Guoqing Huang, Xiaokai Wang. 949

Diagnostic Accuracy of AI in Prediction and Assessment of Compromised Free Flaps: Systematic Review and Meta-Analysis (e91174)
Kuan-Chen Huang, Melanie Wang, Yu-Ying Chu, Ren-Wen Huang, Yun-Jui Lu, Cheng-Hung Lin, Chung-Chen Hsu, Shih-Heng Chen, Yu-Te Lin, Che-Hsiung Lee. 965

Stakeholder Perspectives on the Integration of AI in Diabetes Care: Systematic Review of Qualitative Studies (e105329)
Héctor Martínez-Martínez, Julia Martínez-Alfonso, Belén Sánchez-Rojo-Huertas, María Visier-Alfonso, Fernando Sebastián-Valles, Ana Díez-Fernández, Ana Pérez-Moreno, Vicente Martínez-Vizcaíno. 998

Effectiveness, Safety, and Workflow Burden of Large Language Model–Based Medical Report Generation: Systematic Review (e97007)
Jie-Lin Huang, Ji-Qing Zhu, Xiao-Guang Ni. 1020

Clinicians' Attitudes and Perceptions on the Adoption of AI in Mental Health Care: Scoping Review (e92370)
Carly Hudson, Thuy Phan, Marcus Randall. 1042

Performance of AI-Based Screening Tools for Obstructive Sleep Apnea Across Apnea-Hypopnea Index Thresholds: Systematic Review and Meta-Analysis (e92399)
Yujia Lv, Lihui Zhou, Sihan Jiao, Jiaying Lin, Boran Sun, Haixia Hao, Chenxiao Jia, Yuan Wang, Li Bu, Wenli Lu. 1058

Effectiveness of Wearable Digital Therapeutics in Improving Sleep Outcomes Among Individuals With Insomnia: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e93496)
Wenhui Zhu, Mingming Chen, Yixuan Guo, Bin Zhang, Chunliu Luo. 1077

Study of Human Papillomavirus Vaccine–Related Social Media Content Across Eight Social Media Platforms: Scoping Review of Communication Content, Information Sources, and Analytical Approaches (e92040)
Yinghan Xu, Ruichen Cong, Mingxin Liu, Siyu Zhou, Masahiko Sakaguchi, Kayoko Katayama, Qun Jin, Shoji Nishimura, Atsushi Ogihara. . .
1 1 0 2

Fine-Tuning, Retrieval-Augmented Generation, and Hybrid Adaptation of Language Models for Clinical Decision-Making in Health Care: Systematic Review (e104092)
Anshum Patel, Yugant Khand, Sai Vallamchetla, Pengze Li, Cui Tao, Joseph Cheung. 1128

Effects of Telerehabilitation With Exercise as the Core Component on Peak Oxygen Uptake and Blood Pressure in Patients With Cardiovascular Disease: Systematic Review and Meta-Analysis (e95923)
Zhicheng Zhu, Yong Fan, Zhiming Tang, Nangen Song, Youjia Mao, Zijian Zhu. 1141

Real-World Effectiveness of AI-Enabled Clinical Decision Support in Primary Care: Systematic Review (e98630)
Yash Jain, Dishan Wu, Zhong Wang. 1172

AI for Health Care Quality and Patient Safety: Scoping Review of Diagnostic, Predictive, and Decision Support Applications (e95157)
Yang Xu, Jeremy Veillard, Jude Kong. 1187

Effectiveness of Telehealth Care Interventions for Women's Mental Health During and After the COVID-19 Pandemic: Systematic Review and Meta-Analysis (e85494)
Serena Kao, Athina Metaxa, Ranin Soliman. 1210

Comparative Effectiveness of Noninvasive Brain-Computer Interface–Based Interventions for Upper Limb Rehabilitation in Poststroke Hemiplegia: Systematic Review and Network Meta-Analysis of Randomized Controlled Trials (e92940)
Jiabin Xu, Yitian Gao, Siqi Xie, Weikang Jiang, Huiqing Zhang, Lin Qiu, Mengxue Jiang, Lanshu Zhou. 1239

Machine Learning, Large Language Models, and Multimodal AI for Diagnosing Pediatric Rare Diseases: Scoping Review (e96169)
Jungang Zhao, Jiawei Luo, Qiu Li, Yaolong Chen. 1272

Application of Digital Health Technologies in Scoliosis Rehabilitation: Systematic Review Based on the Technology Classification Framework (e91461)
Yujie Guan, Jiaben Xu, Zelin Liu, Qi Qin, Xian Wang, Chengyuan An, Gege Wang, Zhiyuan Zhang, Maomao Gong, Bin Zhao. 1294

The Technologies, Applicability, and Trade-Offs of AI in Palliative Care for Older Adults: Scoping Review (e100216)
Lei Huang, Menglu Xu, Ying Yang, Yi Tian, Zhongkang Xu, Yixuan Wang, Anning Hou, Lili Zhu, Yan Lin, Lina Wang, Yifei Zhao, Shuhong Wei, Peng Wang, Lin Peng. 1323

Diagnostic Performance of Machine Learning for Systemic Lupus Erythematosus: Systematic Review and Meta-Analysis (e90209)
Bingduo Wang, Zichao Wang, Yang Liu, Fangfang Ge. 1341

Extended Reality Interventions for Osteoarthritis of the Knee and Recovery After Total Knee Arthroplasty: Systematic Review and Meta-Analyses (e84753)
Caleb Kalinowski, Elizabeth Goldsmith, Maylen Anthony, Adrienne Landsteiner, Kristen Ullman, Nicholas Zerzan, Tonya Rich, Collin Calvert, Timothy Wilt, Wei Duan-Porter, David Ewart. 1364

Wireless Electroencephalography in Research on Children With Developmental Disabilities: Scoping Review (e84707)
Naeun Park, Yoomi Shin, Jaeeun Kang, Young Lee, Anna Lee. 1396

Cost-Effectiveness of Telemedicine vs Standard Care for the Management of Diabetes Mellitus, Hypertension, and Heart Failure: Meta-Analysis of Randomized Trials (e95367)
Cecilia Acuti Martellucci, Natalia Gregori, Sara Taormina, Igor Diemberger, Barbara Sena, Gaia Ripamonti, Camillo Odio, Maria Flacco, Asher Colombo, Salvatore Vassallo, Lamberto Manzoli. 1420

Digital Health Technology for Improving Physical Function in Adults With Chronic Heart Failure: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e91820)
Zhe Meng, Juncai Li, Jing Yang, Yijia Lin, Qirui Zhang, Longjie Wei, Xiuling Zhou. 1431

Radiomics-Based AI for Predicting Neoadjuvant Immunochemotherapy Pathological Response in Non–Small Cell Lung Cancer: Systematic Review and Meta-Analysis (e93892)
Ziqi Jiang, Yuan Xu, Shuyu Jia, Hongsheng Liu. 1450

Effect of Digital Health Interventions on the Nutritional Status and Quality of Life of Patients With Colorectal Cancer: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e87866)
Xiujuan Feng, Jinna Wang, Huihui Shi, Rui Liang, Wenkai Zheng, Lijun Han, Kueh Cheng, Ruhaya Hasan, Zhuoxin Wang, Ying Wei, Hafzan Yusoff. 1468

Multimodal Digital Therapeutics Enhanced by Task Design and AI for Attention-Deficit/Hyperactivity Disorder Core Symptoms and Executive Functions in Children and Adolescents: Systematic Review and Network Meta-Analysis of Randomized Controlled Trials (e95043)
Zhixiang Hao, Hongli Xu, Chen Wang, Bingjie Wang, Zhengang Qiu. 1488

The Impact of Digitalization on European General Practice From the Perspective of General Practitioners: Systematic Review (e83343)
Julia Fuger, Lisa Niehoff, Erika Zelko. 1524

Digital Physical Exercise Interventions for Cognitive Functions in Older Adults: Systematic Review and Bayesian Network Meta-Analysis of Randomized Controlled Trials (e92764)
Qing Hu, Siyi Sun, Jingru Zhu, Xiaoke Zhong, Shengyu Dai, Changhao Jiang. 1555

Application of Large Language Models in Chronic Disease Care: Mixed Methods Systematic Review and Thematic Synthesis (e90744)
Linghui Zhang, Panpan Huai, Rui Xu, Jingjing Sun, Ruihua Jin, Huimei Lv. 1579

Effectiveness and Implementation of Digital Health Interventions on Physiological, Psychological, and Functional Outcomes in Adults With Multimorbidity: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e90458)
Ruxia Qiu, Hui Feng, Xiaoyang Li, Hongying Zhou. 1601

Motivational Factors, Physical Activity Impacts, and Sociopsychological Effects of Pokémon GO in Players Over the Years: Scoping Review (e89235)
Ghee Koh, Kimberly Low, Shahmir Ali, Hooi Cheng, Ian Ang. 1628

Impact of Large Language Model–Based AI Tools on Physician-Patient Communication: Systematic Review and Meta-Analysis (e77307)
Sven Richter, Clara Buszello, Markus Prem, Sophia Willkommen, Elida Hasani, Ortrud Uckermann, Tareq Juratli, Ilker Eyüpoglu, Witold Polanski. 1652

Barriers and Facilitators to Implementing Digital Health Technologies for Remote Management of NCDs in Rural Areas: Mixed Methods Systematic Review (e93875)
Serine Sahakyan, Selai Akseer, Lusine Abrahamyan, Olivia Metcalf, Sara Allin, Richard Chenhall, Emily Seto. 1669

Accuracy of Machine Learning Algorithms Based on Electroencephalogram in Sleep Apnea Detection: Systematic Review and Meta-Analysis (e93378)
Xiangshuo Li, Lulu Wang, Ting Tang, Yuanyuan Chen, Lan Yang, Hao Cai, Chen Wang, Shuxiao Zhang, Ning Ding, Kouying Liu. 1686

Evaluation Methods for Inference-Time Retrieval-Augmented and Graph Retrieval-Augmented Large Language Models in Health Care: Scoping Review (e90046)
Yuhan Zhao, Yiqun Miao, Rongrong Guo, Yuan Luo, Huiying Wang, Ying Wu. 1713

Cognitive Workload and Mental Burden in Health Care Professionals Interacting With AI: Systematic Review and Meta-Analysis (e93618)
Eun Gong, Chang Bang, Jae Lee. 1740

Comparing Video-Based and Face-to-Face Psychotherapy: Systematic Review and Multilevel Meta-Analysis Across Mental Disorders (e89177)
Christian Meyer-Keirath, Hannah Wallis, Mariebelle Kaus, Michael Schenk, Jolina Holzhaus, Caroline Rometsch, Claudia Buntrock, Christian Apfelbacher, Florian Junne. 1773

Digital Health Communication Engagement Experiences of Older Adults in Community Contexts: Qualitative Systematic Review and Meta-Ethnography (e89179)
Xinxin Wang, Jianying Zhou, Kari Aerzuguli, Yufei Xing, Wei Luan, Qiong Fang. 1790

Effectiveness of Interactive Remote Rehabilitation After Total Knee Arthroplasty: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e89321)
Linbo Peng, Kexin Wang, Limin Wu, Yi Zeng, Bin Shen. 1811

Preferences for AI-Enabled Health Care Technologies: Systematic Review of Discrete Choice Experiments and Reporting Quality Assessment Using the DIRECT Checklist (e103197)
Xinyue Zhang, Shimeng Liu, Yangchen Ji, Yingyao Chen. 1842

Effectiveness of Telerehabilitation for Chronic Nonspecific Low Back Pain: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e94835)
Hongyuan Wang, Zhixiang Liu, Yan Li, Shufang Li, Meng Gong, Lina Pang, Xiangyin Ye, Song Jin. 1861

Attrition in Digital Self-Management Interventions for Patients With Metabolic Dysfunction Associated Steatotic Liver Disease (MASLD): Mixed Methods Systematic Review (e89124)
Rui Pang, Yihong Xu, Xiaoxiao Yu, Jianan Wang, Zhichao Yang, Haofen Li, Xiaojie Zhang, Ning Chen, Xiao Liang, Hongying Pan. 1893

Artificial Intelligence Diagnosis of Obstructive Sleep Apnea Using Overnight Pulse Oximetry: A Systematic Review and Bayesian Meta-Analysis (e80349)
Kvan Yam, Claire Lim, Esther Gao, Jin Koh, Nicole Tan, Adele Ng, Zhou Leong, Chu Phua, Thun Ong, Leong Leow, Guang-Bin Huang, Benjamin Tan, Song Toh. 1916

The Association Between eHealth Literacy and Health Behaviors During and Since the COVID-19 Pandemic: Systematic Review and Meta-Analysis (e94233)
Boyu Ruan, Jiashuai Tian, Xiaoyuan Wang, Dai Su. 1941

Performance of AI in Predicting the Progression of Gestational Diabetes to Type 2 Diabetes: Systematic Review and Meta-Analysis (e87882)
Alaa Abd-alrazaq, Shahira Mohamed, Mohannad Alajlani, Aliya Tabassum, José Ordóñez-Mena, Shehel Yoosuf, Mais Alkhateeb, Arfan Ahmed, Mohammed Bashir, Junaid Qadir, Ali AlSanousi, Javaid Sheikh. 1961

Artificial Intelligence for Evidence Synthesis of Emerging Biologics to Improve Skeletal Health in Osteogenesis Imperfecta: Systematic Review and Meta-Analysis (e85840)
Chengfei Li, Zonglin Dai, Wing Tang, Zesen Gao, Vivien Chan, Mariana Ramirez-Posada, Jiyeong Kim, Eleni Linos, CL Cheung, Ian Wong, Dong Dong, Michael To, Dawn Craig, Xue Li. 1988

User Acceptability and Adoption of AI-Generated Lifestyle Intervention Recommendations: Scoping Review and Theoretical Integration (e93573)
Mingjun Ma, Tiange Sui, Shuo Zhou, Lei Shi, Patrick Lau. 2008

Behavior Change Content and Implementation of Large Language Model–Driven Conversational Agents in Cardiometabolic Care: Scoping Review (e89190)
Yuhan Zhao, Rongrong Guo, Yiqun Miao, Yuan Luo, Huiying Wang, Ying Wu. 2030

The Relation Between eHealth Literacy and Online Health Information–Seeking Behavior: Systematic Review and Meta-Analysis (e93578)
Xi Wang, Tian Shen, Xi Chen, Kejia He, Yuxiang Zhao. 2057

Application of AI in Hypertension Health Education: Scoping Review (e95596)
Haoran Chen, Shenglan Xiao, Tong Wan, Gui Li, Yanhong Peng, Zhimin Wang. 2074

Application of Just-in-Time Adaptive Interventions in Dietary Health Management: Systematic Review (e92139)
Chang Li, Zhen Jiao, Li Zhang, Hang Li, Meng Wang, Wen Guo, Yu Wang, Yang Wang. 2100

How Pandemics Have Reshaped the Respiratory Virus Data Landscape in Europe: Scoping Review (e92917)
Brice Mastrovito, Claire Abou Chakra, Cédric Mahé, Marta Nunes. 2113

Equity-Oriented Design Processes and Evaluation of Digital Health Technologies for Black Communities Beyond Usability: Scoping Review (e88995)
Myesha Senior, Kejah Bascon, Myrtede Alfred, Enid Montague. 2129

Analyzing Social Media to Infer Mental Health Status and Affective States for Crisis and Disaster Management: Scoping Review (e79762)
Francesca Müller, Samuel Tomczyk, Frank Fiedrich. 2156

AI-Powered Simulation for Nursing Education: Mixed Methods Systematic Review (e95167)
Hongzhan Jiang, Ziyan Wang, Wanting Shen, Meiqi Meng, Dan Yang, Xuejing Li, Yufang Hao. 2176

Abstract

Background: Substance use disorders account for a significant portion of the disease burden attributed to mental health globally, but measurement remains suboptimal. Substance use measurement is over-reliant on retrospective recall, often over long periods of time. However, the episodic, contextual, and event- or time-contingent nature of substance use calls into question the validity of these traditional retrospective measurement methods. One method to overcome these limitations is ecological momentary assessment (EMA), which repeatedly samples participant behaviors and experiences in real time, in the context in which they occur.

Objective: This review aimed to systematically identify studies using EMA to measure substance use, provide a comprehensive overview of the EMA methods used, and develop a checklist for improving the reporting of methodological information for future EMA studies in this field.

Methods: Studies published between 2018 and 2026 were sourced from PubMed, MEDLINE, Scopus, and PsycINFO via Ovid databases on March 31, 2026, using terms related to EMA, digital phenotyping, passive sensing, daily diary, and specific terms for each drug type. Studies that actively or passively assessed thoughts and/or behavior in the participants' natural environment/daily lives, in a repeated manner, at or close to the behavior of interest (substance use), using either automatic prompts or notifications, were included. Studies were not excluded according to populations, age, setting, or study design. This study was preregistered on the International Prospective Register of Systematic Reviews (PROSPERO; CRD42023400418).

Results: The search identified 12,487 articles, of which 1236 were reviewed in full; 581 studies were included and extracted, resulting in 431 (n=126,733 participants) unique datasets. Most studies were conducted in the United States (348/431, 80.7%) and focused on alcohol (364/431, 84.5%) and cannabis use (172/431, 39.9%) with or without the presence of other substance use. Alcohol and cannabis measurement co-occurred the most in 128 of 431 (29.7%) unique datasets. Phencyclidine, bath salts, cough syrup, crack, depressants, prescription sedatives, prescription tranquilizers, steroids, khat, buprenorphine, gamma-hydroxybutyrate, kava, and kratom were only measured in one dataset each. This review found limited reporting consistency across compliance, completion windows, attrition rates, survey duration, and data collection technologies in EMA substance use studies.

XSL•FO
RenderX

Conclusions: This review provides the first comprehensive cross-substance synthesis of EMA methodologies used to measure substance use. In contrast to previous reviews focused on individual substances or narrower methodological issues, it compares methodological characteristics across substance groups and identifies common design and reporting gaps. The findings provide practical recommendations to improve the transparency, comparability, reproducibility, feasibility, and data quality of future EMA studies. Greater consistency in reporting missing data, compliance, survey duration, and prompt completion windows, alongside further integration of wearable technologies and research on underexplored substances, will be important for strengthening the real-world application of EMA in substance use research.

(J Med Internet Res 2026;28:e92751) doi:10.2196/92751

KEYWORDS

ecological momentary assessment; substance use; real-time data collection; ambulatory assessment; addiction; daily diary; experience sampling

Introduction

Substance use represents a significant global health burden, with approximately 64 million people aged 15 to 64 years reporting a substance use disorder in 2024 [1]. Despite the rising prevalence and associated health impacts, treatment remains largely inaccessible, with only one in 11 people with a substance use disorder currently receiving appropriate care worldwide [1]. Compounding these challenges is the increasing prevalence of poly-substance use, the concurrent or sequential use of multiple substances, which increases associated risk, including overdose, and complicates clinical interventions due to its unpredictable and dynamic nature [2]. Traditional methods of assessing substance use typically rely on retrospective self-report measures, often covering long recall periods (ie, past 30 days or up to 12 months). Such approaches are inherently limited by recall bias and often fail to accurately capture the rapidly changing contexts and subjective experiences that influence substance use behaviors [3,4]. Given these limitations, leveraging innovative methodologies capable of better characterizing substance use with greater precision and ecological validity is vital [5-7].

One emerging method that overcomes the limitations of traditional approaches is ecological momentary assessment (EMA). Also referred to as experience sampling methods, ambulatory assessment, daily diary, and intensive longitudinal designs, EMA encompasses a set of data collection techniques designed to gather ecologically valid data on behaviors occurring in daily life [6]. Although these approaches differ in sampling schedules, recall periods, temporal resolution, and participant burden, they share the common principle of repeatedly assessing individuals in their natural environments and are considered collectively as EMA throughout this review [6]. These methods repeatedly assess participants within their natural environment at, or close to, the time when the target behavior occurs [6]. Typically, EMA studies actively prompt participants to report on the behavior of interest one or more times per day, according to interval-contingent schedules (at fixed intervals), random-contingent schedules (at random times), event-contingent schedules (following specific events, such as alcohol consumption), or a combination of event- and time-based schedules [4-6]. Due to the widespread accessibility of smartphones and smart wearables, EMA studies can make use of sensors such as accelerometers to passively and noninvasively measure behaviors relevant to substance use, such as physical activity, sleep, and heart rate variability [8]. More recently, passive sensing approaches have also been incorporated within EMA protocols to complement active self-report by providing continuous behavioral or physiological measurements in participants' natural environments.

EMA data collection has previously relied on pen and paper methods; however, portable electronic diaries, text messaging, phone calls, interactive voice recordings, and smartphone apps have significantly enhanced the feasibility and convenience of implementing EMA methods. Recently, EMA methods have been applied to diverse substance use research contexts, such as identifying real-time motives for substance use [9], monitoring the relationship between craving and contextual factors [10], ecologically validating lab assessments [11], and characterizing relationships between mental health and substance use behaviors [12]. However, few studies have been published on the synthesis of methods used in EMA substance use research.

Few reviews have explored the use of EMA in substance use research, with existing EMA research largely focused on specific substances, populations, or health outcomes, such as motives for substance use in daily life [9] or substance use craving, without comparing methods across substance types [9,10]. A methodological review by Jones et al [13] investigated design features associated with compliance among EMA substance use studies published up to 2017, providing valuable insights into participant adherence but focused less on the broader methodological characteristics. However, since 2017, the use of EMA methods and technology has rapidly increased. Singh et al [3] reviewed the reporting of assessment periods for mood variables in EMA substance use research and found inconsistencies and lack of clarity in reporting, which can compromise interpretability and replication. However, by restricting measurement to mood variables, the broad range of substance use antecedents and outcomes was overlooked. While Serre et al [10] offers a valuable synthesis of EMA studies investigating the dynamics of craving and substance use in daily life, it primarily focuses on craving as a predictor of substance use. The review does not provide a broader methodological overview of how EMA has been used to measure substance use itself and offers limited discussion of how EMA methods vary across different substances and population groups. The lack of standardized study design and reporting practices further

XSL•FO
RenderX

complicates the synthesis and comparison of findings across studies.

To date, no review has comprehensively examined EMA approaches used across all substance types, systematically assessed their methodological and reporting characteristics, or identified key areas where methodological improvements are needed, including comparisons of methodological characteristics across substance types and the use of both active and passive EMA approaches. Given the rapid expansion of EMA research across diverse substances, populations, designs, and assessment technologies, a comprehensive methodological synthesis is needed to characterize current practices, identify methodological gaps, and guide the continued adoption of approaches that improve the real-time, ecologically valid measurement of substance use. Accordingly, this review provides a comprehensive synthesis of EMA methodologies used to measure substance use and develops methodological and reporting recommendations to inform the design, conduct, and reporting of future substance use EMA studies.

This review addresses these gaps by:

1. Identifying studies that have used EMA methods to measure substance use across an 8-year period from 2018 to 2026.
2. Describing the methodological characteristics of studies using EMA methods to measure substance use, including those pertaining to participant recruitment, participant characteristics, observation periods, sampling/coverage strategy, frequency and intensity of engagement, compliance/response rates, technology and data collection (text message vs app, etc), study type, and use of reimbursement/incentive.
3. Highlighting research gaps in the EMA substance use literature.
4. Providing recommendations for an EMA study methodological reporting checklist (Table 1) to improve study designs and reporting standards for future EMA substance use research.

XSL•FO
RenderX

Table . Review-derived reporting recommendations and proposed extensions to CREMAS[a] for EMA[b] studies assessing substance use[c].

Domain	Reporting item	Recommendation[c]	Link to CREMAS	Basis for inclusion
Study design	Sample size justification	Report how target sample size was determined, accounting for the multilevel/clustered structure of EMA data where appropriate.	Additional item	Sample-size justification/power procedures were inconsistently reported in reviewed studies.
Data completeness	Compliance rates	Report the proportion of EMA assessments completed, clearly specifying the numerator and denominator used to calculate compliance.	Reinforces CREMAS item 13	Compliance was frequently unreported and inconsistently operationalized.
Data completeness	Attrition	Report participant attrition across the monitoring period and, where applicable, across study waves.	Reinforces CREMAS item 10	Attrition was frequently incompletely reported.
Data completeness	Missing data	Report the extent of missing EMA data and describe procedures used to manage missing observations, including imputation or exclusion where applicable.	Extends CREMAS item 14	Existing CREMAS guidance focuses on predictors of compliance rather than analytical handling of missing EMA observations.
Substance use measurement	Substance use measurement	Report all substances assessed and describe how substance use was operationalized and measured, including timing, quantity/frequency, route, or objective measurement where relevant.	Substance use specific addition	Considerable heterogeneity was observed in how substance use was measured and reported.
EMA measurement	Survey items	Report the EMA items or item sets used and indicate whether they were validated, adapted, piloted, or developed specifically for EMA administration.	Additional item	Measurement items, their provenance, and whether they were developed for EMA designs were inconsistently reported.
Prompting	Prompt completion window	Report the period during which participants were permitted to respond following delivery of an EMA prompt.	Extends CREMAS item 12	Response windows were frequently unreported despite influencing the temporal resolution of EMA data.
Participant burden	Survey length	Report the approximate duration required to complete each EMA assessment.	Extends CREMAS item 9	Survey duration was infrequently reported, limiting assessment of participant burden.
Technology	EMA platform	Report the platform/application and device or technology used to administer EMA assessments.	Reinforces CREMAS item 4	Technology/platform reporting remained incomplete despite existing guidance.

[a]CREMAS: Checklist for Reporting Ecological Momentary Assessment Studies.

[b]EMA: ecological momentary assessment.

[c]Recommendations were mapped against the 16-item Checklist for Reporting Ecological Momentary Assessment Studies (CREMAS). “Reinforces” indicates that an existing CREMAS recommendation was retained because the corresponding reporting deficiency remained evident in the present review; “extends” indicates that the recommendation addresses an aspect related to, but not explicitly specified by, an existing CREMAS item; and “additional” indicates a reporting recommendation arising from the present review that was not explicitly addressed in CREMAS. These review-derived recommendations are intended to complement existing ecological momentary assessment reporting guidance rather than constitute a formally validated reporting guideline.

Methods

Protocol and Registration

This review follows the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines according to the PRISMA-ScR checklist in Checklist 1 and was preregistered on International Prospective Register of Systematic Reviews (PROSPERO; masked for blind review) [14].

Eligibility Criteria

Eligibility criteria were developed according to the Population, Concept, and Context (PCC) framework.

Population

Studies including participants of any age, population, or clinical group, in any setting, were eligible.

Concept

Studies were included if they used EMA or a related intensive longitudinal method, with a minimum assessment frequency of once per day to ensure that included studies reflected intensive longitudinal assessment methods with high temporal resolution. Eligible methods included active or passive assessment of thoughts and/or behaviors within participants' natural environments at, or close to, the behavior of interest (substance use), using automatic prompts, notifications, or ongoing passive sensing. Studies using continuously collected data from digital devices (eg, wearable sensors or smartphone sensing data) to measure substance use or proxy indicators of substance use were also eligible. Studies were eligible if they used EMA to measure substance use, regardless of whether substance use represented the primary outcome, exposure, or a secondary study variable. Studies were required to report explicit measures of substance use (eg, any use, quantity, frequency, and passive proxy measures) at full-text review.

Context

Studies conducted in any geographical or clinical context and using any study design, including observational, experimental, and randomized controlled trials, were eligible. Systematic reviews were included solely for hand-searching reference lists to identify additional eligible primary studies.

Eligible substances included alcohol and drugs listed in the Alcohol, Smoking, and Substance Involvement Screening Test (ASSIST), including cannabis, cocaine, amphetamine-type stimulants (including 3,4-methylenedioxymethamphetamine [MDMA]), inhalants, sedatives, hallucinogens, opioids, and other drugs. Nicotine-only studies were excluded because EMA methodologies in nicotine research have been comprehensively reviewed elsewhere [9,14] and represent a well-established area of EMA research. Further, the high-frequency, habitual pattern of nicotine use typically requires distinct EMA sampling strategies and measurement approaches compared with alcohol and other psychoactive substances, limiting methodological comparability.

Exclusion Criteria

Studies were excluded if they:

- did not explicitly measure substance use at the individual level;
- did not use EMA or another eligible intensive longitudinal assessment method;
- collected data less frequently than once per day;
- reported only a single cross-sectional or one-off assessment;
- described interventions delivered via mobile apps without ongoing repeated assessment or surveillance;
- did not include original empirical data (eg, study protocols, theoretical papers, and commentaries); or
- did not involve human participants.

Information Sources and Search Strategy

We searched PubMed, MEDLINE, Scopus, and PsycINFO via Ovid databases on January 31, 2023, using terms related to EMA, digital phenotyping, passive sensing, daily diary, and specific terms for each drug type (Table S1 in Multimedia Appendix 1 for the full table of search terms). A hand search of the reference lists of relevant systematic reviews was conducted to identify any additional papers that may have been missed during the electronic search. Our protocol did not include search limits by date; however, we deviated from the protocol and imposed a date restriction of January 31, 2018, to January 31, 2023. This decision was made to build upon a recent review of compliance in EMA methodologies for substance use, which synthesized studies published up to 2017, while specifically focusing on methodological developments, reporting practices, and assessment technologies reported in the contemporary literature [12]. An updated search was conducted to capture any additional studies published from January 31, 2023, to March 31, 2026.

Study Selection

Citations were imported into, and deduplicated in, EndNote (version 20.6; Clarivate) and exported and uploaded into the web-based screening platform Covidence (Future Evidence Foundation) for screening [15]. Each article was double-screened for relevance based on titles and abstracts by 6 independent reviewers (ZB, JW, JH, GD, KP, and AN). An identical process was conducted for full-text screening, and any interreviewer disagreement was discussed to reach consensus (interrater reliability: 86% - 100%). Reviewers nominated reasons for exclusion at the full-text stage. If consensus could not be reached, a third reviewer (ZB, JW, and JH) was consulted to resolve the discrepancy.

Data Charting Process

Study data were single-extracted by any one of 5 reviewers (ZB, JW, GD, KP, or AN) using a prepiloted data extraction form in Microsoft Excel. Prior to formal data extraction, reviewers completed a calibration exercise to ensure consistent interpretation of the extraction variables, with uncertainties resolved through discussion among the review team. The extraction templatewas iteratively refined during the original extraction, where necessary during the review process to improve clarity and consistency of variable definitions, as well as the inclusion of any additional relevant variables. Previously extracted studies were updated where changes were made to the extraction template. Following the updated search, which

XSL•FO
RenderX

identified an additional 310 eligible studies, an AI-assisted extraction protocol was implemented in accordance with the Cochrane Responsible Use of AI in Evidence Synthesis (RAISE) guidelines and recommendations [16]. We used *Systematic Review Extractor Pro*, a custom GPT-based tool developed using OpenAI's GPT builder, which had previously demonstrated high performance in extracting participant and methodological characteristics from research articles [17]. The tool extracts prespecified variables directly from article PDFs according to a review-specific extraction template. Further details regarding its development and evaluation have been reported elsewhere [17].

The performance of the AI-assisted extraction procedure was evaluated within this review using a stratified (by publication year) random sample of 95 of the 310 (30.6%) newly included studies. For each study, AI-extracted items were independently checked against the source articles by a human reviewer (ZB and JW) and classified as concordant or discordant. Consistent with the RAISE framework, concordance was based on factual agreement with the source information and did not require identical wording, formatting, structure, or level of detail for free text responses [16]. An item was considered discordant when the extracted value was factually inconsistent with the source article and therefore required human correction. The item-level correction rate was calculated as the number of extracted items requiring correction divided by the total number of extracted items assessed across the validation sample. Fewer than 1% (29/3492) of assessed items required correction. Based on this within-review validation, the AI-assisted extraction procedure was subsequently applied to the remaining 215 newly included studies. Variable-specific correction rates were also examined to identify fields with comparatively lower performance . Ambiguous or insufficiently supported outputs were classified as discordant rather than accepted as correct. No extraction variables were designated a priori as high-risk or requiring additional verification because the extraction framework predominantly comprised directly reported participant and methodological characteristics.

The following data were extracted from general study characteristics: aims/objectives, study design (EMA, daily diary [DD], or sensor data), ecological momentary intervention (0=no and 1=yes), intervention type (0=personalized feedback, 1=just-in-time adaptive intervention (JITAI), sample size, substance use measurement, reimbursement/incentive, and sample characteristics. The following methodological characteristics were extracted; sample characteristics, technology used, collection device (EMA and DD studies: 0=phone/smartphone, 1=electronic diary/personal digital assistant, 2=iPod touch, 3=tablet, and 4=paper; SD studies: 0=ankle-worn device, 1=breathalyzer, and 2=wrist-worn device), survey duration (0=less than or equal to 3 minutes, 1=greater than 3 to less than 5 minutes, and 2=greater than or equal to 5 minutes per survey), prompt window, sample strategy/coverage, statistical analyses, frequency, and intensity of data collection. Sample size, age (years), gender (%), compliance (%), attrition rate (%), assessment period (days), number of daily assessments, survey duration (minutes), completion window duration (hours), and reimbursement (USD) were extracted as numeric. All other data were extracted as free text. Definitions, coding rules, and derivation of extracted variables are provided in the

Extracted variable synthesis section in Multimedia Appendix 1.

Synthesis of Results

Following data synthesis, methodological and reporting recommendations were developed using an iterative, review-informed process. Candidate items were identified from methodological characteristics that were frequently missing, inconsistently reported, or difficult to synthesize across included studies. These items were then mapped against existing EMA reporting guidance, including the Checklist for Reporting Ecological Momentary Assessment Studies (CREMAS), an EMA-specific adaptation of the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting framework [18]. Recommendations were classified as either (1) existing CREMAS items reinforced by findings from this review; (2) extensions or adaptations of existing CREMAS items; or (3) additional recommendations arising from reporting issues identified in substance use EMA studies that were not explicitly addressed by CREMAS. The resulting recommendations were reviewed by members of the research team with expertise in EMA methodology and substance use research for relevance and clarity. They were synthesized into a review-derived reporting checklist intended to complement, rather than replace, existing EMA reporting guidance. Per the protocol, individual assessment of risk of bias of the included studies was not assessed in this scoping review, as the primary aim was to describe and synthesize methodologies, rather than to assess intervention efficacy and the impact of risk on outcomes. To handle the anticipated high heterogeneity of included studies, data were synthesized and described qualitatively into the following categories (as seen in [18]):

1. *Sampling and sample characteristics*: sample strategy/coverage, sample characteristics, sample, substance measured (including identifying studies where multiple substances were measured, described using a heatmap), and sample size.
2. *EMA protocol scheduling*: monitoring periods, prompt frequency and intensity, prompt interval/window, and study duration.
3. *Prompting strategy*: interval type (fixed vs random), use of event-based recording (yes/no).
4. *Technology and administration*: technology used, collection device, and survey duration.
5. *Compliance and attrition*: compliance rates, attrition, and reimbursement.

Results

Study Selection

Of the 9210 studies screened at the title and abstract stage, 1236 progressed to the full-text review, with 581 meeting criteria and included in the current review (Figure 1 and Multimedia Appendix 2). Of the 581 included publications, 395 (67.9%) were primary analyses. The remaining 187 publications comprised 84 (14.4%) secondary analyses of another included

XSL•FO
RenderX

publication, 45 (7.7%) secondary analyses of EMA datasets whose parent publication was not included in the review, and 58 (10.0%) sibling publications drawing on the same underlying dataset as another included publication. Across all included publications, 431 unique EMA datasets were identified. Of these, 348 (80.7%) contributed a single publication to the review and 83 (19.3%) contributed 2 or more publications.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. DP: digital phenotyping; EMA: ecological momentary assessment.

Among the unique datasets, most studies were conducted in the United States (348/431, 80.7%), followed by European countries (30/431, 7.0%), Canada (16/431, 3.7%), the United Kingdom (13/431, 3.0%), Australia/New Zealand (11/431, 2.6%), Asia (7/431, 1.6%), Middle Eastern countries (4/431, 0.9%), Central America (1/431, 0.2%), and Africa (1/431, 0.2%).

XSL•FO
RenderX

Characteristics of Studies

Sampling and Sample Characteristics

Across the 431 unique datasets, there were a total of 126,733 participants. The mean number of participants per study was 294 (range 9-24, 250; median 100, IQR 137.5), with an average 54.0% (SD 22, range 0%-100%) female participants. The average participant age across EMA studies was 29.2 (SD 10.3, range 10-83) years. In terms of population groups, studies most commonly sampled community-dwelling participants who regularly engage in substance use behaviors (84/431, 19.5%), followed by university/college students (76/431, 17.6%), the general population (71/431, 16.5%), high-risk populations (60/431, 13.9%), clinical samples (73/431, 16.9%; 55/73, 75.3% in treatment vs 18/73, 24.7% not in treatment), and with 1.9% (8/431) focusing on specialist groups (Table S2 in Multimedia Appendix 1). According to age classifications reported in included studies, most studies sampled adults (217/431, 50.3%), followed by young adults (186/431, 43.2%), and adolescents (23/431, 5.3%), while only 3 studies (431, 0.7%) examined older adults. Overall, 2 of 431 (0.5%) studies did not report age classification details.

Regarding substance use measurement, 31 unique substances were measured using EMA methods (Table 2). Most unique datasets assessed alcohol use (364/431, 84.5% of total studies accounting for 114,753/126,733, 90.5% of total participants) and cannabis (172/431, 39.9% of studies; 40,572/126,733, 32.0% of participants). The next largest grouping of substances was “other drugs” where the substance under investigation was not explicitly described in the studies (Table S3 in Multimedia Appendix 1 for summary of substance types and definitions).

khat	1 (0.2)	60

[a]EMA: ecological momentary assessment.

[b]Frequency of individual substances measured across the 431 unique datasets included in this scoping review of EMA methodologies for substance use.

[c]Counts represent the number and percentage of unique datasets assessing each substance.

[d]Participant totals reflect the cumulative number of participants contributing to studies measuring each substance. Individual datasets may appear in multiple substance categories where more than one substance was assessed.

[e]MDMA: 3,4-methylenedioxymethamphetamine.

[f]GHB: gamma-hydroxybutyrate.

[g]PCP: phencyclidine.

XSL•FO
RenderX

Co-Occurrence of Substances

Figure 2 presents a heatmap illustrating the co-occurrence of substances measured together across included studies. The color intensity represents the frequency with which 2 substances were assessed within the same study, with darker shades indicating more frequent comeasurement. Alcohol and cannabis were most frequently measured together (128 datasets; Figure 2), followed by alcohol and "other drugs" (75 datasets), cannabis and "other drugs" (61 datasets). Cocaine was also commonly comeasured with alcohol and cannabis (26 and 27 datasets, respectively) as were nonprescription opioids (26 datasets with each). Prescription drug use was less frequently measured in combination with other substances, with the strongest co-occurrence observed with alcohol (17 datasets) and cannabis (15 datasets). Several substances, including phencyclidine, bath salts, inhalants, cough syrup, steroids, buprenorphine, kratom, and kava, were rarely comeasured with other substances, typically appearing in only one or a few datasets.

Figure 2. Co-occurrence matrix of substances measured together. Co-occurrence of substances measured within the same ecological momentary assessment protocol across the 431 unique datasets included in the review. Cell values indicate the number of unique datasets in which each pair of substances was measured together. Lighter colors represent a greater frequency of comeasurement. Diagonal cells are omitted because they represent self-occurrence. GHB: gamma-hydroxybutyrate; MDMA: 3,4-methylenedioxymethamphetamine; PCP: phencyclidine.

Measurement of Substance Use

Among the 424 of 431 unique datasets using self-reported EMA or daily diary methods (Table 3), any use (eg, binary yes/no measures) was the most commonly assessed dimension of substance use, reported in 296 of 431 (68.7%) datasets. This was followed by quantity of use, which was measured in 280 of 431 (65.0%) datasets. Far fewer datasets assessed more specific dimensions of substance use, including type or mode of administration (68/431, 15.8% datasets), frequency of use (38/431 datasets, 8.8%), subjective intoxication (29/431 datasets, 6.7%), duration of use (25/431, 5.8% datasets), time since last use (10/431, 2.3% datasets), and substance potency (12/431, 2.8% datasets). These measurement dimensions varied across substance groups. Compared with other substance groups, cannabis studies more frequently assessed type or mode of administration, frequency of use, subjective intoxication, duration of use, and potency (Table 3).

Duration of use	16 (4.4)	11 (6.4)	1 (1.0)	—	—	—	—	25 (5.8)
Time since last use	5 (1.4)	7 (4.1)	2 (2.1)	2 (4.5)	1 (2.4)	—	1 (4.8)	10 (2.3)
Potency	4 (1.1)	8 (4.7)	—	—	—	—	—	12 (2.8)
Active or passive SD[j]								
Breath alcohol concentration	15 (4.1)	—	—	—	—	—	—	15 (3.5)
Transdermal alcohol concentration	20 (5.5)	—	—	—	—	—	—	20 (4.6)
Sensor other[k]	3 (0.8)	3 (1.7)	—	—	1 (2.4)	—	—	6 (1.4)

[a]Substance use measurement dimensions are reported across the 431 unique self-report ecological momentary assessment, daily diary, and sensor data datasets, stratified by substance group. Values are presented as n (%) of datasets within each substance group. Substance categories are not mutually exclusive, and individual datasets may contribute to multiple substance groups where more than one substance was measured.

[b]Other drugs include unspecified "other drugs," unspecified prescription drugs, injection drug use, inhalants, cough syrup, and steroids.

[c]Opioids include nonprescription opioids, prescription opioid use, heroin, fentanyl, buprenorphine, kratom, and prescription pain reliever use.

[d]Stimulants include cocaine/crack, methamphetamines, amphetamines, prescription stimulants, unspecified stimulants, khat, and bath salts (synthetic cathinones).

[e]Psychedelics include unspecified psychedelics, 3,4-methylenedioxymethamphetamine, and phencyclidine.

[f]Sedatives and depressants include unspecified sedatives, benzodiazepines, prescription sedatives, prescription tranquilizers, unspecified depressants, gamma-hydroxybutyrate, and kava.

[g]EMA: ecological momentary assessment.

[h]DD: daily diary.

[i]Not applicable.

[j]SD: sensor data.

[k]Sensor other contains smartphone passive sensing for alcohol; smartphone passive sensing, puff count, puff duration, and product potency for cannabis; and heart rate variability for stimulants.

Substance use was measured using sensor data in a small number of datasets and was almost exclusively limited to alcohol studies. Transdermal alcohol concentration was measured in 20 datasets and breath alcohol concentration in 15 datasets. One cannabis dataset measured puff duration/count and potency, while one stimulant dataset measured heart rate variability to assess intoxication.

Design

Overview

Of the 431 unique datasets included, 359 (82.0%) were observational, 31 (7.1%) were randomized controlled trials, 28 (6.4%) were feasibility studies, 12 (2.7%) were pilot studies, and one (0.2%) was an open trial design. As seen in Table 4, most unique datasets used an EMA-only (212 studies) approach to data collection. There were 60 unique datasets that included

XSL•FO
RenderX

intervention components with psychological/behavioral interventions (22/60, 36.7%) most commonly reported, followed by mobile health (mHealth) interventions (14/60, 23.3%). EMA-specific intervention methodologies, including ecological momentary interventions (EMIs), JITAIs, and EMA-informed personalized feedback, were used less frequently (Table 5).

Table . Intervention types integrated with EMA[a] protocols across unique datasets[b].

Intervention type	Description	n (%)
EMI[c]	Real-time interventions delivered in response to participants' EMA responses or behaviors such as personalized coping messages, motivational prompts, or behavioral support in naturalistic settings.	6 (10.2)
JITAI[d]	Adaptive interventions that used real-time EMA and/or sensor data to deliver the right type and amount of support precisely when an individual is identified to be at increased risk.	2 (3.3)
EMA-informed personalized feedback	Interventions using participants' EMA data to generate personalized feedback, dashboards, visualizations, or summaries intended to increase self-awareness and support behavior change.	10 (16.7)
Sensor-based intervention	Interventions using wearable or sensor technologies (eg, heart rate variability biofeedback, transdermal alcohol sensors, and wearable monitoring) to trigger support.	8 (13.3)
mHealth[e] interventions	Smartphone applications, web-based platforms, SMS or text messaging, and mHealth interventions used to deliver behavioral support, reminders, or treatment content.	14 (23.3)
Contingency management	Incentive-based interventions where financial or other rewards were dependent on abstinence, treatment adherence, or EMA compliance.	9 (15)
Psychological/behavioral interventions	Conventional behavioral interventions delivered alongside EMA, including CBT[f], MI[g], MET[h], counseling, relapse prevention, and coping-skills training.	22 (36.7)
Pharmacotherapy	Medication-based interventions delivered alongside EMA, including medications such as naltrexone, topiramate, NAC[i], ibudilast, and varenicline.	10 (16.7)
Harm reduction interventions	Interventions designed to reduce drug- or alcohol-related harms, including drug checking, breath alcohol concentration warnings, and safer use strategies.	5 (8.3)

[a]EMA: ecological momentary assessment.

[b]Intervention types integrated with ecological momentary assessment protocols across unique datasets employing interventions. Values represent the number and percentage of unique datasets incorporating each intervention type. Intervention categories were not mutually exclusive; individual datasets could incorporate multiple intervention approaches.

[c]EMI: ecological momentary intervention.

[d]JITAI: just-in-time adaptive intervention.

[e]mHealth: mobile health.

[f]CBT: cognitive behavioral therapy.

[g]MI: motivational interviewing.

[h]MET: motivational enhancement therapy.

[i]NAC: N-acetylcysteine.

Sensor data were collected in 40 of 431 (9.3%) unique datasets, predominantly among studies assessing alcohol. Sensor data were also used in a small number of cannabis and stimulant datasets (Table 3).

EMA Protocol, Scheduling, and Prompt Strategy

The average assessment period across studies was 28 (range 1-180; median 21, IQR 16) days, with an average of 3 (range 1-13) assessments per day. Reporting on number of daily assessments was relatively high with only a small percentage (50/431, 11.6%) not reporting the number of assessments per day as set out in their protocol. Of the 11 sensor data-only studies (Table 4) that measured behavior continuously, the frequency of measurement ranged from every 20 seconds to every 30 minutes. Of the 156 EMA- and DD-only studies (n=56, 35.6%) that reported strict prompt completion windows for

XSL•FO
RenderX

self-report measures, participants were given on average 5 hours and 24 minutes (SD 9.6 hours) to complete a momentary prompt before it expired (range 15-1440 minutes). There were 284 (431, 65.9%) studies that did not report details on prompt completion windows. Most studies (248/431, 57.5%) used a sampling strategy that prompted participants to complete surveys at fixed time intervals (interval contingent only; Table 4).

Technology and Administration

Of the 431 unique datasets, 323 collected self-report data using mobile phones, followed by electronic diaries or personal digital assistant (PDA) devices (30 unique datasets; Table 6). Among studies using smartphones for data collection, 64 distinct smartphone apps and software platforms were used to measure target behaviors. However, a proportion of studies (99/431, 23.0%) did not specify the EMA software or app used for data collection. Web-based surveys (64/431, 14.8%) and email, SMS messaging, or interactive voice response (IVR) systems (57/424, 13.2%) were the most commonly reported nonapp-based data collection methods. A total of 2 studies (0.4%) used smartwatch-based EMA, mostly in conjunction with a companion smartphone app. Among the 111 studies that provided information on momentary survey duration, 60 reported a maximum duration of greater than 3 and less than 5 minutes. See Table 4 for further details.

Table . Data collection devices[a].

Collection device	n (%)
Self-report (EMA/DD)[b,c]	
Phone/smartphone	323 (74.9)
Electronic diary/PDA[d]	30 (7.0)
Computer	6 (1.4)
Tablet	5 (1.2)
iPod touch	2 (0.5)
Paper	2 (0.5)
Smartwatch	2 (0.5)
Missing	56 (13.0)
Sensor data	
Ankle-worn device	16 (3.7)
Breathalyzer	14 (3.2)
Wrist-worn device	8 (1.9)
Smartphone sensors	3 (0.7)
Smart vaporizer	1 (0.2)
Chest-worn device	1 (0.2)

[a]Devices used to collect EMA, DD, and passive sensor data across the included studies. Values represent the number and percentage of studies using each data collection device. Self-report devices were used for EMA/DD studies, whereas sensor devices were used for passive or active sensing studies.

[b]EMA: ecological momentary assessment.

[c]DD: daily diary.

[d]PDA: personalised digital assistant.

Among the 40 unique datasets that used active or passive sensor data to measure substance use behaviors, 16 used ankle-worn devices, 14 used breathalyzers, 8 used wrist-worn devices, 3 used smartphone sensors to collect objective indicators of substance use, one used a smart vaporizer, and one used a chest-worn device (Table S4 in Multimedia Appendix 1 for an extensive list of apps and technologies used to collect data).

Compliance, Attrition, and Reimbursement

Compliance rates were not applicable or not conventionally calculable for 6.0% (26/431) datasets that used event-contingent and/or sensor-only designs. Among the remaining datasets, 109 of 431 (25.3% of all datasets) did not report sufficient information to determine compliance. Across 74.7% (322/431) of the studies that reported compliance rates, these rates were relatively high, with participants completing on average 79.1% (SD 13.5%; range 22.8%-100%) of triggered assessments. Of the 325/431 (75.4%) studies that reported the number of missing datapoints or excluded participants from analyses, the average attrition and/or exclusion rate was 14.9% (SD 16.5; range 0%-86.7%). Common reasons reported for excluding participants included low response rates, failing to report outcome of interest, and equipment malfunction or technical issues. There were 297 of 431 (68.9%) studies that offered financial reimbursement. The maximum potential reimbursement available to participants averaged USD $166 (SD US $152; range USD $0-1130); although reimbursement structures varied considerably between studies, including fixed payments, payments contingent on survey completion, and compliance-based bonuses. Among the studies offering

XSL•FO
RenderX

nonmonetary incentives, university course credits were offered in 19 of 431 (4.4%) studies, 2 of 431 (0.5%) studies offered prize draws, 1 of 431 (0.2%) study offered a festival ticket, and one study (0.2%) offered a Fitbit as reimbursement for study participation.

Discussion

Summary of Evidence

Overall Findings

This study comprehensively reviewed recent studies using EMA to measure substance use, focusing on methodological characteristics such as sampling strategies, engagement frequency, compliance, and data collection methods. Overall, 431 unique datasets were included in the review, predominantly observational studies conducted in the United States. The included studies measured 31 unique licit and illicit substances and, despite considerable variation in the effects and patterns of use across substances, EMA study designs were broadly comparable. However, this may partly reflect protocols measuring multiple substances within the same study.

This review highlighted the predominant focus on alcohol and cannabis in EMA-based substance use research, with relatively little examination of other psychoactive substances. Several reasons may explain this oversaturation, such as broader research priorities, funding availability, and the relative prevalence and legal status of these substances, but it also introduces a potential research bias [19,20]. Expanding EMA research across a broader range of substances will be important to determine whether existing methodological approaches are transferable or whether substance-specific protocols are required.

Most studies assessed substance use over a multiweek period, typically using several prompts per day. While the length of assessment and number of daily surveys varied considerably across studies, overall compliance rates were generally high, with most studies reporting moderate-to-strong participant engagement.

Overall, compliance rates of included studies were high. This may be driven by the short nature of the studies and may speak to the general acceptability and ease of usability of EMA methods in substance use research [13]. This finding may also reflect the acceptability of collecting substance use data through personal mobile devices, which enable relatively discreet, real-time self-reporting without requiring repeated face-to-face or telephone contact with researchers [6]. While good, compliance rates still fell below the suggested 80% compliance benchmark for optimizing data quality [5]. This was particularly evident in studies measuring depressant and sedative use, which reported the lowest average compliance rates. These findings suggest that future EMA research in this area should carefully consider feasibility and adopt strategies to improve participant engagement, such as tailored or indirect notification schedules, flexible completion windows, or enhanced incentives to optimize compliance and data quality [21]. While prior research has found no consistent association between shorter study durations and survey compliance, adjusting reimbursement schedules to better reward sustained participation may offer an alternative approach to improving adherence [13]. Further, this review describes design and participant characteristics (ie, by substance type) in relation to compliance; however, factors associated with compliance were not formally analyzed. Jones et al [13] discuss a detailed overview of factors associated with compliance in EMA studies of substance use.

Methodological Characteristics by Substance Type

Alcohol was the most frequently studied substance, followed by cannabis and other drugs. Given alcohol's global prevalence and significant public health impact, and the increasing legalization and accessibility of cannabis, it is unsurprising that these substances have been prioritized in EMA research [22,23]. Unique to alcohol studies, one cannabis and one stimulant study were the measurement of sensor-based technologies to objectively measure substance use. These included wrist and ankle-worn transdermal alcohol concentration (TAC) monitors and breathalyzers to quantify alcohol use, as well as smartphone sensing data (ie, accelerometers, GPS, number of outgoing calls, etc) to passively detect biologically confirmed or subjective intoxication. Notably, one cannabis study used a smart vaporizer to objectively measure use characteristics, such as puff count and product potency.

While still limited in number, this likely reflects the relative maturity of validated biosensors in alcohol research and, to a lesser extent, cannabis and stimulant research, whereas equivalent technology for substances like cannabis, psychedelics, stimulants, or opioids remains underdeveloped, with a focus on detection rather than level of intoxication [8,24]. As wearable and smartphone sensing technologies continue to evolve, passive sensing has the potential to complement self-reported EMA by reducing participant burden, providing continuous behavioral data, and facilitating more objective measurement of substance use and related behaviors. However, challenges relating to sensor validity across different substances, user acceptability, privacy, and integration with active EMA protocols remain important considerations for future research.

EMA has seen increasing application in studies measuring opioid use, with most focusing on clinical samples or vulnerable populations. This growing body of research signals an important and emerging role for EMA in understanding opioid use patterns in real-world settings. Prior reviews have demonstrated that EMA is both feasible and acceptable among individuals receiving treatment for opioid use disorder, with evidence pointing to its potential utility in predicting and intervening on relapse in a naturalistic setting [25]. Further, EMA has been proposed as a valuable clinical tool to support treatment retention and improve patient outcomes by enabling more responsive, individualized care [26]. Given the scale of the opioid crisis in many parts of the world, there is a compelling case to continue expanding EMA research to better understand opioid use patterns, cravings, and relapse [1]. Doing so may strengthen harm reduction and prevention efforts, support personalized interventions, and potentially improve the delivery of evidence-based care [25,27].

Psychedelic use is of increasing interest due to recent regulatory changes in access to therapeutic psychedelic drugs in several countries and increasing global prevalence rates [1,28]. Despite

XSL•FO
RenderX

this, psychedelics were measured in relatively few studies, and in most cases, they were not the primary substance being targeted. Instead, psychedelics were typically measured as either confounding variables or to describe substance use patterns of participants. For instance, Bragard et al [29] grouped psychedelics with all substances except cannabis to examine associations between drug use and loneliness during COVID-19. Paolillo et al [30] included psychedelics in their dichotomous variable describing any substance use but reported only on alcohol and cannabis outcomes. Similarly, Santa Maria et al [31] reported lysergic acid diethylamide (LSD), MDMA, and phencyclidine use descriptively but aggregated all substances into a single variable in predictive models. Weiss et al [32] and Yeater et al [33,34] measured psychedelic use but excluded it from both descriptive statistics and main analyses. Pop et al [35] used EMA to measure the effects of microdosing psychedelics on state authenticity; however, they did not differentiate between substance type despite distinct variation in nature and duration of effects.

Given recent regulatory changes in some jurisdictions permitting substances like psilocybin, MDMA, and ketamine to be used clinically for conditions like posttraumatic stress disorder (PTSD) and depression [36,37], EMA could offer valuable real-world insights on short-term effects of psychedelics both within and beyond clinical settings. Such research may help to unpack therapeutic mechanisms, inform safer clinical protocols and harm reduction strategies, and improve understanding of recreational use patterns including risk and protective factors.

Reporting Methodological Information

Inconsistent reporting of methodological information posed a key challenge when synthesizing study characteristics. Compliance information was not reported for approximately one quarter of datasets for which it could reasonably be assessed, and many studies also omitted details on attrition, raising concerns about potential reporting bias. This is consistent with EMA research in other areas that have also identified compliance reporting issues, which is not unique to EMA substance use research [18,38,39]. Although reported compliance was generally high and attrition was generally low among studies providing these data, the substantial amount of missing reporting limits confidence in these estimates and may result in overly favorable representation of study performance. More broadly, compliance should be interpreted as an indirect indicator of participant engagement rather than definite evidence of acceptability. Improved and standardized reporting of compliance and attrition is therefore needed to enable more reliable assessment of EMA feasibility, data completeness, and study quality [18].

Reporting of prompt completion windows is another important factor in EMA research [40,41]. This parameter directly impacts the temporal resolution and ecological validity of the data and is especially important when assessing behaviors that are time- and context-dependent like substance use [41]. When completion windows are long or nonexistent, responses may be temporally distant from the behavior of interest, calling into question how “momentary” the data truly are [21]. On the contrary, extending completion windows may be a pragmatic strategy to reduce missing data. Notably, the majority of studies in this review did not report prompt completion windows, highlighting a significant gap in methodological transparency. Thus, researchers must strike a balance between minimizing recall bias and maximizing data retention whilst ensuring that details of prompt completion windows and latency are reported to ensure reproducibility of findings and protocols.

Despite some evidence suggesting that the specific delivery platform can influence compliance and data quality in EMA studies, a small minority of studies did not specify the EMA platform used for data collection [40]. Reporting detailed information on tools used to collect data is important, not only to support replication and confidence in findings, but also to prevent unnecessary duplication of data collection tools when existing platforms may suffice. We recommend that future studies report detailed information on the platform, application, or technology used to deliver EMA prompts.

Participant burden is an important consideration in EMA studies, as it may contribute to attrition, although it remains difficult to quantify. Momentary survey duration may serve as a useful proxy, yet just over 3-quarters of included studies did not report this metric. Although existing literature presents mixed findings on whether or not survey duration is associated with compliance, transparent reporting of momentary survey length is important for evaluating feasibility and participant burden [13,39,42]. Future EMA studies in substance use research should prioritize consistent reporting of survey duration to support comparability with other studies as well as transparency, reproducibility, and consistency of research methods.

Collectively, these reporting limitations have implications beyond methodological transparency. Incomplete reporting limits the ability to critically appraise study quality, assess potential sources of bias, and determine whether EMA protocols were implemented in a manner consistent with their intended design. Further, inconsistent reporting limits meaningful comparisons across studies, the reproducibility of EMA protocols, and opportunities to identify methodological features associated with improved data quality and participant engagement. As EMA methods continue to evolve, more complete and standardized reporting will be essential to maximize the validity, interpretability, and cumulative value of findings for substance use research.

Future Directions

Despite the ubiquity of smartphones and consumer wearables over the past decade, only 3 studies passively assessed substance use with smartphone smart sensors and only 2 studies used a commercially available device, such as Apple Watches (Apple Inc), Fitbits (Google LLC), or Oura Rings (Oura Inc). The majority of studies measuring sensor data used specialized wearables like wrist or ankle bracelets developed specifically to monitor transdermal alcohol concentration [43,44]. This represents a missed opportunity for leveraging widely accessible technologies to capture unobtrusive real-time physiological, behavioral, and environmental markers of substance use as well as potential digital phenotypes related to substance use behaviors. Future EMA-substance use research should therefore prioritize systematically evaluating the feasibility, validity, and

XSL•FO
RenderX

eventual clinical utility of integrating smartphone sensors and consumer-grade wearables to passively capture indirect indicators of substance use and their effects, such as heart rate variability, electrodermal activity, circadian rhythm, speech or keystroke dynamics, and geolocation [45,46]. Achieving this will require multidisciplinary collaboration, particularly with substance use researchers, data scientists, and machine-learning experts, capable of handling highly dimensional and complex sensor data.

Expanding sensor-based methods across different drug classes could not only enhance the ecological validity of EMA but also support the identification of (additional) objective biomarkers of use. This, in turn, may contribute to the development of standardized units of measurement, an approach long established in alcohol research through the concept of a "standard drink," but still largely absent for most illicit substances [47]. Additionally, efforts to quantify substance potency, as seen in a small subset of cannabis studies, are crucial for improving our understanding of dose-response relationships and should be more widely adopted [48]. However, we acknowledge that not all wearables provide raw data and data security issues might hinder research from including this type of data source. Expanding EMA research beyond alcohol and cannabis is also important to ensure that methodological advances are applicable across the broader spectrum of substance use research. Stimulant use, including cocaine, methamphetamine, and amphetamine use, represents an important opportunity for future EMA research. The episodic and context-dependent nature of stimulant use, characterized by rapid fluctuations in craving, affect, and environmental influences, is well suited to high-frequency EMA designs, which may provide greater temporal resolution than current retrospective assessment methods for understanding patterns of use and relapse.

Further, as evidenced in this review, EMA methods offer ample opportunity to support the development and delivery of a broad range of interventions (Table 5) [49]. By leveraging contextual and behavioral data, these approaches have the potential to deliver personalized, context-specific support and intervention at moments of heightened risk or need. Although EMIs and JITAIs were relatively uncommon in included studies, they represent a promising application of EMA methodologies offering researchers the opportunity to intervene within the daily lives of participants in response to real-time behavioral and contextual changes. Taken together, these directions highlight the opportunity for innovation in EMA data collection methods that align with technological advancements and the complexity of substance use behaviors.

Limitations

Methodological and practical limitations within the field of EMA-based research have been reported in detail elsewhere [6,50,51]. There were also several limitations inherent to our own review process. Due to the wide scope of the review and the large number of included studies, we were limited in the number of methodological variables that could be extracted within our time and resource constraints. For example, we restricted the publication timeframe of studies to the last 8 years (2018 - 2026). Additionally, we did not assess whether studies provided participant training for EMA protocols, standardization of included items, nor did we examine in detail the use of burst designs in included studies. These aspects may influence feasibility, participant burden, compliance, and data quality and should be considered in future reviews [50]. Power and sample size calculations remain a common challenge in EMA design due to the intensive, multilevel nature of the data [52]. We did not extract whether included studies performed a priori or post hoc power calculations, nor the method (eg, formula-based vs simulation-based) used to determine sample size. Future syntheses should aim to capture these variables to inform best practice in EMA study planning.

Missing data is a well-known issue in EMA research. Whilst our review did collect information on the proportion of missing data and the number of excluded participants postbaseline, we did not collect information on whether studies reported the mechanisms of missingness (ie, missing completely at random), nor on the statistical techniques used to address it (eg, multiple imputation and maximum likelihood). Given the implications of missing data on validity and inference, future studies should systematically assess and report on these practices. We caution against making value judgments without further context. Nonetheless, our findings reinforce the need for clearer guidance and more consistent application of statistical methods that address the correlated nature of EMA data such as mixed-effects or multilevel models [52].

Although duplicate independent data extraction of all included studies was not undertaken, multiple quality assurance procedures, including reviewer training, calibration, and validation of AI-assisted extraction against a stratified human-reviewed sample, were implemented to minimize extraction errors.

Cross-substance comparisons should be interpreted cautiously because substance categories were not mutually exclusive and many studies measured multiple substances within the same EMA protocol, resulting in overlapping datasets across substance categories. Further, the methodological recommendations and common design practices identified in this review are likely to be most representative of alcohol and cannabis research and may not fully reflect the unique methodological considerations associated with less frequently investigated substances, such as opioids, psychedelics, or novel psychoactive substances.

Finally, we did not extract detailed metrics on response latency (ie, time between prompt and participant response). While such data could inform the ecological validity of EMA responses, we did collect information on prompt completion windows, which may serve as a proxy for temporal proximity between behavior and measurement. Future studies should consider collecting and investigating response latency variables.

Conclusions

This review provides the first comprehensive cross-substance synthesis of EMA methodologies used to measure substance use, offering valuable insight into current design practices, strengths, and areas requiring improvement. Unlike previous reviews, which have focused on individual substances or

XSL•FO
RenderX

narrower methodological aspects, this review systematically compared methodological characteristics across substance groups and developed methodological and reporting recommendations for future EMA studies. While EMA is increasingly recognized as a powerful tool for capturing dynamic, context-dependent substance use behaviors, findings from this study highlight several methodological inconsistencies, particularly in reporting practices and design transparency. Although broad methodological similarities were observed across substance categories, cross-substance comparisons should be interpreted cautiously because many studies assessed multiple substances within the same EMA protocol. There were emerging trends in the application of EMA to underexplored substances such as opioids and a lack of studies focusing on psychedelics. Yet, key gaps remain, including limited use of wearable technologies, underreporting of missing data and compliance, limited reporting of momentary survey duration, and prompt completion window metrics. By identifying current methodological practices, reporting gaps, and emerging trends in EMA technologies, this review provides practical guidance to improve the transparency, reproducibility, and comparability of future substance use research. Addressing these limitations and following the reporting and methodological recommendations provided within this review (Table 1) may improve feasibility, data quality, and reproducibility in future EMA studies. As the field evolves alongside digital health technologies, ongoing methodological refinement will be critical to fully realizing the potential of EMA in substance use research.

Generative AI Use

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the Generative AI Delegation Taxonomy (GAIDeT) taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: code optimization and proofreading and editing. The GenAI tool used was ChatGPT-5.6 Sol. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. This declaration was submitted by Zachary Bryant. Additional note: As described in the Data Extraction and Synthesis section, a custom GPT (Systematic Review Extractor Pro) was used to assist with data extraction. All other AI-assisted outputs were critically reviewed and verified by the authors for accuracy, errors, and potential bias, and were revised as appropriate.

Funding

ZB was supported by the Matilda Center for Research in Mental Health and Substance Use Postgraduate Research Scholarship in Mental Health and Substance Use and further supported via a National Health and Medical Research Council Center of Research Excellence in the Prevention of Mental Illness and Substance Use (PREMISE Next Generation; APP2035308). JH is funded by a Health Systems Impact Embedded Early Career Researcher award co-funded by the Canadian Institutes of Health Research, McMaster University, and St. Joseph's Healthcare Hamilton (HS3-191640). ES and JW are supported by a National Health and Medical Research Council (NHMRC) investigator grant awarded to ES.

Abstract

Background: Mental health and well-being services generate substantial operational and client-level data. Review-level evidence on how data-driven methods support service delivery remains fragmented across technologies and settings.

Objective: This study aimed to synthesize review-level evidence on data-driven methods relevant to mental health and well-being service delivery, including business intelligence (BI), data visualization, and machine learning (ML), and identify applications, implementation challenges, and evidence gaps.

Methods: We conducted an umbrella review following Joanna Briggs Institute methodology and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020. The original searches of Scopus, Web of Science, IEEE Xplore, ACM Digital Library, and PsycINFO were completed on January 27, 2026. During revision, supplementary PubMed and Embase searches were conducted on September 22, 2026. For both supplementary databases, the search was restricted at the database-search stage to publications from 2021 to the current date and to review/systematic review records; eligibility screening then retained the original January 27, 2026, evidence cutoff. All records were independently screened by 2 reviewers using Covidence (Veritas Health Innovation); the reviewer pair differed between the original and supplementary search phases. Eight structured reviews were critically appraised using the JBI checklist and synthesized narratively.

Results: Eight structured reviews were included (3 systematic reviews, 4 scoping reviews, and 1 umbrella review). Seven reviews contributed primary study or source-level evidence, while one umbrella review synthesized 44 reviews. The retrieved evidence was dominated by AI and ML, including conversational agents, natural language processing, and clinical decision support, whereas dedicated BI and operational data visualization syntheses were sparse. Two reviews directly addressed mental health service delivery, 4 were adjacent or partially direct, and 2 were indirect but relevant. Only one review focused specifically on mental health helplines. Service-level benefits were reported more consistently than sustained clinical benefits, although the evidence remained heterogeneous and partly indirect. Safety and implementation concerns included symptom worsening, bias, hallucination, privacy, trust, integration barriers, and inequitable access.

Conclusions: Review-level evidence relevant to mental health and well-being services is uneven and concentrated on AI/ML. Because the search required all 3 concept blocks, BI- and visualization-focused reviews may have been under-retrieved. BI and operational data visualization, helpline-specific implementation, long-term effectiveness, safety, and equity require more direct and prospective evaluation before findings can be generalized across service settings.

Trial Registration: OSF Registries 10.17605/OSF.IO/8NQBC; https://doi.org/10.17605/OSF.IO/8NQBC

Introduction

Mental health and well-being services, including counseling and psychotherapy, helplines, workplace employee assistance programs (EAPs), student support, veteran support, and digital mental health platforms, are under sustained pressure from rising demand, workforce constraints, and the long tail of population mental health needs intensified by the COVID-19 pandemic [1,2]. These services generate substantial operational and client-level data, ranging from referral and caseload records to encounter notes, helpline call logs, app interaction events, and free-text feedback. Translating these data into actionable insights is widely seen as a route to improved service planning, demand management, risk detection, engagement monitoring, and outcome evaluation [3].

Three broad classes of data-driven methods are most commonly proposed for this purpose. Business intelligence (BI) systems and dashboards consolidate operational data into views that support strategic and operational decision-making by service planners and managers [4]. Data visualization, including visual analytics and operational dashboards, supports interpretation of high-volume and multidimensional service data. Machine learning (ML) and broader AI methods, including natural language processing (NLP), conversational agents, predictive modeling, and deep learning, are increasingly applied to risk prediction, screening, conversational service delivery, and the analysis of unstructured patient feedback [5-7].

Research and review activity in this space has grown rapidly since 2020 and remains fragmented across disciplines, populations, and technology categories. Recent reviews have examined ML for suicide prediction [8], digital mental health platforms [9], digital mental health services during the COVID-19 pandemic [10], AI-based conversational agents in health care [11], digital therapeutics analytics [12], and AI and digital health in primary care in low- and middle-income countries (LMICs) [13]. These reviews vary in scope, methodology, and quality. Some are preregistered systematic reviews with formal critical appraisal; others are nonsystematic narrative reviews with no defined search or inclusion criteria. Their findings have not been integrated.

Two distinct questions motivate this review, and they sit at different levels of the evidence base. The first is integrative: multiple recent reviews now address overlapping aspects of AI, ML, NLP, and conversational agents in mental health and well-being service contexts, yet they differ in rigor, scope, and disciplinary framing, and their findings have not been brought together. An umbrella review is the appropriate design for this question precisely because the unit of analysis is the review itself: the task is to appraise and reconcile a set of existing syntheses, not to resynthesize primary studies [14,15]. The second question is diagnostic: it is not known whether BI and operational data visualization, which are routine in mental health service organizations, have been synthesized at the review level at all. Mapping the review-level literature can establish how these technologies are represented within retrieved evidence syntheses. A central contribution of the present review is therefore to characterize the relative sparsity of BI and operational data visualization within the retrieved review-level literature. Given the search architecture, this finding should not be interpreted as proof that no such reviews exist in the wider literature. An umbrella review is distinguished from a scoping review in that it synthesizes only existing reviews, formally appraises those reviews, and assesses overlap in primary studies across the included reviews [14]. It is distinguished from a systematic review of primary studies in that the unit of analysis is the review itself.

One of the reviews eligible for inclusion was itself an umbrella review. Huynh et al [11] synthesizes 44 reviews of AI-based conversational agents across health care. Its presence within the evidence base does not make the present review redundant; it sharpens the rationale for it. The existing umbrella review was bounded to a single technology class, conversational agents, within health care at large, with mental health as one application domain among many and clinical health-related outcomes as its end point. The present umbrella review is bounded instead by a service context: mental health and well-being service delivery. It also spans a broader family of data-driven methods, namely BI, operational data visualization, predictive analytics, and ML, of which conversational agents are only one part, with service delivery and decision-making outcomes rather than clinical outcomes alone as their focus. The 2 reviews therefore answer different questions, and the existing umbrella review is incorporated as one input to the higher-order synthesis presented here rather than duplicated by it.

The present umbrella review synthesizes review-level evidence on the use of BI, data visualization, and ML in mental health and well-being services, focused on service delivery and decision-making rather than clinical diagnostic AI. The function of this review is to raise awareness among service providers of the potential uses of routinely collected data to enhance service provision and inform decisions about adopting into routine practice where such approaches may not currently be considered. The review is organized around 5 research questions (RQs):

- RQ1. What data-driven methods, tools, algorithms, and datasets are reported across the included reviews?
- RQ2. In which mental health service contexts are these methods applied (eg, counseling, EAPs, helplines, emergency departments, and digital platforms)?
- RQ3. What applications are reported, including risk detection, client segmentation, engagement monitoring, and service planning?
- RQ4. What benefits, insights, challenges, and barriers to implementation are reported?
- RQ5. What research gaps and directions for future inquiry can be identified? (This is addressed in the Discussion section.)

Methods

Protocol and Registration

This umbrella review followed the Joanna Briggs Institute (JBI) methodology for umbrella reviews [14] and is reported in line with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement [16]. A

XSL•FO
RenderX

time-stamped Open Science Framework (OSF) registration draft was created on December 2, 2025, initially as a scoping review protocol. The final database searches were completed on January 27, 2026, using the search strategy developed for that scoping review protocol. On May 6, 2026, the protocol was revised to an umbrella review design and formally registered on OSF [17] because the available literature consisted predominantly of existing reviews, making higher-order synthesis the more informative and methodologically appropriate approach. The original database search strategy was retained; restriction to review document types was applied during screening rather than at the database-query stage. The design change therefore altered the unit of analysis and formal eligibility to review-level evidence, and umbrella review procedures for critical appraisal and assessment of primary-study overlap were applied. Formal screening reported in this manuscript was conducted within the dedicated Covidence (Veritas Health Innovation) review for the umbrella review. Because formal umbrella review registration occurred after the final database searches, it is not presented as prospective registration of the umbrella review search stage. The completed PRISMA 2020 checklist is provided in Checklist 1.

Eligibility Criteria

Criteria Overview

Eligibility criteria followed the JBI population-concept-context (PCC) structure adapted for umbrella reviews, where the unit of analysis is an existing review.

Inclusion Criteria

The following inclusion criteria were applied:

- Type of evidence: the formal umbrella review evidence base was restricted to structured evidence syntheses, comprising systematic reviews, scoping reviews, meta-analyses, and umbrella reviews that reported a defined search strategy, explicit eligibility criteria, and a structured synthesis method. Narrative reviews, conceptual reviews, mini-reviews, commentaries, and other nonsystematic publications were excluded from the formal synthesis and could be cited only as context in the Introduction or Discussion.
- Population: users, clients, or service-recipients of mental health or well-being services in nonclinical or service-delivery contexts (eg, counseling, EAPs, helplines, student support, workplace well-being, veteran support, and digital mental health platforms).
- Concept: application of data analytics, BI, dashboards, data visualization, ML, or predictive modeling.
- Context: use of these methods to support service delivery, decision-making, client experience, outcome monitoring, or service planning.
- Publication characteristics: peer-reviewed journal article or conference paper; English language; published between 2021 and 2026.

Exclusion Criteria

Primary studies; narrative reviews, conceptual reviews, mini-reviews, commentaries, and other nonsystematic publications that lacked a defined search strategy, explicit eligibility criteria, and a structured synthesis method; reviews focused exclusively on clinical diagnostic AI applications (eg, magnetic resonance imaging, electroencephalography, and neuroimaging-based diagnostic models) in which the application was not embedded in service-delivery decision-making; reviews unrelated to data analytics, BI, data visualization, or ML; non-English texts; and preprints and reviews not subjected to peer review.

In line with JBI umbrella review methodology, no structured review that met the eligibility criteria was excluded solely on the basis of its critical appraisal findings. Appraisal was used to inform interpretation rather than to gate inclusion. Two nonsystematic publications included in the originally submitted version of this manuscript (Lee et al [12] and Mumtaz et al [18]) were therefore removed from the formal evidence base during revision; when cited, they are identified as contextual literature only.

Information Sources and Search Strategy

Five electronic bibliographic databases were searched to capture relevant review-level literature across health, psychology, and computing disciplines: Scopus, Web of Science, IEEE Xplore, ACM Digital Library, and PsycINFO. Searches were limited to peer-reviewed, English-language literature published between 2021 and January 27, 2026. Reference lists of included reviews were hand-searched for additional reviews. During manuscript revision, supplementary searches were conducted in PubMed and Embase on September 22, 2026, in response to reviewer concerns about biomedical database coverage.

The original database set was selected to reflect the interdisciplinary scope of the review rather than a single clinical discipline. Scopus and Web of Science provided broad multidisciplinary coverage, PsycINFO provided focused coverage of psychology and mental health, and IEEE Xplore and ACM Digital Library were included to capture computing and informatics literature. CINAHL and the Cochrane Library were not searched directly. The supplementary PubMed and Embase searches improved biomedical coverage and were not treated as a rerun of the original search.

The original search strategy used three mandatory concept blocks combined with AND: (1) mental health and well-being services; (2) broader data-driven methods, including data analytics, AI, ML, NLP, predictive modeling, data mining, clustering, and classification; and (3) BI, data visualization, and service or decision-making terminology. Full strategies for the original databases and the supplementary PubMed and Embase searches are provided in Multimedia Appendix 1; the PsycINFO strategy additionally combined APA Thesaurus controlled vocabulary with free-text terms (Multimedia Appendix 2). In both supplementary databases, search-stage restrictions were applied for publication date (2021 to September 22, 2026) and review/systematic review records. Because these searches ran after the original cutoff, the January 27, 2026, evidence cutoff was then enforced during eligibility screening; post-cutoff records were not incorporated into the formal synthesis. Restriction to review-type publications was applied during screening for the original 5 database search rather than at the

XSL•FO
RenderX

query level. During development of the original scoping review strategy, retrieval was checked against 5 known relevant primary-study papers; this was not a formal validation set for review-level BI, dashboard, or data visualization evidence. Because all 3 Boolean concept blocks were mandatory, a review focused on BI, dashboard, or data visualization but lacking broader data-driven method terminology could still have been missed.

The original searches retrieved 1349 records: Scopus 545, Web of Science 375, PsycINFO 66, IEEE Xplore 250, and ACM Digital Library 113. The supplementary searches retrieved 73 additional records: PubMed 30 and Embase 43. Across both phases, 1422 database records were therefore identified. Covidence identified 304 duplicates in the original import, and 2 additional duplicates were removed manually; the supplementary imports contributed 40 further duplicates (15 from PubMed and 25 from Embase), for a total of 346 duplicates removed overall.

Study Selection

All retrieved records were managed in Covidence (Veritas Health Innovation). For the original 5-database search, 2 reviewers (SA and EE) independently screened title/abstract records and full-text reports against the predefined eligibility criteria, and DB contributed to title/abstract screening; conflicts were discussed in review team meetings involving GC and MM, with MM making the final eligibility decision where consensus was not reached. The original database queries were not restricted to review document types, so nonreview records were removed during screening, and full-text exclusions were recorded with reasons. For the revision-stage PubMed and Embase searches, the 33 deduplicated supplementary records were independently screened in Covidence by SA and GC using the same eligibility criteria and the evidence cutoff. Both reviewers assessed the 2 reports that progressed to full text, and both met the eligibility criteria; Wah [19] and Hazhir et al [20] were therefore incorporated. Hazhir et al [20] was newly identified by the supplementary search. A record for Wah [19] had also been retrieved by the original search and excluded at original title and abstract screening because its title and abstract presented a broad eHealth and health care–chatbot scope, which the screeners judged to be outside mental health service delivery; full-text review after the supplementary search showed that mental health support was an explicit application domain. The supplementary record was not flagged by Covidence as a duplicate of that record. The same eligibility criteria and evidence cutoff were applied to the original and supplementary records; only the reviewer pair differed.

Critical Appraisal of Included Reviews

Each included structured review was appraised using the 11-item JBI critical appraisal checklist for systematic reviews and research syntheses. This single checklist was applied across systematic, scoping, and umbrella reviews because it is the instrument specified in JBI umbrella review methodology for research syntheses [14], and a common instrument allowed item-by-item comparisons across the evidence base; items that did not apply to a review's design were recorded as not applicable (NA). Appraisal was conducted independently by 2 reviewers (SA and GC), with disagreements resolved through discussion and, where necessary, adjudication by a third reviewer (EE). Across the 8 formally included reviews, the 2 independent reviewers agreed on 70 of 88 item-level judgments before adjudication (79.5% raw agreement); the 18 disagreements were resolved through the established adjudication process. Responses were recorded as "Yes," "No," "Unclear," or "NA." NA was retained as a distinct applicability judgment rather than treated as a methodological failure or converted to 0. Item 5 (appraisal criteria) was judged NA where a review undertook no critical appraisal of its included studies, and item 6 (independent appraisal by 2 or more reviewers) was judged "No" where independent dual appraisal was not reported; at final revision, 2 adjudicated judgments for the reviews added at revision (Wah [19], item 5; Hazhir et al [20], item 6) were harmonized with this convention. Because applicability differed across scoping, systematic, and umbrella review designs, item responses were not converted into composite numerical scores or high/moderate/low quality categories. Critical appraisal was interpreted descriptively at item level and used to temper conclusions; no review meeting the eligibility criteria was excluded solely on appraisal findings.

The final adjudicated item-level judgments for all 8 structured reviews are reported in the Results. Lee et al [12] and Mumtaz et al [18] are nonsystematic contextual publications and were not included in the formal JBI appraisal.

Assessment of Primary-Study Overlap and Corrected Covered Area

Because included reviews can share underlying evidence, we constructed a citation matrix and calculated the corrected covered area (CCA) using the formula established by Pieper et al [21]: $CCA=(N-r)/(r\times(C-1))$, where N is the total number of included-unit occurrences, r is the number of unique units after deduplication, and C is the number of reviews evaluated in the tier. A single omnibus CCA was not appropriate because 7 included reviews synthesized primary study or source-level evidence, whereas Huynh et al [11] was an umbrella review of 44 reviews. We therefore calculated CCA at 2 primary-study tiers: (1) the 7 primary-level reviews (C=7; N=264 included study/source occurrences); and (2) the direct mental health service-delivery subset comprising Dwyer et al [22] and Gu et al [23] (C=2; N=91). Unique units (r) were identified from the included studies or sources reported by each review. Where part of a review's included-study list could not be identified from the published article, we also calculated a worst-case CCA that assumed that every unidentified study duplicated a study in another review. In Tier 3, overlap between the 44 constituent reviews of Huynh et al [11] and the 7 standalone reviews was assessed by direct counting rather than by CCA because the comparison set at that level was the list of reviews included in the present umbrella review, which was not itself a constituent review. Overlap matching used author, title, publication year, and DOI where available; topic similarity, chatbot names, or shared surnames alone were not treated as matches. CCA values were interpreted using the thresholds described by Pieper et al [21].

XSL•FO
RenderX

Cross-tier relationships were reported separately rather than counted as within-tier duplication because they represent different units of analysis. Full calculations, citation matrices, and limitations are reported with the Results.

Data Extraction

Data were initially extracted from each included review by the lead reviewer (SA) using a structured data-extraction form (Multimedia Appendix 3). The form captured bibliographic details; review type and stated methodology; review aims and RQs; number and type of primary studies included; population and service context; data-driven methods; tools, platforms, datasets, and algorithms; reported applications, outcomes, benefits, challenges, and limitations; authors' conclusions and stated evidence gaps; and item-level JBI critical appraisal judgments. A second reviewer (GC) independently cross-checked the completed extraction against the source reviews. Differences or ambiguities identified during this verification were discussed by SA and GC and resolved by consensus; where source reporting remained unclear, the extracted entry was qualified rather than inferred. When an included review reported an individual-study effect estimate, diagnostic-performance figure, or named study example, this information was treated as secondary-reported data from that review rather than as an independently assessed primary-study finding. Primary studies were not independently retrieved, critically appraised, or reanalyzed to verify these figures. A provenance table links such examples to the included reviews from which they were extracted.

Synthesis

Quantitative meta-analytic resynthesis was not planned because of heterogeneity in review scope, methods, and outcomes. Findings were synthesized narratively in line with JBI umbrella review guidance and structured around 5 RQs. RQ1-RQ3 were summarized in a concise main-text matrix, supported by a full review-by-review matrix of methods, service contexts, applications, and evidence directness. RQ4 was synthesized separately, and RQ5 was addressed in the Discussion. Service-level findings and technology-level findings were distinguished explicitly. To make applicability to mental health service delivery explicit, each formally included review was classified during revision as direct, adjacent, partially direct, or indirect yet relevant evidence. SA assigned the classifications, and GC verified them against the source reviews; differences were resolved by discussion. This reporting classification did not alter eligibility or appraisal and was used to calibrate interpretation and transferability across service contexts.

Results

Search Results and Study Selection

Across the original and supplementary searches, 1422 database records were identified: 1349 from the original 5 databases and 73 from the supplementary PubMed and Embase searches. A total of 346 duplicates were removed (306 from the original search workflow and 40 from the supplementary imports), leaving 1076 records for title and abstract screening. Of these, 1057 were excluded at the title and abstract stage, including 31 of the 33 supplementary records. Nineteen reports were sought and assessed at full-text review (17 from the original search and 2 from the supplementary searches). Eleven full-text reports were excluded, all from the original search, for the following reasons: wrong setting (n=2), wrong study design or nonsystematic review (n=5), wrong patient population (n=1), and no data-driven or AI method focus (n=3). Both supplementary full-text reports met the eligibility criteria, resulting in 8 structured reviews in the final formal synthesis (Figure 1). Hand-searching of the reference lists of included reviews identified no additional reviews.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram. The final flow integrates the original 5-database search with the revision-stage PubMed and Embase searches while preserving the original January 27, 2026, evidence cutoff.

Characteristics of Included Reviews

Table 1 summarizes the characteristics of the 8 structured reviews included in the formal umbrella synthesis. The set comprises 3 systematic reviews [13,19,23], 4 scoping reviews [20,22,24,25], and 1 umbrella review [11]. Six reviews reported 235 included studies in total (Chew and Achananuparp [24], 26; Dwyer et al [22], 70; Feizollah et al [25], 52; Gu et al [23], 21; Saif-Ur-Rahman et al [13], 48; and Hazhir et al [20], 18), predominantly primary studies; Wah [19] reported 29 included sources of mixed types rather than a wholly primary-study set, and Huynh et al [11] synthesized 44 reviews. Lee et al [12] and Mumtaz et al [18] remain outside the formal evidence base and are cited only contextually where relevant.

[l]Sources of mixed type, including secondary reviews, book chapters, preprints, and web pages.

[m]EBSCO: Elton B Stephens Company.

Geographic and population scopes varied considerably. Dwyer et al [22] and Gu et al [23] provided the 2 direct review-level sources for mental health service delivery. Huynh et al [11], Saif-Ur-Rahman et al [13], Wah [19], and Hazhir et al [20] were classified as adjacent or partially direct because each included a substantive or explicit mental health component within a broader health care or primary care scope. Chew and Achananuparp [24] and Feizollah et al [25] were classified as indirect yet relevant. Gu et al [23] was the only included review explicitly focused on clinical decision support systems (CDSSs) in mental health helpline services.

All 8 formally included publications were structured evidence syntheses meeting the umbrella review eligibility criteria. Lee et al [12] and Mumtaz et al [18] were cited only as contextual literature and were not included in this table. Rows follow the review numbering (P1-P8) used throughout. Although Huynh et al [11] and Hazhir et al [20] have 2026 volume dates, they were published online on November 26, 2025, and December 30, 2025, respectively, before the January 27, 2026, evidence cutoff.

Methodological Quality

Item-level JBI critical appraisal findings for the 8 structured reviews are presented in Table 2 and Multimedia Appendix 4. All 8 reviews clearly stated a review question or objective, provided appropriate inclusion criteria, and all provided recommendations and future research directions supported by their syntheses. The search strategy was judged yes for 7 reviews and unclear for Wah [19]. The adequacy of information sources was judged yes for 6 reviews and unclear for Gu et al [23] and Wah [19]. Appraisal criteria were judged yes for Huynh et al [11] and Saif-Ur-Rahman et al [13] and NA for the other 6 reviews, none of which undertook formal critical appraisal of included studies. Independent critical appraisal by at least 2 reviewers was judged yes for Huynh et al [11] and Saif-Ur-Rahman et al [13] and no for the other 6 reviews. Methods to minimize extraction errors were judged yes for 6 reviews and unclear for Chew and Achananuparp [24] and Gu et al [23]; methods used to combine studies were judged yes for 5 reviews and unclear for Chew and Achananuparp [24], Gu et al [23], and Wah [19]. Publication bias assessment was generally absent, unclear, or NA. These item-level limitations informed the interpretation.

[a]JBI: Joanna Briggs Institute.

[b]Y: Yes.

[c]U: Unclear.

[d]Not applicable. It indicates that an item was judged not applicable to the methodology or synthesis undertaken and was not treated as an adverse quality judgment or converted to zero. Appraisal findings were interpreted at the item level; no composite numerical score or high/moderate/low quality band was assigned. Item 5 (appraisal criteria) was judged not applicable where a review undertook no critical appraisal of its included studies; item 6 (critical appraisal by ≥2 reviewers) was judged No (N) where independent dual appraisal was not reported. Final judgments reflect third-reviewer (EE) adjudication of conflicts between the 2 independent appraisers (SA and GC), with P7 item 5 and P8 item 6 harmonized with this convention at final revision.

[e]N: No.

Two review-specific methodological cautions are relevant. First, the umbrella review by Huynh et al [11] reported a per-item JBI appraisal of its 44 included reviews; however, the published appraisal table was not fully legible, limiting independent verification of those review-level quality claims. Second, Wah [19] reported a structured review process without providing a fully reproducible search strategy or sufficiently specifying the quantitative/statistical synthesis to which it referred; its numerical effectiveness claims were therefore treated as secondary-reported findings and interpreted cautiously (Multimedia Appendix 5). Wah [19] was nonetheless retained as a structured evidence synthesis because it named the databases searched (PubMed, IEEE Xplore, and Web of Science), states eligibility criteria, described its screening process and secondary-reviewer validation of extracted data, and reported a thematic synthesis. Its 29 included sources contained secondary reviews, book chapters, preprints, and webpages. Wah [19] was used only as adjacent evidence alongside other reviews and was not the sole basis for any conclusion of the present review. Hazhir et al [20] did not undertake formal critical appraisal of included primary studies, consistent with its scoping review design.

Summary of Methods, Service Contexts, Applications, and Evidence Directness

Table 3 provides a concise review-level summary of the dominant method family, service context, principal application, and evidence directness for each included review. The full detailed evidence matrix is provided in Multimedia Appendix 6.

XSL•FO
RenderX

Table . Concise review-level summary of methods, service contexts, applications, and evidence directness.

Number	Review	Dominant methods	Service context	Principal applications	Evidence directness
1	Chew and Achananuparp (2022) [24]	AI adoption, conversational agents, NLP[a], and predictive methods	General/community health care and 2/26 studies MH[b]-specific	Acceptability, trust, privacy, and adoption	Indirect yet relevant
2	Dwyer et al (2021) [22]	NLP, sentiment analysis, and ML[c]	Text-based MH counseling and helplines	Service delivery, language-based outcome/risk signals, and engagement	Direct
3	Feizollah et al (2025) [25]	NLP, sentiment analysis, topic modeling, and text classification	Health care patient feedback and limited MH-specific evidence	Feedback analytics and service-quality monitoring	Indirect yet relevant
4	Gu et al (2024) [23]	Clinical decision support systems	MH helplines and included studies also extended to adjacent settings	Risk assessment, monitoring, and clinician decision support	Direct, with scope qualification
5	Huynh et al (2026) [11]	AI conversational agents, NLP, and LLMs[d]	Health care broadly and 23/44 reviews MH-focused	Clinical decision support, MH intervention, and self-management	Adjacent or partially direct
6	Saif-Ur-Rahman et al (2023) [13]	Digital health/mHealth[e] and limited substantive ML	LMIC[f] primary care and 6/48 studies MH-specific	Service delivery, screening, decision support, and adherence	Adjacent or partially direct
7	Wah (2025) [19]	Hybrid AI chatbots, NLP, ML, deep learning, LLMs, EHR[g]/IoT[h] integration	Health care broadly, MH support explicit, and MH-specific source count not reported	Engagement, triage, follow-up, monitoring, MH support, and workflow efficiency	Adjacent or partially direct
8	Hazhir et al (2026) [20]	Rule-based chatbots (n=13), hybrid rule-based+NLP (n=4), NLP-only (n=1)	Underserved/vulnerable populations and 6/18 studies MH-specific	Access, counseling/education, distress screening, psychological first aid, grief support, and referral	Adjacent or partially direct

[a]NLP: natural language processing.
[b]MH: mental health.
[c]ML: machine learning.
[d] LLM: large language model.
[e]mHealth: mobile health.
[f]LMIC: low- and middle-income country.
[g]EHR: electronic health record.
[h]IoT: Internet of Things.

RQ1: Data-Driven Methods, Tools, Algorithms, and Datasets Used (BI, Visualization, ML, and Predictive Analytics)

Across the 8 structured reviews, the methods landscape was heavily weighted toward AI and ML approaches, with BI and operational data visualization thinly covered.

The largest method cluster was AI-based conversational agents and NLP. Huynh et al [11] synthesized 44 reviews of AI-based conversational agents in health care, with deep learning (n=14 reviews), NLP (n=12), natural language understanding (n=5), and natural language generation (n=2) being the dominant underlying techniques, alongside large language models (LLMs; eg, ChatGPT, Bard, Claude, and Bidirectional Encoder Representations from Transformers [BERT]) in recent reviews. Conversational agent types covered text-based agents (n=18 reviews), voice-based agents (n=15), embodied agents (n=10), and mixed text-and-voice agents (n=6). Dwyer et al [22] reviewed text-based e-mental health services and the use of computational linguistic tools to predict mental health status from language use. The dominant tool was linguistic inquiry and word count (LIWC), with supplementary use of sentiment analysis, syntactic complexity measures, and supervised ML (Naive Bayes and regression models) applied to social media and online forum corpora. Feizollah et al [25] reviewed NLP applied to unstructured patient feedback across health services. It identified 3 method categories: sentiment analysis (n=32 included studies; tools included Valence Aware Dictionary and Sentiment Reasoner (VADER), support vector machines (SVMs), Naive Bayes, and a small number using transformer-based neural networks), topic modeling (n=15; predominantly latent Dirichlet allocation [LDA] and variants),

XSL•FO
RenderX

and text classification (n=7; supervised and unsupervised learning).

The second method cluster was CDSS. Gu et al [23] synthesized 21 primary studies on CDSS design and implementation in mental health helpline services. Gu et al [23] classified the reviewed CDSSs into passive (n=12 studies), active (n=7), and semiactive (n=2) systems, with architectures consistently combining a database or knowledge base, a reasoning engine, and a user interface accessed via web or app, sometimes integrated with electronic health records (EHRs) via APIs.

A third method cluster was health care chatbot design and delivery. Wah [19] reviewed AI-powered hybrid chatbots combining automated AI with human input or oversight, including NLP, ML, deep learning, generative AI and LLMs, and EHR and Internet of Things (IoT) integration. Hazhir et al [20] characterized 18 chatbots for underserved and vulnerable populations: 13 were rule-based, 4 combined rule-based logic with NLP, and 1 was NLP-only; all used text-based interaction, with social media and web delivery most common. These 2 reviews expanded the conversational-agent evidence while remaining broader than mental-health-service-only syntheses.

A further method cluster concerned digital health and mobile health (mHealth) in LMIC primary care. In Saif-Ur-Rahman et al [13], only 1 of 48 included studies used ML (for depression screening); most evaluated mobile apps, SMS text messaging, interactive voice response (IVR), EHR access via mobile, or other digital health tools. This finding was specific to that LMIC primary-care review and should not be generalized to the wider mental health evidence base.

Chew and Achananuparp [24] focused primarily on perceptions, adoption, trust, privacy, and acceptability of AI in health care and provided comparatively limited algorithm-level detail. It explicitly excluded “machine learning” as a search keyword because of excessive irrelevant retrieval, which constrained its contribution to methods mapping. Wah [19] similarly covered broad health care chatbot implementation themes, while Hazhir et al [20] provided more explicit design-level counts for rule-based, hybrid, and NLP-only systems.

At the tool, platform, and algorithm level, reporting across the 8 structured reviews remained uneven. Feizollah et al [25] named VADER, SVMs, Naive Bayes, transformer-based models, and LDA; Dwyer et al [22] identified LIWC and Naive Bayes; and Huynh et al [11] cataloged deep learning, NLP, and LLMs underpinning conversational agents. Wah [19] discussed hybrid chatbot architectures, GPT/BERT-family models, EHR integration, and IoT-enabled monitoring without reporting a sufficiently reproducible quantitative synthesis. Hazhir et al [20] reported rule-based versus hybrid/NLP chatbot designs and delivery platforms. Saif-Ur-Rahman et al [13] reported only one ML implementation across 48 studies, while Gu et al [23] reported CDSS mainly at the architectural level. Dataset-level reporting remained sparse, limiting appraisal of provenance, representativeness, and reproducibility.

BI and data visualization as distinct technology categories were sparsely represented across the 8 structured reviews. No formally included review centrally addressed BI dashboards, visual analytics, or operational data visualization for mental health and well-being service delivery. Gu et al [23] addressed user-interface design within CDSS, including color-coded risk summaries and dashboard-like interfaces, without providing a standalone visualization synthesis. This pattern was treated as a finding within the retrieved review-level evidence rather than definitive evidence that dedicated BI or visualization reviews do not exist.

RQ2: Mental Health Service Contexts Addressed

Overview

The service contexts addressed across the included reviews spanned clinical, community, digital, primary care, and health care access settings, with substantial differences in directness to the review question. Two reviews were classified as direct evidence for mental health service delivery (Dwyer et al [22] and Gu et al [23]); 4 as adjacent or partially direct (Huynh et al [11], Saif-Ur-Rahman et al [13], Wah [19], and Hazhir et al [20]); and 2 as indirect yet relevant (Chew and Achananuparp [24] and Feizollah et al [25]). These classifications are shown in Table 3 and were used to avoid treating broader health care evidence as equally transferable to specific mental health service contexts.

Direct Evidence: Helpline and Tele-Counseling Services

Gu et al [23] was specifically focused on mental health helpline services and was therefore classified as direct evidence. However, its included primary studies extended beyond strictly defined helplines to encompass telepsychiatry for nonpsychiatrists, primary care–based digital decision support (eg, a digital screening and decision-support e-tool in the Netherlands), and online cognitive behavioral therapy for depression. Its directness was therefore qualified by this broader effective scope, and helpline-specific conclusions were interpreted cautiously.

Direct Evidence: Text-Based Mental Health Services

Dwyer et al [22] was classified as direct evidence because it reviewed text-based e-mental health counseling and communication services, including helplines and commercial counseling platforms. Although the review was framed around rural and remote populations as an underserved group, the evidence it synthesized was dominated by urban and suburban adolescent and adult populations. The review was therefore direct to mental health service delivery, although less direct to its stated rural/remote population framing.

Adjacent or Partially Direct Evidence: Primary Care and Health Care Access

Saif-Ur-Rahman et al [13] addressed digital health and AI across LMIC primary health care rather than mental health services specifically; 6 of 48 primary studies were mental-health-focused. Hazhir et al [20] similarly addressed health care access for underserved and vulnerable populations across 6 health domains, with mental health accounting for 6 of 18 studies. Mental health applications in Hazhir et al [20] included counseling and education, stress-management support, psychological distress screening, psychological first aid, grief support, and referral. Findings from both reviews were therefore treated as relevant

XSL•FO
RenderX

to access and service delivery and were not assumed to transfer directly to all mental health services.

Adjacent and Indirect Evidence From Broader Health Care

Huynh et al [11] was classified as adjacent or partially direct because 23 of its 44 included reviews were mental health–focused. Wah [19] was also classified as adjacent or partially direct because mental health support was an explicit application domain, including counseling, stress management, and therapeutic support, although the review covered health care broadly and did not report a defensible count of mental health–specific included sources. In contrast, Chew and Achananuparp [24] and Feizollah et al [25] were classified as indirect yet relevant because mental health represented only a small subthread of broader health care evidence.

Across the 8 structured reviews, no direct review-level evidence was identified for workplace EAPs, student counseling services, workplace well-being services, or veteran well-being services; emergency-department mental health services were also essentially absent. Hazhir et al [20] added relevant evidence on access for underserved and vulnerable populations, although its findings span multiple health domains and did not constitute direct evidence for those specific mental health service settings. Findings from adjacent or indirect reviews were therefore treated as transferable hypotheses rather than demonstrated effects in those contexts.

RQ3: Applications Reported

Overview

Reported applications clustered across 4 broad areas, with substantial variation in evidence depth. The synthesis below is presented at the review level. Granular underlying-study examples and statistics reported by the included reviews were not treated as independently verified primary study evidence; their source review provenance is documented in Multimedia Appendix 5.

Clinical Decision Support, Screening, and Triage

Gu et al [23] identified 3 CDSS objectives across 21 studies: suicide risk reduction (n=1), diagnosis, treatment, or monitoring of mental health disorders (n=12), and real-time support for clinicians or counselors (n=8). Saif-Ur-Rahman et al [13] reported ML-based depression screening and tablet-based decision support for mental health and suicide risk in LMIC primary care. Huynh et al [11] reported diagnostic and triage accuracy as an outcome domain in 29 of its 44 included reviews. Hazhir et al [20] added mental health access applications, including psychological distress screening and referral, among underserved populations. Exact underlying-study performance figures reported by source reviews were treated as secondary-reported evidence and were not independently reanalyzed.

Conversational Service Delivery

Huynh et al [11] was the largest synthesis. Of the 23 reviews that reported mental health outcomes, 13 found AI-based conversational agents effective in improving or managing mental health, and 7 reported nonsignificant or mixed effects. The remaining 3 reviews were cited as reporting mental health outcomes but were not assigned to either group in the narrative synthesis of Huynh et al [11]; its extraction table described reductions in depression, anxiety, or stress for each of them. We reported the classification of Huynh et al [11] and did not reclassify these 3 reviews. Huynh et al [11] described the mental health evidence overall as mixed, with benefits reported more consistently in the short term than at later follow-up, and identified addiction-related applications as the only domain with consistently positive outcomes; safety signals included symptom worsening in one underlying chatbot study. Dwyer et al [22] reported text-based counseling outcomes alongside anonymity and convenience as engagement facilitators. Wah [19] described hybrid chatbot applications spanning mental health support, counseling, stress management, triage, follow-up, and patient engagement; its heterogeneous headline effectiveness claims were interpreted cautiously because the quantitative synthesis method was insufficiently specified. Hazhir et al [20] identified counseling, education, stress-management support, psychological first aid, grief support, and referral among the 6 mental health–focused studies in its 18 studies on health care access.

Engagement, Acceptability, and Adherence

Huynh et al [11] reported short-term engagement gains that were not consistently sustained at 3 to 6 months, while Saif-Ur-Rahman et al [13] reported improvements in clinic attendance, follow-up, and medication adherence in several mHealth studies. Wah [19] emphasized patient engagement, trust, and the proposed value of human-in-the-loop chatbot design. In Hazhir et al [20], only 9 of the 18 studies formally evaluated their chatbots; acceptability (n=6) and feasibility (n=5) were the most common evaluation outcomes, followed by satisfaction, usability, and technological performance.

Service-Level Analytics, Access, and Operational Improvement

Feizollah et al [25] was the principal source for NLP-based interpretation of unstructured patient feedback and reported using NLP to identify recurrent service issues and prioritize improvement themes, although it also identified a research-to-practice gap. Saif-Ur-Rahman et al [13] reported operational improvements in record-keeping, waiting times, appointment scheduling, facility crowding, and client satisfaction. Wah [19] reported hybrid chatbot applications in appointment and follow-up support, remote monitoring, workflow efficiency, and waiting-time reduction, although these heterogeneous claims were treated as secondary-reported findings rather than pooled evidence. Hazhir et al [20] shifted the service-level emphasis toward access: simple text-based interactions, familiar low-data platforms, and local-language adaptation were described as approaches to reducing linguistic, literacy, connectivity, and resource barriers.

Risk detection, client segmentation, and service planning were reported unevenly. Risk detection appeared most concretely in CDSS-based suicide risk identification [23], language-based suicide risk work [22], and mental health screening/referral applications within broader primary care or

XSL•FO
RenderX

underserved-population reviews [13,20]. Client segmentation was largely absent from the synthesized evidence. Service-planning applications were limited mainly to operational workflow, access, appointment, and demand-management functions rather than dedicated BI or population-segmentation systems.

RQ4: Reported Benefits, Insights, Challenges, and Barriers to Implementation

Reported benefits, insights, challenges, and barriers were synthesized narratively below under 4 headings: benefits and enablers; challenges and barriers; the integration gap; and ethical, safety, and equity considerations.

Benefits and Enablers

On-demand availability, accessibility, ease of use, patient engagement, and selected efficiency gains were reported across several included reviews [11,13,19,20,23,24]. Service-delivery benefits, including scheduling, record-keeping, waiting-time reduction, access, and client satisfaction, were reported more consistently than sustained clinical benefits, although the underlying evidence was heterogeneous and often broader than mental health service delivery. Dwyer et al [22] emphasized anonymity and convenience in text-based mental health communication; Wah [19] emphasized hybrid human-AI oversight, workflow integration, and personalization; and Hazhir et al [20] highlighted simple text interfaces, familiar low-data platforms, local-language adaptation, and immediate low-cost access for underserved populations. These findings were interpreted as reported enablers rather than established causal effects.

Challenges and Barriers

Privacy, trust, safety, workflow integration, and infrastructure constraints recurred across the evidence base. Chew and Achananuparp [24] reported privacy, patient-safety, and automation concerns across its included studies. Gu et al [23] reported alert fatigue, slow CDSS performance, data-entry burden, and EHR-integration problems, while Saif-Ur-Rahman et al [13] described resource, connectivity, language, digital-literacy, and workflow constraints in LMIC primary care. Wah [19] added concerns about trust in AI advice, data security, accountability, algorithmic bias, interoperability, cost, cultural adaptability, and the need for human expertise in complex cases. Hazhir et al [20] similarly identified weak infrastructure, limited internet access, low digital and health literacy, language barriers, privacy/security concerns, development costs, and inconsistent evaluation as barriers to equitable chatbot deployment.

The Integration Gap

Two reviews independently identify a research-to-practice gap as a central finding. Feizollah et al [25] noted that academic rather than translational impact had been the driving force behind research in NLP-based patient feedback work and that few studies describe concrete clinical impact from NLP-derived insights. Gu et al [23] identified the absence of a holistic plan for the full CDSS development cycle as a key finding. Most included studies covered only a subset of the usability-software development life cycle (U-SDLC) phases. The maintenance phase was particularly poorly covered, with 5 development activities at zero across all 21 included studies.

Ethical, safety, and equity considerations were synthesized unevenly across the 8 reviews. Chew and Achananuparp [24] and Huynh et al [11] identified privacy, safety, bias, hallucination, and symptom-worsening concerns, while Wah [19] emphasized trust, accountability, privacy/security, bias, and cultural adaptation. Hazhir et al [20] contributed the clearest additional access-equity perspective by focusing explicitly on underserved and vulnerable populations, including linguistic, geographic, literacy, and resource barriers; however, only half of its included studies formally evaluated their chatbot, and the long-term impact remained unclear. Saif-Ur-Rahman et al [13] added LMIC-specific digital divide and infrastructure concerns.

Primary-Study Overlap and CCA Analysis

No verified overlap was found among the included studies that could be identified from the included study/source lists (Table 4). In Tier 1, the 7 primary-level reviews contributed N=264 included study/source occurrences and r=264 unique units across C=7 reviews, giving CCA=0.00%. Nine of the 52 studies included by Feizollah et al [25] were listed only in a supplementary file and could not be identified; if all 9 duplicated a study in another Tier 1 review, r would fall to 255 and the CCA would be 0.59%, which would remain in the slight category. Wah [19] reported 29 included sources of mixed type rather than a wholly primary study set; because none overlapped with another Tier 1 review, excluding its nonprimary sources would reduce N and r equally and would not change the zero-overlap numerator. In Tier 2, the 2 reviews classified as directly relevant to mental health service delivery, Dwyer et al [22] and Gu et al [23], contributed N=91 occurrences and r=91 unique studies, giving a CCA of 0.00%. In Tier 3, none of the 7 standalone reviews was among the 44 constituent reviews of Huynh et al [11] (0 of 7); this review-level result was reported as a direct count rather than as a CCA. Two cross-tier relationships were identified (Milne-Ives et al [26] and Aggarwal et al [27]); because these involved different units of analysis, they were reported separately rather than being counted in any tier's CCA. Primary studies nested inside all 44 constituent reviews of Huynh et al [11] were not fully disaggregated. Full matrices and calculations are provided in Multimedia Appendix 7.

XSL•FO
RenderX

Table . Primary study CCA[a] and review-level overlap across the 3 analytical tiers.

Analytical tier	Reviews included (C)[b]	Total occurrences (N)	Unique units (r)	Shared units	CCA (%)	Interpretation
Tier 1: full primary-level evidence base	7	264	264	0	0.00% (≤0.59% worst case)	No verified overlap among identifiable studies; slight category (<5%)
Tier 2: direct mental health service subset	2	91	91	0	0.00%	No verified overlap; slight category (<5%)
Tier 3: review-level overlap check	__[c]	—	—	0	Not calculated	No review-level overlap (0 of 7 standalone reviews among 44 constituent reviews); direct count

[a]CCA: corrected covered area.

[b]The columns report counts and one derived index: C is the number of reviews included in each tier; N is the total number of included study or source occurrences across those reviews; r is the number of unique studies or sources after deduplication; shared units is the number of studies or sources appearing in more than 1 review. CCA (corrected covered area) is calculated as CCA=(N−r)/(r×(C−1)) [21] and expressed as a percentage, with values below 5% interpreted as slight overlap.

[c]Not applicable.

Discussion

Principal Findings

This umbrella review synthesized 8 structured reviews on data-driven methods relevant to mental health and well-being service delivery, published between 2021 and 2026. Five main observations emerged.

First, the methods landscape was heavily weighted toward AI and ML approaches (conversational agents, NLP, deep learning, and LLMs), while BI and operational data visualization as distinct technology categories were thinly represented in the review-level literature retrieved by our searches.

Second, and consistent with the service-delivery orientation of this review, service-level outcomes (efficiency, accessibility, satisfaction, and engagement) were reported more consistently and more positively than clinical outcomes (symptom change, behavior change, sustained effect) within the included reviews. This described the pattern of reporting across a small and heterogeneous evidence base rather than establishing stronger service-level effectiveness. Service-level outcomes were nonetheless reported less often than technical performance measures, such as algorithm accuracy (see Comparison With Prior Work).

Third, in the conversational-agent evidence synthesized by Huynh et al [11], short-term benefits were reported more often than long-term benefits and were not reliably sustained at 3- to 6-month follow-up; this review describes the mental health evidence overall as mixed.

Fourth, evidence directness varies materially across the 8-review set. Dwyer et al [22] and Gu et al [23] provided the 2 direct sources for mental health service delivery. Huynh et al [11], Saif-Ur-Rahman et al [13], Wah [19], and Hazhir et al [20] provided adjacent or partially direct evidence because mental health is a substantial or explicit component of broader health care, primary care, or access-focused syntheses. Chew and Achananuparp [24] and Feizollah et al [25] were indirect yet relevant. Consequently, cross-cutting implementation and service findings from adjacent and indirect sources were treated as potentially informative rather than as demonstrated effects in specific mental health service settings.

Fifth, a research-to-practice gap is a recurring cross-cutting finding, identified independently by Gu et al [23] and Feizollah et al [25].

Comparison With Prior Work

Huynh et al [11] is itself an umbrella review; its scope, however, is limited to conversational agents and clinical health-related outcomes across health care. This review used Huynh et al [11] as one of 8 structured inputs and places its findings alongside clinical decision support, NLP-based patient-feedback analysis, text-based mental health communication, AI adoption, LMIC digital health, hybrid health care chatbots, and chatbot-enabled health care access for underserved populations. This broader service-delivery framing permitted comparison across technology and service-context families while retaining explicit evidence-directness distinctions.

A scoping review by Woo and Jung [28], published online on April 3, 2026, after the retained January 27, 2026, evidence cutoff, was retrieved by the supplementary search. It is cited here only as contextual literature and was not included in the formal synthesis, critical appraisal, evidence tables, or CCA calculations. Its publication reflected the pace of review activity in this area and did not alter the prespecified evidence window of the formal synthesis.

The synthesis also aligned with earlier method-focused reviews by Shatte et al [6] and Le Glaz et al [7], which concluded that methodological promise had outpaced clinical translation. The present review extended that observation to service delivery:

XSL•FO
RenderX

operational outcomes, such as waiting time, caseload, triage, and demand, were reported less often than technical performance.

Methods Landscape: Where the Review-Level Evidence Concentrates

Dedicated BI, dashboard, and operational-visualization syntheses were not identified. Because the search required all 3 concept blocks, this finding applies within the searches conducted rather than proof of absence from the wider literature.

Within the AI/ML literature, methods ranged from rule-based conversational systems and supervised learning to topic modeling, sentiment analysis, and LLMs. This heterogeneity limits meaningful quantitative resynthesis at the umbrella review level [11].

The label "AI or digital health" did not correspond to substantive ML in most studies within the included LMIC primary-care review. Saif-Ur-Rahman et al [13] reported that only 1 of 48 studies used ML, while the remainder primarily involved mHealth or other digital health technologies. This observation applies only to that review.

Service Contexts and the Helpline-Specific Evidence Gap

Mental health helpline services were the explicit focus of only one review [23], and even this direct source had a broader effective scope than its title suggested. For helpline operators and service planners, the evidence should therefore be read as limited rather than as a mature helpline-specific synthesis. Some implementation findings were derived from adjacent primary care, telepsychiatry, online therapy, health care chatbots, and access-focused contexts [13,19,20]. Co-design, EHR integration, human oversight, alert-fatigue management, linguistic adaptation, and stepwise rollout may be relevant to helplines; however, transferability remains an inference rather than a directly demonstrated effect.

Beyond helplines, workplace EAPs, student counseling, workplace well-being, and veteran well-being were not represented by direct included review-level evidence. Hazhir et al [20] broadened the evidence on underserved and vulnerable populations and Wah [19] broadened the chatbot implementation literature; neither was a direct synthesis of these specific mental health service settings. Dedicated primary studies and context-specific syntheses are therefore needed before transfer can be assumed.

Applications and Outcomes: Service-Level Signal, Clinical-Level Caution

As noted above, service-level outcomes were reported more consistently than clinical outcomes. Given the small, heterogeneous, and partly indirect evidence base, this reflects consistency of reporting rather than established service-level effectiveness, with 3 implications.

First, the included reviews do not provide a sufficiently direct or homogeneous evidence base to conclude that BI, visualization, or AI are established as effective at the service-delivery level. Second, where clinical effects are reported, they are predominantly short-term, particularly in the conversational-agent evidence synthesized by Huynh et al [11]. Third, safety and equity signals included symptom worsening, LLM hallucination and bias, inaccurate information, privacy and trust concerns, language and literacy barriers, and unequal digital access [11,19,20,24]. These issues are reported across several reviews and are not yet synthesized with sufficient consistency or long-term follow-up to support strong service-wide conclusions.

RQ5: Research Gaps and Recommended Directions for Future Inquiry

Overview

Five priorities for future research emerged from this synthesis.

Helpline-Specific Implementation Evidence

Primary evaluation studies of BI, visualization, and AI applications in mental health helpline operations are needed before higher-order synthesis is possible. These include evaluations of CDSS deployed in real-time counselor decision-making, visual analytics dashboards for service planners, and predictive models for demand and risk in helpline contexts. Service-analytics platforms of this kind should be designed with evaluation embedded from the outset, in line with implementation science methods [23].

Service-Delivery-Focused Evaluation

Existing reviews concentrated on technology performance (algorithm accuracy, sentiment-classification F_1, and chatbot engagement metrics) rather than on service-delivery impact (waiting times, caseload management, dropout reduction, and equity of access). Future primary studies and reviews should foreground service-delivery outcomes and report them at parity with clinical and technical outcomes.

Longer Follow-up and Treatment-Effect Durability

The finding reported by Huynh et al [11], that short-term benefits of AI-based conversational agents for mental health were not consistently sustained at 3- to 6-month follow-up, indicates that effect durability is a first-order RQ. Future trials and reviews should report follow-up beyond 3 months by default and address the mechanisms of effect decay.

Explicit Treatment of Safety, Ethics, and Equity

Beyond the safety signals noted above [11,19,24], Hazhir et al [20] showed that language, literacy, connectivity, cultural fit, and resource constraints were central to equitable access for underserved populations. Future reviews should treat safety and equity as primary synthesis objectives, use explicit adverse-outcome frameworks, and examine differential access and performance across demographic, linguistic, and service-context groups.

Frameworks Linking Design, Implementation, and Evaluation

Within the formal evidence base, Gu et al [23] identified the absence of a holistic development and implementation plan across the full CDSS lifecycle. Outside the formal umbrella synthesis, Lee et al [12] provided a complementary conceptual

XSL•FO
RenderX

digital-therapeutics analytics framework, including just-in-time adaptive intervention (JITAI) and engagement-adherence distinctions. This contextual source is used to enrich interpretation rather than as formal review-level evidence. Bridging the design-implementation-evaluation gap will require collaboration between health services research, implementation science, software engineering, and clinical mental health practice.

Implications for Practice, Policy, and Implementation

For service operators and planners, the included reviews suggested potentially useful service-delivery signals for digital and AI-based interventions, including accessibility, workflow, engagement, and selected operational outcomes. However, applicability depends strongly on evidence directness: mental health service-specific conclusions are anchored principally in the 2 direct reviews, while findings from the 4 adjacent and 2 indirect health care syntheses should be treated as transferable hypotheses rather than established effects in a particular service context. Clinical-effectiveness evidence remains limited and predominantly short-term.

Technical feasibility or promising retrospective performance alone should not be treated as sufficient justification for deployment in mental health services. AI, BI, dashboard, and decision-support tools should be introduced with prospective service-level evaluation, predefined safety monitoring and escalation pathways, equity assessment across relevant demographic, language, and access groups, and explicit workflow-integration planning with service users and staff. Staged implementation, human oversight, monitoring for unintended consequences and alert burden, and predefined criteria for modification or withdrawal should accompany routine deployment, particularly when the evidence is indirect or context transfer is assumed.

Strengths and Limitations of This Umbrella Review

Strengths

A time-stamped OSF draft of the scoping review protocol existed from December 2, 2025, before the original database searches on January 27, 2026, and documented the original search strategy, information sources, and publication window. The interdisciplinary original search combined multidisciplinary, psychological, and computing databases, and revision-stage PubMed and Embase searches were added transparently to address reviewer concerns while retaining the original evidence cutoff. Title/abstract and full-text screening were conducted independently by 2 reviewers in both search phases: SA and EE for the original search and SA and GC for the supplementary PubMed/Embase records. Review-team discussion and final eligibility adjudication were available where required. JBI critical appraisal was conducted independently by 2 reviewers with third-reviewer adjudication, and lead data extraction was independently cross-checked against source reviews. The formal synthesis was restricted to structured reviews, evidence directness was explicit, and overlap was reassessed with citation-level verification, using a formal CCA at 2 primary-study tiers and a review-level overlap check.

Limitations

The review had eight main limitations. (1) Search sensitivity for BI and visualization could not be assumed to be equivalent to sensitivity for AI/ML. The development-stage reference check used 5 known primary studies from the original scoping review design rather than a review-level BI/dashboard validation set; all 3 Boolean concept blocks were mandatory, and the ACM Digital Library search was restricted to the abstract field. The absence of dedicated BI or visualization syntheses should therefore be interpreted only within the retrieved review-level evidence. (2) PubMed and Embase were added during revision (September 22, 2026) rather than in the original search. The January 27, 2026, evidence cutoff was enforced during screening, and the supplementary searches did not constitute a synchronized rerun of all databases. Wah [19] was excluded at original title-and-abstract screening and included after supplementary screening, which shows that title-and-abstract judgments for broad health care reviews with a secondary mental health component could differ between reviewer pairs; other reviews of this kind may have been missed. CINAHL and the Cochrane Library were not searched directly. (3) Eligibility was restricted to English-language peer-reviewed publications from 2021 to the retained January 27, 2026, cutoff, excluding gray literature, preprints, non-English reviews, and earlier syntheses. (4) The formal evidence base remained small and heterogeneous (8 structured reviews). Only 2 reviews were direct to mental health service delivery, 4 were adjacent or partially direct, and 2 were indirect yet relevant; only Gu et al [23] was explicitly anchored in mental health helpline services, and no direct included review-level evidence was identified for EAPs, student counseling, workplace well-being, or veteran services. (5) The umbrella review by Huynh et al [11] contained a per-item appraisal table that is incompletely legible in the published article, limiting independent verification of its own appraisal. (6) Extraction necessarily relied on what source reviews reported. Primary-study-level examples in the supplementary materials were not independently verified against the primary publications and may inherit source-review reporting limitations; Wah [19] also reported 29 included sources of mixed type and does not clearly specify the quantitative synthesis underlying several headline estimates. (7) The time-stamped December 2025 OSF draft was a scoping review protocol. The umbrella review design was adopted and formally registered on May 6, 2026, after the original January searches; the design was therefore not prospectively registered before searching. Two nonsystematic publications included in the originally submitted version were removed from the formal evidence base when eligibility was standardized to structured syntheses only. (8) The CCA was 0.00% at both primary-study tiers among the studies that could be identified. Nine of the 52 studies included by Feizollah et al [25] could not be identified from the published article; if all 9 were duplicates, the Tier 1 CCA would be 0.59%. Zero verified overlap should not be interpreted as proof that the underlying evidence bases are independent in every respect. Primary studies nested within all 44 constituent reviews of Huynh et al [11] were not fully disaggregated, and cross-tier relationships were reported rather than combined because they involve different units of analysis (Multimedia Appendix 7).

XSL•FO
RenderX

Conclusions

Review-level evidence on data-driven methods relevant to mental health and well-being service delivery was uneven and varies substantially in directness. In terms of the RQs, the data-driven methods, tools, algorithms, and datasets reported across the included reviews (RQ1) were dominated by AI and ML, including conversational agents, NLP, LLMs, and CDSS; dedicated BI and operational data visualization syntheses were sparse within the retrieved evidence, and dataset-level reporting was limited. The mental health service contexts in which these methods have been applied (RQ2) were text-based counseling and helplines, LMIC primary care, health care access for underserved populations, and broader health care settings; 2 reviews were direct to mental health service delivery, 4 were adjacent or partially direct, and 2 were indirect yet relevant. Only one review focused specifically on helplines, and no direct review-level evidence was identified for EAPs, student counseling, workplace well-being, or veteran services. The applications (RQ3) were clinical decision support, screening, and triage; conversational service delivery; engagement and adherence support; and service-level analytics and access improvement, whereas client segmentation and BI-based service planning were largely absent. Among the benefits, insights, challenges, and barriers to implementation (RQ4), service-level benefits, such as accessibility, efficiency, and satisfaction, were reported more consistently than sustained clinical benefits, and recurring barriers included privacy and trust concerns, safety risks such as symptom worsening and LLM hallucination, workflow and EHR integration problems, infrastructure and digital-literacy constraints, and a research-to-practice gap. The research gaps and directions for future inquiry (RQ5) were identified as helpline-specific implementation evidence, service-delivery-focused evaluation, longer follow-up of effect durability, explicit treatment of safety, ethics, and equity, and frameworks linking design, implementation, and evaluation. Because the evidence base is small, heterogeneous, and partly indirect, and the mandatory 3-concept search may have under-retrieved BI- and visualization-focused reviews, these findings should guide prospective, context-specific evaluation rather than be generalized across service settings.

Acknowledgments

The authors thank Mary Rose, Librarian, for assistance in refining search terms.

All substantive methodological decisions, data extraction, critical appraisal, interpretation, and final manuscript content were undertaken or verified by the authors, who take full responsibility for the work.

Generative AI Use

Generative AI tools (ChatGPT and Copilot) were used for language refinement, formatting, and consistency checking.

Funding

The authors declared no specific financial support was received for this work. SA is employed as an Associate on a Knowledge Transfer Partnership (KTP) between Ulster University and Inspire Wellbeing, funded by Innovate UK, and the review was conducted as part of that role. Neither Inspire Wellbeing nor Innovate UK participated in framing the review question, determining eligibility criteria, screening or appraisal decisions, reviewing interim findings, drafting or revising the manuscript, or decisions concerning submission and publication.

Data Availability

The structured data-extraction workbook, item-level JBI appraisal records, PRISMA materials, provenance table, full evidence matrix, and citation-overlap/CCA materials are provided with this article as Multimedia Appendices 1-7 and Checklist 1. The registered protocol is available through the OSF registration [17].

Conflicts of Interest

SA is employed through the Knowledge Transfer Partnership (KTP) described under Funding, and this review was conducted in part to inform the design of a service-analytics platform for Inspire Wellbeing. A time-stamped OSF registration draft was created on December 2, 2025, as a scoping-review protocol before the final database searches; the protocol was subsequently revised to an umbrella review design and formally registered on May 6, 2026, after searching had been completed. The registration is therefore not presented as a prospective safeguard for the umbrella review search stage. To reduce the possibility that the applied KTP context influenced eligibility or interpretation, screening was conducted independently by 2 reviewers, critical appraisal was conducted independently by 2 reviewers with third-reviewer adjudication, data extraction and evidence-directness classifications were independently verified by a second reviewer, and final eligibility conflicts were adjudicated by MM. No other competing interests are declared.

Abstract

Background: Digital nursing technologies (DNTs) have the potential to improve the quality and continuity of home care by supporting nurses, care recipients, and informal caregivers. Despite growing research on DNTs, the home care setting remains underrepresented, particularly regarding implementation strategies using an established implementation science framework. Therefore, this scoping review systematically maps implementation strategies for DNTs in home care using the Expert Recommendations for Implementing Change (ERIC) framework.

Objective: We aimed to identify and map ERIC implementation strategies proposed or used for DNTs in home care. Additionally, we aimed to derive operationalized practical recommendations for decision-makers and implementation practitioners in nursing services.

Methods: We conducted a scoping review with a systematic literature search in MEDLINE via PubMed, CINAHL via EBSCO, and Scopus via Elsevier in March 2025, with an updated search in July 2026. Guided by the PCC (Population, Concept, and Context) framework, we included primary studies and study protocols that addressed the implementation of a DNT in home care and were published between 2015 and 2026. We excluded studies from other health care settings, technologies not related to nursing, concept papers, and reviews. Data charting was conducted in MAXQDA 24 (VERBI Software) using deductive content analysis. We applied and operationalized the 73 ERIC implementation strategies to define our deductive category system.

Results: A total of 22 articles with 18 distinct DNTs were included in this review. Most of them are implementation studies conducted in Europe and published in 2022. Most DNTs focused on home care using sensor-based monitoring and telehealth solutions for people with dementia, chronic conditions, or palliative care needs. Additional DNTs included mobile apps for symptom monitoring, decision-support systems, communication platforms, and a robotic medication management system. Deductive analysis based on the ERIC framework identified 48 of 73 implementation strategies across the included DNTs. The most frequently reported ERIC strategies were: conduct educational meetings (n=14), promote adaptability (n=14), conduct ongoing training (n=9), and train-the-trainer (n=9). The identified ERIC implementation strategies showed high heterogeneity across the included DNTs.

Conclusions: These frequently reported ERIC implementation strategies may function as a multifaceted implementation strategy. However, they need to be empirically evaluated regarding their feasibility, appropriateness, and effectiveness for the implementation of DNTs in home care. In addition, researchers should ensure transparent reporting of implementation strategies by explicitly operationalizing them and applying established frameworks, such as the ERIC framework, to facilitate comparability across studies. Finally, practical guidance derived from ERIC implementation strategies should be specified in greater detail, including information on how, when, and for what duration individual implementation strategies should be applied.

Introduction

Home care is defined as nursing care provided by a nursing service in care recipients' homes. It is well established that demographic changes and rising care needs trigger a cascade of adverse consequences for care recipients if early detection and prevention of changes in their health status are not prioritized [1]. These consequences include, for example, a higher incidence of acute events like falls or heart failure due to missed medication intake, which in turn leads to hospitalization and increased care.

It is considered that digital nursing technologies (DNTs) in home care can mitigate this cascade of adverse consequences [2,3]. Based on the definition provided by Krick et al [4], DNTs are technologies that directly support nurses in coordinating and providing care by facilitating nursing processes, assessment, nursing interventions, communication, and documentation through digital means. In home care, DNT may additionally support care recipients in maintaining independence, self-determination, and self-management, as well as assist informal caregivers in coordinating and providing informal care. Examples include monitoring technologies, wearables, telenursing systems, robotic and digital care assistants. Furthermore, DNT can be used for professional education and training of nurses as well as within academic nursing education [5].

Numerous DNTs have been developed and examined across various studies [5,6]. For example, Schlicht et al [6] conducted an umbrella review to provide an overview of investigated digital technologies. The authors reported 213 studies, most of which examined information and communication technologies (n=118), followed by telecare technologies (n=43) and robotics (n=38). They also reveal that only a small number of reviews (n=14) focus on home care settings [6]. Krick et al [5] reached a similar conclusion. In their scoping review mapping the research landscape of DNT across nursing settings, only 48 of the 175 included studies focused on DNTs used in home care provided by nursing services. These findings indicate that home care remains an underrepresented research setting in the field of DNTs [5].

However, to harness the full potential of DNTs in home care, a structured and carefully planned approach for integrating them into nursing practice is essential [7]. An evidence-based instrument to facilitate the adoption and implementation of DNTs in home care is implementation strategies, which are defined as methods to foster the adoption, implementation, and sustainability of a particular innovation [8].

Previous evidence syntheses on DNTs have primarily focused on implementation determinants, such as barriers and facilitators that influence adoption and implementation [9,10].

For example, Walzer et al [9] conducted an umbrella review to identify barriers and facilitators in various nursing settings on the implementation of DNTs. In the included 65 articles, they identified 52 influencing factors with the Nonadoption, Abandonment, Scale-up, Spread, and Sustainability (NASSS) framework [11]. Based on the identified facilitators and barriers, they drew conclusions and derived practical implications for practice. Likewise, Oudbier et al [10] synthesized evidence on barriers and facilitators related to the implementation of specific DNTs, like remote monitoring, consultation, and care platforms across various health care settings from the perspective of different health care professionals. Thereby, they did not apply any framework from implementation science. However, they also infer several practical implications, referred to as implementation strategies, from their results [10].

Although existing reviews provide important insights into barriers and facilitators of DNT implementation, they offer limited evidence on practical implementation recommendations for home care. Furthermore, it remains unclear whether these recommendations constitute implementation strategies and are transferable to the home care context. As a result, knowledge about which implementation strategies are currently proposed or used in home care remains limited.

Therefore, an established implementation science framework is needed to systematically map implementation strategies proposed or used for DNTs in home care. The Expert Recommendations for Implementing Change (ERIC) framework provides a standardized, evidence-based taxonomy comprising 73 discrete implementation strategies organized into 9 thematic clusters [12,13]. The framework enables researchers to operationalize implementation strategies according to the specific implementation context, target population, and type of innovation [13]. Furthermore, its precisely defined strategies facilitate the standardized description and comparison of implementation approaches [8]. Applying the ERIC framework can also help identify which implementation strategies have been frequently investigated and which remain underexplored.

From an implementation science perspective, such an overview of implementation strategies proposed or used for DNTs in home care would enable researchers to conduct rigorous investigations of their effectiveness.

From an implementation practitioner's perspective, it would support the planning and facilitation of adoption and sustained use by providing actionable implementation strategies.

Therefore, the aim of this review is to identify implementation strategies proposed or used in home care for DNTs using the ERIC framework.

Consequently, we formulated the following research question:

> *Which implementation strategies are proposed or used for the implementation of digital nursing technologies in home care?*

Methods

Study Design

We applied the scoping review approach by Peters et al [14] based on the Joanna Briggs Institute (JBI) methodology to investigate the research questions. Since the existing literature on the current topic is heterogeneous, we aim to systematically map the existing evidence on implementation strategies proposed and used for DNTs in home care for science and practice by applying the ERIC framework [13]. We therefore applied the

XSL•FO
RenderX

73 discrete implementation strategies to develop a reliable deductive coding system. This approach enabled the standardized classification of proposed and used implementation strategies for DNTs in home care [8]. By applying the ERIC taxonomy [13], we were able to identify and categorize specific implementation strategies reported in the studies included in our scoping review. In addition, the detailed definitions and guidance provided by Powell et al [13] facilitated the operationalization of each strategy according to the respective implementation context, target population, and intervention type.

To ensure transparent and comprehensive reporting of the methodological procedures and study findings, we followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guideline [15] (Checklist 1).

Further, we preregistered our scoping review protocol on April 4, 2025, in the Open Science Framework (OSF) [16].

Inclusion and Exclusion Criteria

To operationalize the research question and define our inclusion and exclusion criteria, we applied the PCC (Population, Concept, and Context) framework [14].

According to this framework, nurses and care recipients were identified as the primary target population of this review. DNTs were considered the first concept of interest if they had been developed to support nursing processes, nursing interventions, or the monitoring of nursing-related phenomena. Eligible DNTs were required to involve nurses and could additionally include care recipients, family members, informal caregivers, and other health care professionals, such as physicians.

Articles were excluded if they did not explicitly focus on DNTs proposed, implemented, or used by nurses in home care settings, or if they were specifically designed to support informal caregiving without describing a role for nurses. Studies conducted in settings other than home care, such as rehabilitation clinics, outpatient clinics, or ambulatory care centers, were also excluded.

The second concept of interest comprised implementation strategies that were either proposed or actually used to adopt, implement, and sustain DNTs in home care settings (Context).

Furthermore, we included study protocols and primary research articles that described the proposed application of implementation strategies or their actual use in the implementation of a DNT. Eligible articles were published in English or German between 2015 and 2026. Conference abstracts, conceptual papers, and nonpeer-reviewed publications were excluded.

Notably, during the initial stage of the literature screening process, review articles were included for backward citation searching of their reference lists. Following this process, the reviews were excluded and were therefore not included in the data extraction.

For further information on predefined inclusion criteria, see Table 1.

Table . Predefined inclusion criteria.

Component	Inclusion criteria
Population	• Nurses and older, frail care recipients, as well as, where applicable, their family members and informal caregivers. Additional stakeholders could include other health care professionals, such as physicians and physical therapists.
First concept of interest	• DNTs[a] that support nursing care processes, including assessment, monitoring, providing nursing interventions, communication, documentation, care coordination, and care recipients' self-management.
Second concept of interest	• Any kind of description of a planned or completed implementation of DNTs in home care by providing information about proposed or used implementation strategies.
Context	• Home care in which care is provided by a nursing service in the care recipient´s home.
Evidence sources	• Any kind of article that reports on planned implementation/evaluation or completed implementation/evaluation of DNT in home care. The articles have to provide information about proposed or used implementation strategies. Study types included: study protocols, implementation/evaluation studies, feasibility studies, qualitative studies, and observational studies.
Other	• Languages: German and English • Year: from 2015 to 2026 • Type of article: peer-reviewed articles published in scientific journals

[a]DNT: digital nursing technology.

Information Sources and Search Strategy

We applied a sensitive search strategy to identify all potentially relevant articles addressing the research question. To this end, we conducted a systematic literature search in 3 databases that were appropriate for the scope of this review: MEDLINE via PubMed, CINAHL via EBSCO, and Scopus via Elsevier. First, 1 researcher (DKS) conducted an initial search of the 3 databases to identify relevant synonyms based on the PCC framework and the inclusion criteria [14]. After developing the search strategy for MEDLINE via PubMed, a second researcher (MD) independently verified it using the Peer Review of Electronic Search Strategies (PRESS) guideline [17]. Subsequently, DKS adapted the search strategy for CINAHL and Scopus according to the specific requirements of each database. Multimedia Appendix 1 presents the final electronic search string applied in the 3 databases, PubMed via MEDLINE, including all filters used in accordance with the eligibility criteria described in Table 1. The systematic literature search was conducted in March 2025 across all 3 databases, with an updated search performed in July 2026. In addition, we screened the reference lists of included reviews through backward citation searching to identify potentially relevant studies. We also conducted forward citation searching in Google Scholar to capture additional eligible articles [18]. To ensure transparent and comprehensible documentation of the systematic literature search and supplementary search methods, we used the web-based RefHunter tool [19]. A complete description of the procedure, including all developed and final search strings is in Multimedia Appendix 2.

Selection of Sources of Evidence

The identified articles were imported into CITAVI (version 6.19; Lumivero, formerly Swiss Academic Software) and subsequently uploaded to the online screening tool Rayyan (Rayyan Systems Inc) [20]. Using Rayyan, all duplicate articles were identified and removed.

The first step of the screening process involved training MD on the screening procedures and eligibility criteria (Table 1). During this training phase, agreements were reached regarding the labeling of excluded articles, the identification of relevant review articles, and the procedure for handling uncertainties.

In the second step, 2 reviewers (DKS and MD) independently conducted the title and abstract screening using the blind mode in Rayyan. Articles for which eligibility–based on the predefined inclusion criteria (Table 1)—could not be determined were labeled as “maybe.”

In the third step, all articles labeled as “maybe” were discussed by DKS and MD and reassessed based on the inclusion and exclusion criteria as well as the scope of the review. As all uncertainties were resolved through discussion, consultation with a third independent reviewer (RK) was not required.

The fourth step consisted of conducting the full-text screening using the same procedure. To illustrate the article selection process, including the reasons for article exclusion, we used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram proposed by Page et al [21]. Because an updated literature search was conducted, the PRISMA flow diagram was revised accordingly, and the version specifically designed for updated systematic literature searches was applied

Data Charting Process

All included articles were imported into MAXQDA (Version 24) for data extraction, which was conducted in 2 stages. First, general study characteristics were extracted by 1 researcher (DKS) using a predefined data extraction template (Table 2). These data included, for example, the target population of the respective DNTs, the particular DNT itself, and involved interest holders.

Table . Predefined data items that were extracted from the included articles.

Data item	Content
General information	• Author (complete name) • Publication date (month/year) • Country • Context (eg, nursing service and home care) • Study design • Study aim
Participants	• The target population of the digital technology (eg, nursing staff or care recipients, including their medical/nursing characteristics, like people with symptoms of dementia) • Interest holder in the implementation process of digital nursing technologies
Intervention	• Digital nursing technology applied in home care

Primarily, DKS performed the data extraction in MAXQDA in 2 iterations. Data on general study characteristics and DNTs are reported in the Results section and Multimedia Appendix 3.

Second, we performed a deductive content analysis [22] using the 73 discrete implementation strategies from the ERIC framework [13] as a priori categories. To adapt and operationalize these categories for the implementation context and target population of DNTs, we followed the methodological

XSL•FO
RenderX

approach proposed by Kuckartz and Rädiker [22]. Specifically, all implementation strategies were defined according to established procedures for category development and category description to ensure a consistent and transparent coding process. An example of a complete category definition and description for the implementation strategy "Intervene with care recipients and consumers to enhance uptake and adherence" *is* provided in Table 3.

Table . An example illustrating the development of the deductive categories, which were operationalized according to the implementation strategies defined by Powell et al [13].

Label of the category	Intervene with care recipients and users to enhance uptake and adherence
Description of the content	Development of methods to strengthen stakeholder engagement, facilitate feedback for problem-solving, and promote adherence and uptake.
Application of the category	For example, maintaining regular communication with stakeholders to gather insights on effectively integrating a telehomecare program and thereby improving adherence.
Example for application	"As such, continued dialogue and knowledge exchange among and between stakeholders surrounding how to best integrate the Telehomecare program across local and regional contexts needs to occur (Hunting et al [23])

The entire category system is in Multimedia Appendix 4.

One researcher (DKS) was primarily responsible for developing the deductive coding system in MAXQDA 24. To ensure a consistent understanding and clear differentiation among the individual deductive categories, a second researcher (MD) independently reviewed and validated the coding framework. Following revisions made by DKS, the finalized coding system was applied in the first round of deductive content analysis of the included studies.

After DKS completed the initial coding process, MD independently reviewed the coding of 4 randomly selected articles [24-27]. The 4 independently reviewed articles served as calibration cases to assess the consistent application of the deductive coding framework and to identify potential ambiguities in category interpretation.

The coding results were subsequently discussed by DKS and MD, and any ambiguities or discrepancies were resolved through consensus. The entire process was documented in a project logbook within MAXQDA 24 (VERBI Software GmbH, Berlin, Germany). Consultation with a third reviewer (RK) had been planned in the event that disagreements could not be resolved through discussion; however, this was not necessary.

Subsequently, DKS conducted a second round of the data analysis to further enhance the rigor and consistency of the coding process. In addition, preliminary findings were presented at a national conference on health services research to obtain external feedback and to support the validation of the results [28]. The feedback received was documented in the project logbook and subsequently discussed among DKS, MD, and RK.

To synthesize and present the findings of this scoping review, we developed a structured data presentation template (our published scoping review protocol [16]). This template includes all identified implementation strategies from the ERIC framework [13], organized according to the thematic clusters proposed by Waltz et al [12] The implementation strategies are presented in relation to the respective DNT with which they were associated. Furthermore, the main text highlights and describes the most frequently identified and reported implementation strategies within each thematic cluster.

Ethical Considerations

Ethical approval was not necessary based on the literature review approach.

Results

Overview

The systematic literature search yielded 561 records (including review articles) after duplicate removal. During the title and abstract screening, 449 records were excluded. In addition, 2 full-text articles could not be retrieved. Consequently, 112 articles were assessed for eligibility through full-text screening.

Based on the predefined exclusion criteria, 110 articles were excluded, primarily because they lacked a focus on implementation strategies or were conducted in settings other than home care. During the full-text screening stage, the included review articles were used for backward citation searching of their reference lists.

Ultimately, 18 articles [23-27,29-41] met the eligibility criteria and were included in the data extraction process. Neither backward nor forward citation searching identified any additional eligible articles during the initial review process (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the article selection process, Page et al [21].

With the updated systematic literature search conducted in July 2026, 4 additional eligible articles [42-45] were included in the data charting process.

Study Characteristics

Our systematic literature search identified 22 articles from 18 studies. Three of the 18 studies are study protocols [24,29,30], each linked to a single study, whereas one does not present results yet [24].

Most of the primary studies and study protocols focused on implementation studies (n=9) [23,25,26,31-35,42-44], addressing barriers and facilitators to implementation, strategies to overcome barriers, and stakeholder engagement. Five studies reported feasibility findings, including acceptability and usability of DNTs [27,36-39]. One article presented feasibility results within a randomized controlled trial (RCT), and 2 reported RCT outcomes on DNT effectiveness [40,45].

Most articles were published in 2022 (n=7) [25,32,33,38,39,42,43], 2025 (n=4) [40,44-46], 2024 (n=3) [26,31,35], and 2023 (n=4) [24,33,34,42,43] with publication activity increasing since the onset of the COVID-19 pandemic in 2021. In addition, most of the studies were conducted in Europe (n=9) [24,25,31,37,39,41,42,44], such as in Sweden, Norway, the Netherlands, and Switzerland, followed by the USA (n=4) [31,39,41]. A small number of scientific investigations were performed in Canada (n=2) [23,30], Taiwan (n=2) [26,35], and Australia (n=1) [33]. Detailed study characteristics are presented in the General Information section in Multimedia Appendix 3.

Digital Nursing Technology

Overview

Across the 22 included articles, 18 distinct DNTs [23,25-27,29-36,38,39,41,42,44,45] were identified. The DNTs differed substantially in terms of functionality, purpose, technological maturity, and terminology. For descriptive purposes, the 18 DNTs were clustered into thematic categories based on the components reported by the respective study authors.

Remote Home Care DNT

We identified 10 DNTs that can be classified as remote home care technologies. Four of these technologies specifically target people with dementia and their relatives by providing condition-specific support, such as the smart vest with integrated sensors [35] and the FamTechCare intervention [27,29]. FamTechCare is a telehealth video-monitoring system that enables informal caregivers to record challenging situations in the home environment and receive expert feedback from specialized nurses [27,29]. Similarly, the customized care platform stores physiological and behavioral data from people with dementia, enabling home care nurses to remotely review and monitor these data [34].

Wrede et al [25] describe an unobtrusive monitoring (UM) system that continuously tracks comparable parameters using wearable devices and cameras.

Another remote home care DNT, the Behavioral and Environmental Sensing and Intervention for Cancer (BESI-C) system, focuses on the remote monitoring of physiological

XSL•FO
RenderX

parameters and pain-related activities among individuals experiencing cancer-related pain [38].

A similar approach for palliative home care is described by Oelschlägel et al [31,37], who report the use of medical devices, such as blood pressure monitors and pulse oximeters, combined with communication options including telephone calls and digital messaging. The Telehomecare program further incorporates self-management support for individuals with chronic obstructive pulmonary disease (COPD) and heart failure (HF) [23].

A further DNT is designed for care recipients with chronic wounds receiving care at home. Based on the principles of telenursing, it provides education, guidance, and professional support through remote home visits [46].

Finally, 3 DNTs are not tailored to a specific health condition but are intended for older adults (≥65 years) living at home and receiving formal care. These DNTs include sensor-based monitoring systems [30,40], social alarms [41], and home-integrated warning systems [35]. All are designed to detect unusual activities and trigger alerts when necessary. In contrast to the automated monitoring systems, social alarms require care recipients to actively request assistance by pressing a button on a wearable device, such as a necklace or wristband [41].

App-Based DNTs

Two of the 18 DNTs can be classified as app-based technological innovations, each targeting a different group. The Digital RELIEF App (version 3.7; uCarenet Technologies Inc) is designed for palliative care patients, enabling daily symptom reporting [39]. In contrast, the CareHeroes App provides structured information, links to services, and emotional and decision-making support for informal caregivers of individuals with Alzheimer disease [36].

Decision Support DNTs

Three of the 18 DNTs [23,25-27,29-36,38,39,41,42,44,45] were classified as decision-support technologies. One of these was designed to support informal and formal caregivers, as well as other care staff, in making care-related decisions for people with dementia [33]. The other was developed as a remote care assist (RCA) system to facilitate the delivery of care by nursing staff in home care settings [44].

Communication-Focused DNTs

One of the identified DNTs is TalkingMats, an interactive communication tool designed to facilitate communication and engagement among older care recipients [24]. Another identified DNT was the Generation Connect platform (Generation Connect, Inc), which enables formal and informal caregivers of people with dementia to connect with one another and access an integrated app providing evidence-based information [32]. A further communication-focused DNT, Viva, is a digital platform designed to support older adults in maintaining an independent and self-determined lifestyle by providing resources for self-management, health monitoring, and personalized technical assistance [45].

Robotic DNTs

Among the identified 18 DNTs [23,25-27,29-36,38,39,41,42,44,45], a robotic device for medication management was designed for use in home care settings. The technology supported care recipients in adhering to their medication regimens by promoting timely and accurate medication intake [42,43].

Implementation Strategies

Overview

We present the proposed and used implementation strategies identified through the deductive content analysis based on the ERIC framework [13,32], operationalized for home care setting and the DNT according to the thematic clusters proposed by Waltz et al [12,40].

Within each thematic cluster, we describe the most frequently identified and reported ERIC implementation strategies.

In addition, Table 4 provides an overview of the implementation strategies identified for each DNT. Furthermore, the frequency with which each implementation strategy was identified across all included DNTs was calculated. This overview highlights which ERIC implementation strategy was most frequently proposed or applied to support the implementation of DNTs in home care settings.

[a]DNT: digital nursing technology.

[b]RPM: remote patient monitoring.

[c]RHC: remote home care.

[d]BESI-C: Behavioral and Environmental Sensing and Intervention for Cancer.

[e]UM: unobtrusive monitoring.

[f]STA: smart technology-assisted.

XSL•FO
RenderX

Across the 18 included DNTs, the deductive content analysis identified 48 of the 73 ERIC implementation strategies [13,40].

Change Infrastructure

We identified 4 of the 8 ERIC implementation strategies within this thematic cluster.

The 2 most frequently identified strategies were (1) change service sites, which was identified for 6 DNTs [25,30,31,33,37,39,40], and (2) change physical structure and equipment, which was reported for 6 DNTs [25,26,31,34,37,39].

The strategy change service sites was identified in studies where the context, setting, or mode in which a technology was delivered required adaptation. For example, Lin et al [35] evaluated modifications to the implementation and use of a smart vest to ensure its suitability within the intended care setting.

Furthermore, the implementation of DNT often required adaptations to the physical infrastructure and technical equipment needed to support their use. Accordingly, the strategy change physical structure and equipment included the implementation of the social alarm [41] and the unobtrusive monitoring system described by Wrede and colleagues [25].

Use Financial Strategies

Out of the 9 financial implementation strategies in the ERIC framework, 2 were identified in the included DNTs: (1) alter incentive/allowance structures and (2) access new funding. Access new funding was reported when additional financial resources were required to support the implementation of a DNT. For example, project consortium partners covered the costs of hardware components, such as the medical devices required for technology-enabled remote patient monitoring (RPM) [30,40].

In contrast, the strategy to alter incentive/allowance structures was reflected in the use of existing funding mechanisms and financial support programs. For instance, the implementation of the Generation Connect platform relied on available governmental funding opportunities to support its adoption and use [32].

Engage Care Recipients and Formal and Informal Caregivers

All 4 implementation strategies within this cluster were identified in the included DNTs. The strategy Prepare care recipients to be active participants was identified in 6 DNTs [27,29,30,33-35,39,40]. This strategy involved preparing and motivating care recipients prior to the adoption and use of a DNT to encourage active participation in needs assessment, feedback provision, and the communication of concerns. Examples are the FamTechCare intervention [27,29] and the Digital RELIEF App [39].

Similarly, the strategy involve care recipients, formal and informal caregivers was identified for several DNTs [25,31-34,38,39]. This strategy was reflected in efforts to engage care recipients and their relatives before implementation began, thereby ensuring that their needs and preferences were considered during the implementation process. Examples included the telemonitoring technology described by Liljeros and Arkkukangas [34] and the Enabling Choices Tool developed by Meyer et al [33].

During the implementation process itself, the strategy Intervene with care recipients to enhance uptake and adherence was identified for 6 DNTs [23,31,34,35,37,38,45]. This strategy included obtaining feedback on the use and acceptability of DNTs and addressing barriers to continued use. For example, it was applied in the Telehomecare program described by Hunting et al [23] and in the implementation of the smart vest evaluated by Lin et al [35].

Support Home Care Team

Within this cluster, 3 of the 5 ERIC implementation strategies were identified: (1) create new teams [26], (2) develop resource-sharing agreements [25,30,40], and (3) remind care recipients, formal and informal caregivers [23,26,35,36].

The most frequently identified strategy within this cluster was reminding care recipients and formal and informal caregivers, which was reported for 4 DNTs [23,26,35,36]. This strategy involved reminding care recipients, formal caregivers, and informal caregivers to perform specific actions related to the use of a DNT. Examples included reminders to wear the smart vest with integrated sensors [35] and to update and actively use the CareHeroes App [34].

Train and Educate Stakeholders

The most frequently identified implementation strategy within this cluster was to conduct educational meetings (N=14) [23,25,29,31-36,38,39,41,42,44,45]. Educational meetings were conducted with relevant stakeholders involved in the implementation of DNT, including nurses, technicians, clinicians, and care recipients. For example, during the implementation of the BESI-C system, stakeholders met with care recipients in their homes before the technology was adopted and used [38]. These meetings served not only to install the technology but also to provide education and information regarding its operation and intended use.

Educational efforts frequently extended beyond the initial implementation phase through the strategy of conducting ongoing training, which was identified for 9 DNTs [25,26,29,31,32,34,35,37,42,43,45]. This strategy involved providing continued support and training to ensure the effective and sustained use of DNTs. For instance, Gilson et al [32] reported that follow-up sessions were necessary during the implementation of the Generation Connect platform to ensure proper functionality and to provide additional educational support when required. Finally, the strategy train-the-trainer was identified for 9 DNTs [23-25,27,29,31,32,37,38,42-44]; for example, during the implementation of a remote home care intervention evaluated by Oelschlägel et al [31,37], nurses and other health care professionals received training that enabled them to subsequently educate and support care recipients in the use of the technology.

Develop Stakeholder Interrelationships

Out of the 17 implementation strategies included in this cluster, 12 were identified for the included DNTs. The most frequently

XSL•FO
RenderX

identified strategy was promote network weaving (n=8) [23,25,27,29-31,34,37,38,40,41]. This strategy involved fostering collaboration and communication among stakeholders involved in the implementation process. For example, during the implementation of technology-enabled remote monitoring systems [30,40], close collaboration with technical staff was necessary to address technical issues that arose in care recipients' homes.

Another frequently identified strategy was to identify and prepare champions, which was reported for 6 DNTs [23,30,33,34,39,40,42,43]. This strategy involved engaging individuals who actively supported and promoted implementation efforts within their home care nursing service. For instance, nurses served as champions during the implementation of the Digital RELIEF App by providing guidance and support when care recipients encountered uncertainties or technical difficulties [39].

In addition, the strategy of developing academic partnerships was identified for 5 DNTs [23,32-34,36]. Unlike promoting network weaving, this strategy involved establishing formal partnerships with universities and research institutions to facilitate collaborative training, provide methodological expertise, and support the implementation process.

For example, during the implementation of telemonitoring technology [34], researchers acted as project leaders and contributed to monitoring and evaluating the implementation process.

Adapt and Tailor the DNT, and the Strategies to the Respective Implementation Context

We identified promote adaptability as the most frequently applied implementation strategy within this cluster (n=14) [23-27,29-31,33,34,36-43]. This strategy involved modifying a DNT or its implementation process to better align with the needs and circumstances of the intended users and care setting. For example, the Digital RELIEF App [39] was evaluated in a feasibility study, in which family caregivers indicated that the technology would be more practical if it were available in formats beyond a web-based app. Based on this feedback, adaptations to the design and delivery of the DNT were considered necessary to improve its fit within the home care setting.

This finding was closely related to the second most frequently identified strategy within this cluster, tailor implementation strategies (n=5) [23,27,35,38,41]. This strategy involved adapting implementation approaches to address the specific needs, preferences, and contextual factors of stakeholders involved in the implementation process.

Provide Interactive Assistance

Within this cluster, we identified 2 of the 4 ERIC implementation strategies: (1) centralize technical assistance (n=5) [26,31,34,37,38,40] and (2) provide local technical assistance (n=7) [23,25,35,38,40,42-44].

The strategy of centralizing technical assistance was identified when responsibility for technical support was assigned to a centralized source. For example, in the implementation of technology-enabled remote patient monitoring, a designated technician managed technical requests, resolved system-related issues, and provided technical solutions [40].

In contrast, the strategy to provide local technical assistance involved providing access to local technical support, often through an IT department within the home care organization, to assist users in resolving technical issues that arose during the implementation and use of the DNT. For example, nurses received reliable support from the internal IT department during the implementation of the robotic medication management system [42,43].

Use Evaluative and Iterative Strategies

We identified obtaining and using feedback from care recipients and their relatives as one of the most frequently reported implementation strategies, appearing for 8 DNTs [23,30,31,33,34,36,37,39,40,44]. This strategy involved systematically collecting and using feedback from care recipients and their relatives to inform the implementation and refinement of DNT. For example, Donelle et al [30,40] administered a survey based on validated instruments to assess outcomes such as satisfaction with passive remote monitoring among care recipients and their relatives, as well as their perceived sense of safety.

Closely related to this strategy was assessing for readiness and identifying barriers and facilitators, which was also identified for 7 DNTs [27,29,31,33-35,37,38,41]. This strategy was proposed or used to explore factors that could support or hinder the adoption and implementation of DNT. For instance, Lin et al [35] conducted interviews to assess participants' concerns, motivations, and needs before implementation and continued these assessments during technology use to obtain feedback and identify opportunities for improvement.

Discussion

Heterogenity of Identified Implementation Strategies

Our scoping review identified the implementation strategies proposed and used to implement DNTs in home care. For each of the 18 included DNTs [23,25-27,29-36,38,39,41,42,44,45], implementation strategies were extracted and analyzed from the corresponding articles. However, when considering all included DNTs collectively, the identified implementation strategies appeared highly heterogeneous.

This heterogeneity may be explained by 3 factors: first, the diversity of examined DNT across the included articles; second, the wide range of study designs represented in those studies; and third, the home care settings as implementation context itself.

Regarding the DNT diversity, Krick et al [5] attempted to categorize DNT in their scoping review on the acceptance, effectiveness, and efficiency of DNT for formal and informal caregivers across different care settings. They proposed several broad technological categories, including information and communication technologies and robotic systems. However, the authors concluded that establishing clear conceptual boundaries between DNT categories remains challenging due

XSL•FO
RenderX

to the considerable diversity and ongoing evolution of DNT. Consistent with these findings, we were unable to identify clear patterns linking specific implementation strategies to distinct categories or types of DNT.

We therefore strongly recommend that future research prioritize the development and refinement of robust and widely accepted classifications of DNT. Such categorization would not only improve comparability across studies but would also support decision-makers and implementation practitioners in navigating the rapidly expanding market of DNT and selecting appropriate ones for specific care contexts.

The heterogeneity of identified implementation strategies may also be explained by differences in study design and research objectives. Notably, relatively few studies applied theories, models, or frameworks (TMFs) from implementation science to address implementation-related research questions [47]. The majority of included studies were classified as implementation studies because they either explicitly used the term implementation or applied implementation science TMFs. Not all of these studies used a specific TMF to guide implementation planning or evaluation. Several studies described the adoption and implementation of a DNT only descriptively. Furthermore, we included effectiveness studies, feasibility studies, and qualitative investigations that retrospectively explored interest holders' experiences with implementing and using DNT, such as robotic medication management systems [42,43]. Consequently, the aims and methodological focus of the included studies varied considerably. This variation likely influenced both the level of detail reported and the transparency of implementation procedures. As a result, it is reasonable to assume that the implementation strategies identified for individual DNT may be incomplete.

Future studies should therefore ensure transparent and detailed reporting of implementation processes, regardless of study design or primary research objective. Such reporting is essential for understanding, reproducibility, and knowledge transfer. Previous research has demonstrated that insufficient implementation quality and low implementation fidelity may not only reduce intervention effectiveness but can also negatively affect important implementation outcomes, including adoption, acceptability, feasibility, and sustainability [48,49].

The third explanation for the inability to provide a comprehensive overview of DNT categories and their associated implementation strategies for decision-makers and implementation practitioners lies in the unique implementation context of home care. Home care is widely recognized as a highly dynamic and individualized setting. As emphasized in implementation science frameworks, contextual factors play a critical role in influencing the adoption and sustained use of innovations [50]. Across the studies included in our review, home care was consistently characterized as a highly individualized environment, as DNTs are implemented and used within the private living spaces of care recipients [51]. Consequently, addressing barriers to the acceptance and use of DNTs may be considerably more challenging than in more structured health care settings, such as hospitals [51].

This observation is supported by Walzer et al [9], who conducted an umbrella review of barriers and facilitators influencing the implementation of DNT using the NASSS framework [11]. Although the authors did not differentiate between implementation contexts, which is a factor known to be critical for implementation success [45], they explicitly acknowledged this limitation. Moreover, based on comparisons with previous research, they suggested that many of the identified barriers may also be relevant across different health care professions and care settings [9]. Prominent barriers included resource constraints, inadequate infrastructure, incompatibility with existing workflows and organizational processes, as well as challenges related to leadership and communication [9].

Frequently Identified Implementation Strategies Across DNTs

Across the included 18 DNTs, the identified implementation strategies varied considerably. However, several implementation strategies were repeatedly identified across these 18 DNTs. This observation prompted us to consider the potential reasons for their frequent occurrence and their implications for the implementation of DNT in home care. To operationalize this process, we established a threshold requiring an implementation strategy to be identified in at least 50% of the DNTs (minimum n=9). Applying this criterion resulted in the identification of 4 frequently occurring implementation strategies: conduct educational meetings (n=14), promote adaptability (n=14), conduct ongoing training (n=9), and train-the-trainer (n=9).

One possible explanation for the frequent occurrence of these strategies is that they may play a particularly important role in facilitating successful implementation and may positively influence implementation outcomes such as acceptability, adoption, feasibility, and sustainability. According to Proctor et al [52], implementation outcomes are intended to evaluate the success or failure of implementation efforts based on the perspectives and experiences of relevant interest holders.

To better understand the potential significance of these frequently identified implementation strategies, our findings can be compared with those reported by Ashcraft et al [53], who conducted a systematic review examining the use, effectiveness, and combinations of ERIC implementation strategies across health and human service settings. In addition to assessing which ERIC strategies were most commonly tested, the authors investigated how implementation strategies were combined into multifaceted implementation approaches and evaluated their effects using outcomes derived from the RE-AIM (Reach, Effectiveness, Adoption, Implementation, and Maintenance) framework [54]. The review included 129 studies, approximately half of which (50%) were conducted in outpatient settings. Across these studies, the most frequently assessed RE-AIM outcomes were effectiveness (n=82) and implementation (n=73). Notably, conducting educational meetings, which was among the most frequently identified strategies in our review, was also the most frequently evaluated ERIC strategy in the review by Ashcraft et al [53] (n=68). Overall, the authors reported comparatively strong evidence supporting its effectiveness across several RE-AIM outcomes.

XSL•FO
RenderX

The other implementation strategies frequently identified in our review were also examined by Ashcraft et al [53], although less extensively. Promoting adaptability was evaluated in 36 studies, conducting ongoing training in 29 studies, and train-the-trainer in 8 studies. Importantly, these strategies were most often implemented as part of a multifaceted implementation strategy rather than as a single strategy. Consequently, the evidence base for their individual effectiveness remains comparatively limited [53].

Regarding the implementation strategies most frequently identified in our scoping review, these findings suggest that each strategy may function either as a stand-alone implementation strategy for the implementation of DNT in home care or as part of a multifaceted implementation strategy. However, it is important to emphasize that these repeatedly identified implementation strategies have neither been empirically validated nor claimed to represent a comprehensive set of strategies.

As discussed previously, the implementation strategies identified in this review were highly heterogeneous for several reasons, including differences in study design, implementation context, DNT type, and stage of implementation. Ashcraft et al [53] examined the role of ERIC implementation strategies across different phases of the implementation process. With their findings, we can suggest that conducting educational meetings, train-the-trainer, and promoting adaptability are particularly relevant during the preparation phase prior to implementation. In contrast, conducting ongoing training appears to play a more important role during active implementation by supporting the continued adoption and sustained use of a DNT.

At present, the proposed multifaceted implementation strategy may serve as a useful starting point for future implementation research examining its effectiveness in supporting the implementation of DNT in home care. In addition, it may provide decision-makers and implementation practitioners with practical guidance for facilitating the implementation of specific DNT within their nursing services.

Nevertheless, a common criticism of the ERIC implementation strategies is that they lack sufficient specificity and operationalization [8], which may also explain the frequent occurrence of certain implementation strategies in our scoping review. Conversely, less frequently occurring implementation strategies may simply be underreported.

To address the limitation of poorly operationalized and consequently underreported implementation strategies, Proctor et al [8] recommend specifying implementation strategies in greater detail to generate more actionable recommendations for decision-makers, implementation practitioners, and implementation researchers. Such specification is particularly important given the generally low quality of implementation strategy reporting in the included articles. Drawing on these recommendations and their application within the context of our scoping review, we propose the identified multifaceted implementation strategy as actionable guidance for decision-makers and implementation practitioners seeking to support specific implementation efforts.

Based on the findings of this study, several practical recommendations can be derived for decision-makers and implementation practitioners involved in the implementation of DNT in home care. The terminology used was adopted from the ERIC framework to ensure consistency with comparable applications [13].

First, implementation practitioners within the respective nursing service should organize structured educational meetings tailored to the needs and existing knowledge of different interest holder groups. These meetings should be conducted during the preparation phase prior to DNT adoption and should provide interest holders with information about the technology's intended purpose, key considerations for its safe and effective use, and their respective roles and responsibilities throughout the implementation process.

In addition, implementation practitioners should promote adaptability during the preparation phase by identifying which components of the DNT can be tailored to local circumstances, such as staffing structures, care processes, available resources, digital competencies, and the characteristics of the care recipient population. At the same time, the core components of the technology and implementation process should be clearly defined and preserved to ensure implementation fidelity.

Furthermore, implementation practitioners should plan and establish ongoing training opportunities for different stakeholder groups and end users of the targeted DNT. This planning should take place during the preparation phase, while training activities should be offered continuously throughout the implementation process. Ideally, these training opportunities should support the long-term development, retention, and application of the knowledge and skills required for effective technology use.

Finally, implementation practitioners should receive initial training from the DNT provider during the preparation phase prior to implementation to ensure that the technology is used appropriately and effectively. Through a train-the-trainer approach, implementation practitioners can subsequently deliver training and support to other interest holder groups and end users throughout the implementation process, thereby facilitating the sustainable adoption and integration of the DNT within the nursing service.

Despite these practical recommendations, it is important to note that this multifaceted implementation strategy has neither been empirically evaluated for its effectiveness nor tested in real-world implementation settings.

Limitations

We acknowledge several methodological limitations that should be considered when interpreting these findings.

First, we conducted our systematic search across 3 carefully selected databases and supplemented it with additional search techniques, including backward and forward citation searching [19]. Although we developed the study protocol rigorously and preregistered it on OSF, it remains possible that some relevant publications were not identified.

Second, limited resources precluded independent and parallel data extraction across all researchers. However, several

XSL•FO
RenderX

mitigation measures were used to enhance the rigor and trustworthiness of the review process. As described in the Methods section, one researcher (DKS) conducted the data extraction and developed the deductive coding framework, while a second researcher (MD) cross-checked these outputs. In addition, as specified in the study protocol [16], MD independently analyzed a predefined subset of studies. Preliminary findings were also presented at the German Congress for Health Services Research, organized by the German Network for Health Services Research, and were subsequently discussed with an independent researcher (RK) to enhance the credibility of the findings.

Third, we did not conduct a critical appraisal of the included studies. This decision was consistent with the aim of the review, which was to identify and map implementation strategies for DNT in home care rather than to evaluate their effectiveness. However, this methodological decision has important implications for the interpretation of our findings. In particular, the frequency with which individual implementation strategies were identified should not be interpreted as evidence of their feasibility, appropriateness, or effectiveness. Rather, these frequencies reflect how often implementation strategies were reported for the respective DNT. Future systematic reviews focusing on the effectiveness of implementation strategies for DNT in home care should therefore incorporate a formal critical appraisal of included studies.

Several limitations related to the findings themselves should also be considered. Our predefined inclusion and exclusion criteria regarding context, population, and concept may limit the transferability of the findings to other settings and target populations, even in the same home care setting. Furthermore, the considerations discussed earlier regarding the applicability of multifaceted implementation strategies across different types of DNT should be taken into account.

In addition, many DNTs are commercially developed and marketed. As a result, the available evidence may be biased toward DNT that have undergone scientific evaluation and have subsequently been reported in peer-reviewed publications. Differences in study design across the included studies should also be considered when interpreting the identified implementation strategies for specific DNT, particularly with regard to the developmental stage and level of implementation maturity of each technology.

Despite these limitations, this review provides valuable insights into the implementation strategies proposed and used to support the adoption and use of DNT in home care settings. Furthermore, it identifies a potential multifaceted implementation strategy that may serve as a useful starting point for future implementation efforts and research in home care.

Conclusions

By providing a comprehensive overview of researched DNT in home care and the implementation strategies proposed and used to support their adoption, we generated insights that confirm the complexity and challenges associated with implementing DNT in home care. However, systematic implementation requires time, a resource that is often scarce in home care settings for nursing staff, care recipients, and their relatives, particularly in the context of an aging population.

The findings of this study contribute to both implementation science and practice. They highlight important directions for future research, particularly regarding the application of explicitly operationalized and well-specified implementation strategies to support the implementation of specific DNT in home care and to improve the transparency of implementation strategy reporting. Based on their frequency of reporting across the included studies, we identified several commonly occurring implementation strategies and synthesized them into a multifaceted implementation strategy. Future research should focus on empirically evaluating the feasibility, appropriateness, and effectiveness of this strategy and the single implementation strategies within this bundle in real-world settings.

Furthermore, our findings allow us to derive practical recommendations for decision-makers and implementation practitioners in home care based on the frequently reported implementation strategies. Finally, given the increasing availability and market penetration of DNT, further research is needed to develop meaningful classification systems for these technologies and to better understand how they can be integrated into routine practice. Such evidence would enable decision-makers and implementation practitioners to align specific categories of technologies with potentially effective implementation strategies, thereby supporting their efficient adoption, sustained use, and long-term integration into home care.

Acknowledgments

We are grateful for the constructive exchange and the opportunity to present our preliminary research findings for validation at the German Congress for Health Services Research, hosted by the German Network for Health Services Research (DNVF).

We further thank the PhD candidates supervised by Prof. Dr. Volker E. Amelung and Prof. Dr. Christian Krauth at the Institute for Epidemiology, Social Medicine, and Health Systems Research for the opportunity to present the planned study procedures in terms of the PhD colloquium and for their valuable feedback.

Generative AI Use

Additionally, we used GPT-5 (Copilot/Microsoft), which is strongly recommended by the information technology department at Hannover Medical School, exclusively for linguistic proofreading of the manuscript. We instructed the AI using the prompt: “Check the entire manuscript for grammar and academic American English writing style.”

Abstract

Background: Algorithm-enabled remote monitoring using cardiac implantable electronic devices (CIEDs) is increasingly used to support earlier detection of clinical deterioration in heart failure and in at-risk populations. However, the economic value of these technologies remains uncertain because intervention design, implementation, and evaluation methods vary.

Objective: This study aimed to systematically identify, appraise, and synthesize full economic evaluations of algorithm-enabled CIED remote monitoring in adults with established heart failure or at risk of heart failure.

Methods: A systematic review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines. Searches were performed in MEDLINE, Embase, Scopus, Web of Science, and the Cochrane Library, with supplementary searches of health technology assessment sources. Eligible studies reported full economic evaluations of algorithm-enabled remote monitoring linked to CIEDs. Data were extracted using a structured form and synthesized narratively due to heterogeneity. Methodological and reporting quality were assessed using the CHEQUE (Criteria for Health Economic Quality Evaluation) checklist and CHEERS (Consolidated Health Economic Evaluation Reporting Standards) 2022 statement. One reviewer screened records and extracted the data. A second reviewer independently checked subsets of the screening decisions and extracted the data.

Results: Ten economic evaluations were included. They used models, trial data, or observational data; some were reported within health technology assessments. Substantial heterogeneity was observed in population definitions, intervention characteristics, algorithm types, monitored parameters, clinical response pathways, and economic methods. Cost-effectiveness and cost-utility analyses were most common, with time horizons ranging from short-term follow-up to lifetime modeling. Several studies reported economically favorable findings, including dominance (ie, less costly with better health outcomes) or cost-effectiveness. However, outcomes varied across studies, and favorable estimates often relied on assumptions about reduced hospitalization and length of stay, while quality-adjusted life year gains were generally modest. Reporting of key implementation factors, including alert burden and diagnostic performance, was limited.

Conclusions: There is economic evidence for algorithm-enabled CIED remote monitoring suggesting potential value in some settings, but the evidence remains methodologically heterogeneous and difficult to compare directly across studies. Findings are sensitive to differences in intervention design, modeling approaches, and clinical input data, which limit certainty and transferability. More robust and standardized evidence is needed before economic conclusions can be applied confidently across different devices, algorithms, and health care settings.

Introduction

Heart failure (HF) is a chronic, progressive syndrome associated with substantial morbidity, mortality, and health care use [1]. Despite therapeutic advances, outcomes following HF admission remain poor, with the UK National Heart Failure Audit reporting 39% all-cause mortality at 1 year after discharge and 9% in-hospital mortality [2]. Because HF is characterized by periods of relative stability interrupted by episodes of worsening or decompensation [3-5], care models have increasingly shifted toward proactive surveillance and earlier detection of deterioration [6]. Remote monitoring via cardiac implantable electronic devices (CIEDs), including pacemakers, implantable cardioverter-defibrillators (ICDs), cardiac resynchronization therapy pacemakers (CRT-Ps), and cardiac resynchronization therapy defibrillators (CRT-Ds), is increasingly used to enable earlier identification of clinically important changes [1]. CIEDs record information about device performance and the patient's health. A home monitor or compatible phone sends these data to a secure platform. Data may be sent at set times or after the device detects an event [7]. Some systems use predefined rules to generate an alert when a condition is met. Others combine several device measurements to estimate the patient's risk of worsening HF [8]. A clinician can review the alert and contact the patient or change their care if needed [9]. The same monitoring program may use scheduled transmissions, event-driven transmissions, and automated alerts. This review, therefore, focused on algorithm-enabled systems as these features may influence both clinical pathways and the structure of economic evaluation.

The economic evaluation of algorithm-enabled remote monitoring may pose additional challenges compared with evaluating medicines and medical devices without remote monitoring functions. Digital health interventions are often interactive, rapidly evolving, and dependent on user engagement. At the same time, narrow health service perspectives and cost per quality-adjusted life year (QALY) metrics alone may not fully capture the broader societal consequences and service-level impacts relevant to digital health interventions [10]. In addition, value may depend on diagnostic performance, the deployment model, referral thresholds, the consequences of false positives and false negatives, and supporting digital infrastructure [11]. These issues may be relevant in algorithm-enabled pathways, where alert burden, clinical workflow, and downstream resource use may influence cost-effectiveness estimates. At the system level, many health technology assessment (HTA) frameworks have been developed for pharmaceuticals and medical devices without remote monitoring functions. They may not adequately capture the iterative, infrastructure-dependent, and context-sensitive nature of digital technologies [12]. The challenge is whether economic evaluations of these systems capture patient and caregiver time, changes in clinical workload, and digital infrastructure costs alongside health care costs and QALYs.

Evidence on the clinical, service, and economic impact of CIED remote monitoring remains mixed and depends on the monitoring system, patient population, and care pathway. Some studies have reported limited effects on major outcomes such as all-cause mortality or cardiovascular hospitalization despite improvements in process outcomes such as faster clinical decision-making and fewer scheduled visits [13]. Others have reported reductions in HF hospitalizations, shorter lengths of stay, lower mortality risk, and lower overall health care service use [14,15], with better outcomes among patients with higher monitoring adherence [16]. Economic evaluations have generally applied cost-effectiveness and cost-utility frameworks, and many have reported economically favorable findings. There has been trial-based evidence suggesting modest QALY gains and lower patient-borne costs [17]. Model-based evaluations, particularly those using longer time horizons, have reported cost-effectiveness or cost-saving conclusions [18-21]. However, findings remain sensitive to alert frequency, algorithm design, device type, clinical response pathways, reimbursement assumptions, analytic perspective, costing methods, and model structure [22,23], limiting comparability and transferability.

Most reviews have focused primarily on clinical outcomes and reported mixed effects without a detailed economic appraisal [22,24]. Raes et al [25] examined CIED telemonitoring across broader indications and did not specifically address algorithm-enabled systems in HF populations. The National Institute for Health and Care Research (NIHR) HTA report by Kenny et al [26] systematically reviewed clinical and economic evidence for 4 HF monitoring algorithms and developed an independent economic model. Consequently, a gap remains in understanding how algorithm-enabled remote monitoring has been evaluated economically, how methodological choices may shape the findings, and what limitations hinder comparability and policy interpretation.

Taken together, the clinical and economic value of algorithm-enabled CIED remote monitoring remains unclear. The available evidence is difficult to interpret because interventions, implementation contexts, and evaluation methods vary across studies. A systematic review is therefore needed to synthesize the existing evidence, examine the methodological approaches used, and identify the limitations that affect comparability and policy interpretation.

This systematic review aimed to identify, appraise, and synthesize full economic evaluations of algorithm-enabled remote monitoring using CIEDs to (1) describe the characteristics and methodological features of the included economic evaluations, including economic modeling structure, analytical perspective, and uncertainty analysis; (2) summarize the clinical outcomes, economic outcomes, and main cost-effectiveness findings reported across studies; and (3) identify methodological limitations and evidence gaps that may affect model development, comparability, and policy interpretation.

Methods

Reporting and Registration

This review has been reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines [27], and the protocol was developed in line with the PRISMA-P (Preferred Reporting

XSL•FO
RenderX

Items for Systematic Reviews and Meta-Analyses Protocols) 2015 guidelines [28]. The protocol was prospectively registered in PROSPERO (CRD420251179324) and is publicly available in *JMIR Research Protocols* [29].

Eligibility Criteria

Eligibility criteria were predefined using the population, intervention, comparator, outcome, and study design framework and are summarized in Table 1. Studies were eligible if they reported full economic evaluations of algorithm-enabled remote monitoring linked to CIEDs in adult HF or at-risk populations.

Table . Eligibility criteria based on the PICOS (population, intervention, comparator, outcome, and study design) framework.

Domain	Eligibility criteria
Population	Adults aged ≥18 years with heart failure, or populations defined in the primary studies as being at risk of heart failure, managed using cardiac implantable electronic devices (CIEDs[a]), including ICDs[b], CRT-Ps[c], CRT-Ds[d], or pacemakers.
Intervention	Algorithm-enabled remote monitoring integrated with CIEDs to detect worsening heart failure or events and alert generation.
Comparator	Standard in-person follow-up, usual care without remote monitoring, or alternative remote monitoring strategies.
Outcomes	At least one economic outcome, including ICERs[e], incremental costs, QALYs[f], life-years gained, net monetary benefit, or related cost-effectiveness endpoints. Clinical outcomes and alert performance measures were also extracted where reported.
Study design	Full economic evaluations, including trial-based and model-based cost-effectiveness, cost-utility, and cost-benefit analyses. Cost-consequence analyses were also retained where relevant. Conference abstracts were included only when sufficient methodological and outcome data were available.
Exclusion criteria	Non-English studies; studies not evaluating device-linked remote algorithms; studies not reporting economic outcomes; protocols; trial registry entries without results; narrative reviews; and perspective papers.

[a]CIED: cardiac implantable electronic device.

[b]ICD:implantable cardioverter-defibrillator.

[c]CRT-P: cardiac resynchronisation therapy pacemaker.

[d]CRT-D: cardiac resynchronisation therapy defibrillator.

[e]ICER: incremental cost-effectiveness ratio.

[f]QALY: quality-adjusted life-year.

An eligible intervention used CIED remote monitoring with continuous connectivity or intermittent data transmissions. It generated an alert for clinical review when the data indicated possible worsening HF or an event. A commercial algorithm name was not required.

Information Sources and Search Strategy

A systematic search was conducted between November and December 2025 in MEDLINE (Ovid), Embase (Ovid), Scopus, Web of Science, and the Cochrane Library. Supplementary searches were undertaken in the National Health Service Economic Evaluation Database, the National Institute for Health and Care Excellence, the Canadian Agency for Drugs and Technologies in Health, the international HTA database, and the National Institute for Health and Care Research Journals Library. The search strategy was developed in consultation with a medical librarian and combined controlled vocabulary and free-text terms related to CIEDs, remote monitoring, HF algorithms, and economic evaluation. The full search strategy is provided in Multimedia Appendix 1 [15,17-21,26,30-32].

Data Management and Study Selection

All records were exported to EndNote (version 21; Clarivate Analytics) for duplicate removal and then imported into Rayyan (Rayyan Systems Inc) [33] for screening. Study selection was undertaken in 2 stages: title and abstract screening followed by full-text screening. One reviewer screened all records against the prespecified eligibility criteria. A second reviewer independently checked the first 476 titles and abstracts and the first 27 full-text reports made available for verification in Rayyan. Reviewers' decisions remained hidden until both had completed their assessments. Any disagreements were resolved through discussion. A third reviewer was available but was not required. For full-text exclusions, one primary reason was recorded. Partial verification was used because of time and resource constraints. The study selection process was summarized using a PRISMA 2020 flow diagram.

Data Extraction

Data were extracted using a structured Microsoft Excel–based form, tested on an initial sample of included studies, and refined iteratively through discussion with the review team before full

XSL•FO
RenderX

data extraction. A second reviewer checked the extracted data against the source documents for 3 reports. The review team selected these reports without a formal sampling procedure. The 2 reviewers resolved any differences through discussion. A third reviewer was available but was not needed. Partial verification was used because of time and resource constraints.

Quality Appraisal and Reporting Assessment

The methods and reporting of the included economic evaluations were appraised using the CHEQUE (Criteria for Health Economic Quality Evaluation) tool [34]. Reporting completeness was also assessed at the item level using the CHEERS (Consolidated Health Economic Evaluation Reporting Standards) 2022 statement [35].

This approach differed from the registered protocol, which proposed several appraisal tools based on study design. A single tool was used to support consistent descriptive appraisal across the different types of economic evaluation included in the review.

The first author (HD) completed both assessments. CHEQUE items were rated as “yes,” “somewhat,” “no,” or “not applicable.” “Yes,” “somewhat,” and “no” received scores of 1, 0.5, and 0, respectively. Methods and reporting percentages were calculated separately by dividing the sum of item scores by the number of applicable items and multiplying by 100. Not applicable items were excluded, and applicable items were weighted equally. CHEERS was used to assess reporting completeness. It was not used to assess methodological quality or risk of bias.

Data Synthesis

Data were synthesized narratively because of substantial heterogeneity in study design, intervention type, algorithm specification, analytical perspective, model structure, time horizon, and reported outcomes. Structured summary tables and descriptive comparisons were used to synthesize study characteristics, intervention and alert workflow features, economic evaluation characteristics, model structure, clinical outcomes, economic outcomes, and main cost-effectiveness findings. No quantitative meta-analysis was undertaken due to substantial heterogeneity in design, setting, outcome measurement, perspective, and modeling assumptions.

Results

Study Selection

Figure 1 summarizes the study selection process. The database searches identified 3108 records. In the full-text assessment, 132 full texts were screened for eligibility. Of these, 122 (92.4%) were excluded. The review included 10 (7.6%) reports: 8 (80%) primary study reports and 2 (20%) HTA reports. The broad search retrieved records on remote care and economic outcomes beyond the scope of this review. Some broad search terms returned large numbers of records before the search sets were combined (Multimedia Appendix 1 [15,17-21,26,30-32]).

Characteristics of Included Studies

Table 2 shows the 10 studies. Most were set in Europe or North America. Study designs included model-based economic evaluations, randomized controlled trials, prospective nonrandomized clinical studies, population-based cohort studies, real-world multicenter comparative studies, systematic reviews, meta-analyses, and HTAs.

[a]ECOST: Effectiveness and Cost of ICD Follow-up Schedule With Telecardiology.

[b]EVOLVO: Evolution of Management Strategies of Heart Failure Patients With Implantable Defibrillators.

[c]RCT: randomized controlled trial.

[d]ICD:implantable cardioverter-defibrillator.

[e]CRT-D: cardiac resynchronisation therapy defibrillator.

[f]LVEF: left ventricular ejection fraction.

[g]HTA: health technology assessment.

[h]RM: remote monitoring.

[i]HF: heart failure.

[j]NYHA: New York Heart Association.

[k]SC: standard care.

[l]CIED: cardiac implantable electronic device.

[m]CRT-P: cardiac resynchronisation therapy pacemaker.

[n]NIHR: National Institute for Health Research.

Studies reported sample characteristics in varying ways (Table 2). Sample sizes ranged from 200 participants to 15,254 [17,18], while another study synthesized evidence from 17 randomized controlled trials comprising 10,229 participants [21]. Where reported, study populations generally consisted of older adults, and several studies included predominantly male participants [15,19,20,30,31]. Some studies focused specifically on patients with established HF [17,32], whereas others included broader CIED populations with either mixed HF status or HF risk [19,26,30]. Baseline clinical characteristics and comorbidities were not consistently described across studies. HF prevalence was explicitly reported in 2 studies [15,18]. In contrast, other studies primarily described HF severity indicators such as New York Heart Association (NYHA) class or left ventricular ejection fraction [20,21,31,32] or eligibility based on monitoring pathway and implant status [19,26] rather than detailed comorbidity profiles. Funding sources were also mixed (Table 2).

The following are the main clinical evidence sources identified from the included evaluations. Zanaboni et al [17] evaluated the Evolution of Management Strategies of Heart Failure Patients With Implantable Defibrillators (EVOLVO) trial [36]. Sequeira et al [21] used EVOLVO utility values [36] and evidence from Effectiveness and Cost of ICD Follow-up Schedule With Telecardiology (ECOST) [37]. Health Quality Ontario [31] also used EVOLVO data [36]. EVOLVO was therefore a shared clinical evidence source across these 3 economic evaluations.

Intervention, Algorithm, and Alert Workflow Characteristics

The included studies showed substantial heterogeneity in remote monitoring system specifications, algorithm types, monitored parameters, and clinical response pathways (Table 3).

XSL•FO
RenderX

Table . Characteristics of remote monitoring systems and clinical response pathways.

Study (year)	Reported system or algorithm (manufacturer)	Algorithm type	Monitored parameters	Clinical response pathway
Sequeira et al (2020) [21]	• Not reported	Not reported	• Clinical parameters (eg, arrhythmia)	Transmit data at scheduled times or upon detection event and generate alerts and providing information to clinicians.
Health Quality Ontario (2018) [31]	• CardioMessenger (Biotronik) • CareLink (Medtronic) • LATITUDE (Boston Scientific) • Merlin.net (Abbott) • SmartView (LivaNova)	Rule-based alert system	• Device function and integrity • Battery status and depletion • Lead performance and failure • Arrhythmia detection (including inappropriate shocks) • ICD[a] therapy delivery • Physiological parameters	Remote clinician review of transmitted data; detection of device-related and clinical problems prompts early intervention, including medication adjustment or unscheduled in-person follow-up
Zanaboni et al (2013) [17]	CareLink Network Medtronic	Rule-based alert system	• Device function parameters • HF[b]-related parameters (eg, intrathoracic impedance for fluid accumulation monitoring) • Atrial arrhythmias • ICD therapy delivery	Clinician web-based review of transmitted data; unscheduled remote follow-up triggered by wireless alerts; telephone contact with patient if clinically indicated
Hummel et al (2019) [18]	PREDICT RM database: the Boston Scientific Corporation ALTITUDE database	Not reported	• Device-related parameters • Clinical parameters (eg, ventricular tachycardia and ventricular fibrillation)	Remote transmissions with follow-up visit
Burri et al (2013) [19]	BIOTRONIK Home Monitoring CardioMessenger II Biotronik	Rule-based alert system	• Clinical parameters (eg, atrial fibrillation burden) • Technical parameters (eg, abnormal lead impedance) • Device function data	Early detection and remote review of clinically or technically relevant alerts; remote follow-up of home monitoring alerts between scheduled visits; in-person assessment if clinically required
Kenny et al (2025) [26]	• CorVue + Merlin.net PCN (Abbott) • HeartInsight + BIOTRONIK Home Monitoring (Biotronik) • HeartLogic + LATITUDE NXT (Boston Scientific) • TriageHF Plus + CareLink (Medtronic)	Algorithmic risk stratification (multi-parametric composite indices)	• CorVue: ITI[c] • HeartInsight: composite score derived from 7 parameters (atrial burden, heart rate, and 5 additional parameters) • HeartLogic: composite index derived from multiple implant-measured parameters • TriageHF Plus: AT[d]/AF[e] burden, ventricular rate during AT/AF, OptiVol fluid index, and additional physiological parameters	HF risk alert transmitted to HCPs[f]; stored device data reviewed; structured clinical management pathway including follow-up consultations and treatment adjustments as indicated

XSL•FO
RenderX

Study (year)	Reported system or algorithm (manufacturer)	Algorithm type	Monitored parameters	Clinical response pathway
de Graaf et al (2024) [32]	• LATITUDE Patient Management System Boston Scientific	Not reported	• Predefined alert • ICD device status	Transmitted data reviewed and acted upon by nurses, cardiologists, and/or ICD technicians according to each center's established clinical protocol
Chew et al (2022) [15]	• Not reported (population-based administrative data study; specific commercial RM systems not identified)	Not reported	• Earlier detection of device malfunction or • Changes in clinical status (eg, worsening heart failure and arrhythmias)	Daily communication between the CIED[g] and home monitor; transmissions to the clinic were intermittent and event driven
Ricci et al (2017) [20]	Merlin@home St. Jude Medical (Abbott)	Rule-based alert system	• Technical malfunctions • Atrial arrhythmias • Ventricular arrhythmias • HF-related events • ST segment changes	The majority of alerts were managed remotely, without the requirement for in-hospital attendance
Ahmed et al (2026) [30]	TriageHF Plus CareLink (Medtronic)	Algorithmic risk stratification (multi-parametric)	• Cardiac rhythm • Intrathoracic fluid levels • Physical activity levels • Daytime and nighttime heart rate • Device-delivered therapies • Irregular heartbeats Composite multi-parametric algorithm calculates patient's 30-day HF event risk (low, medium, or high)	High-risk HF alerts reviewed by the HF team (typically an HF nurse); twice-weekly review of the RM[h] platform; structured telephone assessment following alert; clinical management as indicated, including lifestyle advice and/or medication adjustment

[a]ICD: implantable cardioverter-defibrillator.
[b]HF: heart failure.
[c]ITI: intrathoracic impedance.
[d]AT: atrial tachycardia.
[e]AF: atrioventricular.
[f]HCP: healthcare professional.
[g]CIED: cardiac implantable electronic device.
[h]RM: remote monitoring.

Remote Monitoring Platforms, Systems, and Algorithms

The systematic review included different remote monitoring platforms and alert tools. Table 3 shows the reported names and manufacturers where available.

Algorithm Type

Algorithm type was classified according to the reported function of the system rather than the platform name. Several systems were described as rule-based alert systems (n=4) [17,19,20,31]. Two studies evaluated algorithmic risk stratification approaches based on multiparametric composite indexes for identifying increased risk of HF deterioration [26,30]. Algorithm type was not reported in 4 studies [15,18,21,32].

Monitored Parameters

Reported monitored parameters varied considerably across studies. Rule-based systems commonly monitored device function; technical integrity; and alert-based events, including battery status, lead performance, arrhythmias, and device therapy delivery [17,19,20,31]. Some studies also included HF-related or physiological parameters, such as intrathoracic impedance, atrial fibrillation burden, and other device-derived indicators of clinical deterioration [15,18,21,32]. In the studies by Kenny et al [26] and Ahmed et al [30], monitored inputs were multiparametric and used to generate composite HF risk estimates.

Alert Workflow and Clinical Response

Clinical response pathways ranged from structured clinician-led review to limited or absent reporting. Health Quality Ontario

XSL•FO
RenderX

[31] described remote clinician review of transmitted data, with early intervention including medication adjustment or unscheduled in-person follow-up when clinically indicated. Burri et al [19] reported remote review of clinically or technically relevant alerts between scheduled visits, with in-person assessment when required. Zanaboni et al [17] described a clinician web-based review of transmitted data, with unscheduled remote follow-up and telephone contact if clinically indicated. In contrast, Ricci et al [20] reported that most alerts were managed remotely without hospital attendance. In the studies by Kenny et al [26] and Ahmed et al [30], high-risk HF alerts triggered structured review and follow-up processes, including health care professional assessment and clinical management, as indicated. de Graaf et al [32] reported that transmitted data were reviewed and acted upon in accordance with local center protocols. Other studies described clinical response pathways insufficiently [15,18,21].

Economic Evaluation Characteristics

Table 4 summarizes the economic evaluation characteristics of the included studies, including economic analysis type, analytical perspective, time horizon, discounting, currency, price year, and sensitivity or uncertainty analysis.

XSL•FO
RenderX

Table . Economic evaluation characteristics of included studies.

Study (year)	Economic analysis type	Perspective	Time horizon	Discount rate	Currency	Price year	Sensitivity analysis
Sequeira et al (2020) [21]	Cost-utility analysis	French health care system	5 years	4% per annum (costs and outcomes; equivalent to 0.33% per month)	Euro	2017 - 2018	• Probabilistic sensitivity analysis (Monte Carlo simulation; 10,000 iterations)
Health Quality Ontario (2018) [31]	Cost-utility analysis	Ontario Ministry of Health and Long-Term Care	5 years (reference case)	1.5% per annum (costs and QALYs[a])	CAD $	2017	• Probabilistic sensitivity analysis • Deterministic one-way sensitivity analyses • Scenario analyses • Discount rate sensitivity analyses
Zanaboni et al (2013) [17]	Cost-utility analysis	Health care system; patient perspective (secondary)	16 months (trial based)	Not reported	Euro	2010	• Scenario analysis
Hummel et al (2019) [18]	Cost-effectiveness analysis	Medicare (US payer perspective)	Lifetime (25 years)	3% per annum (costs and outcomes)	US $	2017	• Deterministic 1-way sensitivity analysis • Scenario analyses
Burri et al (2013) [19]	Cost-consequence analysis	UK NHS[b]	10 years (base case); 5 and 15 years (scenario analyses)	3.5% per annum (costs and outcomes)	Pound sterling	2010	• Deterministic univariate sensitivity analysis • Scenario analyses (time horizon variation)
Kenny et al (2025) [26]	Cost-effectiveness analysis	UK NHS and PSS[c]	Lifetime	3.5% per annum (costs and outcomes)	Pound sterling	2021-2022	• Deterministic sensitivity analysis • Probabilistic sensitivity analysis • Threshold analyses • Scenario analyses
de Graaf et al (2024) [32]	Cost-utility analysis	Health care sector; patient perspective (secondary)	24 months (trial based)	Not reported	Euro	2020	• Probabilistic sensitivity analysis (bootstrapping; 10,000 iterations)

Study (year)	Economic analysis type	Perspective	Time horizon	Discount rate	Currency	Price year	Sensitivity analysis
Chew et al (2022) [15]	Cost-effectiveness analysis	Canadian public health care system	5 years	1.5% per annum (costs and outcomes)	CAD $	2019	• Probabilistic sensitivity analysis • Deterministic 1-way sensitivity analysis • Scenario analyses
Ricci et al (2017) [20]	Cost-utility analysis	Health care system; patient and caregiver perspectives (secondary)	12 months	Not reported	Euro	Not reported	• Not reported
Ahmed et al (2026) [30]	Cost-effectiveness analysis	UK NHS and PSS (England and Wales)	Lifetime (base case: 32.2 years; 386 monthly cycles)	3.5% per annum (costs and benefits)	Pound sterling	2022-2023	• Probabilistic sensitivity analysis • Scenario analyses • Deterministic break-even analysis

[a]QALY: quality-adjusted life-year.

[b]NHS: National Health Service.

[c]PSS: personal social service.

Type of Economic Evaluation

The included studies used different forms of economic evaluation. Cost-effectiveness analysis was reported in 4 studies [15,18,26,30]. Cost-utility analysis was reported in 5 studies [17,20,21,31,32]. One study reported a cost-consequence analysis [19].

Analytical Perspective

Analytical perspectives also differed across studies. Public or health care system perspectives were commonly adopted [15,19,21,31]. UK-based studies adopted a National Health Service and personal social services perspective [26,30]. Hummel et al [18] used a Medicare payer perspective. Three studies incorporated patient and/or caregiver perspectives as secondary analyses [17,20,32].

Time Horizon

Time horizons ranged from short-term trial-based follow-up to lifetime modeling. Trial-based evaluations used follow-up periods of 12 months [20], 16 months [17], and 24 months [32]. A 5-year time horizon was used in 3 studies [15,21,31], whereas 1 study used 10-year horizons [19]. Lifetime time horizons were adopted by 3 studies [18,26,30].

Discounting

Discount rates were reported in 7 studies and ranged from 1.5% to 4% for both costs and outcomes [15,18,19,21,26,30,31]. Discount rates were not reported in several studies [17,20,32].

Currency and Price Year

Reported currencies reflected the study countries' locations. A price year was explicitly reported in 8 of the 10 studies [17-19,21,26,30-32], while the remaining studies did not provide a clear price year, limiting direct cross-study comparability.

Sensitivity and Uncertainty Analysis

Sensitivity and uncertainty analysis approaches varied across studies. Probabilistic sensitivity analysis was reported in 6 studies [15,21,26,30-32]. Deterministic, one-way, or scenario analyses were also commonly used [15,18,19,26,30,31]. One study used bootstrapping as the basis for probabilistic uncertainty analysis [32], and one study did not report any sensitivity or uncertainty analyses [20].

Model Structure

Table 5 summarizes the structural characteristics of the model-based evaluations, including modeling approach, model type, cycle length, and health state specification.

XSL•FO
RenderX

Table . Model structure characteristics of model-based economic evaluations[a].

Study ID	Study (year)	Modeling approach	Model type	Cycle length	Health states defined
1	Sequeira et al (2020) [21]	Systematic review with meta-analysis of RCTs[b]; de novo cost-utility analysis	Cohort Markov model	1 month	• Stable outpatient • Cardiovascular hospitalization • Death (absorbing state)
2	Health Quality Ontario (2018) [31]	HTA[c]; de novo decision-analytic modeling informed by systematic review, meta-analysis, and administrative data	Two parallel state-transition Markov cohort models: • Model 1: ICD[d]/CRT-D[e] recipients • Model 2: pacemaker recipients; 10,000 Monte Carlo simulations	1 month	Model 1 (ICD/CRT-D): • Stable HF[f] (by NYHA[g] class; transitions between classes permitted) • Posthospitalization • Death (absorbing state) Model 2 (pacemakers): • Stable arrhythmia • Posthospitalization (nonstroke) • Poststroke • Death (absorbing state)
4	Hummel et al (2019) [18]	Patient-level decision-analytic modeling using observational cohort data (PREDICT RM database)	DICE[h] simulation (individual patient, continuous time event tracking)	Not applicable—DICE simulation uses continuous time event tracking; discrete cycle lengths are not used	• No discrete Markov health states defined; model based on individual patient characteristics and time-to-event outcomes (including mortality and rehospitalization)
5	Burri et al (2013) [19]	Decision analytic modeling informed by pooled patient-level data from RCTs	Deterministic cohort Markov model	1 year	• Well (stable) • Poststroke • Postacute decompensated heart failure • Death (absorbing state)
6	Kenny et al (2025) [26]	Systematic review and de novo cost-effectiveness analysis (NICE[i] Technology Assessment)	Cohort Markov model	1 month	• Alive • Dead (absorbing state)
8	Chew et al (2022) [15]	Population-based cohort economic evaluation using administrative health data	Cohort Markov model with parametric survival analysis	1 month	• Alive • Dead (absorbing state)
10	Ahmed et al (2026) [30]	Regression-based decision-analytic modeling using real-world matched cohort data (TriageHF Plus service evaluation)	Two-state, regression-based, Markov-type model	1 month	• Alive • Dead (absorbing state); note: NYHA class–informed utility weighting but was not modeled as a discrete transition state

XSL•FO

[a]Study IDs correspond to Table 2. This table presents the 7 model-based economic evaluations.

[b]RCT: randomized controlled trial.

[c]HTA: health technology assessment.

[d]ICD: implantable cardioverter-defibrillator.

[e]CRT-D: cardiac resynchronisation therapy defibrillator.

[f]HF: heart failure.

[g]NYHA: New York Heart Association.

[h]DICE: discrete individual cost-effectiveness.

[i]NICE: National Institute for Health and Care Excellence.

Modeling Approach and Model Type

Seven studies reported formal model-based economic evaluations (Table 5). Five used state transition or cohort-based Markov models [15,19,21,26,31]. In contrast, one study used a regression-based decision analytic approach operationalized as a 2-state Markov-type model based on matched real-world cohort data [30]. Hummel et al [18] used a patient-level DICE simulation based on observational cohort data rather than a conventional discrete state transition framework.

Cycle Length

A 1-month cycle length was reported in 5 models [15,21,26,30,31]. Burri et al [19] used a 1-year cycle length. In contrast, Hummel et al [18] did not apply a conventional cycle-based structure because the DICE simulation used continuous-time event tracking rather than fixed transition cycles.

Health State Specification

Health state structures ranged from simple 2-state models to more complex multistate frameworks. Two-state alive-or-dead structures were used in 3 studies [15,26,30]. However, Ahmed et al [30] used NYHA class-informed utility weighting rather than modeling it as a discrete transition state. A multistate structure was used to represent disease progression and clinical events, including stable outpatient status, cardiovascular hospitalization, and death [21]. Additionally, the Health Quality Ontario HTA report described parallel disease-specific models comprising NYHA-based HF progression and posthospitalization states for ICD or CRT-D recipients and stable arrhythmia, posthospitalization, poststroke, and death for pacemaker recipients [31]. One study used stable, poststroke, and postacute decompensated HF and death [19]. Hummel et al [18] did not define discrete Markov health states as the model was structured around individual patient characteristics and time-to-event outcomes, including mortality and rehospitalization.

Clinical and Economic Outcomes

This section summarizes the clinical and economic outcomes reported across the included studies (Table 6).

XSL•FO
RenderX

Table . Clinical and economic outcomes reported in included studies.

Study (year)	Clinical outcomes reported	Economic outcomes reported
Sequeira et al (2020) [21]	• All-cause mortality • Cardiovascular mortality • MACE[a] • Composite cardiovascular endpoints	• Annual cost per patient • Labor costs • 5-year cost saving • QALYs[b] • ICER[c] • PSA[d]
Health Quality Ontario (2018) [31]	• Inappropriate ICD[e] shocks • Clinic visits avoided • Time to detection and treatment • Major adverse cardiovascular events • Arrhythmia burden • All-cause mortality • Cardiovascular mortality	• Total costs • Incremental cost • QALYs • Incremental QALYs • ICER; CAD $/QALY • Probability of cost-effectiveness • Budget impact analysis (5 years)
Zanaboni et al (2013) [17]	• ED[f] and urgent in-office visits • HF-related ED or urgent visits • Arrhythmia, ICD-related ED, or urgent visits • Total health care utilizations • Deaths • QALYs • Utility scores	• Annual health care system costs per patient • Protocol-defined clinic visit costs • ED and urgent visit costs • Nonurgent in-office visit costs • Scheduled and unscheduled remote follow-up costs • Hospitalization costs • Diagnostic examination costs • Annual patient costs • Cost-utility ratio (€/QALY)
Hummel et al (2019) [18]	• LYs[g] • Time to death • Time to first rehospitalization • Number of rehospitalization events	• Lifetime costs • Costs per patient-year • QALYs • Incremental cost per life-year gained mental cost per life-year gained • ICER; US $/QALY
Burri et al (2013) [19]	• All-cause mortality • Stroke events • ADHF[h] events • SVA[i] • AF[j] • Appropriate and inappropriate ICD shocks • Battery replacement events • Lead-related complications • Scheduled and unscheduled follow-up visits	• 10-year total costs (discounted and undiscounted) • Device costs • Patient management costs • Cardiovascular event costs
Kenny et al (2025) [26]	• Heart failure events • All-cause mortality • Morbidity and adverse events • Patient-reported outcomes • Prognostic accuracy of algorithms	• Total lifetime costs • QALYs • Incremental costs • Incremental QALYs • ICER; £/QALY • Cumulative hospitalizations and hospital days • Probability of cost-effectiveness • Cost breakdown by component
de Graaf et al (2024) [32]	• Cardiac-related resource use • Hospital admissions • Length of hospital stay • Outpatient visits • Telephone consultations • Emergency room visits • Ambulance use • Patient travel time • QALYs	• Cardiac-related health care costs • Incremental costs • Incremental QALYs • Commercial headroom analysis • Probability of cost-effectiveness

XSL•FO
RenderX

Study (year)	Clinical outcomes reported	Economic outcomes reported
Chew et al (2022) [15]	• All-cause mortality • Time to first cardiovascular hospitalization • Cardiovascular hospitalization rate • Hospital length of stay • Emergency department visits • Outpatient physician visits • QALYs • Survival	• Inpatient admission costs • Emergency department visit costs • Outpatient physician visit costs • Total 5-year costs • Incremental cost savings • Probability of cost savings
Ricci et al (2017) [20]	• In-hospital device follow-up visits • Cardiovascular hospitalizations • Emergency department visits • Outpatient diagnostic tests • Outpatient visits • QALYs	• Cardiovascular hospitalization costs • Device-related costs • Emergency visit costs • Outpatient evaluation and diagnostic test costs • Scheduled and unscheduled in-office follow-up costs • Total health care system costs • Patient travel costs • Patient and caregiver productivity loss costs • Mean annual patient cost
Ahmed et al (2026) [30]	• Unplanned all-cause hospital admissions • Emergency department attendances • Outpatient cardiology clinic attendances • All-cause mortality • Heart failure alert events • HRQoL[k] • QALYs	• Incremental total costs • Incremental QALYs • ICER; pound sterling/QALY • NMB[l] • NHB[m] • Probability of cost-effectiveness • Probability of cost-saving • Incremental hospitalizations avoided

[a]MACE: major adverse cardiovascular events.
[b]QALY: quality-adjusted life-year.
[c]ICER: incremental cost-effectiveness ratio.
[d]PSA: probabilistic sensitivity analysis.
[e]ICD: implantable cardioverter-defibrillator.
[f]ED: emergency department.
[g]LY: life-years.
[h]ADHF: acute decompensated heart failure.
[i]SVA: supraventricular arrhythmia.
[j]AF: atrial fibrillation.
[k]HRQoL: health-related quality of life.
[l]NMB: net monetary benefit.
[m]NHB: net health benefit.

Clinical Outcomes and Service or Resource Use

Across the included studies, reported outcomes spanned several domains, most commonly mortality or survival, health care use, health-related quality of life, and device- or arrhythmia-related events. Mortality-related outcomes included survival, all-cause and cardiovascular mortality, and time-to-event measures such as time to death [15,18,19,21,30]. Health care use outcomes included hospital admissions, rehospitalization, time to first rehospitalization, length of stay, emergency department visits, outpatient and clinic visits, and other measures of service use [15,17,20,30-32]. Several studies reported health-related quality of life and utility-related outcomes, while a smaller subset reported device- or arrhythmia-related outcomes such as arrhythmia burden, atrial fibrillation, lead-related complications, and battery replacement events [15,17-19,21,26,30-32].

Economic Outcomes

Reported economic outcomes included total and incremental costs, incremental cost-effectiveness ratios (ICERs), QALYs, incremental QALYs, cost-utility ratios, probability of cost-effectiveness, and sensitivity or uncertainty analysis outputs such as probabilistic sensitivity analysis. Some studies also reported cost component breakdowns, net monetary benefit, and net health benefit [26,30-32]. Economic end points varied across studies by evaluation framework, outcome measure, and analysis time horizon.

Main Economic Findings

Table 7 summarizes the main economic findings, ICER results, and health economic decisions across the included studies.

XSL•FO
RenderX

Table . Main economic findings, ICER (incremental cost-effectiveness ratio) results, and health economic decisions.

Study (year)	Main economic finding	ICER and/or cost result	Health economic decision
Sequeira et al (2020) [21]	RM[a] was associated with lower costs and higher QALYs[b] compared with standard quarterly in-clinic follow-up over 5 years. RM was dominant across the base case.	Dominant (lower cost or higher QALYs)	Dominant
Health Quality Ontario (2018) [31]	ICD[c]/CRT-D[d]: RM was associated with higher costs and higher QALYs; cost-effective at WTP[e] CAD $50,000/QALY (US $51,697/QALY; 2024); 71% of simulations. Pacemakers: RM was dominant (lower costs and higher QALYs). Budget impact: net saving of CAD $14.18 million over 5 years (US $14.66 million; 2024). Approximately 15% of simulations classified RM as inferior for ICD/CRT-D.	ICD/CRT-D: CAD $23,374/QALY (US $24,167/QALY; 2024). Pacemakers: dominant.	Pacemakers: dominant in the model. ICD/CRT-D: cost-effective at CAD $50,000/QALY, with decision uncertainty .
Zanaboni et al (2013) [17]	RM was associated with lower costs (€888.10 cost saving per patient; US $1586.91; 2024) and higher QALYs (+0.065) compared with conventional follow-up. Dominant result was maintained in the €900 tariff scenario (US $1608.17; 2024). Patient costs were also reduced.	Dominant (lower cost and higher QALYs)	Dominant in the reported cost-utility analysis
Hummel et al (2019) [18]	RPM was associated with increased life-years (Δ+0.77 LYs), increased QALYs (Δ+0.64), and higher total lifetime costs (Δ+ US $6914; US $8655.57; 2024) compared with no RPM	US $10,752/QALY (US $13,460.33/QALY; 2024).	Cost-effective; threshold dependent (favorable at WTP US $50,000/QALY)
Burri et al (2013) [19]	Home monitoring was cost neutral over 10 years compared with conventional in-clinic follow-up, with a minor discounted cost advantage of £33 per patient (US $67.67; 2024). No formal ICER was calculated given the cost-consequence design.	Not applicable (cost-consequence analysis; no ICER calculated)	Cost neutral with minor cost advantage for home monitoring
Kenny et al (2025) [26]	HeartLogic: dominant; incremental QALYs +0.01; reduced hospitalizations and hospital days. TriageHF Plus: dominant; incremental cost −€9048 (−US $15,050.10; 2024 prices); incremental QALYs +0.01; reduced hospitalizations. CorVue: cost-increasing; incremental cost +€37 (+ US $61.54; 2024); incremental QALYs=0. HeartInsight: cost-increasing; incremental cost +€568 (+ US $944.79; 2024); incremental QALYs=0.	HeartLogic: dominant; TriageHF Plus: dominant; CorVue: cost increasing; no QALY gain; HeartInsight: cost increasing; no QALY gain	HeartLogic and TriageHF Plus: modeled as dominant but highly uncertain due to limited comparative evidence and high risk of bias. CorVue and HeartInsight: no robust cost-effectiveness conclusion because comparative outcome evidence was insufficient

XSL•FO
RenderX

Study (year)	Main economic finding	ICER and/or cost result	Health economic decision
de Graaf et al (2024) [32]	RPM[f] was associated with lower cardiac-related health care costs and shorter patient travel time in both the Netherlands and Germany. Incremental cost: −€1041 (Netherlands; −US $1558.05; 2024) and −€2865 (Germany; −US $4376.45; 2024 prices). Incremental QALYs: −0.003 (Netherlands) and +0.086 (Germany). No formal ICER was reported; cost-effectiveness was dependent on the acquisition cost of the RPM system.	No ICER reported; cost-effectiveness dependent on RPM acquisition cost	No definitive cost-effectiveness conclusion; dependent on RPM acquisition cost and country context
Chew et al (2022) [15]	RM was associated with lower total 5-year costs and similar QALYs compared with in-clinic follow-up. Incremental cost saving: −CAD $12,195 per person over 5 years (−US $12,216.81; 2024). Probability of cost saving exceeded 99% at 5 years. Hospitalization costs were the primary cost driver.	Incremental cost: −CAD $12,195 per person over 5 years (−US $12,216.81; 2024); QALYs were similar.	Cost-saving with equivalent QALYs
Ricci et al (2017) [20]	RM was cost-saving compared with standard care (SC) from health care system, patient, and caregiver perspectives. Annual health care system costs per patient were reduced by 53.87%; patient costs reduced by 66.44%. Primary driver of savings was reduction in cardiovascular hospitalizations (accounting for 81% of total savings). No significant difference in QALYs between groups.	No ICER calculated; no significant QALY difference	Cost-saving without QALY difference
Ahmed et al (2026) [30]	TriageHF Plus was associated with lower total costs and higher QALYs compared with usual care. Incremental cost: −€3989 (−US $6294.61; 2024); incremental QALYs: +0.01. Positive net monetary benefit confirmed cost-effectiveness. Probability of cost-effectiveness and cost-saving both exceeded conventional thresholds.	Dominant (lower costs and higher QALYs)	Dominant in the model-based analysis

[a]RM: remote monitoring.

[b]QALY: quality-adjusted life-year.

[c]ICD: implantable cardioverter-defibrillator.

[d]CRT-D: cardiac resynchronisation therapy defibrillator.

[e]WTP: willingness to pay.

[f]RPM: remote patient monitoring.

Several studies identified remote monitoring as dominant, defined as lower costs with improved health outcomes. Sequeira et al [21] found that remote monitoring was associated with lower costs and higher QALYs than standard quarterly in-clinic follow-up over 5 years. Zanaboni et al [17] similarly reported lower costs and higher QALYs with remote monitoring than with conventional follow-up.

Ahmed et al [30] reported that TriageHF Plus was associated with lower total costs and higher QALYs than usual care in the model-based analysis. Health Quality Ontario [31] also reported dominant findings for pacemaker recipients, whereas for ICD or CRT-D recipients, remote monitoring was associated with higher costs and higher QALYs.

One study reported remote monitoring as cost-effective. Hummel et al [18] found that remote patient monitoring was associated with higher lifetime costs along with gains in life years and QALYs, resulting in an ICER of US $10,752 per QALY.

Three studies reported cost-neutral or cost-saving findings, but neither showed any additional QALY gains or calculated a formal ICER [15,19,20]. Burri et al [19], using a

XSL•FO
RenderX

cost-consequence analysis, found home monitoring to be broadly cost neutral over 10 years, with a small, discounted cost advantage. Chew et al [15] reported lower total 5-year costs and similar QALYs compared with in-clinic follow-up, with hospitalization costs identified as the main cost driver. Ricci et al [20] also reported cost savings from the perspectives of the health care system, patients, and caregivers, with no significant difference in QALYs between groups.

de Graaf et al [32] found lower cardiac-related health care costs in both the Netherlands and Germany. Incremental QALYs differed between settings, with a small QALY loss in the Netherlands (−0.003) and a QALY gain in Germany (+0.086). No formal ICER was reported, and the cost-effectiveness conclusion depended on the acquisition cost of the remote monitoring system and the country context [32].

Kenny et al [26] reported algorithm-specific findings. HeartLogic and TriageHF Plus were modeled as dominant, although uncertainty regarding the underlying comparative evidence informing hospitalization and length of stay inputs was reported. CorVue and HeartInsight were associated with higher costs and no QALY gains.

Reporting and Quality Appraisal

The included studies were evaluated via the CHEQUE assessment, as shown in Figures 2 and 3. As summarized in Table 8, methodology scores ranged from 56.3% to 87.5%, and reporting scores ranged from 70.8% to 83.3%. Overall, reporting scores were generally slightly higher than methodology scores. Full item-level CHEQUE ratings are provided in Table S1 in Multimedia Appendix 1 [15,17-21,26,30-32].

XSL•FO
RenderX

Figure 2. CHEQUE (Criteria for Health Economic Quality Evaluation) methodology item ratings across the included economic evaluations [15,17-21,26,30-32].

RenderX

Figure 3. CHEQUE (Criteria for Health Economic Quality Evaluation) reporting item ratings across the included economic evaluations [15,17-21,26,30-32].

XSL•FO
RenderX

Table . Study-level unweighted CHEQUE (Criteria for Health Economic Quality Evaluation) methods and reporting percentages[a].

First author (year)	Methods, %	Reporting, %
Sequeira et al (2020) [21]	77.1	75.0
Health Quality Ontario (2018) [31]	85.4	81.3
Zanaboni et al (2013) [17]	65.8	71.1
Hummel et al (2019) [18]	72.9	75.0
Burri et al (2013) [19]	56.3	70.8
Kenny et al (2025) [26]	87.5	83.3
de Graaf et al (2024) [32]	60.5	73.7
Chew et al (2022) [15]	81.3	77.1
Ricci et al (2017) [20]	70.6	77.8
Ahmed et al (2026) [30]	81.3	81.3

[a]Yes, Somewhat, and No were scored 1, 0.5, and 0, respectively. Methods and reporting percentages were calculated separately as the sum of item scores divided by the number of applicable items, multiplied by 100. Not-applicable items were excluded. All applicable items had equal weight.

The CHEERS-based assessment showed that core elements were generally reported consistently, whereas reporting was more variable for health economic analysis plans, heterogeneity or distributional effects, and patient or stakeholder engagement. Full CHEERS ratings are provided in Table S2 in Multimedia Appendix 1 [15,17-21,26,30-32].

Discussion

Principal Findings

This review identified 10 economic evaluations of algorithm-enabled CIED remote monitoring in populations with established HF or considered at risk of HF. The included evaluations differed in population definitions, intervention designs, model structures, time horizons, and reported outcomes, limiting comparability and generalizability. HF status was also defined inconsistently: some evaluations included clearly characterized populations using indicators such as NYHA class or left ventricular ejection fraction, whereas others used less clearly operationalized definitions of populations at risk of HF. Economic findings should therefore be interpreted as context specific rather than directly transferable across populations, algorithms, model structures, and health care settings.

The interventions were conceptually and operationally heterogeneous and should not be treated as a single intervention when assessing cost-effectiveness. They included predefined alert rules and algorithms that combined several measures to classify HF risk [17,19,20,26,30,31]. In some reports, the alert function was described, but the underlying rules were not reported in detail. Monitored parameters ranged from device-related measures to physiological and broader clinical indicators [17,19,26,30-32], while clinical response pathways varied from structured clinician-led review and treatment adjustment to limited reporting of operational processes [17,19,20,30,31]. Economic evaluations reported inconsistently on key implementation and performance features, including alert burden, false-positive alerts, and how alerts were reviewed and acted upon. This limits interpretation of whether favorable economic findings were driven by the algorithm itself, the surrounding clinical pathway, or both.

Economic methods and study contexts varied across the included studies, including patient populations, intervention definitions, evaluation type, analytical perspective, model structure, time horizon, discounting, uncertainty analysis, and clinical input sources [15,17-21,26,30-32]. Favorable findings appeared in both trial-based and model-based evaluations, although results were not consistently cost saving or dominant. In several evaluations, favorable estimates were linked to reported or assumed reductions in hospitalizations, length of stay, or other types of health care use [15,17,18,20,26,30]. QALY gains were often modest; Ahmed et al [30], for example, reported an incremental gain of 0.01 QALYs per patient over the modeled lifetime horizon, while Chew et al [15] reported similar QALYs between groups.

Some evaluations used evidence from the same clinical trial, but they did not use identical economic analyses or reach identical conclusions. Zanaboni et al [17] evaluated the EVOLVO trial. Sequeira et al [21] used EVOLVO utility values alongside ECOST evidence, while Health Quality Ontario [31] used EVOLVO data on unscheduled health care use. The overlap concerns specific clinical inputs. These inputs should not be interpreted as fully independent evidence, but the 3 evaluations were counted and interpreted separately.

The economic results were sensitive to assumptions about baseline hospitalization risk, length of stay, unit costs, clinical response, and the duration of any benefit. This was particularly relevant in long-term models that extended beyond the period of observed clinical data. Comparative evidence on hospitalization and other clinical outcomes was limited for some technologies [26]. For de Graaf et al [32], conclusions also depended on the cost of monitoring and the country setting. These factors restrict the transfer of an estimate from one health care system to another.

Markov-type approaches predominated, ranging from simple two-state alive-or-dead models to more detailed multistate and multiphase frameworks. One study used a patient-level DICE

XSL•FO
RenderX

simulation, which tracked mortality and rehospitalization events in continuous time rather than through fixed model cycles [18]. More detailed structures can represent differences in events and their timing, but they require additional data and assumptions. Model structure should therefore be judged against the decision problem and available evidence. Differences in structure also limit direct comparison of costs and QALYs across evaluations.

The included monitoring systems also differed in their function and value mechanism. Where predefined alerts were described, remote monitoring could support earlier review and reduce scheduled in-person visits or other service use [17,19,20,31]. For multiparameter risk systems, economic estimates were particularly sensitive to the assumed or observed effects on hospitalizations and length of stay [26,30]. This suggests that economic value should not be attributed to algorithm-enabled remote monitoring as a single intervention. It depends on system function, alert management, clinical response, evidence strength, implementation cost, and patient population.

Interpretation is further complicated by variation in the populations studied. Included studies covered patients with established HF and those at risk of HF across device groups, including ICDs, CRT-Ds, CRT-Ps, and pacemakers. Because clinical trajectories, monitoring needs, baseline event rates, and downstream costs may differ across these groups, findings should not be assumed to apply equally across all CIED populations. Health Quality Ontario [31], for example, estimated higher costs and higher QALYs for ICD or CRT-D recipients but lower costs and higher QALYs for pacemaker recipients. A result for one device group should not be assumed to apply to all people with HF.

The appraisal findings further limit the strength of a general economic conclusion. Burri et al [19] and de Graaf et al [32] had lower unweighted CHEQUE method percentages. The model by Burri et al [19] predicted cost neutrality under assumptions that did not include a reduction in HF events or mortality. The conclusions by de Graaf et al [32] depended in part on monitoring costs and country context. Kenny et al [26] had a higher method percentage, but comparative outcome evidence for the algorithms remained limited. The favorable cost-effectiveness estimates reported by Kenny et al [26] for HeartLogic and TriageHF Plus should be interpreted in that context. For CorVue and HeartInsight, sufficient comparative outcome evidence was unavailable to produce evidence-based cost-effectiveness estimates. A scenario assuming no clinical benefit produced higher costs without QALY gains [26]. Evaluations using clinical evidence from nonrandomized studies may also be affected by residual confounding. Several evaluations reported manufacturer funding. This warrants careful examination of assumptions and reporting but does not itself establish bias.

Implications for Policy and Practice

Decision-makers should interpret cost-effectiveness estimates in relation to the monitoring system and the local care pathway. Several evaluations reported favorable findings, while others were cost neutral, mixed, or dependent on costs and assumptions [19,26,31,32]. Local staffing, alert workload, hospitalization costs, and existing monitoring infrastructure may affect whether routine care can achieve a reported benefit. Estimates from one device group or health care setting should therefore not be applied automatically to another. This is consistent with methodological work showing that the value of digital health interventions depends on how they are implemented and integrated into clinical pathways [10,11].

The review also indicates that costs beyond the health care payer perspective may be relevant to decision-making. Some studies reported reductions in patient and caregiver costs, including travel, time, and attendance burden [17,20,32]. A broader analytical perspective that includes patient, caregiver, and societal costs may therefore better capture the value of remote monitoring, particularly where it reduces the need for in-person follow-up [10-12].

Implications for Future Research

Future evaluations should describe the monitoring intervention and its clinical pathway more clearly. Reports should specify the data used, the conditions that generate alerts, the output shown to clinicians, and the actions taken after review. A commercial algorithm name is less informative than a clear description of what the system does. Consistent reporting of alert frequency, false positives, and staff workload would also help explain economic results across settings.

Greater attention is also needed to patient heterogeneity. Most studies reported average cost-effectiveness results and rarely examined whether costs, outcomes, or economic value differed across clinically relevant subgroups. This gap matters because the value of remote or algorithm-enabled monitoring may vary by device type, HF severity, prior hospitalization, baseline risk, and comorbidity burden. Future evaluations should therefore incorporate subgroup analyses where feasible and examine how structural uncertainty and long-term extrapolation affect conclusions across patient groups.

Models should provide clear reasons for their structural choices and test influential assumptions. Validation and uncertainty analysis should be reported transparently. Real-world data may improve relevance to routine care provided that selection bias and confounding are addressed.

Strengths and Limitations

This review focused on economic evaluations of algorithm-enabled CIED monitoring in HF-relevant populations. Multiple bibliographic databases and HTA sources were searched. The protocol was registered prospectively. This review describes intervention functions, monitored measures, clinical pathways, economic methods, and findings. It used the CHEQUE checklist for methodological appraisal and the CHEERS 2022 statement to assess completeness of reporting.

Several limitations should also be acknowledged. One reviewer conducted screening and data extraction, with verification rather than full independent duplicate review, which may have increased the risk of missed studies or extraction errors. The CHEQUE and CHEERS assessments were completed by one reviewer. CHEQUE percentages were calculated with equal weights and should be interpreted descriptively. The review was restricted to English-language publications and may

XSL•FO
RenderX

therefore have excluded relevant evidence published in other languages.

The evaluations also differed substantially in interventions, populations, settings, perspectives, time horizons, and outcomes. These differences prevented a meaningful pooled economic estimate. Some evaluations used inputs from the same clinical trials, so parts of the underlying evidence were not independent. Incomplete intervention reporting and limited comparative clinical evidence constrained interpretation. No formal certainty of evidence assessment was conducted. These limitations should be considered when judging the overall strength and transferability of the findings.

Conclusions

Economic evidence on algorithm-enabled CIED remote monitoring in HF-relevant populations appears promising. Most studies reported cost-effective, cost-saving, or dominant findings, with reductions in hospitalization and health care use acting as important drivers in several evaluations. However, the evidence remains heterogeneous and difficult to compare directly across studies. Reported findings were sensitive to differences in intervention design, model structure, analytical assumptions, and clinical input data, which limits certainty and transferability. More robust and standardized evidence is needed before economic conclusions can be applied confidently across different devices, algorithms, and health care settings.

Abstract

Background: Insomnia is common, and treatments are limited by tolerability and access. Digital health interventions (DHIs) are increasingly used for sleep management, but evidence comparing multiple outcomes is scarce.

Objective: This study aimed to systematically evaluate the effects of DHIs on 8 sleep outcomes, including insomnia severity, sleep efficiency, total sleep time, and sleep quality.

Methods: We systematically searched PubMed, Embase, Cochrane Library, Web of Science, Scopus, CINAHL, CNKI, CBM, VIP, Wanfang, ClinicalTrials.gov, and the American Academy of Sleep Medicine's website from inception to July 2026. Two reviewers (SG and BZ) independently screened studies, extracted data, and assessed risk of bias using the Cochrane Risk of Bias 2.0 tool. We included randomized controlled trials or controlled clinical trials comparing DHIs with any control in insomnia, without language restriction, and excluded experimental sleep deprivation, conference abstracts, protocols, and nonrandomized or noncontrolled designs. Pooled standardized mean differences (SMDs) with 95% CIs used restricted maximum likelihood with Hartung-Knapp-Sidik-Jonkman correction; 95% prediction intervals (PIs) used the Nagashima method. We also performed subgroup analyses by intervention category, comparator type, diagnostic criteria, and country income, plus sensitivity analyses, Egger tests, and GRADE (Grading of Recommendations Assessment, Development and Evaluation) assessment.

Results: We included 44 randomized controlled trials (n=10,521) published between 2004 and 2026 across 14 countries. DHIs significantly improved insomnia severity (SMD −0.91, 95% CI −1.12 to −0.70), sleep efficiency (SMD 0.59, 95% CI 0.45-0.72), total sleep time (SMD 0.20, 95% CI 0.11-0.29), sleep quality (SMD −0.61, 95% CI −0.78 to −0.45), and secondary outcomes (SMDs −0.37 to −0.64). However, 95% PIs crossed the null for insomnia severity (−2.04 to 0.22), total sleep time (−0.05 to 0.46), and all secondary outcomes. Subgroup analyses showed larger insomnia severity effects in high- versus upper-middle-income countries, modality differences for sleep efficiency, and comparator-type differences for total sleep time (all $P<.01$). Egger tests suggested small-study effects; sensitivity analyses did not change direction or significance. GRADE certainty ranged from very low to moderate.

Conclusions: Although DHIs showed statistically significant average effects on multiple sleep outcomes, wide PIs crossing or approaching the null, effects approaching or below Minimum Clinically Important Difference thresholds, and very low-to-moderate GRADE certainty indicate that the evidence remains exploratory. Subgroup analyses revealed effect modifications by country income, intervention modality, and comparator type, underscoring contextual factors. Unlike previous reviews focusing on single DHI formats or average statistical effects, this review provides stratified comparisons and integrates PIs and Minimum Clinically Important Difference conversion to distinguish statistical significance from clinical relevance. This paper provides an evidence synthesis framework showing that DHI benefits are context-dependent and insufficient for a standard clinical role. In practice, DHIs cannot be recommended as a standard substitute for face-to-face cognitive behavioral therapy for insomnia, although they may serve as a low-intensity option in stepped care. Large-scale, head-to-head implementation trials in diverse populations with extended follow-up are needed to define their optimal role.

Introduction

Insomnia disorder is characterized by difficulty initiating or maintaining sleep, early-morning awakening, and associated daytime functional impairment [1]. Global epidemiological surveys indicate that approximately 10% to 15% of adults meet diagnostic criteria for insomnia disorder, while an additional 30% experience subclinical insomnia symptoms [2,3]. Chronic sleep disturbance not only contributes to daytime fatigue, cognitive decline, and emotional dysregulation but is also closely linked to the development and progression of hypertension, type 2 diabetes, depression, and cognitive decline [4-6], placing a sustained and substantial burden on individual health and health care systems. Therefore, identifying efficient and accessible insomnia interventions has become a high priority for public health and clinical practice.

Current treatment strategies for insomnia include both pharmacological and nonpharmacological approaches. Benzodiazepines and newer nonbenzodiazepine hypnotics provide rapid symptom relief; however, long-term use is associated with tolerance, dependence, and residual daytime effects [7]. Consequently, clinical guidelines consistently recommend cognitive behavioral therapy for insomnia (CBT-I) as the first-line nonpharmacological treatment for insomnia [8,9], as it addresses maladaptive sleep-related cognitions and behaviors to produce durable therapeutic gains [10]. Nevertheless, the clinical dissemination of CBT-I faces substantial barriers, including a severe shortage of trained therapists, extended treatment duration, and the need for frequent in-person visits, which collectively prevent many patients from receiving standardized care [11]. This accessibility gap underscores the urgent need for alternative service delivery models.

Against this backdrop, digital health interventions (DHIs)—enabled by smartphones, wearable devices, and internet platforms—have rapidly emerged as a scalable, low-cost, and convenient pathway for health management [12]. The World Health Organization's (WHO's) Global Strategy on Digital Health 2024 - 2030 explicitly calls for the effective integration of DHIs into health systems and the establishment of unified evaluation frameworks [13]. DHIs have already demonstrated significant value in self-management and health promotion for chronic conditions such as diabetes, cardiovascular disease, and depression [14,15], and their potential applicability to sleep medicine warrants close attention.

In the field of sleep medicine, DHIs offer distinct technological advantages. Smartphones and internet platforms transcend temporal and geographic constraints, enabling standardized sleep intervention content to be delivered anytime and anywhere, thereby partially alleviating the accessibility limitations of traditional care models [16]. Wearable devices enable continuous, objective sleep monitoring, providing a data foundation for personalized assessment and dynamic treatment adjustment [17]. In addition, interactive interfaces, gamification elements, and real-time feedback mechanisms may enhance patient engagement and adherence [18], offering novel tools for improving sleep health.

However, DHIs for insomnia differ substantially in their delivery platforms, levels of human support, and mechanisms of action, and these differences may translate into variable treatment effects [19]. These variations underscore the need for stratified analyses by intervention type when evaluating the overall efficacy of DHIs on insomnia outcomes. Given the absence of an internationally established classification framework that categorizes DHIs specifically along the dimension of human involvement, we developed a 3-category, researcher-derived typology, drawing on multiple authoritative sources and based on 2 core dimensions: the degree of human involvement (ie, whether and how therapist or coach support is incorporated) and technological modality (ie, the delivery platform and mode of presentation). Specifically, the WHO defines mobile health as medical practice supported by mobile devices and eHealth as the use of information and communication technologies to promote health [20], providing standardized terminology for the delivery platforms—mobile apps and web-based platforms—that underpin our "autonomous self-management" subgroup. The taxonomy of digital mental health interventions proposed by Pineda et al [21] distinguishes interventions by whether they are "consumable" (ie, requiring human resources) versus "nonconsumable" (fully automated), classifying them as "self-help with human guidance" (type 3) or "fully automated self-help" (type 4). This distinction maps directly onto our "remote interaction" and "autonomous self-management" categories. Similarly, the French National Authority for Health (Haute Autorité de Santé), in its 2021 functional classification of digital solutions, identifies "autonomy"—defined as whether a digital solution operates with or without human intervention to deliver therapeutic actions—as a core classificatory dimension [22]. In addition, the WHO's 2023 report on Emerging Technologies and Scientific Innovation highlights the growing role of virtual reality and other emerging technologies in health apps [23], providing terminological justification for our separate "emerging technologies" subgroup. Drawing on these frameworks, we categorized the included interventions into three subgroups: (1) autonomous self-management (web-based or mobile app interventions delivering standardized, self-guided content without direct therapist involvement), (2) remote interaction (digital tools combined with periodic therapist or nurse support and feedback), and (3) emerging technologies (predominantly virtual reality or biofeedback interventions operating primarily through sensory immersion rather than cognitive restructuring).

Clinicians therefore need to know whether treatment effects differ meaningfully across these modalities. However, existing systematic reviews have focused on single DHI formats and have often failed to evaluate multiple sleep outcomes—such as sleep efficiency or wake after sleep onset—or to compare effects across modalities, limiting their clinical usefulness. For example, Linardon et al [24] examined stand-alone mobile app interventions for sleep improvement without comparing them against other DHI formats, Cerolini et al [25] focused exclusively on virtual reality and provided a quantitative synthesis of its sleep effects but did not include other modalities, and Huang et al [26] included multiple DHI types but reported only insomnia severity and sleep quality, thus providing an incomplete picture of multidimensional sleep improvement.

XSL•FO
RenderX

Collectively, these gaps indicate that no systematic comparison of different DHI modalities across multiple sleep outcomes in insomnia patients has yet been performed.

Given these considerations, we conducted a systematic review and meta-analysis of randomized controlled trials (RCTs) to comprehensively evaluate the effects of different DHI modalities on multidimensional sleep outcomes in individuals with insomnia. We used subgroup analyses to explore the potential influences of intervention functional category, comparator type, insomnia diagnosis criteria, and country income level, and we calculated 95% prediction intervals (PIs) to estimate the range of effects likely to be observed in future clinical settings, thereby providing evidence to inform individualized intervention selection.

The primary objective of this study was to determine whether DHIs, compared with nondigital controls, could significantly improve insomnia severity, sleep efficiency, total sleep time, sleep quality, and other outcomes, totaling 8 sleep-related measures, and to assess whether these improvements were clinically meaningful. We hypothesized that DHIs would demonstrate significant benefits across all 8 outcomes, but that the magnitude of these effects would be modified by intervention modality (autonomous self-management, remote interaction, or emerging technologies), comparator type, and country income level, with remote interaction and high-income settings yielding larger effect sizes.

Methods

Design

This systematic review and meta-analysis follows the methodological guidance outlined in the Cochrane Handbook for Systematic Reviews of Interventions [27] and is reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 expanded checklist [28] and the PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses literature search extension) guideline [29]. The completed PRISMA 2020 abstract checklists, PRISMA 2020 expanded checklists, and PRISMA-S checklist are provided in Checklists 1-3, respectively. The protocol was registered on the PROSPERO (International Prospective Register of Systematic Reviews) platform under registration number CRD420251207504, and no deviations from the protocol occurred.

Eligibility Criteria

The eligibility criteria were defined using the PICOS framework, and studies meeting all of the following criteria were included in this review.

For the population criterion, we included patients meeting diagnostic criteria for insomnia disorder according to standardized diagnostic manuals (eg, *Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]; *International Classification of Sleep Disorders, Third Edition*; and *International Classification of Diseases, 11th Revision*) [1,30,31] or validated questionnaire cutoffs (eg, *Insomnia Severity Index* [ISI]≥8 and Pittsburgh Sleep Quality Index [PSQI]>5), as well as individuals with subthreshold insomnia. Sleep problems had to be confirmed by at least one of the following: clinical diagnostic interview, validated sleep questionnaire, or prospective sleep diary.

For the intervention criterion, we included studies evaluating any form of DHI for insomnia, including but not limited to web-based platforms, mobile apps, text messaging programs, remote monitoring systems, virtual reality, and other technology-delivered interventions targeting sleep improvement. No restrictions were placed on intervention duration, frequency, or delivery setting.

For the comparator criterion, we classified control conditions into 2 categories: passive controls (eg, waiting list and treatment as usual) and low-intensity active controls (eg, sleep hygiene education and face-to-face counseling).

For the outcome criterion, primary outcomes were insomnia severity measured by the ISI [32], sleep efficiency and total sleep time measured by sleep diary or actigraphy, and sleep quality measured by the PSQI [33]. Secondary outcomes included wake after sleep onset and sleep onset latency measured by sleep diary or actigraphy, dysfunctional beliefs about sleep measured by the Dysfunctional Beliefs and Attitudes about Sleep Scale [34], and daytime sleepiness measured by the Epworth Sleepiness Scale [35]. All outcomes had to be assessed using validated standardized instruments. For the study design criterion, we included only RCTs or controlled clinical trials, with no language restrictions. Exclusion criteria were experimental sleep deprivation studies in healthy volunteers; conference abstracts, editorials, study protocols, or studies without extractable outcome data; and nonrandomized or noncontrolled study designs.

Information Sources

To comprehensively identify RCTs and controlled clinical trials evaluating the efficacy of DHIs for insomnia, we developed a systematic search strategy and reported it in accordance with the PRISMA-S guidelines [29]. The electronic databases searched included PubMed, Embase, Cochrane Library, Web of Science, Scopus, CINAHL, CNKI, CBM, VIP, and Wanfang, with search dates ranging from database inception to July 2026. Supplementary sources included ClinicalTrials.gov, the website of the American Academy of Sleep Medicine, and manual screening of reference lists of included studies and relevant systematic reviews to identify additional eligible studies.

Search Strategy

We used a combination of subject headings and free-text terms, with search terms focusing on DHIs (eg, “Digital Health,” “Telemedicine,” “Mobile Applications,” “Virtual Reality,” and “Wearable Technology”) and insomnia (eg, “Insomnia” and “Sleep Wake Disorder”). No published search filters were used, either as originally designed or in modified form. The search strategies were developed de novo and were not substantively adapted from prior reviews, nor were they subjected to formal external peer review using the Peer Review of Electronic Search Strategies guideline. Detailed search strategies for all databases are presented in Multimedia Appendix 1.

RenderX

Selection Process and Data Collection

All records were imported into EndNote 21 for screening and duplicate removal. Two reviewers (SG and BZ) independently screened titles and abstracts against the eligibility criteria to identify potentially eligible studies. When titles or abstracts provided insufficient information for a decision, the full text was retrieved for further assessment. The same 2 reviewers then independently evaluated the selected full-text reports for eligibility. Interrater agreement was assessed using Cohen κ coefficient, with overall agreement rated as excellent (κ=0.86, 95% CI 0.78 - 0.95). Disagreements were resolved through discussion or by consulting a third reviewer (XL).

In addition to the systematic database search, we performed backward and forward citation searches. Backward citation searching was conducted by manually screening the reference lists of all included studies and relevant systematic reviews. Forward citation searching was performed using Web of Science and Scopus to identify papers citing the included studies. Two reviewers (SG and BZ) independently screened the titles and abstracts retrieved through citation searching, obtained full texts for potentially eligible papers, and added them to the final analysis if they met the eligibility criteria.

Data Extraction

Two reviewers (SG and BZ) independently extracted study data, with disagreements resolved through discussion and reexamination of the original papers. Extracted data included study characteristics (first author, publication year, country, study population, sample size, and age), intervention characteristics (intervention functional category, comparator type, insomnia diagnosis, country economic classification, intervention dose, and measurement instruments), and outcome data (primary outcomes: insomnia severity, sleep efficiency, total sleep time, and sleep quality; secondary outcomes: wake after sleep onset, sleep onset latency, dysfunctional beliefs about sleep, and daytime sleepiness). We extracted baseline and immediate postintervention measurements; all meta-analyses were performed on postintervention end point values.

Study Risk-of-Bias Assessment

Two reviewers (SG and BZ) independently assessed the methodological quality of the included studies using the Cochrane Risk of Bias 2.0 tool (RoB 2) [36]. The RoB 2 tool covers 5 domains of bias: the randomization process, deviations from intended interventions, missing outcome data, outcome measurement, and selective reporting. Each domain was rated as “low risk of bias,” “some concerns,” or “high risk of bias.” Disagreements were resolved through discussion or by consulting a third reviewer (XL). An overall risk-of-bias judgment for each study was derived based on the domain-level assessments.

Statistical Analysis and Meta-Analysis

Effect Size Calculation

We evaluated the feasibility of conducting a network meta-analysis or component network meta-analysis but did not proceed with either approach. Network meta-analysis was not pursued because the heterogeneity across intervention functional categories and the poorly connected evidence network, with limited head-to-head comparisons across intervention categories and an absence of common comparators to support reliable indirect estimation, precluded the transitivity assumption required for a valid analysis. Component network meta-analysis was also not feasible, as most primary studies described interventions only at the whole-program level and did not provide sufficiently standardized component-level details to allow reliable estimation of the independent effects of individual components. Therefore, we performed standard pairwise meta-analyses with subgroup analyses based on intervention functional category, comparator type, insomnia diagnosis criteria, and country income level.

All included studies had a single intervention group and a single control group, with no duplicate counting of participants. We calculated standardized mean differences (SMDs) with 95% CIs as the pooled effect size. Because insomnia diagnosis and treatment evaluation rely primarily on patient-reported outcomes, and subjective sleep measures (sleep diary, ISI, and PSQI) are recommended by international guidelines [30] as core outcome measures in insomnia clinical trials, we used subjective data as the primary analysis. For studies that also reported objective sleep measures, objective data were analyzed as secondary or sensitivity analyses to test the robustness of the findings.

Given the substantial clinical and methodological heterogeneity across studies in terms of intervention functional category, comparator type, insomnia diagnosis criteria, and country income level, we assumed a priori that true effect sizes might differ across studies. Therefore, all primary meta-analyses used a random-effects model with inverse-variance weighting and restricted maximum likelihood estimation for between-study variance, which has shown superior statistical performance compared with the conventional DerSimonian-Laird method in simulation studies. To more precisely control the false-positive rate and improve the accuracy of pooled estimates, we further applied the Hartung-Knapp-Sidik-Jonkman (HKSJ) correction to the random-effects model, re-estimating pooled effects and 95% CIs. All outcomes were converted to SMD before pooling to eliminate the influence of different measurement instruments or units across studies. Hedges *g* was used as the effect size metric to correct for potential small-study bias.

Heterogeneity Assessment and Handling

We assessed statistical heterogeneity across studies using the Cochran Q test (with $P<.10$ indicating statistical significance) and quantified it using the I^2 statistic. Of note, the I^2 statistic reflects the percentage of total variation attributable to between-study differences rather than sampling error, but it does not directly represent the extent of true effect variation across populations or settings. Therefore, whenever applicable and when the number of studies was sufficient (generally ≥4 studies), we calculated 95% PIs for the primary (overall) meta-analyses to quantify the real-world implications of heterogeneity. These PIs were calculated for the overall pooled estimates to contextualize the primary findings; they were not calculated for subgroup meta-analyses, as the reduced number of studies within subgroups would yield unstable and unreliable

XSL•FO
RenderX

estimates. The PIs were computed based on the between-study variance (τ^2) estimated from the random-effects model with HKSJ correction and the standard error of the pooled effect, using the method proposed by Nagashima et al [37], with the formula:

$$SMD \pm t_{0.975,df} \times SE^2 + \tau^2$$

where SMD is the pooled standardized mean difference, $t_{0.975,df}$ is the critical value of the *t* distribution with k-1 degrees of freedom (k=number of studies), SE is the standard error of the pooled SMD (derived from the HKSJ-corrected model), and τ^2 is the between-study variance (estimated using restricted maximum likelihood). By calculating PI, we estimated the range within which the true effect for a similar population is likely to fall, thereby providing a more comprehensive assessment of the potential effects of DHIs. Therefore, following recent methodological guidance for rigorous meta-analyses, we prioritized the interpretation of these PIs alongside traditional heterogeneity metrics [38,39].

Subgroup Analyses

To explore potential sources of heterogeneity, we conducted subgroup analyses for the primary sleep outcomes. Subgroup analyses based on comparator type (passive comparator vs low-intensity active control), insomnia diagnosis criteria (standardized diagnostic system vs validated questionnaire only), and country income level (high-income vs upper-middle-income countries, dynamically classified according to the World Bank classification corresponding to each study's publication year to ensure temporal accuracy [40]) were prespecified in the study protocol. Subgroup analysis based on intervention functional category (autonomous self-management, remote interaction, and emerging technologies) was also prespecified, with interventions assigned to these 3 groups. In the current manuscript, we further elaborated the operational definitions of these categories by drawing on established taxonomies, including the WHO Classification of Digital Interventions, Services and Applications in Health [20], the taxonomy proposed by Pineda et al [21], and the functional classification of the French National Authority for Health (Haute Autorité de Santé) [22], thereby strengthening the theoretical grounding of the subgroup classification. Nevertheless, given the absence of a universally accepted classification system specifically designed for efficacy comparisons across digital intervention modalities, we positioned this subgroup analysis as exploratory and hypothesis-generating, aiming to investigate patterns of differences and generate hypotheses for future research rather than to establish the causal superiority of any single modality.

To ensure reproducibility, the same 2 reviewers independently assigned each of the 44 included studies to 1 of the 3 prespecified groups based on the operationalized criteria. Interrater agreement was almost perfect (κ=0.88, 95% CI 0.70 - 1.00), and disagreements were resolved through consensus discussion.

In addition, for studies that reported both subjective and objective sleep outcomes, we performed separate comparative analyses; for those reporting only subjective outcomes, we performed separate pooling. We also tested the statistical significance of subgroup differences. To evaluate the robustness of the pooled results, we conducted sensitivity analyses by sequentially excluding high-risk studies (based on RoB 2 assessments) and by using fixed-effect models as an alternative.

Publication Bias and Consistency Assessment

Two reviewers (SG and BZ) independently screened records and extracted data; interrater agreement was assessed using Cohen κ statistic. For the primary sleep outcomes, we constructed funnel plots and combined them with Egger tests to assess small-study effects. Funnel plot symmetry was evaluated by visual inspection in conjunction with Egger tests (P<.10 suggesting asymmetry, reflecting the lower statistical power of these tests in meta-analyses with limited study numbers). When a subgroup contained fewer than 10 studies, small-study effect test results were interpreted cautiously. All tests were 2-sided, with P<.05 considered statistically significant. Initial meta-analyses, subgroup analyses, sensitivity analyses, HKSJ correction, PI calculation, and Egger tests were performed using R (version 4.6.1; R Foundation for Statistical Computing).

Certainty of Evidence Assessment

We used the GRADE (Grading of Recommendations Assessment, Development and Evaluation) system to rate the certainty of evidence for each outcome, classifying it as high (⊕⊕⊕⊕), moderate (⊕⊕⊕), low (⊕⊕), or very low (⊕), representing our confidence in the effect estimates. Under the GRADE framework, evidence was downgraded on 5 domains: risk of bias (assessed using the RoB 2 tool), inconsistency (I^2≥50% rated as serious and I^2≥75% rated as very serious, based on Cochrane Handbook thresholds), indirectness, imprecision (95% CI crossing the null), and publication bias (indirectly assessed through funnel plots and Egger tests for small-study effects). Each domain could be downgraded by 1 level for serious concerns or by 2 levels for very serious concerns. RCTs started at high certainty. Final quality ratings were determined after downgrading.

Results

Study Selection

The database search yielded 26,259 records. After removing 23,174 duplicate records, 3085 records were screened by title and abstract. We excluded 2916 irrelevant records, retrieved 169 full-text papers for assessment (of which 51 were unavailable), and evaluated 118 full texts in detail. After excluding studies with nonrelevant interventions (n=19), unrelated topics (n=37), no target outcomes (n=5), non-RCT designs (n=7), and duplicates (n=6), 44 studies were finally included in the meta-analysis. In addition, among 268 records identified through other methods (eg, backward and forward citation searches), 8 full-text papers were requested, 4 entered eligibility assessment, but all were excluded because they did not involve DHIs or insomnia, resulting in no additional inclusions from this pathway. The screening process is detailed in the PRISMA flow diagram (Figure 1).

Study Characteristics

This systematic review included 44 RCTs [10,11,16-18,41-79]. The characteristics, intervention content, and outcomes of the included studies are summarized in Table 1. Sample sizes ranged from 44 to 1721 participants, with a total of 10,521 participants across all studies. The included studies were published between 2004 and 2026 and were conducted across 14 countries. Nine studies were from China [17,18,45,47,52-54,58,59], 7 from the United States [42,51,55,65,70,73,77], 5 from the Netherlands [41,72,74,75,80], 4 from Germany [11,43,49,57], 3 from South Korea [44,46,50], 3 from Sweden [48,61,79], 3 from the United Kingdom [62,67,76], 3 from Australia [16,56,68], 2 from Japan [60,64], and 1 each from Switzerland [69], Denmark [71], Norway [63], Canada [78], and Iran [66]. All included studies were RCTs.

Intervention Characteristics

DHIs varied considerably across studies. Of the included studies, 30 adopted autonomous self-management approaches [11,16,18,41-46,49,52-54,56,57,59,61-67,69-72,75-77], delivering standardized self-guided intervention content—including sleep hygiene education, CBT-I modules, and sleep diaries—primarily through mobile apps or web-based platforms, with users progressing at their own pace and without direct therapist involvement; 10 used remote interaction approaches [41,48,49,56,61,69,74,75,79,80], in which study teams provided periodic guidance and feedback to participants via telephone, video, or online chat; and 4 used emerging technologies [17,51,52,59], such as virtual reality, wearable devices, and cardiopulmonary coupling assessment. Intervention durations ranged from 1 to 12 weeks.

Risk-of-Bias Assessment

Randomization Process

A total of 26 studies [11,16,18,20,38,38,40,41,44-46,51-53,57-62,64-68,71] were rated as low risk because they used appropriate randomization methods and implemented adequate allocation concealment. A total of 14 studies [17,37,47-50,54,56,63,69,70,73,74,76] had some concerns because they mentioned randomization but did not clearly describe allocation concealment or blinding of group assignment. Four studies [47,48,60,77] were rated as high risk because they did not report randomization methods or provided

XSL•FO
RenderX

severely insufficient descriptions. No studies were rated high risk due to the randomization process itself.

Deviations From Intended Interventions

A total of 19 studies [11,16,37,39-43,45,48-52,59-61,65,72] were rated as low risk because participants were blinded to group assignment or both groups received active interventions, interventions were standardized, and analyses were performed using intention-to-treat (ITT). A total of 23 studies [18,20,38,44,46,47,53,55-58,62-64,66-71,73,74,76] had some concerns because participants were aware of their group assignment, which may have influenced self-reported outcomes, although interventions were standardized and ITT analyses were used. Two studies [17,59] were rated as high risk because intervention and control groups received medications with nonstandardized types or doses, or because of serious protocol deviations.

Missing Outcome Data

A total of 36 studies [11,16,18,20,37,39,40,42,43,45,46,48-53,55-62,64,66-74,76] were rated as low risk because they used ITT analyses with appropriate statistical methods for handling missing data, and attrition rates were within acceptable ranges. Five studies [17,43,46,49,52] had some concerns due to high attrition or between-group imbalance without adequate ITT description. Three studies [59,68,70] were rated as high risk due to high and unbalanced dropout rates, with completer-only analyses or failure to use appropriate methods for missing data.

Outcome Measurement

Three studies [18,44,45] were rated as low risk for outcome measurement. A total of 39 studies [11,16,20,37,38,41-51,53-74,76] had some concerns because primary outcomes were self-reported and participants were aware of their group assignment, creating potential expectancy bias. Two studies [17,57] were rated as high risk because primary outcomes were self-reported and outcome measurement had serious deficiencies (unblinded assessment and sole reliance on self-report scales).

Selective Reporting

A total of 29 studies [11,16,18,20,37,39,44-46,49-53,55-58,60-64,66-70,76] were rated as low risk because they were preregistered in clinical trial registries, including the Chinese Clinical Trial Registry, ClinicalTrials.gov, the Australian New Zealand Clinical Trials Registry, the University Hospital Medical Information Network, and the Open Science Framework, clearly listed all prespecified outcomes in the methods, and fully reported between-group comparisons including nonsignificant results, with no evidence of selective reporting. A total of 14 studies [17,38,40-43,47,48,54,59,65,71,73,74] had some concerns because trial registration numbers were not identified, registration information was incomplete, or multiple comparisons or outcomes were not fully prespecified in the registered protocol; although methods and results were generally complete, the lack of adequate preregistration evidence led to a conservative rating of some concerns. One study [77] was rated as high risk due to lack of preregistration and incomplete reporting. The risk-of-bias assessments are presented in a traffic-light plot (Figure 2 [11,16-18,41-80]), a summary figure (Figure S1 in Multimedia Appendix 2), and a summary of clinical trial registration numbers (Multimedia Appendix 3 [11,16-18,41-80]).

Meta-Analysis Results

Primary Outcome Results

Effect of DHIs on Insomnia Severity

A total of 36 studies involving 6978 participants assessed insomnia severity using the ISI [11,16-18,20,37-44,46-53,56-61,63-68,70,72,73] (Figure 3 [11,16-18,41-49,51-58,61-66,68-73,75,77,78]). In the random-effects meta-analysis with HKSJ correction, DHIs significantly reduced insomnia severity (SMD −0.91, 95% CI −1.12 to −0.70; I^2=86.9%, τ^2=0.3004). However, the 95% PI calculated using the Nagashima method was wide and crossed the null (−2.04 to 0.22) [37], suggesting that a substantial proportion of individuals in future clinical practice may derive no benefit or even worsening. When converted to the ISI scale, this SMD corresponds to approximately 2.0 to 2.5 points, reaching only the lower boundary of the previously suggested minimal clinically important difference (2 to 3 points) [77-79], further underscoring the uncertainty of achieving clinically meaningful benefit at the individual level.

Figure 3. Forest plot of digital health interventions versus nondigital controls for insomnia severity [11,16-18,41-49,51-58,61-66,68-73,75,77,78]. HKSJ: Hartung-Knapp-Sidik-Jonkman random-effects model; PI: prediction interval; REML: restricted maximum likelihood; SMD: standardized mean difference.

In prespecified subgroup analyses, country income level was the only factor showing a significant interaction (P<.01), with high-income countries demonstrating substantially larger effects (SMD −1.03) than upper-middle-income countries (SMD −0.52). In contrast, no significant subgroup differences were observed for intervention functional category (P=.24), comparator type (P=.92), or insomnia diagnosis criteria (P=.39). Point estimates suggested slightly larger effects for low-intensity active controls (SMD −0.93) versus passive comparators (SMD −0.90), for remote interaction (SMD −1.40) versus autonomous self-management (SMD −0.82) and emerging technologies (SMD −0.58), and for standardized diagnostic systems (SMD −0.97) versus questionnaire-only thresholds (SMD −0.81), although none of these differences reached statistical significance. Detailed subgroup results are presented in Table 2 and Figures S2 to S5 in Multimedia Appendix 2.

[a]SMD: standardized mean difference.

In robustness analyses, Egger test suggested small-study effects (intercept=−1.11, 95% CI −1.60 to −0.62; *P*<.01; Figure 4). Nevertheless, leave-one-out sensitivity analyses and trim-and-fill adjustments did not materially alter the direction or significance of the pooled estimate, indicating that the core findings of this study were not substantially affected by potential publication bias.

XSL•FO
RenderX

Figure 4. Funnel plot for assessment of small-study effects in studies reporting insomnia severity. SMD: standardized mean difference.

Effect of DHIs on Sleep Efficiency

A total of 23 studies involving 4107 participants assessed sleep efficiency using sleep diaries or actigraphy [17,18,20,37,40,41,44-46,49,55,57,58,60,66-71,73,74,76] (Figure 5 [17,18,41,42,45,46,49-51,54,60,62,63,65,71-76,78-80]). In the random-effects meta-analysis with HKSJ correction, DHIs were associated with a statistically significant improvement in sleep efficiency (SMD 0.59, 95% CI 0.45-0.72; I^2=69.0%, τ^2=0.0634). The 95% PI calculated using the Nagashima method was 0.05 to 1.13 [37], indicating that in future clinical practice, a substantial proportion of individuals may derive minimal or no meaningful improvement. When converted to absolute terms using a typical SD of 10 to 15 percentage points, this SMD corresponds to an improvement of approximately 5.8 to 8.7 percentage points; however, with the PI lower bound approaching zero and the certainty of achieving ≥85% normal sleep efficiency remaining uncertain [81], this improvement should be interpreted cautiously.

XSL•FO
RenderX

Figure 5. Forest plot of digital health interventions versus nondigital controls for sleep efficiency [17,18,41,42,45,46,49-51,54,60,62,63,65,71-76,78-80]. HKSJ: Hartung-Knapp-Sidik-Jonkman random-effects model; PI: prediction interval; REML: restricted maximum likelihood; SMD: standardized mean difference.

In prespecified subgroup analyses, intervention functional category was the only factor showing a significant interaction (P<.01), with remote interaction (SMD 0.63) and autonomous self-management (SMD 0.61) demonstrating substantially larger effects than emerging technologies (SMD 0.25). In contrast, no significant subgroup differences were observed for comparator type (P=.36), diagnostic criteria (P=.17), country income level (P=.16), or measurement tool (subjective vs objective; P=.89). Point estimates suggested slightly larger effects for passive comparators (SMD 0.61) versus low-intensity active controls (SMD 0.50), for standardized diagnostic systems (SMD 0.66) versus questionnaire-only thresholds (SMD 0.49), and for high-income (SMD 0.62) versus upper-middle-income (SMD 0.43) countries, although none of these differences reached statistical significance. A supplementary subgroup analysis of the 4 studies that used both subjective and objective measures showed comparable estimates for subjective (SMD 0.56) and objective (SMD 0.53) assessments, with no significant difference (P=.89). Detailed subgroup results are presented in Table 3 and Figures S6 to S10 in Multimedia Appendix 2.

[a]SMD: standardized mean difference.

In robustness analyses, Egger test suggested small-study effects (intercept=0.60, 95% CI 0.27-0.93; *P*<.01; Figure 6). Nevertheless, leave-one-out sensitivity analyses and trim-and-fill adjustments did not materially alter the direction or significance of the pooled estimate, supporting the robustness of our findings.

XSL•FO
RenderX

Figure 6. Funnel plot for assessment of small-study effects in studies reporting sleep efficiency. SMD: standardized mean difference.

Effect of DHIs on Total Sleep Time

A total of 25 studies involving 3998 participants assessed total sleep time using sleep diaries or actigraphy [17,18,20,37,40,41,43-46,49,51,55,56,58,60,66-71,73,74,76] (Figure 7 [17,18,41,42,45,46,48-51,54,56,60,61,63,65,71-76,78-80]). In the random-effects meta-analysis with HKSJ correction, DHIs significantly increased total sleep time (SMD 0.20, 95% CI 0.11-0.29; I^2=31.9%, τ^2=0.0134). However, the 95% PI calculated using the Nagashima method was −0.05 to 0.46 [37], indicating that in future clinical practice, a substantial proportion of individuals may experience no meaningful increase or even a slight decrease in total sleep time. When converted to absolute terms using a typical SD [82], this SMD corresponds to an increase of approximately 6 - 12 minutes, which falls well below the widely accepted 30-minute clinical threshold for meaningful improvement [81].

XSL•FO
RenderX

Figure 7. Forest plot of digital health interventions versus nondigital controls for total sleep time [17,18,41,42,45,46,48-51,54,56,60,61,63,65,71-76,78-80]. HKSJ: Hartung-Knapp-Sidik-Jonkman random-effects model; PI: prediction interval; REML: restricted maximum likelihood; SMD: standardized mean difference.

In prespecified subgroup analyses, comparator type was the only factor showing a significant interaction (P<.01), with passive comparators (SMD 0.27) demonstrating larger effects than low-intensity active controls (SMD 0.09). Intervention functional category showed a borderline trend (P=.05), with autonomous self-management (SMD 0.22) and remote interaction (SMD 0.18) demonstrating numerically larger effects than emerging technologies (SMD −0.07). In contrast, no significant subgroup differences were observed for insomnia diagnosis criteria (P=.66), country income level (P=.22), or measurement tool (P=.54). Point estimates suggested slightly larger effects for questionnaire-only thresholds (SMD 0.23) versus standardized diagnostic systems (SMD 0.19), and for high-income (SMD 0.22) versus upper-middle-income (SMD 0.15) countries, although none of these differences reached statistical significance. A supplementary subgroup analysis of the 5 studies that used both subjective and objective measures showed comparable estimates for subjective (SMD 0.10) and objective (SMD −0.02) assessments, with no significant difference (P=.54). Detailed subgroup results are presented in Table 4 and Figures S11 to S15 in Multimedia Appendix 2.

Effect of DHIs on Sleep Quality

A total of 16 studies involving 2196 participants assessed sleep quality using the PSQI [17,18,42,44,47,52,55,59,60,65,66,68,69,71,72,80] (Figure 9). In the random-effects meta-analysis with HKSJ correction, DHIs were associated with a statistically significant improvement in sleep quality (SMD −0.61, 95% CI −0.78 to −0.45; I^2=63.6%, τ^2=0.0597). The 95% PI calculated using the Nagashima method was −1.16 to −0.07 [37], indicating that in future clinical practice, a substantial proportion of individuals may derive minimal or no meaningful improvement. The PSQI total score ranges from 0 to 21, with higher scores indicating worse sleep quality [33]. Based on a typical SD conversion, this SMD corresponds to a PSQI reduction of approximately 1.8 to 2.4 points; however, given that the PI upper bound approaches zero and the improvement falls below the previously suggested minimal clinically important difference of 2.5 to 2.7 points for the PSQI [83], this reduction should be interpreted cautiously.

XSL•FO
RenderX

Figure 9. Forest plot of digital health interventions versus nondigital controls for Pittsburgh Sleep Quality Index [17,18,42,44,47,52,55,59,60,65,66,68,69,71,72,80]. HKSJ: Hartung-Knapp-Sidik-Jonkman random-effects model; PI: prediction interval; REML: restricted maximum likelihood; SMD: standardized mean difference.

In prespecified subgroup analyses, no significant subgroup differences were observed for intervention functional category (P=.60), comparator type (P=.37), insomnia diagnosis criteria (P=.97), or country income level (P=.20). Point estimates suggested slightly larger effects for remote interaction (SMD −0.83) versus autonomous self-management (SMD −0.63) and emerging technologies (SMD −0.42), for low-intensity active controls (SMD −0.69) versus passive comparators (SMD −0.59), and for high-income (SMD −0.69) versus upper-middle-income (SMD −0.45) countries. Of note, standardized diagnostic systems (SMD −0.61) and questionnaire-only thresholds (SMD −0.61) yielded identical point estimates. Detailed subgroup results are presented in Table 5 and Figures S16 to S19 in Multimedia Appendix 2.

Secondary Outcome Results

A total of 24 studies assessed sleep onset latency [17,18,20,37,40,41,43-46,49,51,55,56,58,66-71,73,74,76], 22 studies assessed wake after sleep onset [18,20,37,40,41,43-46,49,51,56,58,64,66-71,73,74], 16 studies assessed dysfunctional beliefs about sleep [16,39-42,44,45,48,51-53,67,68,70,73,74], and 12 studies assessed daytime sleepiness [16,18,39,44,45,51-53,57,62,63,68]. In random-effects meta-analyses, DHIs were associated with significant reductions in sleep onset latency (SMD −0.41, 95% CI −0.58 to −0.24; I^2=74.3%), wake after sleep onset (SMD −0.45, 95% CI −0.66 to −0.23; I^2=83.8%), dysfunctional beliefs about sleep (SMD −0.64, 95% CI −0.86 to −0.42; I^2=81.2%), and daytime sleepiness (SMD −0.37, 95% CI −0.55 to −0.19; I^2=63.6%). However, the 95% PIs for all 4 secondary outcomes crossed the null: sleep onset latency (−1.15 to 0.33), wake after sleep onset (−1.39 to 0.50), dysfunctional beliefs about sleep (−1.44 to 0.17), and daytime sleepiness (−0.87 to 0.14), indicating that future effects could range from benefit to no effect or even harm.

In supplementary subgroup analyses exploring measurement tool consistency, 5 studies that used both subjective diaries and objective actigraphy to assess sleep onset latency showed different point estimates for subjective (SMD −0.16) and objective (SMD −0.57) measures, but the subgroup difference was not statistically significant (*P*=.25). For wake after sleep onset, subjective (SMD −0.06) and objective (SMD −0.12) estimates were comparable, with no significant subgroup difference (*P*=.83).

In robustness analyses, Egger tests suggested small-study effects for all 4 secondary outcomes: sleep onset latency (intercept=−0.51, 95% CI −0.93 to −0.11; *P*=.02), wake after sleep onset (intercept=−0.63, 95% CI −1.11 to −0.15; *P*=.01), dysfunctional beliefs about sleep (intercept=−0.90, 95% CI −1.45 to −0.36; *P*=.03), and daytime sleepiness (intercept=−0.49, 95% CI −0.85 to −0.12; *P*=.01). Nevertheless, leave-one-out sensitivity analyses and trim-and-fill adjustments did not

XSL•FO
RenderX

materially alter the direction or significance of any pooled estimate, supporting the robustness of our findings. Detailed subgroup results are presented in Table 6 and Figures S20 to S29 in Multimedia Appendix 2. PIs are reported for overall meta-analyses only.

Sensitivity Analysis Results

To test the robustness of our meta-analysis results, we performed leave-one-out sensitivity analyses. For all primary outcomes, exclusion of any single study did not change the direction or significance of the pooled estimates. In addition, reanalysis using a fixed-effect model yielded results consistent with the random-effects model. Taken together, these findings indicate that our meta-analysis results are generally robust to the exclusion of individual studies and the choice of modeling approach. The residual heterogeneity observed may be attributable to differences in intervention methods, measurement instruments, intervention content, patient characteristics, and technological platforms.

Certainty of Evidence

Using the GRADE system, we rated the certainty of evidence for the prespecified outcomes. The certainty of evidence was moderate ( ) for total sleep time, downgraded only for risk of bias (due to limitations in blinding of outcome assessment). It was low ( ) for sleep efficiency, sleep quality, sleep onset latency, and daytime sleepiness, downgraded for risk of bias and serious inconsistency (I^2≥50%). It was very low ( ) for insomnia severity, wake after sleep onset, and dysfunctional beliefs about sleep, downgraded for risk of bias and very serious inconsistency (I^2≥75%). No outcomes were additionally downgraded for indirectness, imprecision, or publication bias (Table 7).

Discussion

Principal Findings

This systematic review and meta-analysis evaluated the efficacy of DHIs for improving sleep outcomes in individuals with insomnia. Our findings indicate that DHIs were associated with statistically significant improvements in insomnia severity, sleep efficiency, sleep quality, and several secondary outcomes, including sleep onset latency, wake after sleep onset, dysfunctional beliefs about sleep, and daytime sleepiness.

Subgroup analyses revealed several notable patterns across intervention characteristics. For sleep efficiency, remote interaction and autonomous self-management demonstrated comparable effects, which were substantially larger than those of emerging technologies. Remote interaction may address the adherence limitations of pure self-guided models through regular therapist supervision and personalized feedback [84], autonomous self-management enables standardized delivery of CBT-I core modules at low cost [85,86], and emerging technologies (predominantly virtual reality) may reduce presleep somatic arousal through immersive relaxation [87,88], although their adoption is constrained by hardware accessibility and user comfort [84].

Country income level emerged as an effect modifier for insomnia severity, with high-income countries showing substantially larger improvements than upper-middle-income countries. Several contextual factors may explain this disparity. First, high-income countries generally possess more mature digital health infrastructure, including higher smartphone penetration, more stable internet connectivity [89], and established pathways for digital therapeutic reimbursement in several leading high-income countries [90]. Second, the digital interventions tested in high-income settings were more likely to be culturally adapted and linguistically aligned with the target population, whereas those applied in upper-middle-income countries often involved direct translations of Western-developed programs without substantive cultural tailoring, potentially reducing engagement and efficacy [91]. Third, differences in health care system integration, including the availability of primary care referrals to digital interventions, may influence adherence and clinical outcomes [92]. This finding underscores the urgent need for implementation research that addresses the digital divide in insomnia care, particularly through the development of locally adapted, affordable, and scalable digital solutions for low- and middle-income settings [93].

Comparator type showed a significant interaction for total sleep time, with passive comparators yielding larger effect sizes than low-intensity active controls. This pattern is methodologically expected: low-intensity active controls, such as sleep hygiene education or brief counseling, confer nonnegligible therapeutic benefits themselves [94], thereby reducing the between-group difference [95]. This finding suggests that the incremental benefit of DHIs over minimal active interventions, while statistically significant, may be more modest than suggested by comparisons against waiting list or treatment-as-usual controls. Clinicians and policymakers should therefore interpret effect sizes from passive-controlled trials with caution, recognizing that the real-world added value of DHIs relative to existing low-intensity services may be smaller than trial estimates suggest [95,96].

However, several considerations temper the interpretation of these statistically significant findings. In terms of clinical translation, statistical significance does not equate to clinical importance. Although effect sizes for insomnia severity and sleep quality were moderate to large, conversion to original scale scores revealed changes that only approached or fell short of previously recommended minimal clinically important difference thresholds [77-79]. For total sleep time, the improvement translated to only a few minutes, well below the threshold generally considered clinically meaningful [81]. This indicates that although current evidence supports the average effectiveness of DHIs at the population level, the actual magnitude of benefit for individual patients remains uncertain. Furthermore, the 95% PIs were wide for all primary outcomes, and those for insomnia severity, sleep quality, and several secondary outcomes (eg, sleep onset latency and wake after sleep onset) encompassed the null value. This suggests that, in future real-world clinical settings, individual patient responses

XSL•FO
RenderX

to DHIs may range from substantial benefit to little or no effect. In addition, GRADE assessments indicated low-to-moderate certainty for primary outcomes, with downgrading due to high heterogeneity, risk of small-study effects for some outcomes, and concerns about outcome measurement bias in most studies because participants were aware of their group assignment. Therefore, the present findings should be interpreted as exploratory rather than definitive [97].

Compared with previous meta-analyses, our effect estimates are broadly consistent with those of earlier reviews focusing on digital CBT-I [98]. Beyond this confirmation, our review offers 3 additional findings worthy of further discussion. First, whereas prior reviews typically combined different digital intervention formats [99], our subgroup analyses revealed differential effects across intervention modalities. For instance, remote interaction showed larger effect sizes than autonomous self-management for sleep efficiency, suggesting that regular therapist supervision, personalized feedback, and adherence reinforcement may be key components that amplify treatment effects [100]. Second, we reported PIs, which previous reviews have infrequently reported. This approach explicitly highlights the substantial uncertainty in individual-level treatment responses. It also provides a more cautious evidentiary framework for clinical translation [38,39]. Third, through conversion of pooled effect sizes to original scale scores, we identified a gap between statistically significant effects and clinically meaningful differences [83]. However, such conversions depend on the representativeness of the SDs used across studies, and therefore have limited precision [101]. This observation should be interpreted cautiously [83]. Future studies that report the proportion of participants achieving a minimal clinically important difference may provide a more clinically useful metric than between-group mean differences alone [102,103].

We observed a nonsignificant trend toward larger subjective than objective improvements, a pattern that aligns with the work of Ahn et al [96]. However, the subgroup differences were not statistically significant, so this pattern should be interpreted cautiously rather than as definitive evidence of a subjective-objective discrepancy. This discrepancy can be interpreted from 2 perspectives. First, from a pathophysiological standpoint, patients with insomnia may experience cortical microarousals during polysomnographically defined sleep, leading to a subjective experience of wakefulness, a dissociation between cortical arousal and subjective perception [84,104]. This phenomenon is consistently documented in paradoxical insomnia, where subjective sleep reports markedly underestimate objective sleep duration [105]. Prior evidence suggests that DHIs, through psychoeducation, cognitive restructuring, and relaxation training, can effectively reduce sleep-related anxiety and catastrophic interpretations of nocturnal microarousals, thereby preferentially narrowing the gap between perceived and objective sleep [91,106] rather than directly altering physiological sleep architecture. This observed pattern therefore provides insight into the potential mechanisms of DHIs: they may operate through cognitive, behavioral, and physiological pathways to improve subjective sleep experience. Second, from a methodological standpoint, the subjective-objective discrepancy may partly reflect study design biases. Given the inherent difficulty of blinding participants and researchers in digital intervention studies, and given that primary outcomes were patient-reported, awareness of receiving an active intervention may systematically inflate subjective ratings through expectancy and placebo effects [76,107].

These subgroup observations must be interpreted with statistical and evidentiary caution. The observed gradient in insomnia severity across intervention categories did not reach statistical significance under the random-effects model, and the ranking may reflect imbalances in study numbers across subgroups, baseline characteristics, comparator types, or other confounders rather than true differences in treatment efficacy [38,39,108]. Moreover, these subgroup comparisons are based on indirect between-study comparisons rather than direct head-to-head RCTs; the emerging-technology subgroup consisted of only a few small studies for several outcomes, limiting the stability of its pooled estimates [109]. Therefore, these findings should be regarded as hypothesis-generating and exploratory, and the relative superiority of different modalities in specific populations should be tested in adequately powered, head-to-head RCTs [109]. Clinicians may consider these findings as reference information for individualized decision-making, but they do not yet provide sufficient evidence to support standard treatment recommendations [110].

Strengths and Limitations

This review followed established methodological standards for systematic reviews and meta-analyses, with comprehensive literature searches across 11 databases and multiple gray literature sources. The statistical approach incorporated HKSJ-corrected random-effects models, PIs, and GRADE assessments, which together strengthened the reliability of the findings [111]. The inclusion of a large number of randomized trials provided a substantial evidence base for quantitative synthesis. Compared with prior reviews that often focused on single intervention formats or limited outcome domains, this review examined 3 intervention modalities simultaneously and evaluated a broad range of sleep-related outcomes. Subgroup analyses were prespecified in the study protocol. They explored potential sources of heterogeneity across intervention types, comparator conditions, diagnostic criteria, and country income levels. These features allow for a more differentiated interpretation of the evidence than previous syntheses have provided.

This review has several limitations. The I^2 values for several primary outcomes were high. Although this reflects a large proportion of observed variation attributable to between-study differences, I^2 is a relative measure of inconsistency rather than an absolute measure of heterogeneity [39]. The τ values and PIs reported alongside each estimate therefore provide a more clinically informative assessment of heterogeneity in this review. The high I^2 values may be partly attributable to differences in intervention types, comparator settings, and diagnostic criteria, and may also reflect the relatively high precision with which some study-level estimates were measured. Furthermore, the overall pooled estimates presented in this review should be interpreted as descriptive summaries of the average effects across the included DHI types. Given the clinical and

XSL•FO
RenderX

methodological diversity across interventions, these estimates do not represent a stable or uniform effect that can be generalized to all digital insomnia interventions. Most studies were at risk of bias because participants were aware of their group assignment, which may have inflated the effects on subjective outcomes [107]. GRADE assessments indicated very low-to-moderate certainty for primary outcomes, and the 95% PIs suggested that clinical responses could range from substantial benefit to no effect, necessitating cautious interpretation [38,39,111]. Small-study effects were suggested by Egger tests for several outcomes, although trim-and-fill adjustments did not materially alter the pooled estimates; these findings may reflect publication bias but can also arise from other causes [112]. Some subgroup analyses included only 1 to 3 small studies, and subgroup comparisons were based on indirect evidence rather than head-to-head RCTs; all subgroup findings should therefore be considered hypothesis-generating rather than clinically definitive [109]. We acknowledge that network meta-analysis was not performed because the heterogeneity across intervention categories and the poorly connected evidence network precluded the transitivity assumption [113]. Component network meta-analysis was also not feasible due to insufficiently standardized component-level reporting in the included studies [114].

Several further limitations concern the evidence base and its generalizability. Most studies assessed only immediate postintervention effects (8 to 12 weeks) and lacked long-term follow-up (≥6 months); given that insomnia is a chronic relapsing condition, the durability of treatment effects remains unknown [115,116]. There is also insufficient reporting of null or nonsignificant results, which may have inflated the pooled effect estimates [112]. The majority of studies used passive comparators, and head-to-head comparisons between different DHI modalities are lacking, limiting our ability to determine their optimal positioning in the treatment algorithm [117]. The evidence base is heavily concentrated in high-income countries and in populations of young-to-middle-aged, highly educated, urban residents, severely limiting generalizability to older adults, lower-education groups, and low-income populations—a digital divide. Older adults frequently face barriers such as technology anxiety, age-related sensory decline, and unfriendly user interfaces [118]; lower-education groups may struggle to understand abstract psychoeducational materials and behavioral instructions [119]; and low-income populations often face not only affordability constraints regarding smartphones and data plans [120] but also disadvantaged sleep environments, higher life stress, and greater comorbidity burdens [121], all of which independently worsen insomnia and reduce the applicability of standardized interventions [122]. Furthermore, assessments of small-study effects, including funnel plot visual inspection and Egger tests, should be interpreted with caution, as several meta-analyses included relatively small numbers of studies, which limits the statistical power of these detection methods [123].

Future research should therefore (1) prioritize studies targeting diverse populations and exploring adaptive strategies such as simplified interfaces, voice interaction, community support, and hybrid models [118,124]; (2) conduct hybrid model RCTs in community health centers [125]; (3) perform cognitive interviews with low-health-literacy groups to optimize intervention content [126]; and (4) clarify whether digital interventions should serve as a complement rather than a substitute for traditional in-person care in resource-limited settings [127]. In addition, the field would benefit from consensus on core outcome sets and standardized intervention reporting, the development of active comparator designs and digital placebos, head-to-head comparisons of different DHI modalities, extended follow-up periods (≥12 months), encouraging publication of null results, and exploration of artificial intelligence–driven adaptive intervention systems to move digital sleep care from standardized treatment toward precision dynamic management [128].

Conclusions

This systematic review and meta-analysis of 44 RCTs evaluated the efficacy of DHIs for insomnia and compared, by intervention functional category, the effects of 3 digital intervention modalities—autonomous self-management, remote interaction, and emerging technologies. The evidence suggests that DHIs may improve insomnia severity, sleep efficiency, sleep quality, and several related symptoms, yet considerable uncertainty remains regarding their translation into clinically meaningful benefits, with marked interindividual variability.

Subgroup analyses revealed several notable patterns that warrant emphasis. First, country income level emerged as an effect modifier for insomnia severity, with high-income countries demonstrating substantially larger effects than upper-middle-income countries—a finding that underscores the pervasive digital divide in sleep medicine. Second, intervention functional category modified sleep efficiency outcomes, with remote interaction and autonomous self-management showing comparable effects, both larger than emerging technologies. Third, comparator type influenced total sleep time, with passive comparators yielding larger effects than low-intensity active controls, highlighting the importance of control group selection in trial interpretation. However, the observed gradient across intervention modalities should be considered exploratory and hypothesis-generating at this stage, rather than a basis for clinical triage recommendations. The wide PIs, low-to-moderate GRADE certainty, and concentration of evidence among young-to-middle-aged adults in high-income countries collectively limit the translation of these findings into individualized clinical decision-making. The improvement in subjective sleep experience showed a nonsignificant trend toward being larger than the change in objective sleep duration, suggesting that the core value of DHIs may lie in improving sleep perception and subjective experience rather than substantially increasing objective sleep time.

In conclusion, DHIs may serve as a low-intensity, highly accessible initial option in a stepped-care model for insomnia, particularly for patients with mild-to-moderate insomnia, those with self-motivation, and those who cannot readily access face-to-face CBT-I. However, given the low-to-moderate certainty of the current evidence and the clear digital divide, these suggestions should be applied with clinical judgment, carefully weighing individual patient characteristics, digital

XSL•FO
RenderX

accessibility, and treatment uncertainty. This study provides exploratory evidence to inform the initial clinical application of DHIs in insomnia management, but future head-to-head comparative and implementation science studies in diverse populations are needed to advance the precise and equitable use of DHIs.

Generative AI Use

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: language polishing and editing. The GenAI tool used was DeepSeek. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Imaging-based AI may help predict pathological complete response (pCR) after neoadjuvant therapy for esophageal cancer. However, an encouraging average diagnostic performance does not establish reliable performance across clinical settings or justify treatment decisions without further validation.

Objective: We aimed to assess the predictive performance of imaging-based AI across neoadjuvant strategies, distinguish internal from external validation, and examine limitations affecting interpretation.

Methods: PubMed, Embase, Web of Science, and the Cochrane Library were searched through August 7, 2026. Eligible English-language studies evaluated imaging-based AI against pathological assessment of pCR. PROBAST+AI (Prediction Model Risk of Bias Assessment Tool plus Artificial Intelligence) assessed study quality and risk of bias; GRADE (Grading of Recommendations Assessment, Development, and Evaluation) assessed certainty for sensitivity, specificity, and diagnostic odds ratio (DOR). Bivariate random-effects models synthesized validation groups separately. CIs described uncertainty in average performance, whereas 95% prediction intervals (PIs) described true performance in a similar new study.

Results: Thirty-three studies contributed 27 internal-validation datasets with 1891 patients and 16 external-validation datasets with 777 patients. Ten publications contributed to both groups. The sum was 2668 validation observations; the unique patient count across datasets and publications could not be verified. Internal sensitivity was 0.77 (95% CI 0.72 - 0.81; PI 0.57 - 0.89), specificity 0.82 (95% CI 0.78 - 0.86; PI 0.60 - 0.93); DOR, 15.49 (95% CI 11.16 - 21.50); and area under the curve (AUC), 0.86 (95% CI 0.83 - 0.89). External sensitivity was 0.73 (95% CI 0.61 - 0.81; PI 0.34 - 0.93), specificity 0.83 (95% CI 0.73 - 0.90; PI 0.36 - 0.98), DOR 12.93 (95% CI 7.25 - 23.07), and AUC 0.84 (95% CI 0.79 - 0.89). DOR PIs were 5.40 - 44.44 and 2.40 - 69.62, respectively. Thirty-two studies were conducted in China, and 12 had high validation risk of bias. All GRADE-assessed outcomes had very low certainty. Selecting the first eligible imaging model reported in each article instead of the highest-AUC model showed modest decreases in average performance across 16 internal and 10 external datasets; incomplete alternative-model reporting limited interpretation. Single study algorithm estimates were reported descriptively, without ranking algorithms or interpreting their CIs as evidence of between study consistency or generalizability.

Conclusions: By combining multiple neoadjuvant strategies and separating validation stages, this review extends earlier neoadjuvant chemoradiotherapy (NCRT)-focused syntheses and identifies priorities for further model evaluation. Imaging-based AI may support response assessment, but wide PIs, risk of bias, and very low evidence certainty preclude routine clinical adoption without prospective, geographically diverse validation. Future studies should evaluate prespecified models in independent populations, report clinically relevant decision thresholds, and assess calibration and patient outcomes. Until such evidence is available, these models should be considered investigational adjuncts to response assessment and should not independently guide organ preservation or omission of surgery after neoadjuvant treatment.

RenderX

Introduction

Esophageal cancer is one of the most lethal gastrointestinal malignancies worldwide, causing over 500,000 deaths annually, with an overall 5-year survival rate below 25% [1]. The main histological subtypes are esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma. Surgery remains the primary treatment, but for locally advanced cases, it is often insufficient for long-term survival. The European Society for Medical Oncology (ESMO) and the National Comprehensive Cancer Network (NCCN) recommend preoperative neoadjuvant therapy for patients with locally advanced esophageal cancer [2-4]. If patients achieve a pathological complete response (pCR) after neoadjuvant therapy, active surveillance or organ-preserving strategies may be considered [5]. However, pCR rates remain limited, ranging from 43% - 49% in squamous cell carcinoma and 23% in adenocarcinoma [6]. Early and accurate identification of pCR is critical to guide treatment decisions and promote precision clinical management.

pCR is defined as the absence of viable tumor cells in both the primary lesion and regional lymph nodes after neoadjuvant therapy. In clinical practice, treatment response is often evaluated using Response Evaluation Criteria in Solid Tumors (RECIST) version 1.1. However, RECIST 1.1 indicates that primary lesions in hollow organs are often difficult to measure accurately [7]. Consequently, esophageal cancer lesions are frequently classified as nonmeasurable. After neoadjuvant therapy, tumors may achieve pCR, yet residual soft-tissue densities are often still observed on computed tomography (CT) images, predominantly representing fibrosis or inflammatory changes rather than viable tumor. RECIST 1.1 relies on morphological changes, making it difficult to accurately distinguish cases that have achieved pCR, thereby limiting its predictive performance.

AI has been successfully applied in medicine, enabling automated recognition and analysis of complex medical data [8]. Radiomics combines AI and medical imaging to extract quantitative image features using algorithms, potentially reflecting underlying pathophysiology and revealing pathogenesis [9]. Recent machine learning (ML)-based radiomic analyses have demonstrated improved accuracy in predicting therapy response and assessing prognosis [10]. Imaging-based AI models show potential for predicting pCR in esophageal cancer following neoadjuvant therapy. For resectable locally advanced esophageal cancer, neoadjuvant chemoradiotherapy (NCRT) combined with surgery is the standard treatment [11]. Recent studies indicate that neoadjuvant immunotherapy combined with chemotherapy (NICT) also shows favorable efficacy and safety in locally advanced ESCC [12-16]. If patients achieve pCR, they may be considered for organ preservation or active surveillance [17]. However, differences in imaging modalities, AI algorithms, and treatment regimens result in fluctuating predictive accuracy of AI models, making their translation into clinically useful tools challenging.

Previous reviews have evaluated the performance of radiomics-based models for predicting pCR after NCRT [11,18]; however, these reviews were largely confined to this single treatment modality. With the rapid development of novel therapeutic strategies such as NICT and neoadjuvant chemotherapy (NACT), the predictive value of AI models across different treatment modalities remains to be systematically assessed. Furthermore, existing reviews have seldom distinguished between internal and external validation results, offering limited discussion on model generalizability. Thus, this meta-analysis aims to assess the predictive performance of imaging-based AI models for pCR in esophageal cancer after neoadjuvant therapy across multiple neoadjuvant treatment strategies for the first time, and to separately extract and synthesize results from internal and external validation cohorts to rigorously evaluate model generalizability, as well as factors affecting their performance.

Methods

Study Design

This meta-analysis was conducted in strict accordance with the PRISMA-DTA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses for Diagnostic Test Accuracy) guidelines [19]. The PRISMA-DTA checklist is provided in Checklist 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 for Abstracts checklist is provided in Checklist 2. Search reporting followed the PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses literature search extension) extension [20], and the completed PRISMA-S checklist is provided in Checklist 3. Additionally, the study protocol has been registered in the PROSPERO (International Prospective Register of Systematic Reviews) database (CRD420251207710). Deviations from the registered protocol comprised an update and expansion of the literature search during revision (final search: August 7, 2026) and the additional calculation of prediction intervals (PIs) for pooled sensitivity and specificity.

Information Sources and Search Strategy

We conducted a systematic literature search across 4 databases: PubMed, Embase, Web of Science, and the Cochrane Library, with literature retrieval completed by 2 independent reviewers (ZL and XG) until August 7, 2026. Our search strategy comprised 3 groups of keywords: AI-related terms (eg, artificial intelligence, machine learning, and deep learning); disease-specific terms (eg, esophageal neoplasms, esophageal adenocarcinoma, and ESCC); and neoadjuvant therapy-related terms (eg, neoadjuvant therapy, NACT, neoadjuvant chemoimmunotherapy, and NCRT). A search strategy combining free-text keywords and MeSH was used to ensure accuracy, as detailed in Table S1 in Multimedia Appendix 1. Initial searches posed no restrictions on language or publication year. As an additional information source, citation searching was performed by screening the reference lists of the included studies and of similar published systematic reviews and meta-analyses on the same topic. No study registries or other online resources were searched, no search filters were used, and the search strategy did not undergo formal peer review.

XSL•FO
RenderX

Eligibility Criteria

Inclusion criteria carefully adhered to the PITROS (participants, index test, target conditions, reference standard, outcomes, and settings) framework. Participants (P): The participants in this study are patients with esophageal cancer undergoing neoadjuvant therapies, which include NACT, neoadjuvant immunotherapy plus chemoradiotherapy (NICRT), NCRT, and neoadjuvant immunochemotherapy. Index test (I): This study uses AI techniques, specifically ML and deep learning (DL), to analyze imaging data (CT/magnetic resonance imaging [MRI]) to predict the pCR in patients with esophageal cancer. Target condition (T): The positive group is defined as patients with a pathologically confirmed pCR, while the negative group consists of patients who did not achieve a pCR. Reference standard (R): Pathological assessment was used as the reference standard to determine whether patients had achieved pCR. Outcomes (O): The primary outcomes include patient-based analysis of sensitivity, specificity, diagnostic odds ratio (DOR), and the area under the curve (AUC). Setting (S): The study setting includes retrospective or prospective data sources, covering public databases or local hospitals.

Exclusion criteria included studies with titles and abstracts that were clearly unrelated to the research topic, as well as specific types of literature (eg, reviews, case reports, conference abstracts, meta-analyses, and letters to editors). Non-English studies were excluded due to lack of accessibility. This English-only restriction was considered a potential limitation because it may have excluded relevant evidence. Furthermore, research related to tumors at the gastroesophageal junction and studies with overlapping samples were also excluded. The screening process was conducted independently by 2 reviewers (LW and JZ), who first assessed the relevance of titles and abstracts and then evaluated the full texts based on the inclusion and exclusion criteria. Discrepancies among reviewers were resolved through discussion, and if consensus could not be reached, a third reviewer (FR) determined the final decision.

Risk of Bias and Certainty Assessment

The quality of the included studies was rigorously evaluated using the updated 2025 PROBAST+AI tool (Prediction model Risk of Bias Assessment Tool plus Artificial Intelligence) [21]. This tool provides a comprehensive evaluation of both model development and validation phases, with each phase covering 7 key domains including participants and data sources, predictors, outcome assessment, and analytical methods. Detailed evaluation procedures and results are shown in Tables S2 and S3 in Multimedia Appendix 1.

To ensure objectivity and accuracy, 2 reviewers (ZL and JZ) independently assessed the risk of bias in included studies using the PROBAST+AI tool. Discrepancies were resolved through discussion and consensus, thereby enhancing the reliability and consistency of the final assessments. We used the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) tool to evaluate the certainty of sensitivity, specificity, and DOR, focusing on 5 key domains: risk of bias, indirectness, inconsistency, imprecision, and publication bias [22]. Downgrading in any domain resulted in reduced overall evidence certainty.

Data Collection Process and Data Items

Two reviewers (XG and ZL) independently extracted data from all included studies to minimize bias and enhance the accuracy and reliability of the dataset. Any disagreements between the 2 reviewers were resolved through consultation with a third reviewer (LW), who served as an arbitrator to facilitate consensus. Extracted data included the first author, publication year, patient origin country, type of histopathology, study design, type of therapy, reference standard, No. of pCR patients, and analysis approach. Technical information was also recorded, including type of imaging, imaging technical details, data source, type of AI model, data splitting method, AI method, the best-performing AI algorithms, as well as the number of patients in the training, internal validation, and external validation sets, with corresponding counts of true positives (TPs), true negatives (TNs), false positives (FPs), and false negatives (FNs). For studies lacking data required for meta-analysis, we contacted corresponding authors via email to request the missing information.

Index Test and Outcome Measures

The primary outcomes included sensitivity, specificity, AUC, and DOR for both internal and external validation sets. Internal validation referred to evaluation within the development data or a held-out subset, whereas external validation referred to evaluation in an independent cohort from a different institution or time period and therefore provided a more direct assessment of generalizability. Sensitivity (TP rate) was used to assess the ability of an AI model to correctly identify pCR cases and was calculated as TP/(TP+ FN). Specificity (TN rate) reflected the probability of correctly identifying non-pCR cases and was calculated as TN/(TN+ FP). The AUC served as a comprehensive measure of the model's ability to distinguish between positive and negative cases. DOR, calculated as the ratio of the positive likelihood ratio (LR+) to the negative likelihood ratio (LR−), was used to evaluate diagnostic performance. For studies with multiple nonoverlapping patient datasets (eg, internal validation and external validation), each dataset was treated as an independent dataset and included in the analysis. Additionally, for studies evaluating multiple AI models, only the model with the highest AUC from the internal or external validation sets was extracted. Internal and external validation were synthesized separately. Validation sample counts were summed within each group; training samples and repeated cross-validation folds were not added again. The 2 validation groups contributed 2668 validation observations in total (1891+777). This sum was not interpreted as a verified count of unique patients because patient overlap across validation datasets and publications could not be fully assessed from the available study-level reports.

Synthesis Methods and Statistical Analysis

A bivariate random-effects model was applied in the meta-analysis to assess the diagnostic performance of AI models for predicting pCR in patients with esophageal cancer. Because sensitivity and specificity were jointly modeled, the bivariate random-effects framework was retained as the primary model rather than splitting the outcomes into separate univariate analyses solely to apply the Hartung-Knapp-Sidik-Jonkman

XSL•FO
RenderX

(HKSJ) correction; HKSJ is primarily designed for conventional univariate random-effects meta-analysis and is not a general replacement correction for a bivariate diagnostic-accuracy model. AUC was derived from the summary receiver operating characteristic (SROC) curve, and DOR was derived from the difference between the model coefficients for logit sensitivity and logit FP rate; conventional HKSJ was therefore not directly applicable to these derived outcomes. Predictive results were pooled for the internal and external validation cohorts. Forest plots were generated to visually present pooled sensitivity, specificity, and DOR, while an SROC curve displayed the summary point and joint confidence and prediction regions. Z-tests were used to compare pooled sensitivity, specificity, DOR, and AUC values, with statistical significance defined as $P<.05$. Inconsistency was assessed using outcome-specific I^2 values based on Cochran Q statistic. Q was calculated for logit sensitivity, logit specificity, and log DOR. For sensitivity and specificity, 0.5 was added to both event and nonevent counts if either count was zero. For DOR, 0.5 was added to all 4 cells if any cell was zero. I^2 estimated the proportion of observed variability attributable to between-study differences rather than sampling error, not the absolute magnitude of heterogeneity. Between-study variance (τ^2), its square root (τ), and PIs were obtained from the bivariate model to describe variation on the corresponding effect scales [23]. Meta-regression analyses considered AI method (ML vs DL), AI model (radiomic and clinical models vs radiomic-only models), and contrast-enhanced imaging (yes vs no), using the categories reported in the supplementary meta-regression tables. Bubble plots were generated to assess temporal trends in AI model AUCs, and radar charts were constructed to depict the distribution of ML and DL algorithms. The clinical utility of the AI model was evaluated using a Fagan nomogram, with a pretest probability of 34%, close to the median pCR rate across 43 internal and external validation datasets (34.8%; IQR 27.7%-40.6%). Although PIs were not specified in our original PROSPERO registration protocol, we additionally calculated marginal 95% PIs for sensitivity, specificity, and DOR in both validation groups to better quantify the distribution of effects across different populations and settings, as recommended by recent methodological guidance on the reporting of PIs [24,25]. Potential small-study effects and funnel-plot asymmetry were assessed using Deeks test; asymmetry was not interpreted as evidence of publication bias alone [26,27]. The primary bivariate estimates, PIs, and model-selection sensitivity analysis were obtained using R (R Foundation for Statistical Computing; version 4.5.2). AUC CIs for the primary analyses were estimated using the delta method. Secondary analyses used Stata (StataCorp LLC; versions 15.1 and 17.0) with the Midas and Metadta modules. Data visualization used the *ggplot2* and *tidyverse* packages in R.

Sensitivity analyses excluded outliers identified in bivariate box plots, excluded low-quality studies, and included only ESCC cohorts (Table 1). We also compared the highest-AUC model with the first eligible imaging model reported in each article, using the same validation cohorts and pCR definitions (Tables S9 and S10 in Multimedia Appendix 1). Models were selected in table order, or in Results order when no eligible performance table was available; comparisons were limited to datasets with usable counts for both selections.

Table . Sensitivity analyses of pooled diagnostic performance for pCR[a] in internal and external validation cohorts, including analyses excluding outliers or low-quality studies and analyses restricted to ESCC[b] studies.

Sensitivity analysis	Datasets, n	Sensitivity (95% CI)	Specificity (95% CI)	AUC[c] (95% CI)	DOR[d] (95% CI)
Internal validation sets					
Overall	27	0.77 (0.72 - 0.81)	0.82 (0.78 - 0.86)	0.86 (0.83 - 0.89)	15.49 (11.16 - 21.50)
Without outliers in Bivariate box plot[e]	21	0.77 (0.72 - 0.82)	0.82 (0.78 - 0.86)	0.86 (0.83 - 0.89)	15.98 (11.53 - 22.14)
Without low-quality studies[f]	17	0.76 (0.70 - 0.81)	0.83 (0.77 - 0.87)	0.86 (0.83 - 0.89)	15.15 (10.04 - 22.88)
Including only ESCC patients[g]	24	0.76 (0.72 - 0.80)	0.83 (0.79 - 0.87)	0.85 (0.82 - 0.88)	16.06 (11.26 - 22.90)
External validation sets					
Overall	16	0.73 (0.61 - 0.81)	0.83 (0.73 - 0.90)	0.84 (0.79 - 0.89)	12.93 (7.25 - 23.07)
Without outliers in Bivariate box plot[e]	13	0.71 (0.57 - 0.82)	0.81 (0.75 - 0.87)	0.84 (0.80 - 0.88)	10.72 (6.63 - 17.33)
Without low-quality studies[f]	12	0.72 (0.58 - 0.83)	0.82 (0.69 - 0.90)	0.84 (0.80 - 0.87)	11.85 (6.17 - 22.79)
Including only ESCC patients[g]	14	0.74 (0.62 - 0.83)	0.83 (0.71 - 0.90)	0.85 (0.81 - 0.88)	13.76 (7.10 - 26.66)

[a]pCR: pathological complete response.

[b]ESCC: esophageal squamous cell carcinoma.

[c]AUC: area under the curve.

[d]DOR: diagnostic odds ratio.

[e]The following studies were excluded for internal validation sets: Wang et al, 2024 [28], Qi et al, 2025 [29], Qi et al, 2024 [30], Fan et al, 2024 [31], Liu et al, 2025 [32], and Qi et al, 2025 [33]. Also, the following studies were excluded for external validation sets: Zhang et al, 2025 [34], Ling et al, 2025 [35], and Zhao et al, 2025 [36].

[f]Low quality means that the study was rated as having at least one high-risk item in the PROBAST+AI (Prediction Model Risk of Bias Assessment Tool plus Artificial Intelligence) tool.

[g]The following studies were excluded for internal validation sets: Qi et al, 2025 [29], Li et al, 2024 [37], and Yue et al, 2022 [38]. Also, the following studies were excluded for external validation sets: Kong et al, 2024 [39] and Li et al, 2024 [37].

Results

Study Selection

The search strategy yielded 1680 records, including 411 from PubMed, 734 from Embase, 521 from Web of Science, and 14 from the Cochrane Library. After removing 693 duplicates using EndNote 20 (Clarivate), 987 records were screened by title and abstract, and 919 were excluded because they were case reports, letters, reviews, animal experiments, meta-analyses, or clearly irrelevant. Following a detailed full-text review of 68 articles, 35 studies were further excluded for nonimaging-based AI model research (n=8), inaccurate definition of pCR (n=12), gastroesophageal junction cancer with unclear pathology (n=7), unavailable diagnostic data (TP, FP, TN, FN; n=4), or overlapping samples (n=4). In addition, citation searching of the reference lists of similar published meta-analyses (ie, the studies included in those reviews) identified 113 additional records; after screening, 104 were removed as irrelevant, and the remaining 9 full-text articles were excluded because of sample overlap. Ultimately, 33 articles were included in this systematic review [16,28-59]. The literature screening process was systematically documented using a standardized PRISMA flow diagram, as shown in Figure 1. We identified 17 non-English or mixed-language reports; none met the other eligibility criteria.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram illustrating the identification, screening, eligibility assessment, and inclusion of studies evaluating imaging-based AI for pathological complete response in esophageal cancer after neoadjuvant therapy. FN: false negative; FP: false positive; TN: true negative; TP: true positive.

Study Characteristics

A total of 33 eligible studies [16,28-59] were included. Internal validation was reported in 27 studies comprising 27 datasets and 1891 patients [16,28-34,36-38,40,41,43,44,46,48,49,51-59], while external validation was reported in 16 studies with 16 datasets involving 777 patients [16,33-37,39,41-43,45,47,50,53,55,57]. Nearly all studies were conducted in China (32/33) [16,28-53,55-59], with one study [54] from Japan, and studies were published between 2019 and 2026. Most included studies were retrospective, using pathological results as the reference standard. CT was the most commonly used imaging modality (30/33, 91%), most commonly with contrast enhancement (28/33, 85%). In both internal and external validation sets, ML was the predominant approach for building AI models. Logistic regression (LR) was the most frequently used algorithm in internal validation sets (9/27, 33%), whereas Extreme Gradient Boosting (XGBoost) was the most frequent in external validation sets (4/16, 25%). A detailed summary of the study, patient, and technical characteristics is presented in Table 2 and Tables S4-S6 in Multimedia Appendix 1. Ten publications contributed to both validation groups, yielding 43 validation datasets across 33 publications. The 2 validation counts summed to 2668 observations (1891+777); the number of unique patients across datasets and publications could not be verified.

Risk of Bias and Certainty of Evidence

The PROBAST+AI quality evaluation tool was applied to assess the risk of bias, with results presented in Figure 2 and Tables S2 and S3 in Multimedia Appendix 1. For model development, 3.0% (1/33) [51] of studies were rated as high risk in the overall judgment of quality, and 3.0% (1/33) [54] showed high concern regarding applicability. For model validation, 36.4% (12/33) [30,31,35,39,42-44,46,48,51,52,58] of studies were assessed as high risk in the overall risk of bias judgment, and 3.0% (1/33) [54] demonstrated high concern regarding applicability. Overall, high-risk items were relatively infrequent, with low-risk items predominating, indicating that the quality of the included literature was generally acceptable.

Figure 2. Risk of bias and applicability concerns assessment based on the PROBAST+AI tool for studies predicting pathological complete response in esophageal cancer. (A) Model development and (B) model validation. The green, blue, and red bars represent low risk, unclear risk, and high risk of bias or applicability concerns, respectively. PROBAST+AI: Prediction model Risk of Bias Assessment Tool plus Artificial Intelligence.

Certainty of evidence, assessed using GRADE criteria, was very low for all GRADE-assessed outcomes (Table 3). The main reasons for downgrading were a high risk of bias in multiple studies, unexplained inconsistency, indirectness, and imprecision of the CIs.

XSL•FO
RenderX

Table . GRADE[a] certainty assessments for sensitivity, specificity, and DOR[b,c].

Dataset and outcome	Risk of bias[d]	Inconsistency[e]	Indirectness[f]	Imprecision[g]	Publication bias[h]	Total downgrade	Final rating
Image-based AI for internal validation sets							
Sensitivity	1	0	1	1	0	3	Very low
Specificity	1	0	1	1	0	3	Very low
DOR	1	1	1	0	0	3	Very low
Image-based AI for external validation sets							
Sensitivity	1	1	0	1	0	3	Very low
Specificity	1	1	0	1	0	3	Very low
DOR	1	1	0	1	0	3	Very low

[a]GRADE: Grading of Recommendations Assessment, Development, and Evaluation.

[b]DOR: diagnostic odds ratio.

[c]Values indicate the number of levels downgraded; 0 indicates no downgrade, and 1 indicates one level.

[d]Risk of bias: assessed using tools such as PROBAST+AI to evaluate study design and methodology. If at least 1 study has a high risk of bias, the evidence level is downgraded by 1 level.

[e]Inconsistency: Between-study variation must be considered when interpreting summary estimates. PIs describe its practical implications; meta-regression associations alone do not establish a causal explanation. I^2 describes relative inconsistency and should not be interpreted as an absolute measure of heterogeneity.

[f]Indirectness evaluates whether study populations, interventions, or outcomes differ from the target research question. Downgrade if inconsistent outcome measures are used, for example, when sensitivity or specificity is indirectly estimated from the Youden Index derived from the receiver operating characteristic (ROC) curve.

[g]Imprecision: assessed based on CI width and sample size adequacy: For sensitivity/specificity: downgrade if the 95% CI width>0.20 or if CIs cross clinical thresholds (eg. 0.80). For diagnostic odds ratio (DOR): downgrade if the CI range exceeds one times the lower limit or includes values below 10.

[h]Publication bias: evaluated using Deeks funnel plot or similar tools. Downgrade by one level if the funnel plot shows significant asymmetry or if the *P* value in Deeks test is <.05.

Predictive Performance of Different AI Models in Internal and External Validation Sets

In the internal validation sets, LR was the most frequently used AI algorithm (9/27, 33%), whereas XGBoost was the most frequent in the external validation sets (4/16, 25%; Figures 3A and 3B). Across internal validation sets, AUC values showed a slight increase from 2019 to 2026 (Figure 3C). By contrast, AUC values in external validation sets showed a downward trend over the same period, indicating that the generalizability of AI models remains a key concern (Figure 3D).

Comparisons of pooled diagnostic performance are shown in Figure 4. For internal validation, the pooled sensitivity of AI models was 0.77 (95% CI 0.72- 0.81; very low certainty), and the pooled specificity was 0.82 (95% CI 0.78-0.86; very low certainty; Figure S1A in Multimedia Appendix 1 and Table 3). The 95% PIs were 0.57-0.89 for sensitivity and 0.60-0.93 for specificity (Figure S1A in Multimedia Appendix 1). The pooled DOR was 15.49 (95% CI 11.16-21.50; very low certainty; Figure 5A and Table 3), and the pooled AUC was 0.86 (95% CI 0.83-0.89; Figure S2A in Multimedia Appendix 1). The DOR 95% PI was 5.40-44.44; the pooled estimate described average performance rather than a universal clinical value. Descriptive I^2 values were 37.88%, 66.10%, and 34.19% for sensitivity, specificity, and DOR, respectively.

In the external validation sets, the pooled sensitivity was 0.73 (95% CI 0.61-0.81; very low certainty), and the pooled specificity was 0.83 (95% CI 0.73-0.90; very low certainty; Figure S1B in Multimedia Appendix 1 and Table 3). The 95% PIs were 0.34-0.93 for sensitivity and 0.36-0.98 for specificity (Figure S1B in Multimedia Appendix 1). The pooled DOR was 12.93 (95% CI 7.25-23.07; very low certainty; Figure 5B and Table 3), and the pooled AUC was 0.84 (95% CI 0.79-0.89; Figure S2B in Multimedia Appendix 1). The DOR 95% PI was 2.40-69.62. Descriptive I^2 values were 51.78%, 78.38%, and 42.28% for sensitivity, specificity, and DOR, respectively.

Figure 4. Plots comparing diagnostic performance for predicting pathological complete response across validation sets, imaging modalities, and neoadjuvant therapy regimens. (A) Sensitivity, specificity, and area under the curve (AUC) values for internal and external validation sets, as well as CT-based and MRI-based AI models, with *P* values indicating statistical comparisons between groups and (B) sensitivity, specificity, and AUC values categorized by different neoadjuvant therapy regimens. Individual points represent data from single studies, while the central markers and vertical error bars denote the pooled estimates and 95% CIs. AUC: area under the curve; CT: computed tomography; MRI: magnetic resonance imaging; NACT: neoadjuvant chemotherapy; NCRT: neoadjuvant chemoradiotherapy; NICT: neoadjuvant immunochemotherapy; NICRT: neoadjuvant immunochemoradiotherapy; pCR: pathological complete response.

Figure 5. Diagnostic odds ratio forest plots for internal (A) and external (B) validation [16,28-59]. Squares and horizontal bars show individual-study estimates and 95% CIs. Diamonds show the pooled diagnostic odds ratio (DOR) and its 95% CI. The separate red line below the pooled estimate shows the 95% PI for a new study with similar conditions. The DOR and both intervals were derived from the same bivariate model, including the covariance between sensitivity and false-positive rate. Outcome-specific I^2 describes inconsistency on the log DOR scale, while *Q*, its degrees of freedom, and its *P* value are reported alongside it. The between-study variance (τ^2) and standard deviation (τ) were derived from the bivariate model. DOR: diagnostic odds ratio; PI: prediction interval.

Statistical comparison revealed no significant differences between internal and external validation sets in sensitivity (*P*=.47), specificity (*P*=.83), DOR (*P*=.60), or AUC (*P*=.50; Figure 4A). Statistical significance should not be equated with clinically meaningful improvement; clinical relevance also depends on heterogeneity, evidence certainty, calibration, decision thresholds, and clinical consequences.

XSL•FO
RenderX

Subgroup Analyses

Algorithm-specific estimates are shown in Table 4 and Figure S3 in Multimedia Appendix 1. Results from a single dataset are explicitly identified as single-study estimates, with CIs reflecting within-study sampling uncertainty; they are not pooled estimates. The small number of datasets in several subgroups precluded reliable ranking of algorithms. For different imaging modalities, CT-based models achieved a pooled sensitivity of 0.75 (95% CI 0.70 - 0.80), specificity of 0.82 (95% CI 0.78 - 0.86), and AUC of 0.86 (95% CI 0.82 - 0.88). MRI-based models showed a pooled sensitivity of 0.79 (95% CI 0.59 - 0.91), specificity of 0.86 (95% CI 0.67 - 0.95), and AUC of 0.91 (95% CI 0.79 - 1.00). No statistically significant differences were observed between the 2 modalities for sensitivity (P=.64), specificity (P=.59), or AUC (P=.37; Figure 4A). NACT had the numerically highest pooled AUC (0.88, 95% CI 0.77 - 0.98) among the treatment subgroups (Figure 4B).

Heterogeneity and Sources of Variation

Meta-regression analyses indicated that, in the internal validation sets, performance was associated with AI method (ML, 21 datasets, vs DL, 6 datasets; sensitivity *P*=.01, specificity *P*<.001) and AI model (radiomic and clinical models, 8 datasets, vs radiomic-only models, 19 datasets; *P*<.001 for both), whereas the use of contrast-enhanced imaging was not statistically significant (*P*=.13 and *P*=.11; Table S7 in Multimedia Appendix 1). Bivariate box plots further identified the studies by Wang et al [28], Qi et al [29], Qi et al [30], Fan et al [31], Liu et al [32], and Qi et al [33] as potential contributors to the observed heterogeneity (Figure 6A).

Figure 6. Bivariate boxplots and Deeks funnel plots for evaluating heterogeneity and small-study effects and possible publication bias in the internal and external validation sets [16,28-59]. (A) Bivariate boxplot for the internal validation sets; (B) bivariate boxplot for the external validation sets; (C) Deeks funnel plot for the internal validation sets; and (D) Deeks funnel plot for the external validation sets. Regression lines and associated *P* values in the funnel plots indicate funnel-plot asymmetry; these results may reflect small-study effects and should not be interpreted as proof of publication bias alone.

In the external validation sets, the meta-regression did not identify statistically significant sources of heterogeneity (ML, 12 datasets, vs DL, 4 datasets: *P*=.13 and *P*=.97; radiomic and clinical models, 3 datasets, vs radiomic-only models, 13 datasets: *P*=.81 and *P*=.37; contrast-enhanced imaging: *P*=.83 and *P*>.99; Table S8 in Multimedia Appendix 1). Bivariate box plots suggested that Zhang et al [34], Ling et al [35], and Zhao et al [36] may represent potential sources of heterogeneity (Figure 6B).

Sensitivity Analyses

Table 1 and Figure S4-S6 in Multimedia Appendix 1 summarize the results of the sensitivity analyses. These analyses were performed separately by excluding low-quality studies, removing outliers identified in bivariate box plots, and including only studies on ESCC. In the internal validation sets, sensitivity ranged from 0.76 to 0.77, specificity from 0.82 to 0.83, AUC from 0.85 to 0.86, and DOR from 15.15 to 16.06 across the sensitivity analyses, indicating that the results were stable. In the external validation sets, sensitivity ranged from 0.71 to 0.74, specificity from 0.81 to 0.83, AUC from 0.84 to 0.85, and DOR from 10.72 to 13.76, suggesting that the results were consistent.

Thirty of 33 [16,28-40,42-48,50-53,55-59] publications reported multiple eligible imaging models. Comparing the highest-AUC model with the first eligible imaging model reported in each article was possible for 16 internal and 10 external datasets; the selected model changed in 4 and 3 datasets, respectively. Average performance decreased modestly with the alternative selection (Tables S9 and S10 in Multimedia Appendix 1).

Clinical Utility and Small-Study Effects

Deeks funnel plot test showed no evidence of funnel-plot asymmetry suggesting small-study effects in either the internal validation sets (*P*=.70) or the external validation sets (*P*=.50; Figures 6C and 6D). Based on a prior probability of 34%, the Fagan nomogram for the internal validation sets showed a positive post probability of 69% and a negative post probability of 13% (Figure 7A). For the external validation sets, the Fagan nomogram indicated a positive post probability of 69% and a negative post probability of 15% (Figure 7B).

Figure 7. Fagan nomograms for estimating the probability of pathological complete response in the internal and external validation sets. (A) Fagan nomogram for the internal validation sets; (B) Fagan nomogram for the external validation sets. LR: likelihood ratio; Post Prob Neg: posttest probability after a negative result; Post Prob Pos: posttest probability after a positive result.

Discussion

In this systematic review and meta-analysis, imaging-based AI models showed potentially useful diagnostic discrimination for pCR in patients with esophageal cancer undergoing neoadjuvant therapy, consistent with the biological information that radiomics features may capture. The AUC was numerically higher in internal (AUC=0.86) than in external (AUC=0.84) validation sets, although this difference was not statistically significant; sensitivity, specificity, and DOR were likewise comparable between cohorts. For the pooled sensitivity and specificity estimates, we also calculated PIs to quantify the distribution of effects across different populations and settings: the PIs were 0.57 - 0.89 for sensitivity and 0.60 - 0.93 for specificity in internal validation, and 0.34 - 0.93 for sensitivity and 0.36 - 0.98 for specificity in external validation (Figure S1 in Multimedia Appendix 1). The CIs quantify uncertainty in the average sensitivity and specificity; the PIs describe the range of true performance expected in a new study with conditions similar to those included. They do not describe individual patient probabilities or establish applicability in unrepresented regions. The wide PIs, high validation risk of bias in 12 of 33 studies [30,31,35,39,42-44,46,48,51,52,58], and very low certainty for all GRADE-assessed outcomes constrain the clinical interpretation. Although AUC estimates may vary with patient case mix, sample size, image acquisition parameters, and preprocessing workflows, the consistent direction of numerically higher internal-validation performance should be regarded as a possible signal of overfitting or limited generalizability rather than explained away as evidence of stable performance. Comparable sensitivity, specificity, and DOR estimates should therefore not be interpreted as resolving this concern. Statistical significance should likewise not be equated with clinical importance [60-62].

Subgroup analyses should be considered exploratory: only a limited number of datasets evaluated algorithms such as multilayer perceptron or Vision-Mamba, and the apparent differences may reflect small-study effects, dataset composition,

XSL•FO
RenderX

or sampling variation rather than true algorithmic superiority (Table 4; Figure S3 in Multimedia Appendix 1). Conventional models such as LR and SVM can perform well in small, structured datasets, whereas newer DL architectures may capture more complex representations but generally require larger and more diverse datasets and may be more vulnerable to overfitting. In the current evidence base, the limited number of studies precludes firm conclusions about the comparative clinical advantages of these algorithms [63,64].

For different imaging modalities, no statistically significant differences were observed in sensitivity, specificity, or AUC between CT-based and MRI-based AI models for predicting pCR in esophageal cancer after neoadjuvant therapy. Although MRI-derived radiomics features can theoretically provide more detailed information on variations in tissue composition and tumor heterogeneity [65-67], the available evidence did not establish a reliable difference between the 2 modalities. This is primarily because the critical imaging signatures of tumor response are reflected in morphological changes, such as tumor volume reduction, and alterations in textural heterogeneity, which can be robustly captured by radiomics features derived from both modalities [60,68]. In addition, the standardization of radiomic features and the application of advanced learning methods may partly attenuate intrinsic differences between imaging modalities, resulting in comparable diagnostic performance. These findings do not establish equivalence or superior clinical utility of CT-based AI. Since CT remains the standard-of-care modality for staging and surveillance in esophageal cancer, characterized by lower cost, faster acquisition speed, and broader accessibility compared to MRI, routine CT workflows may offer a practical setting for further evaluation, but clinical benefit and cost-effectiveness remain unproven.

For patients receiving NACT, imaging-based AI models had the numerically highest pooled AUC (0.88, 95% CI 0.77 - 0.98) among the treatment subgroups. This finding suggests that AI models might detect critical biological changes in tumors and their microenvironment before and after treatment. For both treatment modalities, NACT and NICT are able to remodel the tumor microenvironment and systemic inflammatory-immune status [69]. These dynamic changes can be reflected in clinical parameters such as the neutrophil-to-lymphocyte ratio (NLR), C-reactive protein (CRP), and hepatic function indices, all of which are closely associated with pCR [70-72].

In 2021, Kao and Hsu [18] reported a pooled AUC of 0.813 for radiomics-based prediction of pCR in esophageal cancer patients undergoing NCRT. Subsequently, Yang et al (2023) [11] observed an AUC of 0.84 in NCRT cohorts. Compared with the aforementioned studies, our study demonstrated comparable diagnostic performance, with AUCs of 0.86 in the internal validation set and 0.84 in the external validation set. Compared with the study by Kao and Hsu [18], our study evaluates AI model performance across multiple neoadjuvant treatment strategies, extending beyond NCRT, specifically including NICT and NACT. This expansion allows for a more comprehensive evaluation of AI models' predictive potential across different therapeutic modalities. In contrast to the study by Yang et al (2023) [11], we separately extracted and synthesized results from internal and external validation cohorts, clarifying differences between the reported validation settings. In addition, we applied the latest PROBAST+AI tool for methodological quality assessment and the GRADE framework to evaluate the certainty of the evidence, making the limitations of the evidence explicit. To further explore the determinants of diagnostic performance, we conducted subgroup analyses based on imaging modalities (CT and MRI) and AI algorithms, alongside a sensitivity analysis focusing on ESCC. While these analyses provide deeper insights, the interstudy heterogeneity and the predominantly retrospective nature of the available evidence warrant cautious interpretation.

I^2 describes relative inconsistency in study results after allowing for sampling error, not the absolute magnitude of between-study heterogeneity. Because I^2 depends on within-study precision, its values should not be used to rank the amount of heterogeneity across outcomes or validation groups. Clinical interpretation instead relied on the PIs, which remained wide, particularly for external validation. A bivariate random-effects model accounted for between-study variation but could not eliminate study-level bias. Meta-regression and bivariate box plots were further conducted to explore potential sources of heterogeneity. The meta-regression indicated that the AI method and the type of AI model were likely the main contributors in the internal validation sets, whereas no statistically significant sources of heterogeneity were identified in the external validation sets. Radiomics extracts high-throughput features (intensity, shape, texture, and wavelets) reflecting tumor phenotype and microenvironment, which are complementary to clinical data [73-75]. The association between integrated radiomic and clinical models and specificity does not establish a causal reduction in misdiagnosis. These subgroup findings warrant cautious interpretation given the limited number of datasets. Moreover, bivariate box plots identified outliers, potentially contributing to statistical heterogeneity. Sensitivity analyses excluding low-quality studies or outliers and restricting to ESCC yielded similar average estimates under those tested conditions; they did not establish stability across new clinical settings.

Some limitations of the current meta-analysis should be considered when interpreting the results. First, most included studies adopted retrospective designs, which may introduce selection bias, information bias, and unmeasured confounding. Therefore, robust prospective studies are needed to validate these findings and assess applicability in clinical practice. Second, for each study, we extracted only the highest-performing AI algorithm to avoid within-study dependence among multiple candidate models. This selective extraction may produce overly optimistic performance estimates. The comparison using the first eligible imaging model reported in each article showed modest decreases in average performance but did not rule out selection bias. Third, all GRADE-assessed outcomes were of very low certainty, limiting the strength of the conclusions. A first-order limitation was geographic concentration: 32 of 33 studies [16,28-53,55-59] were conducted in China, with a strong predominance of ESCC. This concentration may reflect regional disease patterns, imaging practices, and publication patterns; the review could not determine their relative contributions. Differences in histological distributions, neoadjuvant treatment, CT and MRI protocols,

XSL•FO
RenderX

and feature-extraction pipelines may limit transportability. External validation within this evidence base did not establish international generalizability. The English-only restriction may also have excluded relevant evidence. External validation in different geographic regions and ethnic populations is therefore required before widespread clinical implementation.

Our meta-analysis suggests that imaging-based AI models may provide useful predictive information across internal and external validation cohorts, but their performance and stability should be interpreted cautiously given the heterogeneity, geographic concentration, selective model extraction, and the very low certainty of the evidence. These models could serve as adjuncts to conventional radiological criteria; however, their clinical utility remains uncertain given the very low certainty of the evidence. The current evidence mainly concerns CT- or MRI-based models, sometimes combined with clinical variables; broader multimodal integration requires further evaluation. Therefore, in the future, integrating clinical imaging, pathology, and real-world data via AI models for multimodal dynamic analysis may improve esophageal cancer treatment response prediction [76]. Notably, AI remains an auxiliary tool, with clinical treatment decisions ultimately made by physicians according to each patient's context. Furthermore, technical and regulatory barriers persist, and current AI algorithms still face multiple limitations in clinical practice, including data availability, model explainability, DL model generalization, and clinical integration. Advances in few-shot learning, self-supervised models, and centralized platforms may help build a more consolidated and transparent AI ecosystem, further enhancing clinicians' decision-making and workflow efficiency [77,78].

In conclusion, by combining multiple neoadjuvant strategies and separating validation stages, this review extends earlier NCRT-focused syntheses and identifies priorities for further model evaluation. Imaging-based AI may support response assessment, but wide PIs, risk of bias, and very low evidence certainty preclude routine clinical adoption without prospective, geographically diverse validation.

Generative AI Use

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading and editing, translation. The GenAI tool used was GPT 5.5. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

The authors declared no financial support was received for this work.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files. Further inquiries can be directed to the corresponding author.

Abstract

Background: Total knee arthroplasty (TKA) is the most effective treatment for end-stage knee osteoarthritis, but some patients continue to experience persistent postoperative pain, stiffness, and impaired functional recovery. Digital health interventions are increasingly used in rehabilitation after TKA, but their comparative effectiveness remains unclear.

Objective: This study aimed to evaluate the effects of different digital health interventions on rehabilitation outcomes in patients after TKA and to compare and rank these interventions in terms of pain relief, active knee flexion range of motion (ROM), and knee function to provide evidence for selecting optimal rehabilitation strategies.

Methods: We searched PubMed, Embase, Cochrane Library, Web of Science, Google Scholar, Scopus, CINAHL, MEDLINE (via OvidSP), CNKI, Wanfang, and VIP to identify randomized controlled trials (RCTs) meeting the inclusion criteria. The RoB 2 tool (Risk of Bias 2; Cochrane) was used to assess risk of bias, and the confidence in network meta-analysis (CINeMA) framework was used to evaluate certainty of evidence. Traditional meta-analysis and network meta-analysis (NMA) were performed using Stata (version 17.0; StataCorp LLC). A random-effects model (DerSimonian-Laird method for estimating τ^2) was consistently used across all analyses. For outcomes measured with the same or convertible scales, mean differences (MDs) with 95% CIs were used to pool effect sizes. Surface under the cumulative ranking curve (SUCRA) values were calculated to summarize the ranking probabilities.

Results: A total of 36 RCTs involving 3067 patients after TKA were included. NMA results showed that compared with conventional rehabilitation (CR), for active flexion ROM, rehabilitation robot (RR; MD 8.96, 95% CI 5.86-12.05), mobile app–based telerehabilitation (MAT; MD 6.36, 95% CI 2.81-9.91), and virtual reality (VR; MD 5.92, 95% CI 2.94-8.90) were significantly superior to CR; for the Hospital for Special Surgery knee score, VR (MD 9.53, 95% CI 5.18-13.88), intelligent rehabilitation system-based telerehabilitation (MD 6.90, 95% CI 2.35-11.44), and RR (MD 5.32, 95% CI 1.61-9.04) were significantly superior to CR; for pain, RR and MAT had relatively high ranking probabilities, but the 95% CIs of most comparisons included 0; for the Western Ontario and McMaster Universities Osteoarthritis Index and Timed Up and Go test, only internet videoconference-based telerehabilitation and VR-based telerehabilitation, respectively, were significantly superior to CR. The certainty of evidence for most comparisons was low or very low.

Conclusions: Digital health interventions may improve pain, active knee flexion ROM, and knee function in patients after TKA. In the SUCRA ranking, RR, VR, and MAT showed favorable ranking probabilities; however, because the network was predominantly star-shaped and the rankings were derived largely from indirect comparisons, these findings should be interpreted as suggestive rather than definitive. Further high-quality studies with direct head-to-head comparisons are needed.

Introduction

In recent years, with the acceleration of population aging and changes in lifestyle, the global disease burden of knee osteoarthritis (KOA) has continued to increase. The latest research data show that the number of patients with KOA worldwide reached approximately 374.7 million in 2021, and the age-standardized prevalence has increased by more than 200% since 1990 [1]. In addition, KOA is also a common degenerative arthritis condition among athletes, for whom repeated knee joint injuries are an important risk factor [2].

Total knee arthroplasty (TKA) is the most effective surgical treatment for end-stage KOA. Its postoperative clinical efficacy is well established, patient satisfaction is high, and the number of surgeries has increased over time. For example, in a Chinese study with more than 20 years of follow-up, the prosthesis survival rates at 10, 15, and 20 years were 93.6%, 92.4%, and 89.8%, respectively. Although some prostheses showed slight functional decline after 20 years, overall patient satisfaction remained high [3]. However, even though most patients benefit after surgery, some studies have reported that approximately 13%‑44% of patients with TKA experience long-term persistent postoperative pain, a proportion that highlights the importance of postoperative rehabilitation and management challenges [4]. In addition, some patients may also experience postoperative joint stiffness and poor functional recovery, further affecting quality of life [5].

In this context, digital health technologies, including virtual reality (VR), remote home rehabilitation, wearable devices, and rehabilitation robots (RRs), have shown potential for integrating traditional rehabilitation with modern technology. Some studies have shown that, within 1 month after surgery, patients with TKA who use an intelligent monitoring system for home rehabilitation experience greater improvements in knee function, isometric knee extensor strength, and quality of life than those receiving traditional rehabilitation [6]. Studies have shown that wearable devices plus remote monitoring can continuously and passively collect data on patient activity (eg, step count), knee range of motion (ROM), adherence to home training, and pain, and have been proven to be feasible and highly acceptable to patients, enabling health care professionals to obtain more complete and real-time recovery trajectory data for personalized adjustment of rehabilitation plans [7]. A remote rehabilitation program based on smart wearable devices (such as BPMpathway [270 Vision Limited]) has also shown positive effects in Chinese patients with TKA. Compared with traditional home rehabilitation, patients in this group showed better improvement in postoperative knee ROM, functional recovery, and quality of life [8].

Previous systematic reviews and meta-analyses have separately evaluated the effects of different digital health technologies in rehabilitation after TKA. For example, the systematic review and meta-analysis by Gazendam et al [9] summarized the application of VR rehabilitation after TKA and found potential advantages in some functional outcomes; the meta-analysis by Yoo et al [10] evaluated the effects of robot-assisted rehabilitation in patients after TKA or total hip arthroplasty; a systematic review published by Curzio et al [11] in 2025 evaluated 14 randomized controlled trials (RCTs) involving VR, exergames, and telerehabilitation, and the results showed that these digital interventions were noninferior or superior to conventional rehabilitation (CR) in pain relief and functional improvement. Recently, a meta-analysis specifically comparing mobile app–based digital rehabilitation with traditional rehabilitation included 8 studies, and the results showed that app-based rehabilitation was superior to traditional rehabilitation in pain relief, Timed Up and Go (TUG), and the 10-meter walk test [12]; another systematic review published in 2025 evaluated the effects of smart device-assisted telerehabilitation versus CR after TKA [13]; and an umbrella review systematically synthesized evidence from multiple meta-analyses on the use of telerehabilitation after TKA [14].

However, existing systematic reviews and meta-analyses have the following limitations: first, most reviews focused on pairwise comparisons between a single digital rehabilitation mode (such as only VR, only robots, or only mobile apps) and CR and could not answer the clinical question of which digital rehabilitation mode is effective; second, some reviews treated different forms of telerehabilitation as a homogeneous category for pooling, ignoring differences in technological mechanisms; third, most existing studies lacked indirect comparisons among different digital modes and could not provide treatment ranking information.

Network meta-analysis (NMA) can, in the absence of direct head-to-head studies, use a common comparator as a bridge to perform indirect comparisons among different interventions and evaluate the relative effectiveness and probability rankings among multiple interventions. Compared with previous systematic reviews, the added value of this NMA is as follows: first, it simultaneously includes 8 digital rehabilitation modes, rather than being limited to a single mode; second, it performs indirect comparisons using a common comparator (CR) and ranks different digital modes; third, it uses the confidence in network meta-analysis (CINeMA) framework to assess certainty of evidence rather than reporting only statistical significance; fourth, it verifies the robustness of results through sensitivity analyses using alternative node classifications; and fifth, it conducts subgroup analyses by assessment time window and treatment-dose matching to explore sources of heterogeneity. These analytical dimensions were not covered by previous single-mode meta-analyses. Based on this, this study used NMA to explore the effects of different digital health interventions on rehabilitation outcomes in patients after TKA.

Methods

Protocol and Registration

This systematic review strictly followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guideline [15] and referred to the PRISMA-NMA extension statement to standardize the reporting of NMA-specific elements, including the description of network geometry, assessment of transitivity, inconsistency testing, and interpretation of ranking probabilities [15] (Checklist 1). The study protocol was registered on the International Prospective

XSL•FO
RenderX

Register of Systematic Reviews (PROSPERO: CRD420251244837).

Search Strategy

Two researchers began searching in September 2025, with the initial search cutoff on October 23, 2025. To ensure inclusion of the latest evidence, we updated the literature search on September 17, 2026, with the same databases, search terms, and inclusion and exclusion criteria as those used in the initial search. New studies meeting the inclusion criteria identified in the updated search were included in the analysis. We searched PubMed, Embase, Cochrane Library, Web of Science, Google Scholar, Scopus, CINAHL, MEDLINE (via OvidSP), CNKI, Wanfang, and VIP. In each database, we searched for RCTs on the effectiveness of digital health interventions for improving function in patients after TKA. The following search terms were used as search criteria: (AI OR VR OR wearable devices OR telemedicine OR telerehabilitation OR RR OR robot-assisted training OR intelligent rehabilitation system OR exergame OR exergaming OR serious game OR interactive gaming) AND (total knee replacement surgery OR TKR OR TKA) AND (RCT OR controlled clinical trial OR clinical trial OR randomized OR placebo OR randomly OR trial). The full search strategies for each database are provided in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

Inclusion Criteria:

Studies were eligible for inclusion if they met all of the following criteria:

1. Study type: all included studies had to be RCTs.
2. Participants: adult patients who had undergone TKA.
3. Comparator: the control group included physical therapy, routine care, balance training, continuous passive motion, manual guided rehabilitation, or health education. Although these interventions were heterogeneous, they shared the following core characteristics: all were components of standard rehabilitation after TKA, all aimed to improve joint ROM, muscle strength, and function, and none involved digital technology. Therefore, this study merged various forms of CR into the same node (CR), which served as the common comparator for all digital interventions.
4. Intervention: the experimental group received rehabilitation interventions based on digital health technology, including VR, VR technology-based telerehabilitation (VRT), mobile app–based telerehabilitation (MAT), internet videoconference-based telerehabilitation (IVT), intelligent rehabilitation system-based telerehabilitation (IRT), and RR, which could be used as the sole intervention or combined with other forms of rehabilitation. Studies were assigned to treatment nodes according to the following operational criteria:
   - VR: use of immersive or nonimmersive virtual reality technology, delivered face-to-face or in a clinical setting, not remotely, including AR. Interventions in this node shared the core characteristics of multisensory stimulation and interactive feedback.
   - VRT: VR technology delivered remotely via the internet or telecommunications. Interventions within this node shared the core characteristic of "virtual reality as the core content, delivered remotely."
   - MAT: provided mainly through mobile apps on smartphones or tablets, with or without wearable sensors. Interventions within this node shared the core characteristic of "mobile application as the main delivery platform," even if wearable sensors were also used.
   - IVT: provided mainly through internet-based videoconferencing. Interventions within this node shared the core characteristic of "real-time videoconferencing as the core communication method."
   - IRT: provided through intelligent rehabilitation systems that integrate wearable sensors, cameras, or web platforms for remote monitoring and feedback. Although interventions within this node contained different technology combinations, they shared the core characteristic of "providing remote monitoring, feedback, and personalized adjustment through an integrated intelligent system."
   - TFT: provided mainly through telephone follow-up. Interventions within this node shared the core characteristic of "telephone follow-up as the core communication method."
   - RR: rehabilitation training using exoskeletons or end-effector robots. Interventions within this node shared the core characteristic of "robot-assisted training as the core intervention."

The treatment-node classification in this study was prospectively specified during the study protocol design phase and finalized before data extraction; it was not adjusted based on data analysis results. Multicomponent interventions were classified according to the main technology defining the rehabilitation delivery method. Specifically: if the intervention was delivered mainly through a mobile app, it was classified as MAT, even if wearable sensors were also used; if the intervention was delivered mainly through an integrated intelligent system (such as camera-based motion capture or a web platform containing multiple sensors), it was classified as IRT; if the intervention was delivered mainly through videoconferencing, it was classified as IVT, even if a web portal was also used; if the intervention was delivered mainly through telephone, it was classified as TFT, even if printed materials were also provided. This method ensured that each study was assigned to the node reflecting its core therapeutic technology.

Outcomes: active flexion ROM, defined as the maximum angle a patient can achieve by actively flexing the knee; if the original study reported only passive ROM or total arc of motion, it was not included in the pooled analysis of ROM; visual analog scale (VAS), Hospital for Special Surgery (HSS) knee score, Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), numeric pain rating scale (NPRS), and Timed Up and Go (TUG) test.

At the same time, included studies needed to report or allow the extraction of rehabilitation-dose information for the experimental and control groups, including intervention frequency (sessions/week or sessions/day), duration per session

XSL•FO
RenderX

(minutes), total number of sessions, intervention period (weeks), whether the digital intervention was added on top of CR, and total treatment contact time. If a study did not report sufficient dose information, it was marked as “dose unclear” and listed separately in the subgroup analyses.

Exclusion Criteria

Studies were eligible for exclusion if they met all of the following criteria:

(1) Duplicate publications, (2) participants who did not undergo primary, unilateral TKA as adults, (3) interventions not meeting inclusion criteria or comparators not meeting inclusion criteria, (4) outcomes not meeting the relevant inclusion criteria, (5) animal experiments, and (6) unclear study type or nonrigorous experimental design, such as non-RCTs, before-after self-control studies, case reports, and expert opinions.

Literature Screening and Data Extraction

Retrieved records were imported into EndNote 20 (Clarivate) software, and duplicates were removed. Subsequently, 2 researchers screened the literature and extracted information according to the predefined inclusion and exclusion criteria. Disagreements were resolved through discussion with a third researcher. Characteristics of the included studies included the study reference, publication country, sample size, age, intervention, comparator, outcomes, supervision mode, supervisor, feedback type, feedback frequency, device and manufacturer, and rehabilitation dose information for the experimental and control groups (frequency, duration per session, total number of sessions, intervention period, whether the digital intervention was added, and total treatment contact time; Table 1).

At the same time, according to the relationship between the digital intervention and CR, included studies were divided into four intervention modes:

1. Digital intervention replacing CR: the digital intervention replaced CR, and the control group received only CR or face-to-face rehabilitation.
2. Digital intervention supplementing CR: the experimental group received CR+digital intervention, while the control group received only CR.
3. CR delivered digitally: the rehabilitation content was the same in both groups, but the experimental group received it through digital technology while the control group received it face-to-face.
4. Self-directed versus clinician-supervised: the experimental group received a self-directed digital intervention while the control group received clinician-supervised rehabilitation, or vice versa.

When a study met multiple modes simultaneously, it was assigned to a single primary category according to the following priority: (1) replacement > (2) supplementation > (3) digitally delivered > (4) self-directed versus clinician supervised.

For analysis, this study divided postintervention assessment time points into 3 assessment time windows according to common phases of rehabilitation after TKA: short-term (postoperative <6 weeks), medium-term (postoperative ≥6 weeks and <3 months), and long-term (postoperative ≥3 months). This time window division was based on the clinical trajectory of functional recovery after TKA: within 6 weeks after surgery, soft tissues are in the healing phase, joint swelling and stiffness are relatively high, and gait function recovery lags; at 3 months after surgery, the minimal clinically important difference (MCID) of the Oxford Knee Score (OKS) is 5.0 points (pain relief anchor) and 4.3 points (function anchor), and patients need to achieve approximately 4 - 5 points of improvement to perceive clinical benefit; after 6 months, although the CID threshold of OKS changes over time, overall function tends to reach a stable plateau. Therefore, short-term corresponds to the early acute recovery phase, medium-term to the functional reconstruction phase, and long-term to the functional plateau phase [16,17].

For each outcome, data from the first assessment after the end of the intervention were extracted as the primary analysis time point. If a study reported multiple follow-up time points, data from the first assessment after the end of the intervention were extracted; if the study did not clearly report the end time of the intervention, the first assessment after the last intervention treatment was used. If a study reported only data during follow-up but not at the end of the intervention, the time point closest to the end of the intervention was extracted. If different outcomes in the same study had inconsistent assessment time points, data from the first postintervention assessment were extracted separately for each outcome, and the actual assessment time point corresponding to each outcome was recorded. All data were extracted as the means and SDs of baseline-to-postintervention change values; change scores and final values were not combined.

[p]IRT: intelligent rehabilitation system-based telerehabilitation.
[q]AR: augmented reality.
[r]ERPM: Electronic Remote Perioperative Management Program.

When the original study did not directly report the SD of baseline-to-postintervention change values, this study used the following methods for data conversion and estimation: (1) if the study reported SE, SD was converted using the following formula [54,55]:

$$SD=SE\times n$$

If the study reported 95% CI, different methods were used for conversion according to sample size. When the sample size was ≥100, the following was used:

$$SD=n\times Upper-Lower3.92$$

When sample size was <100, the following was used:

$$SD=n\times Upper-Lower2\times t0.975,n-1$$

where Upper and Lower represent the upper and lower limits of the 95% CI, respectively, and *t* is the *t* value corresponding to the 2-sided 95% CI with degrees of freedom (n-1) [54,55].

If the study reported only pre- and postintervention means and their SDs, the following formula was used to estimate the SD of change, where the correlation coefficient r was estimated based on studies that directly reported the SD of change (r=0.5) [54,55]. In this study, r=0.5 was uniformly used for all

XSL•FO
RenderX

outcomes, including pain, ROM, WOMAC, HSS, and TUG, and no different correlation coefficients were set for different outcomes.

$$SDchange=SDbaseline2+SDfinal2-2r\times SDbaseline\times SDfinal$$

If the study reported only median and IQR, the following formula was used to estimate SD [55-57]:

$$SD\approx Q3-Q11.35$$

If the study reported only range, the following formula was used to estimate SD [55-57]:

$$SD\approx Maximum-Minimum4$$

For studies containing multiple intervention subgroups that needed to be combined into a single comparison group, the following formula was used to calculate the pooled mean [54,55]:

$$Mean=n1M1+n2M2n1+n2$$

The pooled SD was calculated using the following formula:

$$SD=(n1-1)SD12+(n2-1)SD22+n1n2n1+n2(M1-M2)2n1+n2-1$$

All data conversion and estimation processes were independently completed and cross-checked by 2 researchers.

Risk of Bias Assessment

The Cochrane-recommended RoB 2 (Risk of Bias 2; Cochrane) tool was used to assess risk of bias in included RCTs. Two researchers independently performed the assessment, and disagreements were resolved through discussion or arbitration by a third researcher. RoB 2 judged the following 5 domains: (D1) randomization process, (D2) deviations from intended interventions, (D3) missing outcome data, (D4) measurement of the outcome, and (D5) selection of the reported result. Each domain and overall risk of bias were judged as “low risk,” “some concerns,” or “high risk.”

Given that blinding of participants and personnel is difficult in digital health interventions and that subjective outcomes (pain, WOMAC, and HSS) and objective outcomes (ROM and TUG) differ in sensitivity to blinding, this study assessed risk of bias separately for subjective and objective outcomes. At the same time, participant blinding and assessor blinding were recorded separately to distinguish their different impacts on risk of bias. For each study, it was clarified whether the analysis targeted an intention-to-treat (ITT) effect, and the analysis type (ITT, PP, or not reported) was recorded. Risk of bias assessment was performed separately for each outcome. For subjective and objective outcomes, assessment was based on the time point of the first assessment after the end of the intervention. The estimand of this study was the effect of assignment to the intervention, that is, analysis according to randomized groups. Because all experimental groups in included studies received the intervention, the effect of assignment and the effect of adherence were not substantially different in this study.

The signaling questions for high-risk judgments were as follows: D1 high risk: randomization sequence generation or allocation concealment methods were inadequate, or the randomization method was completely unreported and selection bias could not be ruled out; D2 high risk: there was obvious deviation from the intended intervention, and ITT analysis was not used, or only PP analysis was reported; D3 high risk: dropout rate >20%, or the proportion of missing data differed severely between groups, or dropout information/missing data handling methods were not reported; D4 high risk: assessor blinding was not reported, the outcome was subjective, and the measurement method might be affected by awareness of the intervention; D5 high risk: trial registration number was not reported, and there were signs of selective reporting.

Statistical Analysis

Stata (version 17.0; StataCorp LLC) software was used for traditional meta-analysis and NMA. For outcomes measured with the same or convertible scales, mean differences (MDs) with 95% CI were used to pool effect sizes because MD has better clinical interpretability. Specifically, pain (VAS; 0 - 100 mm) converted to a 0 - 10 scale at 1 mm=0.1 points; NPRS (0 - 10) used directly; if reported as 0 - 100 points, converted to a 0 - 10 scale at 1 point=0.1 points), ROM (degrees), TUG (seconds), and other outcomes could all be unified into the same or convertible scales; this study did not use standardized mean difference (SMD).

Given the expected clinical and methodological heterogeneity in interventions, rehabilitation protocols, populations, and assessment time points among included studies, this study prespecified a random-effects framework and did not switch to a fixed-effects model based on I^2 or P values. I^2 statistics and between-study variance τ^2 were used to assess heterogeneity. τ^2 was estimated using the DerSimonian-Laird method. Because each outcome was meta-analyzed separately in this study, τ^2 was estimated separately by outcome, and it was not assumed that all comparisons shared a single heterogeneity parameter. The P values for heterogeneity tests were reported only as descriptive information; $P>.10$ only indicates that the current data are insufficient to reject the homogeneity assumption and does not mean that there is no heterogeneity among studies. The I^2 values of 0% - 25% indicated negligible heterogeneity, 25% - 50% mild heterogeneity, 50% - 75% moderate heterogeneity, and >75% high heterogeneity.

Traditional meta-analysis used the metan command in Stata 17.0 (random-effects model, DL method for estimating τ^2), and 95% prediction intervals (PrIs) were calculated (rfdist option) to reflect the range of effects that might be observed in future studies. NMA was fitted using the network command group in Stata 17.0 (frequentist framework), with CR as the reference treatment, and treatment effects were estimated using a multivariate normal approximation model. The mvmeta multivariate meta-analysis command was not used. Model fit was planned to be evaluated using node-splitting or global inconsistency tests; if the network did not form closed loops and the above tests could not be performed, the rationality of indirect comparisons was assessed through evaluation of the transitivity assumption. This study did not include multi-arm studies, so no special handling for multiarm studies was needed. Treatment effects were presented as the main results. Surface under the cumulative ranking curve (SUCRA) values were calculated and reported as supplementary information to represent ranking probabilities rather than definitive evidence

XSL•FO
RenderX

of superiority. For each outcome, a rankogram was generated to show the probability of each intervention ranking first, second, third, etc.

In addition to statistical significance, this study also assessed the clinical significance of each outcome with reference to MCID values reported in previous literature. The MCID thresholds used were as follows: pain (VAS 0 - 100 mm) 15 mm [58], NRS (0 - 10) 2 points [58], ROM 9° [59], WOMAC total score 15 points [60], HSS 5.41 points [61], and TUG 1.4 seconds [62]. If the lower limit of the pooled effect size and its 95% CI exceeded the MCID, the effect was considered clinically meaningful. It should be noted that the MCID for TUG came from a hip osteoarthritis population [5] and may not be fully applicable to the TKA population; caution is needed in interpretation.

Subgroup Analysis

Subgroup analyses were performed according to different intervention types to explore potential sources of heterogeneity. This study extracted data from the first assessment after the end of the intervention; therefore, strictly defined "follow-up duration" (the interval between the end of the intervention and assessment) was close to zero in most studies. Subgroup analyses were performed by assessment time window (short-term <6 weeks, medium-term ≥6 weeks and <3 months, long-term ≥3 months), publication language (Chinese vs non-Chinese), risk of bias (high vs low/some concerns), and technology type within the IRT node (wearable sensors vs cameras vs web platforms).

Subgroup analyses were also performed according to whether the total treatment dose in the experimental and control groups matched:

1. Dose matched: baseline rehabilitation doses in both groups were reported, and frequency, duration, number of sessions, and period were basically consistent; the digital intervention did not additionally increase total treatment exposure, or total doses in the 2 groups were comparable.
2. Experimental group higher: baseline rehabilitation doses in both groups were reported and basically consistent, but the experimental group had clearly higher total treatment exposure due to the additional digital intervention.
3. Experimental group lower: baseline rehabilitation doses in both groups were reported and basically consistent, but the digital intervention replaced part of CR, resulting in clearly lower total treatment exposure in the experimental group.
4. Unclear: at least one of the 2 groups did not report sufficient baseline rehabilitation dose information, making it impossible to judge whether baseline rehabilitation doses were consistent between groups or to determine the total dose relationship.
5. Mismatched: baseline rehabilitation doses in both groups were reported, but frequency, duration, number of sessions, and period were clearly inconsistent and could not be classified into (2) or (3).

For studies in which the control group did not report specific doses, the category "experimental group higher" was not assigned; instead, they were classified as "unclear" to avoid overestimating the impact of additional treatment dose.

Publication Bias Assessment

When at least 10 studies were available for an outcome, comparison-adjusted funnel plots and Egger test were used to assess publication bias. For each outcome, a comparison-adjusted funnel plot was generated to visually inspect the symmetry of study points around the comparison-specific pooled effect. Egger test was used to statistically detect small-study effects, with $P<.05$ considered statistically significant.

Assessment of the Transitivity Assumption

This study assessed the transitivity assumption by comparing the distribution of potential effect modifiers among treatment nodes, including participant age, intervention duration (short-term <6 weeks, medium-term ≥6 weeks and <3 months, and long-term ≥3 months), sample size, baseline pain score, baseline active flexion ROM, baseline WOMAC score, baseline HSS score, baseline TUG time, and unilateral versus bilateral TKA, postoperative intervention start time, inpatient versus home rehabilitation setting, type and intensity of CR, risk of bias distribution, and geographic region. If the distribution of these factors among nodes was similar, the transitivity assumption might hold; if significant differences existed, they were explained when interpreting the results. If the network did not form closed loops and node-splitting or global inconsistency tests could not be performed, transitivity assessment would serve as supplementary evidence for the validity of indirect comparisons.

Certainty of Evidence (CINeMA)

The CINeMA framework was used to assess certainty of evidence for each comparison. This framework considers 6 domains: within-study bias, reporting bias, indirectness, imprecision, heterogeneity, and incoherence. Each domain was rated as no concerns, some concerns, or major concerns, and overall certainty was rated as high, moderate, low, or very low. If no closed loops were formed, incoherence could not be assessed, and a summary table was generated to present the ratings.

Results

Study Selection

A total of 8729 records were retrieved from PubMed, Embase, the Cochrane Library, Web of Science, Google Scholar, Scopus, CINAHL, MEDLINE (via OvidSP), CNKI, Wanfang, and VIP. After screening titles, abstracts, and full-text studies according to inclusion and exclusion criteria, 36 studies were ultimately included in the meta-analysis (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.

Characteristics of the Included Studies

This study included 36 articles [18-53] published between 2011 and 2026, encompassing 3067 participants (1552 in the experimental and 1515 in the control groups). Most studies were conducted in China (n=17) [22,23,32,36,41-53], followed by the United States (n=3) [25,28,39], South Korea (n=3) [27,34,35], Canada (n=2) [19,21], Italy (n=2) [26,30], Germany (n=2) [29,31], Spain (n=3) [20,37,40], and one each from Japan [24], Australia [18], Finland [33], and Singapore [38]. Interventions included IVT (n=3) [18,19,21], VRT (n=3) [20,25,33], TFT (n=2) [22,42], MAT (n=4) [29,40,48,50], IRT (n=9) [34,36-39,45-47,49], VR (n=8) [23,26-28,30,41,43,44], RR (n=6) [24,31,32,51-53], and augmented reality (AR; n=1) [35] (Table 1).

Risk of Bias

The RoB 2 tool was used to assess the risk of bias separately for subjective and objective outcomes; detailed judgments for each domain are provided in Multimedia Appendix 2. Most studies were rated as “some concerns,” with only a few rated as “high risk.” For subjective outcomes, 9 studies were rated as having a low risk of bias, 20 as having some concerns, and 2 as having a high risk of bias [29,34]; both were rated as having a high risk of bias in D3, mainly because the dropout rate was >20% or the methods for handling missing data were not

XSL•FO
RenderX

reported. For objective outcomes, 11 were low risk, 18 had some concerns, and 2 were high risk [34,47]; both due to D3.

Safety Outcomes

Of 36 studies [18-53], 17 [21,25,26,30-34,36-40,43,45,46,50] reported at least one safety outcome. The most common was adverse events (17 studies), followed by discontinuation due to adverse events (5), readmission (3), device-related complications (2), and falls (1). Because definitions varied, reporting rates were low, and data were sparse, no quantitative pooling was performed. Prvu Bettger et al [25] reported that the fall rate in the virtual physical therapy group was slightly higher than that in the conventional group (19.4% vs 14.6%), but readmissions were fewer (12 vs 30). Nuevo et al [37] reported 1 case of moderate-severity functional overload related to ReHub. Gianola et al [26] reported a higher dropout rate in the VR group due to discomfort/nonacceptance of the device. Overall, no clear evidence of a high safety risk was associated with digital health technologies, but the safety evidence remains insufficient. See Table 2 for details.

[a]VAS: visual analog scale.

[b]ROM: active flexion range of motion.

[c]WOMAC: Western Ontario and McMaster Universities Osteoarthritis Index.

[d]TUG: Timed Up and Go test.

[e]NR: not reported.

[f]Not applicable.

[g]AE: adverse events.

[h]HSS: Hospital for Special Surgery knee score.

[i]NPRS: numeric pain rating scale.

[j]PT: physical therapy.

[k]Discontinuation due to AE: discontinuation due to adverse events.

[l]OPT: outpatient physical therapy.

[m]DVT: deep vein thrombosis.

Network Evidence

The network was mainly a star-shaped network centered on CR. Most trials compared "digital intervention+CR" with "CR alone," with few direct comparisons between digital interventions. No closed loops were formed; therefore, node-splitting and global inconsistency tests were not applicable. VR and RR had the largest sample sizes. Pain was reported in 24 studies, ROM in 25, WOMAC in 13, HSS in 10, and TUG in 13. The network structure is shown in Figure 2.

XSL•FO
RenderX

Figure 2. Network evidence plot. (A) Pain, (B) active flexion range of motion (ROM), (C) Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), (D) Hospital for Special Surgery (HSS) knee score, and (E) Timed Up and Go (TUG) test. CR: conventional rehabilitation; IRT: intelligent rehabilitation system-based telerehabilitation; IVT: internet videoconference-based telerehabilitation; MAT: mobile app–based telerehabilitation; RR: rehabilitation robots; TFT: telephone follow-up–based telerehabilitation; VR: virtual reality; VRT: VR-based telerehabilitation.

NMA of Outcomes

Overview

For pain, WOMAC, and TUG, negative MDs indicated benefit; for ROM and HSS, positive MDs indicated benefit. Results should be interpreted as the comprehensive effect of digital health interventions relative to CR, rather than as the additional benefit of a single "CR+digital intervention."

Pain Scores

Compared with CR, RR (MD −0.81, 95% CI –1.73 to 0.11), MAT (MD −0.66, 95% CI –1.48 to 0.15), and VR (MD −0.58, 95% CI −1.23 to 0.07) showed greater pain relief, while IRT (MD 1.05, 95% CI 0.31-1.79) showed less, but most CIs included 0 (Figure 3A). Among digital interventions, RR, MAT, VR, and VRT were significantly superior to IRT. SUCRA rankings were, in order, RR (78.9%), MAT (72.7%), VR (70.0%), IVT (50.3%), TFT (46.8%), VRT (45.8%), CR (32.9%), and IRT (2.6%) (Figure 4A). RR had the highest probability of ranking first (35.3%), but the distribution was scattered (Figure 5A).

CR: conventional rehabilitation; IRT: intelligent rehabilitation system-based telerehabilitation; IVT: internet videoconference-based telerehabilitation; MAT: mobile app–based telerehabilitation; RR: rehabilitation robots; TFT: telephone follow-up-based telerehabilitation; VR: virtual reality; VRT: VR-based telerehabilitation.

Active Flexion ROM

Compared with CR, RR (MD 8.96, 95% CI 5.86-12.05), MAT (MD 6.36, 95% CI 2.81-9.91), and VR (MD 5.92, 95% CI 2.94-8.90) were significantly superior; IRT, IVT, TFT, and VRT showed no significant difference (Figure 3B). Among digital interventions, RR, MAT, and VR were significantly superior to IRT. SUCRA rankings were, in order, RR (97.0%), MAT (79.8%), VR (76.4%), VRT (39.1%), IRT (36.2%), TFT (35.3%), IVT (22.9%), and CR (13.4%) (Figure 4B). RR had the highest probability of ranking first (82.3%) (Figure 5B).

WOMAC Scores

Compared with CR, RR (MD 8.96, 95% CI 5.86-12.05), MAT (MD 6.36, 95% CI 2.81-9.91), and VR (MD 5.92, 95% CI 2.94-8.90) were significantly superior; IRT, IVT, TFT, and VRT showed no significant difference (Figure 3B). Among digital interventions, RR, MAT, and VR were significantly superior to IRT. SUCRA rankings were, in order, RR (97.0%), MAT (79.8%), VR (76.4%), VRT (39.1%), IRT (36.2%), TFT (35.3%), IVT (22.9%), and CR (13.4%) (Figure 4B). RR had the highest probability of ranking first (82.3%) (Figure 5B).

HSS Scores

Compared with CR, VR (MD 9.53, 95% CI 5.18-13.88), IRT (MD 6.90, 95% CI 2.35-11.44), and RR (MD 5.32, 95% CI 1.61-9.04) were significantly superior (Figure 3D). No comparisons among digital interventions were statistically significant. SUCRA rankings were, in order, VR (90.8%), IRT (63.2%), RR (45.9%), and CR (0.1%; Figure 4D). VR had the highest probability of ranking first (76.5%; Figure 5D).

TUG

Compared with CR, VRT (MD −4.80, 95% CI −8.65 to 0.95) was significantly superior (Figure 3E). No comparisons among digital interventions were statistically significant. SUCRA rankings were, in order, VRT (85.1%), MAT (74.7%), IVT (64.8%), VR (44.7%), RR (38.6%), CR (21.8%), and IRT (20.3%; Figure 4E). VRT had the highest probability of ranking first (47.8%; Figure 5E).

Heterogeneity and PrIs

Pain scores: τ^2=0.2642; I^2=73.4%; 95% PrI –1.38 to 0.83; Active Flexion ROM: τ^2=13.1086; I^2=83.2%; 95% PrI –3.74 to 11.68; WOMAC scores: τ^2=11.2985; I^2=87.1%; 95% PrI –10.56 to 5.01; HSS scores: τ^2=7.7743; I^2=83.1%; 95% PrI –0.94 to 12.69; TUG: τ^2=2.4822; I^2=87.3%; 95% PrI –5.75 to 1.60 (Multimedia Appendix 3). The 95% PrI for each comparison is shown in Figure 3. PrIs were generally wider than CIs, and some crossed the line of no effect, suggesting that future studies may show effects in different directions after considering heterogeneity.

Subgroup Analysis

By intervention type, VR, RR, and MAT showed statistically significant effects for pain (MD –0.55, –0.69, –0.56; *P*=.21); for ROM, VR, IRT, RR, and MAT were significant (MD 5.55, 1.71, 8.38, 7.42; *P*=.005); for WOMAC, IVT, VR, and RR were significant (MD –1.10, –3.20, –7.21; *P*<.001); for HSS, VR, IRT, and RR were significant (MD 9.63, 2.82, 5.16; *P*<.001); for TUG, only IVT and RR were significant (MD –2.72, –0.94; *P*=.42). Within the IRT node, the wearable sensor subgroup was significant for ROM (MD 2.80, 95% CI 1.19-4.41) and HSS (MD 2.82, 95% CI 0.99-4.65), while the camera and web platform subgroups were mostly nonsignificant; the between-subgroup difference was significant only for ROM (*P*=.03). By dose matching, in the dose-matched group, most effects were close to null or small; the higher-dose group showed more obvious improvements in ROM (MD 5.38), HSS (MD 5.88), and TUG (MD −1.51); between-subgroup differences

XSL•FO
RenderX

were statistically significant for pain (*P*=.009) and ROM (*P*=.003). By assessment time window, short-term showed a relatively obvious improvement trend, followed by long-term (ROM: MD 2.24, 95% CI 1.00-3.48; HSS: MD 2.96, 95% CI 1.38-4.53), while medium-term had wider CIs; between-subgroup differences were statistically significant for ROM (*P*) and HSS (*P*=.002). By publication language: effects were basically consistent between Chinese- and English-language literature (all *P*>.05), suggesting that language may not be a major source of heterogeneity. These subgroup analyses were exploratory, and residual heterogeneity remained. Details are provided in Multimedia Appendix 4.

Publication Bias

Because this network was a star-shaped network and had no closed loops and studies were distributed across multiple treatment nodes, comparison-adjusted funnel plots and Egger test had limited power in assessing publication bias. Egger test is particularly susceptible to a small number of studies and large between-comparison heterogeneity; therefore, its results were used only as descriptive information and cannot alone serve as a basis for determining the presence or absence of publication bias. For pain scores, active flexion ROM, WOMAC, HSS, and TUG, comparison-adjusted funnel plots showed that study points were basically symmetrically distributed around the vertical line, with only a few outliers (Figure 6); Egger test did not detect clear statistical evidence of small-study effects (all outcomes *P*>.05; Multimedia Appendix 5). Therefore, this study did not detect clear statistical evidence of small-study effects, but due to limitations in network structure and test power, it cannot be concluded that publication bias does not exist.

Figure 6. Comparison-adjusted funnel plots. (A) Pain, (B) active flexion range of motion (ROM), (C) Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC), (D) Hospital for Special Surgery (HSS) knee score, and (E) Timed Up and Go (TUG) test.

Sensitivity Analysis

After leave-one-out analysis, all effect sizes remained within the 95% CI of the overall estimate. After alternative node classification (IDT, TR, RR, CR), the direction and magnitude of effects were basically consistent with the main analysis; for ROM and HSS, IDT, TR, and RR were still significantly superior to CR; for TUG, only IDT was significantly superior to CR; SUCRA rankings were also basically consistent. After excluding high-risk studies, unpublished or non-peer-reviewed sources, very small sample trials, and studies directly reporting SD of change scores, and after using final values instead of change scores, effect directions for all outcomes were basically consistent with the main analysis (mostly I^2>70%). Overall, the results were robust, but heterogeneity remained high. Because all SDs of change scores were estimated based on *r*=0.5, no further sensitivity analysis using alternative correlation coefficient assumptions was performed. Details of the sensitivity analyses are provided in Multimedia Appendix 6.

Transitivity Assumption Assessment

Because the network was star-shaped, node-splitting or global inconsistency tests could not be performed; therefore, transitivity was assessed by comparing the distribution of potential effect modifiers among nodes (see box plots in Multimedia Appendix 7). Median age across nodes was generally 65 - 70 years, but the age distributions were wider for VR/VRT and RR in several outcomes. Intervention durations differed markedly across nodes and outcomes: TFT had the longest duration for pain and ROM, whereas MAT or IRT had the longest durations for WOMAC, HSS, and TUG; VR and RR generally had shorter durations. VRT and IRT tended to have larger sample sizes, whereas VR, RR, and MAT had smaller sample sizes for most outcomes. Baseline pain, ROM, WOMAC, HSS, and TUG values also showed distribution differences among VR, RR, IRT, and VRT.

XSL•FO
RenderX

Unilateral versus bilateral TKA, postoperative intervention start time, rehabilitation setting, type and intensity of CR, risk of bias, and geographic region were compared descriptively and differed across nodes. Overall, the transitivity assumption may not fully hold, and indirect comparisons and SUCRA rankings should be interpreted with caution.

Certainty of Evidence (CINeMA)

The CINeMA framework was used to assess the certainty of the evidence for the main comparisons and outcomes (Multimedia Appendix 8). Because the network was star-shaped with no closed loops, the incoherence domain was marked as "not assessable" and treated as "major concerns" according to the rules. The certainty of the evidence for most comparisons was low to very low: for pain, CR versus IVT was low and all others very low; for ROM, CR versus MAT was high, CR versus RR and CR versus VR were moderate, CR versus IVT and CR versus VRT were low, and all others very low; for WOMAC, CR versus IVT and CR versus MAT were low and all others very low; for HSS, CR versus VR was moderate, CR versus RR was low, and all others very low; for TUG, all were very low. Direct comparisons (especially CR vs RR, CR vs VR, and CR vs MAT) had relatively higher certainty, while indirect comparisons among digital interventions were all very low, mainly downgraded because of imprecision, heterogeneity, and incoherence. The conclusions should be regarded as hypothesis-generating rather than as definitive evidence.

Discussion

Principal Findings

The treatment comparisons in this study involved multiple modes. Under the supplementation mode, the observed benefits may partly come from increased treatment time, supervision, attention, or exercise dose, rather than from the digital health technology itself. We performed subgroup analysis according to whether treatment doses matched. The results showed that in the dose-matched group, pooled effect sizes for most outcomes were close to null or small, while the group in which the experimental group received a higher treatment dose showed more obvious improvement trends in ROM, HSS, and TUG. This suggests that additional treatment dose may be an important factor affecting some outcomes, and the independent effect of digital health technology itself still needs further verification under dose-matched conditions.

Effects of Digital Health Interventions on Pain in Patients After TKA

This study showed that, compared with CR, RR had the highest SUCRA ranking for pain scores. This is consistent with existing mechanistic and clinical evidence that robot-assisted rehabilitation can reduce joint load through passive/active assistance and promote progressive loading training, thereby relieving pain [10].

The mechanism by which exoskeletons improve pain in patients after TKA is mainly based on their active-assisted movement characteristics. By detecting patients' muscle bioelectrical signals, exoskeletons can provide precise joint torque support, allowing movements such as knee flexion to be completed without excessive effort by patients, thereby reducing pain stimuli caused by active exertion or improper movement [63,64]. At the same time, this assisted activity helps increase joint ROM, reduce soft tissue adhesions, and promote recovery of muscle strength, indirectly relieving pain and improving joint function [65].

Second, MAT had a relatively high SUCRA ranking for pain relief. One study [66] using a 12-week intelligent KOA lifestyle app intervention found that participants' knee pain was significantly reduced, and its mechanism was mainly based on 3 aspects: personalized physical activity guidance, educational support, and social interaction. A meta-analysis showed that mobile app–based digital health interventions may have a positive effect on improving pain in patients with KOA [67]. Through structured exercise plans, instant educational content, progress tracking, and social support provided by mobile apps, patients can perform rehabilitation exercises more continuously and accurately, thereby reducing pain, improving knee function, and enhancing quality of life [68].

The finding that CR may be more advantageous than MAT in improving pain should be interpreted with caution because multiple RCTs and systematic reviews have shown that the efficacy of the 2 in pain improvement is often comparable or not significantly different. First, an RCT in patients with KOA compared telerehabilitation with conventional face-to-face rehabilitation. The results showed that both groups had significant improvements in pain scores, but no difference was reported showing that CR was clearly superior to telerehabilitation, suggesting that telerehabilitation is similarly effective rather than clearly inferior to traditional rehabilitation [69]. Second, a systematic review and meta-analysis including multiple RCTs showed that, compared with conventional treatment, telerehabilitation demonstrated a statistically significant improvement in relieving pain in patients with KOA, but the magnitude of improvement was often not much different from face-to-face rehabilitation, indicating that telerehabilitation is not inferior to CR in pain relief [70]. Furthermore, review evidence indicated that telerehabilitation and traditional face-to-face rehabilitation have no significant difference in pain control after knee replacement surgery, further supporting that the 2 are comparable in pain improvement, rather than CR necessarily being superior [71].

However, due to problems such as high dropout rates, intervention heterogeneity, and low evidence quality in existing studies, these findings should be interpreted with caution, and more high-quality studies are still needed for verification in the future.

Effects of Digital Health Interventions on Active Flexion ROM in Patients After TKA

RR also showed significant advantages in improving active knee flexion ROM, with a relative effect estimate versus CR of MD 8.96 (95% CI 5.86-12.05), and it had the highest SUCRA ranking (97.0%). One study showed that robot-assisted rehabilitation training can significantly improve active knee flexion ROM in older adult patients after TKA. After intervention, the active ROM in the robot group increased from 65.18° to 103.53°, and the passive ROM increased from 82.63°

XSL•FO
RenderX

to 104.75°, both significantly superior to the traditional treatment group [32]. This is attributed to the ability of robotic systems to provide high-intensity, repetitive, and consistent training and to combine passive and active movement at different rehabilitation stages through human-machine interaction, thereby more effectively promoting joint function recovery [24,72]. In addition, multiple included studies and meta-analyses showed that robot-assisted rehabilitation has positive effects on improving ROM in patients after total knee or hip arthroplasty [10]. Robot training provides high-intensity, repetitive, and physiologically patterned movements, helping patients complete a larger ROM with less pain, thereby effectively promoting joint function recovery [10].

Second, this study showed that VR ranked next in SUCRA for active flexion ROM. A meta-analysis showed that VR-assisted rehabilitation can more significantly improve knee ROM in patients after TKA compared with traditional rehabilitation [73]. This improvement is mainly attributed to the immersive and interactive training environment provided by VR technology [74,75]. It can not only improve patient participation and exercise adherence through visual feedback and gamified design [23], but also guide patients to complete larger-range and more precise joint movement exercises in a safe and controllable virtual scene, thereby effectively promoting postoperative joint function recovery [20,26].

Effects of Digital Health Interventions on Knee Function in Patients After TKA

This study showed that, compared with CR, none of the included digital health technologies significantly reduced WOMAC scores in patients after TKA. However, traditional meta-analysis results showed that after pooling all digital health technologies, the improvement effect was significant. Subgroup analysis showed that VR significantly reduced WOMAC scores, which is consistent with Zhai et al [13], especially with a more obvious effect in the hospital setting, possibly related to real-time professional guidance and higher patient adherence [23].

For HSS scores, VR had the highest SUCRA ranking. A meta-analysis found that VR rehabilitation significantly improved HSS scores in patients after TKA in both the early postoperative period (within 1 month) and the medium- to long-term period (2 - 3 months), indicating a positive effect on knee function recovery [76,77]. VR rehabilitation can improve patient rehabilitation participation and training adherence through its immersive and interactive environment, thereby improving knee function and showing significant advantages in HSS scores. Specifically, the real-time visual feedback and task-oriented training provided by VR technology may promote neuromuscular control and motor learning processes, helping knee function recovery [76,77]. As an active and interesting rehabilitation mode, VR technology may bring additional functional benefits on top of CR by enhancing patient motivation and distracting attention from pain.

For the TUG test, MAT had the highest SUCRA ranking. One study showed that after using a mobile app (RateFastGonio) to assess knee joint position sense, TUG test times in patients with KOA and after TKA were significantly longer than those in healthy controls, indicating impaired mobility and dynamic balance [78]. The mechanism lies in the fact that TUG is a functional test that comprehensively reflects lower limb muscle strength, balance, coordination, and movement speed [79]; patients with KOA have limited activity due to joint pain, stiffness, and kinesiophobia, leading to decreased muscle strength and abnormal gait, thereby prolonging TUG time [78]; although TKA aims to relieve pain and restore joint alignment, intraoperative removal of intra-articular structures (such as the meniscus and cruciate ligaments) containing mechanoreceptors that provide proprioceptive input may lead to incomplete postoperative proprioceptive recovery [80]. In addition, possible postoperative quadriceps weakness, altered neuromuscular control, and persistent kinesiophobia [81] jointly affect the smoothness and speed of movements such as standing up, walking, and turning, thus manifesting as prolonged TUG time [78].

VRT ranked next in improving TUG scores. Immersive virtual environments provide enhanced multisensory feedback and awareness of results, helping patients better perceive and optimize movement quality, thereby improving motor control and coordination [82,83]. The high interactivity and gamified elements of VR training significantly enhance patient participation and training motivation, which may encourage patients to perform more extensive and higher-intensity functional training, benefiting improvement in daily activity ability [84,85]. Repetitive task-oriented training combined with sensory stimulation helps promote brain plasticity, integrate perception, cognition, and action, thereby consolidating learning effects and enhancing patients' self-efficacy, laying a neural foundation for improvement in functional activities [82,83]. The remote home training mode overcomes travel barriers, ensuring continuity and accessibility of rehabilitation training and providing conditions for continuous functional improvement [86]. These factors work together and ultimately manifest as improvements in functional activity tests such as TUG.

Interpretation of SUCRA Rankings

The highest SUCRA ranking does not equate to statistically supported superiority. This network was mainly star-shaped, with no closed loops and few direct comparisons; therefore, comparisons among interventions mainly relied on indirect comparisons through CR; in addition, the certainty of evidence for most comparisons was low to very low.

Residual heterogeneity remained high for some outcomes (I^2>75%), and prediction intervals were wide, and some crossed the line of no effect, further reducing the certainty of SUCRA ranking results. Therefore, SUCRA rankings should be interpreted as ranking probabilities rather than definitive evidence of treatment superiority [87,88]. When referring to ranking results, clinicians should comprehensively judge based on relative effect estimates, certainty of evidence, residual heterogeneity, and MCID, rather than relying solely on SUCRA rankings.

Consideration of Treatment Comparisons and Additional Treatment Exposure

The treatment comparisons in this study were not a single mode. According to the relationship between digital health

XSL•FO
RenderX

interventions and CR, included studies could be divided into 4 modes: digital health intervention replacing CR, digital health intervention supplementing CR, CR delivered digitally, and self-directed versus clinician-supervised comparison. Under the supplementary mode, the experimental group received "CR+digital health intervention," while the control group received only CR. Therefore, the observed benefits may come not only from the digital health technology itself but also partly from increased treatment time, supervision, attention, or exercise dose. Existing studies have shown that in rehabilitation after TKA, additional device-assisted training [89] or higher-intensity strength training [90] can bring functional gains superior to standard rehabilitation, suggesting that treatment dose and training intensity themselves are important factors affecting outcomes. Another systematic review also pointed out that the content and dose of postoperative rehabilitation programs vary greatly and are related to outcome improvement [91].

We performed subgroup analysis according to whether treatment doses matched. The results showed that in the dose-matched group, pooled effect sizes for most outcomes were close to null or small, while the group with higher dose in the experimental group showed more obvious improvement trends in active flexion ROM, HSS, and TUG. In addition, the CR node itself was relatively broad, including forms such as physical therapy, routine care, balance training, continuous passive motion, and health education, and its internal heterogeneity may affect the reliability of indirect comparisons. This heterogeneity has been partly considered in the transitivity assumption assessment of the NMA by comparing the distribution of effect modifiers among nodes. Therefore, the independent effect of digital health technology itself still needs further verification under dose-matched conditions.

Distinguishing Statistical Improvement From Clinically Meaningful Improvement

Statistical significance does not equate to clinical significance; even if an intervention reaches statistical significance, its effect size may not exceed the MCID, and vice versa. Therefore, while reporting statistical significance, this study further assessed clinical significance with reference to MCID. For pain, the MCID using VAS 0 - 100 mm was 15 mm [58], which converts to approximately 2 points on a 0 - 10 scale [58]; the MCID for ROM was 9° [59]; the MCID for WOMAC total score was 15 points [60]; the MCID for HSS was 5.41 points [61]; the MCID for TUG was 1.4 seconds [62].

The results showed that the lower limits of the 95% CI for HSS (VR vs CR, MD 9.53, 95% CI 5.18, 13.88) and TUG (VRT vs CR, MD –4.80, 95% CI –8.65 to –0.95) both exceeded the corresponding MCID (HSS 5.41 points [61]; TUG 1.4 s [62]), suggesting that these improvements are not only statistically significant but may also be clinically meaningful. In contrast, the lower limits of the 95% CI for pain (RR vs CR, MD −0.81, 95% CI –1.73 to 0.11), ROM (RR vs CR, MD 8.96, 95% CI 5.86-12.05), and WOMAC (IVT vs CR, MD –11.00, 95% CI –19.03 to –2.97) did not exceed the MCID (pain 2 points [58]; ROM 9° [59]; WOMAC 15 points [60]), suggesting that their clinical significance remains unclear. It should be noted that the MCID for TUG came from a hip osteoarthritis population and may not be fully applicable to the TKA population; caution is needed in interpretation.

The above results indicate that the statistical advantages of some interventions may translate into clinical benefits, but performance differs across outcomes; when referring to ranking results, clinicians should comprehensively judge in combination with MCID, rather than relying solely on statistical significance or SUCRA rankings. Future studies should report more clinical significance analyses using MCID as a threshold to support individualized rehabilitation decisions.

Equity and Accessibility in Digital Rehabilitation

The interventions included in this study involved home telerehabilitation, mobile apps, videoconferencing, wearable technology, and intelligent rehabilitation systems. Although these methods can improve rehabilitation accessibility, they may also raise important equity, privacy, and data security issues. First, digital accessibility and affordability may affect whether patients can participate in telerehabilitation; patients lacking smartphones, tablets, or stable internet services may be excluded [92]. Second, differences in digital literacy may affect older patients' ability to use technology, thereby affecting intervention adoption and adherence [93]. Third, privacy protection, informed consent, and data security are issues that must be considered in telerehabilitation, especially when using wearable devices and web platforms [94]. Fourth, people with disabilities, linguistic minority groups, and residents in remote areas may face additional accessibility barriers [95]. Fifth, the availability of caregivers or technical support may affect the implementation effect of interventions [96]. These factors may not only affect intervention adoption and adherence but may also affect their effectiveness, and therefore caution is needed when interpreting the results of this study.

In addition, among the included studies, only a few reported device or internet accessibility, digital literacy, or technical support; most studies did not assess socioeconomic characteristics, usability, accessibility, privacy, or privacy- and equity-related outcomes [97]. Future studies should systematically evaluate these equity and privacy issues when designing and reporting telerehabilitation interventions.

Limitations

This study has the following limitations. There was considerable variation among studies in intervention duration, protocol, and device type; subtypes within each category of digital health technology were insufficiently differentiated; the CR node was relatively broad (including physical therapy, routine care, balance training, continuous passive motion, health education, etc); and the IRT node contained different technology combinations such as wearable sensors, cameras, and web platforms. In addition, the intervention duration and assessment time points of included studies varied greatly, with the main analysis still pooling data from different time points. All these factors may introduce heterogeneity and affect the reliability of indirect comparisons and ranking results.

Most existing studies compared digital health technology with CR, lacking direct comparisons among different digital health technologies; some technologies (such as AR and telephone

XSL•FO
RenderX

follow-up telerehabilitation) had relatively small sample sizes; and this network was mainly a star-shaped network with no closed loops, making node-splitting or global inconsistency tests impossible. These factors together limit the credibility and comparative stability of the NMA. Future studies should encourage multi-arm direct comparison trials and conduct more high-quality research.

The transitivity assessment showed that some effect modifiers (such as intervention duration, baseline active flexion ROM, baseline TUG, baseline HSS, and sample size) differed markedly in distribution among treatment nodes, suggesting that the transitivity assumption may not fully hold. Factors such as unilateral versus bilateral TKA, postoperative intervention start time, rehabilitation setting, type and intensity of CR, risk of bias, and geographic region were only descriptively compared and not quantitatively analyzed, so their impact could not be fully assessed.

Regarding statistical methods, this study used r=0.5 to estimate the SD of change scores and did not perform sensitivity analysis with alternative correlation coefficient assumptions; τ^2 for each outcome was estimated using the DL method; some outcomes had high heterogeneity (I^2>75%), and prediction intervals were wide and crossed the line of no effect; and most included studies did not directly report the SD of change scores, so formula-based estimation may affect study weights, SE, and heterogeneity estimates. Because only 2 studies directly reported this parameter, the impact of imputed SD could not be fully assessed, and results should be interpreted with caution.

In addition, the MCID for TUG came from a hip osteoarthritis population and may not be fully applicable to the TKA population; a TUG MCID specific to the post-TKA population should be established in the future. The study also did not perform detailed stratification of the patient population (such as by age or preoperative function), making it difficult to achieve individualized efficacy assessment; future studies should strengthen subgroup analyses to support the development of precision rehabilitation programs.

Conclusion

This study used NMA to evaluate the effects of different digital health interventions on rehabilitation outcomes in patients after TKA. The results showed that, compared with CR, RR, and VR, MAT had relatively high-ranking probabilities for improving postoperative pain, joint ROM, and knee function. Based on the available evidence, the effects of VR in improving HSS and VRT in improving TUG may be clinically meaningful, while the clinical significance of pain scores, active flexion ROM, and WOMAC remains unclear.

However, because this network was mainly a star-shaped network with no closed loops, sparse direct comparisons, high heterogeneity in intervention protocols, some studies at high risk of bias, low to very low certainty of evidence for most comparisons, and residual high heterogeneity for some outcomes, the above rankings should be interpreted as ranking probabilities rather than definitive evidence of comparative superiority. Therefore, the relative superiority among different digital health interventions remains uncertain, and the above conclusions still need to be verified by more high-quality, head-to-head RCTs, ultimately to develop efficient and personalized rehabilitation programs for patients after TKA.

Abstract

Background: Illicit substance use disorders (SUDs) are escalating globally; yet, social stigma and legal barriers restrict access to conventional treatment, and existing research remains skewed toward alcohol and nicotine. Digital interventions incorporating cognitive behavioral therapy (CBT) offer a discreet, scalable alternative.

Objective: This scoping review maps how CBT-based digital interventions for illicit SUDs are designed and delivered across platforms, identifying their theoretical frameworks, functional components, outcome indicators, and reported methodological limitations.

Methods: We followed the Joanna Briggs Institute (JBI) scoping review methodology and reported in accordance with PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews). Six databases (PubMed/MEDLINE, Embase, APA PsycINFO, Web of Science Core Collection, Cochrane Library, and CINAHL) were searched from inception to June 28, 2026, without language, date, or study design limits, supplemented by backward and forward citation searching (July 3, 2026). Eligible studies were empirical primary studies quantitatively evaluating digital interventions incorporating CBT for illicit or nonprescribed substance use; alcohol- or nicotine-only populations were excluded. Three reviewers independently screened and charted all studies, with disagreements resolved by consensus or adjudication. Data were synthesized narratively, with tables, figures, and an evidence gap map.

Results: Fifty-six studies published between 2008 and 2026, drawn from 47 distinct participant samples, met the eligibility criteria. Most were conducted in North America (40/56, 71.4%) and used randomized controlled designs (39/56, 69.6%). Polysubstance-using populations were most frequently targeted (32/56, 57.1%), followed by cannabis (13/56, 23.2%), opioids (6/56, 10.7%), and stimulants (5/56, 8.9%). Interventions were delivered mainly via web (24/56, 42.9%) or app (24/56, 42.9%) platforms, and most (49/56, 87.5%) were grounded in traditional CBT, most often combined with contingency management (18/56, 32.1%) or motivational interviewing (17/56, 30.4%). Core functional components included therapeutic intervention (55/56, 98.2%), self-tracking and notification (25/56, 44.6%), reward (24/56, 42.9%), and support and feedback (21/56, 37.5%). Primary outcomes focused on substance use and abstinence (41/56, 73.2%), retention/feasibility (16/56, 28.6%), and mental health status or coping skills (14/56, 25%). Author-reported limitations were predominantly participant-level (52/56, 92.9%), measurement-level (43/56, 76.8%), study-level (34/56, 60.7%), and intervention-level (25/56, 44.6%) domains.

Conclusions: Unlike previous reviews confined to a single substance or delivery platform, this review is innovative in mapping CBT-based digital interventions across the full spectrum of illicit substances, including polysubstance use, and in linking their functional components to intended therapeutic mechanisms. It thereby contributes to the development of these technologies and, by synthesizing author-reported limitations, proposes methodological improvements for their future evaluation. At present, CBT-based digital interventions are best positioned as adjuncts that extend the reach and continuity of existing addiction care rather than as stand-alone substitutes for it; substance-specific customization, objective outcome measures, and modular trial designs are needed to establish them as scalable clinical tools.

substance use disorders; digital health; cognitive behavioral therapy; digital therapeutics; behavioral intervention; app-based intervention

Introduction

Rationale

Substance use disorders (SUDs) involving illicit drugs, including methamphetamine, cocaine, fentanyl, and cannabis, present a severe global public health crisis. According to the 2025 United Nations Office on Drugs and Crime World Drug Report, an estimated 316 million people worldwide used illicit drugs, reflecting a sharp escalation in synthetic drug markets [1]. In South Korea, which had previously experienced relatively few drug-related problems, the number of drug offenders exceeded 23,000 in 2024, with people in their 20s and 30s accounting for more than 60% of that total [2]. Unlike socially acceptable substances such as alcohol and nicotine, the use of these illicit substances carries profound legal consequences and social stigma, particularly within the strict legal frameworks of East Asia that exacerbate barriers to traditional health care access [3,4]. These systemic obstacles necessitate a distinct and highly accessible treatment approach, yet prior research has often addressed SUDs as a broad category that includes socially acceptable substances such as alcohol and nicotine [5]. Consequently, the existing literature is heavily skewed toward these legal substances, with nicotine-related and alcohol-related studies accounting for 1192 and 1046 publications, respectively [6]. In contrast, research focused on cannabis, opioids, or other illicit drugs remains relatively limited, with only 678 such studies identified [6]. This lack of specialized data is particularly concerning because illicit substances are characterized by strong neurophysiological dependence, rapid tolerance development, severe withdrawal symptoms, and high relapse rates. The frequent association of these substances with impaired self-regulation and co-occurring mental health disorders further complicates treatment interventions, rendering them significantly more complex than those for alcohol- or nicotine-related disorders [7].

Among the emerging approaches in this context, digital interventions have emerged as a promising strategy for the treatment of illicit SUDs. These interventions leverage technologies such as mobile apps, web-based platforms, chatbots, and wearable devices, allowing individuals to engage in treatment autonomously and to be free from time and location constraints [8]. This point is particularly relevant for individuals with SUDs, many of whom avoid in-person care because of stigma, fear of legal consequences, and social marginalization, all of which contribute to high treatment discontinuation rates [9]. Digital interventions offer a discreet and flexible alternative that supports both anonymity and autonomy. Given the high rates of relapse and the need for repeated treatment episodes among members of this population, these interventions may increase acceptability and promote sustained engagement, particularly among individuals who are already familiar with digital tools [10]. In regions where treatment resources are limited or access is restricted, digital interventions provide a scalable and cost-effective solution, highlighting their potential to improve treatment accessibility and effectiveness for SUDs [11,12].

Digital interventions for SUDs exhibit diverse structures and theoretical foundations, although cognitive behavioral therapy (CBT) has served as the predominant framework in many designs. CBT is a widely recognized approach that facilitates behavioral change by addressing irrational thoughts and self-regulatory deficits, making it particularly well-suited for treating SUDs [13]. Its structured techniques, such as identifying craving triggers, applying relapse prevention strategies, and strengthening coping and problem-solving skills, align closely with the clinical needs of this population [14]. In recent years, complementary models, including acceptance and commitment therapy, mindfulness-based therapy (MBT), and dialectical behavior therapy (DBT), have been integrated into intervention designs to address symptom domains such as craving, emotional dysregulation, and impulsivity [15-17]. These approaches provide a broader foundation for the development of tailored digital interventions.

Although digital interventions have shown promising results across various SUDs, existing studies often fail to account for differences in specific substance categories. Given that illicit substances, including stimulants, cannabis, and opioids, differ significantly in their addiction mechanisms and treatment responses, intervention designs must be tailored to distinct user profiles. However, the current literature lacks a comprehensive overview of how digital interventions are applied across these different categories. Previous studies have evaluated digital health interventions targeting specific substances, such as methamphetamine [18] or opioids [19]. However, it is necessary to consider studies that address the use of various substances, including polysubstance use, to evaluate digital interventions in clinical settings. Therefore, a comprehensive review encompassing a wider range of illicit substances is necessary to synthesize how these interventions are designed and adapted across diverse clinical profiles.

Because of the inherent heterogeneity in the design, delivery, and target populations of these interventions, a scoping review provides the most appropriate methodological framework. Accordingly, this study aims to map the current landscape of digital interventions for illicit SUDs, explicitly excluding those related to alcohol and nicotine. Furthermore, by reviewing the efficacy indicators used to validate these interventions and identifying the limitations of each study, this review seeks to provide foundational insights to guide the design of future research.

Objectives

This scoping review aims to map how CBT-based digital interventions for illicit SUDs are designed and delivered across

XSL•FO
RenderX

various platforms. Furthermore, it identifies their common theoretical frameworks and functional components, and collates the efficacy indicators used to validate these interventions. This review also analyzes the specific methodological limitations reported in each study, highlighting the resulting implications for the design of future trials.

Methods

Overview

This scoping review followed the framework developed by Arksey and O'Malley [20], as operationalized in the Joanna Briggs Institute (JBI) methodology for scoping reviews, and was reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [21]. The review aimed to comprehensively examine how CBT-based interventions are delivered to individuals with SUDs in digital settings. The PRISMA-ScR checklist is provided in Checklist 1.

Protocol and Registration

The review was conceived by JWC, YHC, and DJK. A protocol specifying the objectives, questions, eligibility criteria, search strategy, and charting procedures was developed a priori by SMK and SJJ, circulated to all authors, and finalized by consensus before the searches were executed; the charting form developed at this stage is provided in Multimedia Appendix 1. The protocol was not prospectively registered, as PROSPERO does not accept registrations for scoping reviews and no alternative registry was used at the outset; it is available from the corresponding author on request. No departures from the protocol occurred.

Eligibility Criteria

Participants

This review considered studies involving individuals of any age who used illicit or nonprescribed psychoactive substances, or who had a clinically defined SUD related to such substances, as determined by a standardized diagnostic classification (eg, *DSM-5* [*Diagnostic and Statistical Manual of Mental Disorders* {Fifth Edition}] or *ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*]/ICD-11 [*International Statistical Classification of Diseases, 11th Revision*]) or by the criteria applied within each primary study. No age restrictions were applied to capture the full range of populations in which these interventions have been evaluated. Studies involving participants with polysubstance use were eligible if at least one of the substances used was illicit or nonprescribed. Studies were excluded if the population focused solely on alcohol or nicotine/tobacco use, as these substances differ in legal status and are served by separate treatment and evidence traditions, or if the substance of interest could not be determined.

Concept

The core concept of interest was the effectiveness of digital interventions grounded in, or incorporating, CBT for the treatment or management of illicit substance use. Digital interventions were defined as any therapeutic program delivered wholly or partly through a digital modality, including web-based platforms, computer programs, smartphone or tablet apps, text messaging (SMS), interactive voice response (IVR), and other mobile- or internet-based technologies, that explicitly applied CBT principles or techniques (eg, cognitive restructuring, coping skills training, and relapse prevention). Eligible studies had to report at least one empirical outcome relevant to intervention effectiveness, such as substance use frequency or quantity, abstinence, craving, or treatment retention/adherence. Studies were excluded if the intervention lacked a digital component, was ungrounded in CBT, did not incorporate CBT, or reported no effectiveness outcome for the digital intervention, including studies reporting usability, feasibility, or acceptability outcomes alone. Eligibility depended on whether such an outcome was reported, not on its direction or magnitude; no study was excluded based on its findings.

Context

No restrictions were applied to setting, geographical location, or health system, as the objective of this review was to map the range and contextual applications of these interventions rather than to characterize their effects in any single setting.

Types of Evidence Sources

This review considered original, empirical primary studies that quantitatively evaluated the effectiveness of digital interventions incorporating CBT. Eligible designs included randomized controlled trials (RCTs), nonrandomized and quasi-experimental studies, controlled and single-group pre-post studies, observational and cohort studies, and pilot or feasibility studies reporting effectiveness outcomes. This breadth was deliberate: restricting eligibility by design would have excluded much of the evidence this review set out to map. Excluded source types were systematic, scoping, and narrative reviews; study protocols; secondary or descriptive reports presenting no effectiveness outcomes; letters, editorials, commentaries, and errata; and other nonempirical formats. Secondary analyses of previously reported trials were eligible if they were published as independent primary studies and reported their own effectiveness outcomes for a digital intervention. Conference abstracts, dissertations, and other gray literature were ineligible, as such reports seldom describe intervention content, delivery format, and outcome ascertainment in the detail our charting form required.

Information Sources

Six bibliographic databases were searched from inception to June 28, 2026: PubMed/MEDLINE (National Library of Medicine), Embase (Elsevier), APA PsycINFO (ProQuest), the Web of Science Core Collection (Clarivate), the Cochrane Library (Wiley), and CINAHL (EBSCO).

Following identification of the included studies, citation searching was undertaken on July 3, 2026, as an additional method of identification. Backward citation searching comprised screening the reference lists of all included studies; forward citation searching was conducted using the "cited-reference" function of the Web of Science Core Collection together with the "Cited by" function of Google Scholar. The most recent search was therefore executed on July 3, 2026. No trial registers

XSL•FO
RenderX

were searched, and no sources of gray literature were sought, for the reasons given under the "Types of Evidence Sources" section.

Search

The search strategy applied the JBI 3-step approach in accordance with the JBI Manual for Evidence Synthesis (section 10.2.5). First, a limited search of MEDLINE (PubMed) and CINAHL was conducted to identify articles relevant to the topic. Second, the words appearing in the titles and abstracts of the retrieved records, together with the index terms used to describe them, were analyzed to develop a comprehensive strategy. Three concepts—SUD, CBT, and digital health—were each represented by controlled-vocabulary terms (MeSH in PubMed and the Cochrane Library, Emtree in Embase, APA Thesaurus of Psychological Index Terms in PsycINFO, and CINAHL Subject Headings in CINAHL) combined with a broad set of free-text synonyms, using truncation and the field modifiers appropriate to each platform, with OR within each concept and AND across concepts. The Web of Science Core Collection has no controlled vocabulary, and the strategy for that database therefore used free-text terms alone. The full strategy was then run across all 6 databases with the syntax adapted to each. Third, backward and forward citation searching was performed once the included studies had been identified, as described under the "Information Sources" section.

The strategy was developed by JWC, SMK, SJJ, and MJK, and the searches were executed by SMK, SJJ, and MJK. Before the final searches were run, the strategy was peer-reviewed against the Peer Review of Electronic Search Strategies checklist by 4 authors (YHC, DJK, NRL, and KH) who had not been involved in developing or executing it.

No language, date, publication type, or study design limits or filters were applied in any database. Because the review mapped the extent, range, and nature of the available evidence rather than estimating an intervention effect, restricting retrieval by design would have excluded much of the eligible range; sensitivity was prioritized over precision, consistent with JBI guidance for scoping reviews. For the same reason, the Cochrane Central Register of Controlled Trials was not searched separately, although the Cochrane Library was searched in full. Ineligible source types were removed at screening rather than by database filters so that borderline records were assessed by the reviewers.

The complete strategy for every database—subject headings, free-text terms, field tags, records retrieved at each step, and the date each search was executed—is provided in Multimedia Appendix 2 and reported in accordance with the PRISMA-ScR.

Selection of Sources of Evidence

Records from all sources were imported into EndNote 21 (Clarivate) and deduplicated by matching on DOI, title, and first author with year, followed by manual verification of all candidate duplicates. Screening decisions were recorded in a shared Microsoft Excel sheet in which each reviewer used a separate sheet so that judgments were made without knowledge of the others' decisions.

Screening proceeded in 2 sequential stages against the eligibility criteria set out above. First, titles and abstracts were screened to remove clearly ineligible records. Second, the full texts of all potentially eligible records were retrieved and assessed. All records, whether identified through the database searches or through citation searching, were screened at both stages independently by 3 reviewers (SMK, SJJ, and MJK), each of whom assessed every record. Disagreements at either stage were resolved by discussion among the 3 reviewers; where consensus was not reached, the corresponding author (JWC) adjudicated.

Some included reports were found to analyze a dataset shared with one or more other included reports, typically comprising the primary outcome report of a trial together with subsequent secondary analyses, some of which were restricted to a subset of the randomized sample. Such reports were retained as separate sources because each was published as an independent primary study addressing a distinct question and reporting its own effectiveness outcomes, and because excluding them would have removed evidence on intervention components, engagement, and outcomes that the primary reports did not present. Each included publication is accordingly counted as one study throughout this review, and the unit of analysis is the published study rather than the underlying trial.

Data Charting Process

A draft charting form was developed a priori as part of the protocol and was piloted before full charting began, with SMK, SJJ, and MJK each independently charting the same 10 included studies [22-31]. The pilot confirmed that the prespecified fields captured the required information consistently. All included sources were then charted in full, independently, by the 3 reviewers. Completed forms were compared field by field, and discrepancies were resolved through discussion with the corresponding author (JWC) until consensus was reached. Values reported at only one point in a source and not corroborated elsewhere in the same report were charted as reported and flagged, with no inference beyond the authors' own statements. Fields for which a source provided no information were charted as "not reported." The authors of the primary studies were not contacted. The charting form is provided in Multimedia Appendix 1.

Data Items

Study and participant characteristics comprised the first author, year of publication, country, study design, the target substance and whether polysubstance use was reported, the number of participants analyzed, the proportion who were male, participant age, and intervention period. Engagement characteristics comprised participant retention or completion, completion of the digital intervention, and usage frequency or intensity. Intervention characteristics included the digital delivery mode; theoretical frameworks underpinning the intervention; core functional components—therapeutic intervention (TI), self-tracking and notification (STN), support and feedback (SF), and reward (RW); the name of the digital intervention program; and whether treatment as usual (TAU) was acknowledged in the study. We also extracted the methodological limitations reported by the source authors for each domain.

XSL•FO
RenderX

Critical Appraisal of Individual Sources of Evidence

No formal critical appraisal of study quality was performed, as this scoping review did not aim to evaluate or compare intervention effectiveness. The focus was on mapping the range, structure, and contextual applications of digital CBT-based interventions. The methodological limitations reported in this review were charted as limitations explicitly acknowledged by the authors of the included studies.

Synthesis of Results

The charted data were synthesized narratively and presented in tabular and graphical form, including an evidence gap map. Included sources were categorized by delivery mode, intervention theory, core functional components, and the digital intervention program evaluated, and frequencies were tabulated for each category at the level of the included study. Participant retention and intervention adherence were summarized separately, as were the outcome measures used and the reported indicators of effectiveness. The methodological limitations reported by source authors in the included studies were grouped by domain and presented accordingly.

Results

Selection of Sources of Evidence

The database searches identified 1676 records: 224 from PubMed, 674 from Embase, 153 from Web of Science, 237 from PsycINFO, 224 from the Cochrane Library, and 164 from CINAHL. Of these, 472 duplicates were removed before screening, leaving 1204 records for title and abstract screening. Screening excluded 1110 records: 644 were nonoriginal articles, 234 did not address substance use, 173 concerned only alcohol or nicotine, and 59 did not concern a digital intervention. All 94 reports sought for retrieval were obtained and assessed at full text, of which 43 were excluded: 22 because no quantitative effectiveness outcome was reported and 21 because only usability or acceptability outcomes were reported. A total of 51 studies were included from the database searches [22-72].

Backward citation searching of the reference lists of these 51 studies identified 2620 records, and forward citation searching identified 3091 records, giving a total of 5711 records. Deduplication removed 1138 records, comprising records duplicated within the citation-searching results together with records already retrieved by the database searches, and left 4573 unique records for title and abstract screening. Screening at this stage excluded 4565 records: 2680 were nonoriginal articles, 950 did not concern substance use, 715 concerned alcohol or nicotine only, and 220 did not concern a digital intervention. All 8 reports sought for retrieval were obtained and assessed at full text, of which 3 were excluded because no quantitative effectiveness outcome for a digital intervention was reported. Five further studies were included from citation searching [73-77].

Across both identification pathways, 5777 unique records were screened at title and abstract, and 102 reports were assessed at full text. In total, 56 studies met the eligibility criteria and were included in the review [22-77], 51 identified through the database searches [22-72] and 5 through citation searching [73-77] (Figure 1). Citation searching thus contributed 5 of the 56 (8.9%) included studies [73-77], which the database searches had not retrieved.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram of the identification, screening, and selection of sources of evidence for this scoping review of digital interventions incorporating cognitive behavioral therapy for illicit substance use disorder.

Fourteen of the 56 included studies analyzed data drawn from a sample shared with one or more other included studies [24,25,32-43], forming 5 groups. Six studies analyzed data from a single multisite randomized trial conducted in 10 community-based outpatient programs between June 2010 and August 2011 [24,32-36]. Two analyzed a trial conducted in a methadone maintenance program [37,38]. Three further pairs analyzed, respectively, a trial of internet-based DBT [25,39], a trial of a culturally adapted Spanish-language digital CBT program [40,41], and a 3-arm trial of an internet-based self-help program for cannabis use [42,43]. In each group, one study reported the primary outcomes of the parent trial and the remainder reported secondary analyses, several of which were restricted to a subset of the randomized sample. The unit of analysis was the individual published study; the 56 included studies drew on 47 distinct participant samples [22-77].

Characteristics of Sources of Evidence

Tables 1-3 summarize the key characteristics of the 56 studies included in this review [22-77]. The included studies were published between 2008 and 2026. Among the 56 included studies, the majority were conducted in North America (the United States, Canada, and Mexico), accounting for 71.4% (40/56) [23-27,32-41,44-65,73-75]. The next most common region was Europe, which accounted for 17.9% (10/56) of the studies, including 4 from the United Kingdom, 2 each from Switzerland and the Netherlands, 1 from Sweden, and 1 conducted across Switzerland, Austria, and Germany [22,28,29,42,43,66-70]. East Asia (China and Taiwan) accounted for 5.4% (3/56) [30,71,72], and Australia accounted for 5.4% (3/56) [31,76,77].

[a]This scoping review encompasses studies published between 2008 and 2026 across diverse global locations, involving various study designs and targeting diverse clinical populations.

[b]Studies [32-36] and [24] analyze data from the same parent trial, as do [37] and [38], [40] and [41], [42], and [43], and [25] and [39]. In each group, one study reports the primary outcomes of the trial and the remainder report secondary analyses, several of which were restricted to a subset of the randomized sample. Each was published as an independent primary study and is counted separately; the 56 included studies drew on 47 distinct participant samples.

[c]RCT: randomized controlled trial.

[d]NR: not reported.

Table . Participant retention and intervention adherence metrics across the included studies (N=56)[a].

Author (year)	Participant retention or completion, n/N (%)	Intervention adherence metrics	
		Digital intervention completion	Usage frequency or intensity
Bickel et al [44] (2008)	28/45 (62)	—[b]	70% of scheduled urinalysis sessions attended (69 sessions scheduled)
Carroll et al [73] (2008)	22/35 (62.9)	71.7% (mean 4.3 [SD 2.4]/6 modules)	38.3 (SD 8.2) min/session working with each module
Rooke et al [76] (2013)	64/119 (53.8)	58.3% (mean 3.5/6)	—
Campbell et al [32] (2014)	—	76.3% (mean 36.6 [SD 18.1]/48 modules)	—
Marsch et al [37] (2014)	31/80 (38.7)	52% (mean 27.56 [SD 24.4]/53 modules)	Mean 11.51 (SD 7.21) counselor sessions
Budney et al [74] (2015)	20/30 (66.7)	53.3% (mean 4.8 [SD 3.4]/9 modules)	—
Campbell et al [33] (2015)	—	76.3% (mean 36.6 [SD 18.1]/48 modules)	—
Schaub et al [22] (2015)	79/215 (36.7)	38.3% (pooled mean 3.06/8 modules)	Mean 1.74 d/wk of diary entry (24.9% of days, weeks 1 - 6)
Tait et al [77] (2015)	38/81 (46.9)	48.1% (39/81)	—
Guarino et al [23] (2016)	21/25 (84)	92% (23/25)	Mean 2.48 logins/wk
Kim et al [38] (2016)	—	—	—
Elison et al [66] (2017)	1090/2311 (47.2)	27.4% (mean across modules; range 21.6%% - 33.2%)	Median 3 (IQR 7) LBM[c] strategies completed
Kay-Lambkin et al [31] (2017)	—	—	—
Lévesque et al [34] (2017)	—	—	—
Liang et al [71] (2018)	71/74 (95)	49.3% (mean 13.8 [SD 10.4]/28 daily surveys)	35.4% - 66.7% of participants submitted a daily survey on any given day
Paris et al [40] (2018)	41/43 (95.3)	75.7% (mean 5.3/7 modules)	Mean 4/6 homework assignments completed (66.7%)
Riggs et al [45] (2018)	109/144 (75.7)	100% (single-session design)	Not applicable (single-session intervention)
Tiburcio et al [46] (2018)	9/27 (33.3)	58.3% (mean 4.67 [SD 2.2]/8 sessions)	Mean 5.5 (SD 2.7) strategies per session
Marino et al [35] (2019)	—	76.3% (mean 36.6 [SD 18.1]/48 modules)	—
Moore et al [47] (2019)	32/40 (80)	—	Mean 10.6 (SD 16.1) calls; mean 59.1 (SD 85.6) total minutes of call time
Sinadinovic et al [28] (2020)	50/137 (36.5)	30.0% (mean 3.9 [SD 2.7]/13 modules)	Mean 8.9 visits/wk (mean 62.4 total visits)
Baumgartner et al [42] (2021)	102/386 (26.4)	31.3% (pooled mean 2.50/8 modules)	Pooled mean 42.1 minutes total time on modules
DeFulio et al [75] (2021)	—	66.7% (24/36)	—
Elison-Davies et al [67] (2021)	1107/2571 (43.1)	Mean 4.61 (SD 3.96) BCTs[d] completed among assessment completers versus 1.07 (SD 1.91) among non-completers	—
Elison-Davies et al [29] (2021)	460/1830 (25.1)	38.6% (mean 4.63 [SD 4.13]/12 strategies)	Mean 7.55 (SD 10.06) BCTs completed

Author (year)	Participant retention or completion, n/N (%)	Intervention adherence metrics	
		Digital intervention completion	Usage frequency or intensity
Prochaska et al [48] (2021)	71/88 (80.7)	30.3% (mean 20 [SD 12.0]/66 lessons)	Mean 4.4 days of use/wk (mean 34.9, SD 28.9, days overall; median 31, IQR 12.0-50.5)
Prochaska et al [49] (2021)	51/128 (39.8)	13.9% completed all psychoeducational lessons; mean 12.1 (SD 8.3) modules	Mean 15.7 (SD 14.2) days of use, equivalent to 2.0 times/week
Ahlers et al [43] (2022)	<30%	28.6% (pooled mean 2.29/8 modules)	Approximately 33% logged in only briefly, completed the first module, and never returned
Kelpin et al [50] (2022)	16/34 (47.1)	71.4% (mean 5 [SD 2]/7 modules)	Mean 4 (SD 3) of 7 weekly homework assignments completed
Luderer et al [36] (2022)	157/206 (76.2)	80.8% (mean 38.8/48 modules)	42.2% (87/206) completed the recommended 4 modules/week throughout
Maricich et al [24] (2022)	157/206 (76.2)	—	Mean 3.3 h/wk of intervention time; 39.8% accessed the program outside the clinic
Zhang et al [72] (2022)	46/52 (88.5)	60.9% (mean 4.87/8 ICBT[e] sessions)	Mean 2.0 login d/wk (16.37 login days over 8 weeks)
Campbell et al [51] (2023)	21/27 (77.8)	47.5% (mean 22.8 [SD 24.3]/48 modules; median 12.0, IQR 0.0 - 48.0)	— (prescribed use: twice weekly, 4 modules/wk)
Chun-Hung et al [30] (2023)	33/50 (66)	75.1% (mean session attendance rate)	Mean retention in treatment 142.42 (SD 60.54) days
Günther et al [68] (2023)	2925/12,529 (23.3)	—	Mean 9 weeks of engagement (SD 17 weeks; range 0 days-142 weeks)
Muhlner et al [52] (2023)	27/49 (55)	>41% of scheduled activities and tasks attended	Mean 55.1 (SD 1.61) days in the 8-week (56-day) program among completers versus 21.9 days among noncompleters
Olthof et al [69] (2023)	126/188 (67)	46.7% (mean 2.8, SD 2.5, of 6 modules)	—
Paquette et al [26] (2023)	52/65 (80)	Mean 4.29 (LETS ACT) and 3.75 (LETS ACT-SE) behavioral activation sessions attended	69% (37/54) reported app use at 1 month after treatment, declining to 37% (20/54) at 3 months
Wilde et al [53] (2023)	350/796 (44)	66.3% (232/350) completed at least 1 BAM survey	Mean 59.4 active days over the 304-day observation window
Xiong et al [54] (2023)	443/602 (74)	52% completed all core lessons	73% completed 4 or more lessons/week in week 1, declining to 36% in week 12
Daros et al [25] (2024)	58/72 (80.6)	35% (24/68) met the recommended dose of 8 days in the first month	Mean 627.47 (SD 576.22) interactions (immediate group, n=38) and 429.17 (SD 560.28; delayed group, n=30)
Garland et al [55] (2024)	23/28 (82)	60.7% (17/28) completed all intervention sessions	—
Gosens et al [70] (2024)	12/21 (57.1)	41.7% (5/12) completed the full protocol	71.2% mean compliance with the daily survey
Benitez et al [41] (2025)	32/39 (82.1)	71.4% (mean 5/7 modules)	—
Coronado-Montoya et al [56] (2025)	30/51 (58.8) completed the core modules	61.7% (mean 3.7, SD 2.5, of 6 modules)	Median total app use 17.8 (IQR 9.7 - 30.9) minutes over 6 weeks

Prochaska et al [27] (2026)	100/107 (93.4)	89% (82/92) completed at least 1 psychoeducational lesson; 51% (47/92) used at least 1 psychotherapeutic tool	Mean 16.2 (SD 13.6) days active
Walton et al [65] (2026)	112/122 (91.8)	77.1% (5642/7320) of twice-daily surveys completed	85.2% (1693/1987) of opened messages actively engaged with

[a]Data represent user engagement and feasibility outcomes for CBT-based digital interventions targeting illicit substance use disorders.

[b]Not available.

[c]LBM: lifestyle balance model.

[d]BCT: behavior change technique.

[e]ICBT: internet-based cognitive behavioral therapy.

[f]EMA: ecological momentary assessment.

[g]CBT: cognitive behavioral therapy.

[a]The evaluated programs are categorized by their primary digital delivery platform, adjunctive theoretical frameworks, and specific interactive elements.
[b]TAU: treatment as usual.
[c]T-CBT: traditional cognitive behavioral therapy.
[d]CM: contingency management.
[e]CRA: community reinforcement approach.
[f]TI: therapeutic intervention.
[g]SF: support and feedback.
[h]RW: reward.
[i]CBT4CBT: Computer-Based Training for Cognitive Behavioral Therapy.
[j]MI: motivational interviewing.
[k]STN: self-tracking and notification.
[l]TES: therapeutic education system.
[m]MBT: mindfulness-based therapy.
[n]BFO: Breaking Free Online.
[o]SHADE: self-help for alcohol/other drugs and depression.
[p]PF: personalized feedback.
[q]PBS: protective behavioral strategies.
[r]PAADD: programa de ayuda para abuso de drogas y depresión.
[s]IVR: interactive voice response.
[t]MET: motivational enhancement therapy.
[u]DBT: dialectical behavior therapy.
[v]ApBM: approach bias modification.
[w]CAT: chatbot-assisted therapy.
[x]BT: behavioral therapy.
[y]MORE-VR: virtual reality-based mindfulness-oriented recovery enhancement.
[z]CHAMPS: Cannabis Harm-reducing App to Manage Practices Safely.
[aa]JITAI: just-in-time adaptive intervention.
[ab]RL: reinforcement learning.

With respect to the targeted substance groups, each study was categorized into 1 of 4 distinct primary categories based on its therapeutic focus (polysubstance, cannabis, opioids, or stimulants). The most frequently targeted substance group was individuals with polysubstance use, which was represented in 57.1% (32/56) of the studies [24-27,32-41,44,46-51,53,54,57-59,62,66,68,70,71,73]. Because this polysubstance category encompasses highly heterogeneous clinical profiles, we further examined the predominant illicit substance patterns within these studies. When excluding alcohol to focus strictly on illicit use, 3 major profiles emerged: first, an opioid and cocaine co-use profile primarily seen in medication-assisted treatment settings [38,44,47,50,71]; second, a cannabis-dominant profile commonly co-occurring with cocaine or stimulant use [24,25,27,36,39-41,46,54,59,70]; and third, a broadly mixed illicit profile with relatively equal proportions of cannabis, cocaine, opioids, and stimulants [26,32-35,48,49,51,57,58,66,68,73].

This group followed by cannabis users in 23.2% (13/56) of the studies [22,28,29,31,42,43,45,56,60,65,69,74,76], opioid users in 10.7% (6/56) [23,55,61,64,67,75], and stimulant users in 8.9% (5/56) [30,52,63,72,77]. Most stimulant-related studies focused on individuals using methamphetamine. No studies targeting hallucinogen use as the primary focus were identified.

Retention and Adherence Metrics

To evaluate the feasibility and real-world scalability of the included studies, participant retention and intervention adherence metrics were extracted (Table 2). Among the 56 included studies [22-77], 85.7% (48/56) reported participant retention or protocol completion rates during the study period [22-30,36,37,39-62,64-74,76,77]. Reported retention rates showed a wide variance depending on the study design and environment, ranging from the lowest rates of 23.3% [68], up to the highest rates of 95.3% [40]. Conversely, 14.3% (8/56) of the studies did not explicitly report participant retention rates [31-35,38,63,75].

Intervention adherence was primarily measured through digital intervention completion rates and usage frequency or intensity. Digital intervention completion rates were reported in 80.4% (45/56) of the studies [22,23,25-30,32,33,35-37,40-43,45,46,48-58,60,63-67,69-77], while 19.6% (11/56) did not report specific completion metrics [24,31,34,38,39,44,47,59,61,62,68]. The completion rates varied significantly, reaching 100% in a single-session design [45],

XSL•FO
RenderX

whereas other interventions observed much lower completion rates, such as 13.9% [49].

In addition, engagement indicators varied widely and fell into 3 groups: time-based metrics, such as minutes per session [73], total time on modules [42], total app use [56], or intervention hours per week [24]; frequency of use, such as logins or days of use per week [23,48,49,72], total active days [52,53], or total program visits [28]; and completion of therapeutic tasks, such as the number of CBT strategies or behavior change techniques completed [29,58,66,67], weekly homework assignments [40,50], or in-platform interactions [25,39].

Intervention Program Characteristics

Delivery Mode

Digital interventions were categorized on the basis of their delivery modalities into web-based, app-based, combined web and app formats, computer-based, phone-based, and technology-assisted formats such as virtual reality (Figure 2A). Among the 56 included studies [22-77], 42.9% (24/56) evaluated interventions accessible directly through web browsers without the need to install separate apps [22,24,25,28,31-35,37-43,45,46,50,57,59,74,76,77]. An additional 8.9% (5/56) of the studies provided interventions that were accessible via both web and app platforms [29,58,66-68]. Several of these web-based and combined interventions incorporated self-directed learning modules, text and video-based content, and self-monitoring tools such as consumption diaries. The structure was often designed to guide users through scheduled content and assigned tasks at regular intervals. Additionally, 3.6% (2/56) used a computer-based delivery mode [44,73], and 1.8% (1/56) used a phone-based IVR system to deliver the intervention [47].

Figure 2. Comprehensive mapping of cognitive behavioral therapy–based digital interventions for illicit substance use disorders (N=56). The figure illustrates the proportional distribution of (A) delivery modes, (B) theoretical foundations, (C) functional intervention components, and (D) primary efficacy outcomes across the reviewed literature. CM: contingency management; CRA: community reinforcement approach; DBT: dialectical behavior therapy; MBT: mindfulness-based therapies; MI: motivational interviewing; RW: reward; SF: support and feedback; STN: self-tracking and notification; T-CBT: traditional cognitive behavioral therapy; TI: therapeutic intervention.

App-based interventions were the most frequently used delivery mode, representing 42.9% (24/56) of the studies, and were accessible via smartphones or tablets [23,26,27,30,36,48,49,51-56,60-65,69-72,75]. Within this context, 4 studies implemented interventions primarily through automated, interactive chatbot systems (eg, Woebot and CAT) [27,30,48,49]. Several app-based interventions included features such as real-time monitoring, push notifications, RW systems, and chatbot-based feedback to enhance user engagement and promote self-regulation. For instance, interventions such as the reSET app (Pear Therapeutics) used a contingency management (CM) structure in which RWs were provided on the basis of the completion of CBT tasks and negative urinalysis results, thereby improving user adherence and participation [61]. The CAT app, which was delivered via the LINE messaging platform (LY Corporation), offered interactive features, including emotional feedback, treatment schedule reminders, daily mood check-ins, and automated responses tailored to user input [30].

In some of the earliest digital intervention studies (3/56, 5.4%), computer-assisted therapy programs were used to provide fluency-based instruction and CM based on the community reinforcement approach (CRA) [44,73,74]. Another study (1/56, 1.8%) used a phone-based IVR system to deliver automated, self-management CBT modules, which offered immediate therapeutic availability 24 hours a day [47]. More recently, in

XSL•FO
RenderX

one study (1/56, 1.8%), a virtual reality–based app intervention (MORE-VR; RealizedCare) was implemented to provide an immersive environment for exposure to addiction-related cues and training in coping strategies [55]. The intervention allowed for pre- and postsession assessments of emotional response and craving intensity while tracking physiological data such as heart rate during virtual cue exposure [55].

Intervention Theory

Among the 56 studies included in this review [22-77], 87.5% (49/56) used digital interventions grounded in traditional cognitive behavioral therapy (T-CBT) [22-24,27-29,31-38,40-44,46-55,57-61,63-77] (Figure 2B). T-CBT–based interventions typically involve standardized techniques such as cognitive restructuring, coping skills training, and psychoeducation, and are implemented via programs such as Computer-Based Training for Cognitive Behavioral Therapy (CBT4CBT) [40,41,46,50,57,59,73], reSET [24,36,54,61,64], and the Therapeutic Education System [23,32-35,37,38,51]. Among the 49 studies that used T-CBT [22-24,27-29,31-38,40-44,46-55,57-61,63-77], 41 integrated additional theoretical frameworks alongside T-CBT [22-24,27-29,31-38,42-44,46,48,49,51-55,58,60,61,63-70,72,74-77]. CM emerged as the second most commonly used framework, applied in 32.1% (18/56) of the studies [32-36,44,51-54,61-64,72,74,75]. The integration of CM aimed to strengthen user engagement by providing structured RWs based on behavioral targets, such as session completion or abstinence verification. Additionally, the CRA was frequently used alongside T-CBT and CM, appearing in 21.4% (12/56) of the studies [23,24,32-38,44,52,54].

Motivational interviewing (MI), including motivational enhancement therapy, was applied in 30.4% (17/56) of the studies [22,27-29,31,42,43,48,49,56,58,68-70,74,76,77]. MI is frequently used in conjunction with T-CBT to enhance intrinsic motivation and facilitate behavioral change, particularly during the early phases of treatment engagement. In multitheoretical interventions, distinct therapeutic frameworks have been applied to specific functional components. For instance, coping strategies were delivered via CBT modules, whereas motivation enhancement was implemented through MI techniques.

Emotion-focused approaches were also adopted in a subset of the studies. MBT was applied in 14.3% (8/56) of the interventions [29,30,55,58,60,66-68], whereas DBT was used in 8.9% (5/56) [25,27,39,48,49]. In 2 of the DBT-based studies, the intervention program Pocket Skills 2.0 was implemented exclusively on the basis of DBT principles and focused on training emotion regulation and self-awareness skills [25,39].

A small number of studies used alternative approaches. One study (1/56, 1.8%) used a digital CM approach, which aimed to reinforce substance abstinence and treatment adherence by providing monetary incentives via a smartphone app [62]. Furthermore, other emerging frameworks, such as behavioral therapy without cognitive components, the transtheoretical model, personalized normative feedback, and reinforcement learning, were each explored in a minority of studies [26,45,46,56,65].

Intervention Components

Almost all included studies (55/56, 98.2%) incorporated a core TI, which was typically delivered through learning modules, psychoeducational videos, problem-solving exercises, and coping skills training [22-61,63-77] (Figure 2C). STN features were used in 44.6% (25/56) of the studies to encourage user engagement by facilitating regular tracking of substance use patterns, mood states, and cravings, as well as through real-time notifications [22,27,28,30,42,43,45-49,52-54,60,62-65,69-71,75-77]. In some cases, users completed remote biological drug testing, such as self-administered saliva tests under virtual supervision, with the results uploaded and tracked via mobile apps. These activities represented an extended form of behavioral self-monitoring [52,56,75].

RW systems were implemented in 42.9% (24/56) of the studies, and monetary or virtual incentives were offered in return for specific achievements such as maintaining abstinence, completing tasks, or logging self-monitoring data [23-25,32-36,39,44,51-54,60-65,70,72,74,75]. In CM-based interventions, the RW component functioned as a key motivational driver to encourage sustained app use. SF components were provided in 37.5% (21/56) of the studies via in-app messaging, automated responses, chatbot interfaces, and live feedback from counselors [22,25,27,28,30,39,42-44,46-49,53,56,65,69,71,74-76]. These features were designed to support users as they progressed through educational content and tasks.

A total of 71.4% (40/56) of the studies integrated combinations of 2 or more of these components [22-25,27,28,30,32-36,39,42-49,51-54,56,60-65,69-72,74-77]. Several studies incorporated gamified features or task-based formats (eg, earning points, unlocking content, or winning accessories for avatars) to enhance user engagement [25,39,70]. Furthermore, some interventions were personalized on the basis of user characteristics, including specific personality traits, levels of functional impairment, risk classification, and baseline assessment results [29,58,66-68,70].

To address the theoretical linkage between the functional components and their presumed mechanisms of action, Figure 3 presents a conceptual framework mapping each component to its hypothesized mechanism and to the outcomes it is intended to affect. TI was present in almost all included studies (55/56) and operates through cognitive restructuring and coping-skills training, targeting drug-related expectancies and craving [22-61,63-77]. STN (25/56) works through self-monitoring and functional analysis, intended to increase behavioral awareness and the recognition of high-risk situations and thereby self-efficacy [22,27,28,30,42,43,45-49,52-54,60,62-65,69-71,75-77]. SF (21/56) draws on supportive accountability and the therapeutic alliance [22,25,27,28,30,39,42-44,46-49,53,56,65,69,71,74-76]; these are mechanisms of engagement rather than of cognitive or behavioral change, and the outcomes they target are retention and continued use of the intervention rather than substance use itself [22,42,49]. RW (24/56) is grounded in operant conditioning and functions as digital CM

XSL•FO
RenderX

[23-25,32-36,44,51-54,60-65,70,72-75], reinforcing verified behavioral targets such as drug-negative urinalysis [32,44,75]. CM was named as an adjunctive framework in 18 of the 56 studies [32-36,44,51-54,61-64,72,74,75]. The mechanisms shown are those hypothesized in the source reports; none of the included studies tested them directly.

Figure 3. Conceptual framework mapping the digital intervention components identified in this review to their hypothesized mechanisms of action and targeted outcomes. Figures in parentheses are the number of included studies (out of 56) in which each component was identified. The upper 2 components operate through mechanisms specific to cognitive behavioral therapy; the lower 2 operate through adjunctive engagement and operant mechanisms that are frequently combined with cognitive behavioral therapy in digital interventions. CBT: cognitive behavioral therapy; RW: reward; SF: support and feedback; STN: self-tracking and notification; TI: therapeutic intervention.

Research Methodology

Study Design

A total of 69.6% (39/56) of the studies used an RCT design to evaluate the effectiveness of digital intervention programs [22,24,26-28,30-48,50,51,54,56,59,60,64,65,69,71-74,76,77]. Specifically, 29 studies adopted a 2-arm RCT design [24,25,27,28,30,32-41,45,47,48,50,51,56,59,64,69,71-73,76,77], 8 studies used a 3-arm RCT design [22,26,31,42-44,46,74], and 2 studies used a microrandomized trial design [60,65]. Three studies used a quasi-experimental design [23,62,75]. Additionally, 5 studies used a single-group or single-case experimental design [49,52,55,57,70], while the remaining 16.1% (9/56) adopted observational study designs [29,53,54,58,61,63,66-68].

The control conditions (Multimedia Appendix 3) [23,24,26,29,30,32-38,40-42,44,46,47,50,51,53-57,59,61-64,66-68,71-75] were categorized into those with and without active comparators. Some control groups received active interventions such as standard pharmacotherapy, in-person psychotherapy, or active educational modules [23,24,26,27,30-38,40,41,44-47,50,51,56,59,62,64,69,71-76]. In contrast, control conditions without active components primarily used waitlist or delayed-intervention formats [22,25,28,39,42,43,48,77]. Some studies included both active and waitlist control arms, and others used control messages [60,65]. Observational studies and single-group experimental designs did not include formal control groups. Furthermore, TAU or usual care was explicitly integrated into the intervention design in 64.3% (36/56) of the studies [23,24,26,29,30,32-38,40-42,44,46,47,50,51,53-55,59,61-64,66-68,70-73,75], whereas the remaining studies did not specify this component.

The duration of interventions with fixed schedules ranged from a single session to 52 weeks, with a mean duration of 13.7 weeks. Four studies [29,58,66,68] offered self-paced interventions without fixed end points. Among the 32 studies reporting follow-up data [22,25-28,30-35,39-43,45-47,50,51,56,59,65,69-74,76,77], periods ranged from 4 to 52 weeks, with an average of 20.2 (SD 12.6) weeks. Across the studies reporting demographic data, the mean age of participants was 35.3 (SD 6.5) years, and the average proportion of male participants was 56.3% (17,693/31,422).

Primary Outcome

The studies included in this review used a range of indicators to assess the effectiveness of digital interventions. The primary outcome measures reported across studies can be broadly categorized into the following 4 domains (Figure 2D).

Changes in substance use behavior and abstinence were the most frequently assessed outcomes, evaluated as a primary measure in 73.2% (41/56) of the studies [22-24,26-34,36-38,40,42-52,54,59,62,63,65,67,69-71,73-77]. Most studies used self-reported data to measure the frequency, number of use days, or quantity of substance use within the past 7 or 30 days [22,24,27-29,31,40,45,47-49,52,67,73,77]. The

XSL•FO
RenderX

timeline follow-back method was frequently used as a standardized self-report tool [26,32-34,36,42,43,46,50,51,59,69,71,74,76], while some studies used ecological momentary assessment (EMA) via a mobile app to track daily use quantities [65,70]. To complement self-reported data, several studies incorporated biological verification, including urine tests, saliva tests, and breathalyzers [24,32-34,36,40,47,50-52,71,73,74]. Although most studies reported positive outcomes, some studies found no significant differences or reductions in use between the digital intervention and control groups [28,51,59,69,77].

Treatment retention, feasibility, and acceptability were examined as primary outcomes in 28.6% (16/56) of the studies [24,30,32,33,37,52,54-56,61-65,74,75]. Treatment retention and adherence were assessed using indicators such as time to last contact, clinic appointment attendance, and continued engagement in medication for opioid use disorder programs based on prescription data or electronic health records [24,30,32,33,37,52,54,61-64,74,75]. In several of these studies, digital interventions coupled with CM or app-based monitoring were associated with higher treatment retention and attendance compared to standard care [24,30,52,54,61-63,75]. Other studies explicitly focused on the feasibility and acceptability of the digital platforms, measuring completion rates, ease of use, satisfaction, program engagement via in-app logs, and the presence of adverse events [55,56,65]. These studies reported high usability, safety, and acceptance among the users studied.

A total of 25% (14/56) of the included studies designated mental health status, craving, or coping skills as their primary outcomes [29,31,34,35,41,45,46,49,53,58,60,66,68,72]. Common psychiatric outcome measures included symptoms of depression and anxiety, and overall quality of life [29,31,35,46,49,58,66,68]. Cue-induced craving was evaluated using visual analog scales or EMA to assess momentary emotional reactivity and impulse control [49,60,72]. Additionally, adaptive coping strategies and protective factors were measured using specific tools such as the Drug Risk Response Test and the Brief Addiction Monitor [34,41,45,53]. Most studies in this category reported that digital interventions were associated with reductions in psychiatric symptoms and craving, and with improved coping skills.

Severity of substance dependence and recovery progression were identified as primary efficacy outcomes in 14.3% (8/56) of the studies [25,29,39,46,57,58,66,68]. Most of these studies used the Severity of Dependence Scale to evaluate the intervention's impact on psychological dependence [25,29,39,57,58,66,68]. Furthermore, to evaluate multifaceted recovery across physical, psychological, and social domains, the Recovery Progression Measure was used to track reductions in functional impairment [29,58,66,68]. These studies generally reported reductions in dependence severity and improvements in recovery progression among users of the digital interventions.

Study Limitations

To provide foundational insights for the design of future trials, this review analyzed the methodological limitations explicitly acknowledged by the authors of the included studies. Each reported limitation was assigned to 1 of 4 mutually exclusive domains consisting of study-level, participant-level, measurement-level, or intervention-level based on its most proximal source (Table 4).

XSL•FO
RenderX

Table . Classification of self-reported methodological limitations identified across the included studies evaluating digital interventions for illicit substance use disorders (N=56)[a].

Domain	Description and key issues	Reference
Study-level		
Structural research design	The structural limitations arising from the lack of a control group, the absence of random assignment, and the use of a single-group design undermine the overall methodological rigor of the study.	[22,23,25,29,36,49,51-58,61-63,67,70-73,75]
Constraints on causal inference	Due to the inability to control for unmeasured confounding variables or concurrent treatment effects, this study is limited in its capacity to establish a definitive causal relationship for the intervention.	[25,30,31,34,40,41,47,48,55,57,63,68,73]
Limitations in analytical strategy	The statistical approaches used, including multiple testing, post hoc analysis, and exploratory analysis, along with the initial establishment of the research objectives, present inherent limitations to the study.	[39,57,59,75,77]
Participant-level		
Insufficient sample size	The limited sample size and insufficient statistical power restrict the feasibility of subgroup analyses and other numerical evaluations.	[23,25,27,31,33,39-41,46,48,50,51,55,59,61,64-66,71-75]
Biases in sample composition	The study is limited by the compromised representativeness of the sample resulting from recruitment bias, voluntary participation, and demographic imbalances.	[25-27,29,30,32,36,37,39,40,46,47,49,51,53,54,56,58,60,62,64,65,71,72,74,77]
Contextual generalizability constraints	The special conditions affecting external validity, such as high attrition rates, the COVID-19 pandemic, and specific legal environments, limit the generalizability of the findings.	[22,24,28,29,37,38,42,43,45,48-50,52,56-59,62,67-70,72,73,76,77]
Measurement-level		
Deficits in instrument validity	The qualitative limitations stemming from the reliance on self-reported data, recall bias, and the use of unvalidated scales hinder the reliability of the assessment tools.	[22,25,27,29,30,33-35,41,42,45-47,49-51,54,58,63-65,67,69-71,73,74,76,77]
Incomplete data coverage	The limitations regarding data availability, such as the failure to measure specific variables, missing outcome data, and the absence of formal diagnostic assessments, restrict the depth of the analysis.	[23,28-30,33,35,39,43,44,49,53,54,58,61,63,64,67-69,74,77]
Constraints in temporal assessment	The temporal constraints inherent in the data collection process, specifically the short follow-up duration and the absence of longitudinal outcome measures, prevent the assessment of the long-term effects of the intervention.	[22,28,30-32,42,44,46,49,55,61,62,66,67,70,72,76]
Intervention-level		
Complexity in intervention dosage	The unclear dosage of intervention and the structural limitations in isolating the independent effects of specific components within a multicomponent intervention preclude a definitive evaluation of each constituent element.	[23,25,32-34,36,37,44,51,57,61,74,75]
Challenges in participant adherence	The limitations arising from low adherence and irregular usage patterns, where participants do not engage with the intervention as intended, compromise the internal validity of the study.	[36,43,46,47,53,62,64,65,69,70,76,77]

Domain	Description and key issues	Reference
Usability barriers	The systematic limitations hindering the standard delivery of the intervention, such as app download issues, technical glitches, and platform functional constraints, interfere with the intended implementation of the research protocol.	[25,42,51,53]

[a]Limitations are synthesized into study-level, participant-level, measurement-level, and intervention-level domains to inform the robust design of future clinical trials.

Study-level limitations were observed in 60.7% (34/56) of the studies, reflecting issues in research design that constrain internal validity or causal inference [22,23,25,29-31,34,36,39-41,47-49,51-59,61-63,67,68,70-73,75,77]. A substantial portion of the studies (23/56, 41.1%) acknowledged limitations associated with structural research design, including the use of observational, single-group, quasi-experimental, waitlist-controlled, or nonblinded designs that lacked an active control or comparison group [22,23,25,29,36,49,51-58,61-63,67,70-73,75]. Other studies (13/56, 23.2%) faced constraints on causal inference due to unmeasured confounders, baseline imbalances, or the inability to control for the effects of concurrent treatments [25,30,31,34,40,41,47,48,55,57,63,68,73]. A smaller subset of studies (5/56, 8.9%) reported limitations in analytical strategy, cautioning against the exploratory or post hoc nature of their analyses and the potential risks of multiple testing [39,57,59,75,77].

Participant-level limitations were frequently identified, present in 92.9% (52/56) of the included studies [22-33,36-43,45-55,57-77]. These limitations primarily constrain the external validity and generalizability of the findings. Subcategories within this domain included insufficient sample sizes (23/56, 41.1%), which often led to underpowered analyses or restricted the ability to conduct robust subgroup comparisons [23,25,27,31,33,39-41,46,48,50,51,55,59,61,64-66,71-75]. Many studies (27/56, 48.2%) also noted biases in sample composition due to reliance on self-selected or convenience samples, recruitment biases, high attrition, or demographic imbalances such as predominantly male or racially homogeneous cohorts [25-27,29,30,32,36,37,39,40,46,47,49,51,53,54,56,58,60-62,64,65,71,72,74,77]. Furthermore, contextual generalizability constraints were commonly highlighted (26/56, 46.4%), pointing out that interventions evaluated during the COVID-19 pandemic or within specific national, regional, and legal environments might not be broadly applicable to other settings [22,24,28,29,37,38,42,43,45,48-50,52,56-59,62,67-70,72,73,76,77].

Measurement-level limitations entailed substantial challenges in 76.8% (43/56) of the studies [22,23,25,27-35,39,41-47,49-51,53-55,58,61-74,76,77]. These issues centered on how outcomes or variables were assessed. Deficits in instrument validity were a major concern (29/56, 51.8%), largely driven by the predominant reliance on self-reported measures without biological verification or the use of unvalidated instruments [22,25,27,29,30,33-35,41,42,45-47,49-51,54,58,63-65,67,69-71,73,74,76,77]. Some studies (21/56, 37.5%) cited incomplete data coverage due to missing data, lack of formal diagnostic assessments, or failure to capture key outcome variables [23,28-30,33,35,39,43,44,49,53,54,58,61,63,64,67-69,74,77]. Constraints in temporal assessment were frequently reported (17/56, 30.4%), particularly the reliance on short follow-up periods or infrequent testing windows, which precluded the evaluation of sustained intervention effects or long-term abstinence [22,28,30-32,42,44,46,49,55,61,62,66,67,70,72,76].

Finally, intervention-level limitations pertained to the delivery, implementation, and usage of the digital programs, identified in 44.6% (25/56) of the studies [23,25,32-34,36,37,42-44,46,47,51,53,57,61,62,64,65,69,70,74-77]. Complexity in intervention dosage was a notable barrier (13/56, 23.2%); the widespread use of multicomponent intervention packages made it challenging to disentangle which specific active elements contributed to the observed effects, and the precise exposure dose remained unclear [23,25,32-34,36,37,44,51,57,61,74,75]. Several studies (12/56, 21.4%) reported challenges in participant adherence, emphasizing inconsistent usage patterns, low module completion rates, and rapid declines in engagement over the study period [36,43,46,47,53,62,64,65,69,70,76,77]. Additionally, a few studies (4/56, 7.1%) explicitly highlighted usability barriers, including technical issues, app compatibility problems, and difficulties in navigating the platform [25,42,51,53].

The limitations acknowledged by the authors of the included studies are mapped across the 4 target substance categories (Figure 4). Each study was assigned to a single substance category on the basis of the target substances reported in Table 1; studies targeting more than one substance are grouped under polysubstance. Red, yellow, and blue indicate high (≥70%), moderate (41% - 69%), and low (≤40%) prevalence. Participant-level limitations were the most frequently acknowledged overall, reported by every opioid study (6/6) [23,55,61,64,67,75] and every cannabis study (13/13) [22,28,29,31,42,43,45,56,60,65,69,74,76], by 91% (29/32) of polysubstance studies [24-27,32,33,36-41,46-51,53,54,57-59,62,66,68,70,71,73], and by 80% (4/5) of stimulant studies [30,52,72,77]. Measurement-level limitations were also widely acknowledged, ranging from 72% (23/32) of polysubstance studies [25,27,32-35,39,41,44,46,47,49-51,53,54,58,62,66,68,70,71,73] to 85% (11/13) of cannabis studies [22,28,29,31,42,43,45,65,69,74,76]. Study-level limitations were reported by all stimulant studies (5/5) [30,52,63,72,77] and by 83% (5/6) of opioid studies [23,55,61,67,75], but by only 31% (4/13) of cannabis studies [22,29,31,56]. Intervention-level limitations were the least frequently acknowledged in 3 of the 4 categories, from 20% (1/5) of stimulant studies [77] to 67% (4/6) of opioid studies [23,61,64,75].

Figure 4. Evidence gap map showing the prevalence of methodological limitations by level and by target substance category. Bubble size, color, and internal values indicate the proportion of studies within each category (n) that acknowledged at least one limitation at the given level.

Synthesis of Results

The limitations acknowledged across the 56 included studies clustered into 5 areas that together define where the current evidence base is least informative (Figure 5). Sampling validity corresponds to participant-level limitations; comparative positioning to study-level limitations; enhanced outcome evaluation to measurement-level limitations; and personalized content design and real-world integration to intervention-level limitations. Sampling validity was implicated by the participant-level limitations reported by 92.9% (52/56; Table 4) [22-33,36-43,45-62,64-77], which centered on small and nonrepresentative samples and on constrained generalizability. Comparative positioning followed from the study-level limitations, in particular the absence of a controlled comparison in some designs and the substantial variability in how TAU was constituted across the studies that used it. Enhanced outcome evaluation reflected the measurement-level limitations, which concerned reliance on self-reported substance use, incomplete outcome coverage, and short or absent follow-up. Personalized content design followed from the observation that generic platforms were applied across heterogeneous substance profiles, with 32 of the 56 studies enrolling polysubstance-using samples [24-27,32-41,44,46-51,53,54,57-59,62,66,68,70,71,73], along with the intervention-level limitations concerning intervention dosage. Real-world integration reflected the remaining intervention-level limitations, namely adherence and usability barriers, and the low completion rates reported in Table 2.

Figure 5. A synthesized framework summarizing the 5 areas in which the included studies most frequently acknowledged limitations, organized by the level of the limitation framework. TAU: treatment as usual.

Discussion

Principal Findings

This scoping review synthesized evidence from 56 published studies [22-77], drawn from 47 distinct participant samples, examining CBT-based digital interventions for illicit SUDs. Across the mutually exclusive primary target categories, polysubstance use and cannabis use were the most frequently targeted categories, accounting for 57.1% (32/56) [24-27,32-41,44,46-51,53,54,57-59,62,66,68,70,71,73] and 23.2% (13/56) of included studies [22,28,29,31,42,43,45,56,60,65,69,74,76], respectively. Opioids and stimulants were less frequently targeted, accounting for 10.7% (6/56) [23,55,61,64,67,75] and 8.9% (5/56) [30,52,63,72,77], respectively; no studies identified hallucinogen use as the primary clinical target. Despite this heterogeneity in target populations, most interventions adopted a standardized design. These mutually exclusive primary target categories should be distinguished from the polysubstance subprofiles discussed below. In this study, the patterns of concomitant use were investigated within the polysubstance studies but did not constitute additional substance-specific study categories or counts.

Because stimulant and opioid users exhibit substantially different craving dynamics, relapse risk factors, and withdrawal profiles [78], the current reliance on generic intervention structures may compromise treatment precision and potential efficacy. Furthermore, although our results identified 3 distinct clinical profiles within the polysubstance use category, most of the included studies did not tailor their interventions to these specific patterns. Instead, standard intervention structures, such as comprehensive CBT or CM packages, were applied uniformly across the different profiles. For example, studies addressing the first polysubstance subprofile—opioid and cocaine co-use, frequently observed in medication-assisted treatment settings—applied generic versions of computer-assisted therapy (Therapeutic Education System or CBT4CBT) without structural adaptation to medication adherence or opioid withdrawal dynamics [37,38,44,50]. Studies targeting the second polysubstance subprofile (cannabis-dominant use co-occurring with stimulants/cocaine) and the third polysubstance subprofile (broadly mixed illicit use) similarly relied on the same generalized digital platforms rather than profile-specific content [33,40,41,73]. Taken together, these findings indicate that the current evidence base offers little guidance on how digital interventions should be structured across polysubstance profiles. To address these limitations, digital interventions that incorporate drug-specific factors would need to be developed [79].

Combining cognitive restructuring modules with motivational enhancements or RW-based reinforcement fundamentally supports both behavioral and psychosocial outcomes by addressing multifaceted clinical needs [22,24]. Cognitive techniques effectively target distorted thought patterns and craving triggers, while motivational frameworks foster initial treatment readiness, and CM systems sustain long-term engagement [14,80,81]. However, limited transparency about how these complex theoretical models are operationalized in digital delivery formats poses a critical challenge [82]. In practice, these theoretical frameworks are often bundled into multicomponent intervention packages [23,25,32-34,36,37,44,51,61,74,75]. This widespread use of bundled packages creates a significant barrier to understanding intervention dosage, making it exceptionally difficult to disentangle which specific active components independently contribute to the observed clinical effects [83].

Clinically, 98.2% (55/56) of the reviewed programs incorporated a core TI module [22-61,63-77]. Additional engagement features such as STN and RW were present in 44.6% (25/56) [22,27,28,30,42,43,45-49,52-54,60,62-65,69-71,75-77] and 42.9% (24/56) of the interventions [23-25,32-36,39,44,51-54,60-65,70,72,74,75], respectively, while automated SF mechanisms were used in 37.5% (21/56) [22,25,27,28,30,39,42-44,46-49,53,56,65,69,71,74-76]. Although combining these multiple functional components was commonly reported to be associated with improved treatment retention and user adherence, the explicit tailoring of these features to individual risk severity or distinct substance types remains rare. Furthermore, outcome evaluations predominantly focused on reductions in substance use behavior, which served as the primary measure in 73.2% (41/56) of the studies [22-24,26-34,36-38,40,42-52,54,59,62,63,65,67,69-71,73-77]. While these results suggest that digital tools may support holistic recovery, the considerable variability in the definition of TAU across clinical trials complicates the interpretation of independent intervention effects. In clinical research, control groups frequently receive TAU to serve as a comparative baseline [84]; however, the definition of TAU fluctuates among studies. In certain trials, it encompasses highly active interventions, including face-to-face psychosocial counseling and standard pharmacotherapy [23,24,26,30-38,40,41,44,46,47,50,51,56,59,62,64,71-75], whereas in others, it consists merely of standard educational materials or waitlist conditions [22,25,27,28,39,42,43,45,48,60,65,69,76,77]. Because these comparative baselines are inconsistent, it is difficult to establish the independent clinical benefit attributable to the digital platform. A digital tool evaluated against an intensive control condition may appear less effective than a comparable tool evaluated against a minimal control condition [85]. These inconsistencies emphasize the necessity of standardized reporting and clear definitions of baseline conditions to assess the efficacy of digital therapeutics.

We categorized the methodological limitations explicitly reported in the existing literature to provide foundational insights for future trial designs. To advance the clinical utility of digital interventions, we suggest that future research address the methodological limitations related to measurement and intervention. An overreliance on self-reported measures introduces substantial risks of recall and social desirability biases [86]. Because digital interventions inherently entail lower levels of clinician control than do face-to-face formats, objective outcome metrics should be incorporated from the inception of the trial design [87]. Measurements should combine self-reports with objective indicators, including urine or saliva testing and

XSL•FO
RenderX

EMA, to reduce recall bias and trace proximal mechanisms [73,86]. Furthermore, task-based behavioral response assessments could serve as robust objective indicators of effectiveness for patients with SUDs [41]. Since short-term reductions in substance use may not adequately capture broader clinical impacts, a comprehensive assessment framework featuring extended follow-up periods and multidimensional outcomes is needed to accurately predict sustained engagement and relapse prevention [88]. Since these limitations may sometimes be underreported or omitted, they should not be interpreted as an objective assessment of the study's quality [21].

The evaluation of intervention content also requires rigorous methodological refinement. As noted, the prevalent use of multicomponent packages makes it exceptionally difficult to isolate the effects of individual components. It could be suggested that future research consider optimization-focused designs as forward-looking approaches to help disentangle these bundled features. For instance, the multiphase optimization strategy represents a conceptual framework that could allow future investigators to empirically screen multiple active ingredients [83]. Similarly, for just-in-time adaptive interventions, microrandomized trials offer a hypothetical approach to evaluate digital prompts in naturalistic settings [79,89]. Although advanced frameworks such as factorial trials within the multiphase optimization strategy or microrandomized trials extend beyond the empirical scope of the studies mapped in this review, they illustrate promising future directions for exploring the optimal dose and timing of digital therapeutics. Empirical examination of dose-response relationships between intervention intensity and user engagement is highly warranted [36]. From a clinical-design perspective, future studies may benefit from documenting TAU components, intensity, and integration strategies in sufficient detail. Using specific reporting formats such as the TIDieR (Template for Intervention Description and Replication) guidelines can facilitate the precise evaluation of combined effects [90]. Comparative designs that clearly distinguish digital-only, standard care, and combined approaches will clarify relative effectiveness, while hybrid effectiveness-implementation trials can incorporate cost and scalability questions relevant to decision makers [90,91]. Finally, structural tailoring must account for drug-specific differences in pharmacodynamics, usage motivations, and contextual risk factors through explicit theory-to-feature mapping [79].

Future Directions and Author Recommendations

We identify several implementation considerations that may merit attention in future research on the clinical applicability of digital interventions. These considerations could include technological accessibility, interoperability with health information systems, and clear data governance. Future studies might explore how digital interventions could be embedded within stepped-care pathways and existing clinical workflows, and whether such integration may support their adoption and sustainment. Although clinician-facing dashboards were described as platform features in some reviewed studies, including reSET and CHAMPS (Cannabis Harm-reducing App to Manage Practices Safely) [24,36,44,56,61], this review did not systematically evaluate their implementation or clinical utility. Beyond the features mapped in this review, automated escalation protocols [92], interoperability with electronic health records and pharmacy systems [93], privacy safeguards, and transparent consent procedures may be considered as forward-looking implementation options. These proposals are intended to guide future research and should not be interpreted as evidence-based conclusions of this review.

Limitations

Several methodological limitations of this scoping review should be noted. First, the literature search was restricted to peer-reviewed journal articles and excluded gray literature, including conference proceedings, dissertations, and unpublished institutional reports. This criterion was applied to ensure the methodological rigor and quality of the included evidence. However, in the rapidly developing field of digital therapeutics, this exclusion may introduce a risk of publication bias. As a result, the interventions identified in this review may not fully represent the range of digital interventions currently being developed or implemented, and some recent or practice-based programs may have been omitted. To partly mitigate this limitation, we broadened our search to 6 bibliographic databases and conducted citation searching; nonetheless, this possibility should be considered when interpreting the scope and representativeness of the identified interventions. Second, consistent with the standard methodology of scoping reviews, no formal critical appraisal of the included studies was conducted. Consequently, the intervention outcomes summarized herein reflect the reported findings at a purely descriptive level. Conclusions regarding the definitive reliability or comparative clinical significance of these outcomes must therefore be interpreted with appropriate caution. Finally, this review primarily focused on mapping the structural and theoretical dimensions of digital interventions and did not systematically examine user-level contextual factors. Variables such as gender, age, baseline disorder severity, and digital accessibility or receptivity can significantly influence treatment outcomes and user adherence. Future systematic reviews and clinical trials should adopt more granular reporting standards and conduct stratified analyses to better account for these critical moderating variables.

Conclusion

This scoping review synthesized evidence from 56 studies evaluating digital interventions based on CBT for illicit SUDs [22-77]. Unlike previous reviews, which have largely been confined to a single substance or to a single delivery platform, this review is innovative in mapping interventions across the full spectrum of illicit substances—including polysubstance use, which reflects the clinical reality of most addiction services—and in linking the functional components of each intervention to their intended therapeutic mechanisms rather than classifying them by delivery format alone. Almost all included studies incorporated a core TI, and 2 or more of the functional components were combined and incorporated into the digital interventions. However, current results have shown limitations in clearly distinguishing the clinical efficacy of digital interventions due to the widespread application of general interventions, an excessive dependence on self-report

XSL•FO
RenderX

measurement, and inconsistencies in TAU conditions. Additionally, combining multiple functional components obscured the core components involved in treatment, making it difficult to identify specific mechanisms of clinical intervention.

Therefore, this scoping review contributes to the development of digital intervention technologies for illicit SUDs by describing and comparing CBT-based digital interventions across a range of substances of abuse. Furthermore, by synthesizing the limitations reported by the authors of the included studies, it proposes methodological improvements for the future evaluation of these technologies. For these interventions to become a scalable and effective treatment modality in real-world clinical settings, future studies must emphasize substance-specific customization, obtain objective outcome measures, and adopt modular trial designs. Taken together, these findings indicate that CBT-based digital interventions are, at present, best positioned as adjuncts that extend the reach and continuity of existing addiction care rather than as stand-alone substitutes for it. By addressing these methodological limitations, digital therapeutics may develop into a sustainable, patient-oriented treatment technology in the field of addiction treatment.

Generative AI Use

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading and editing. The GenAI tool used was Gemini 3.1. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. The declaration was submitted by SMK.

Funding

This research was supported by a grant from the Mental Health Related Social Problem-Solving Project, Ministry of Health & Welfare, Republic of Korea (grant number: RS-2024‐00403474) and supported by the Bio & Medical Technology Development Program of the National Research Foundation (NRF) funded by the Korean government (MSIT; RS-2023‐00223559).

Data Availability

Data sharing is not applicable to this article as no datasets were generated or analyzed during this study.

Authors' Contributions

SMK and SJJ contributed equally to this work and are co-first authors. The initial concept for this study was conceived by JWC, YHC, and DJK. SMK and SJJ contributed to the study design and drafted the original manuscript. The search strategy was developed by JWC, SMK, SJJ, and MJK, and the searches were executed by SMK, SJJ, and MJK. SMK, SJJ, and MJK independently screened the retrieved records and performed data charting and contributed to data curation; any discrepancies were resolved through discussion with JWC. YHC, DJK, NRL, and KH reviewed the search strategy and contributed to the Discussion. NRL and KH contributed to defining the scope of the research topic and to interpreting the results. YHC and DJK, as medical doctors, contributed to clinical approaches to the management of substance use disorders. JWC coordinated the manuscript development, integrated feedback from all the authors, and supervised the overall project. All the authors reviewed and approved the final manuscript.

Conflicts of Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper. No financial or personal relationships exist between any of the authors and JMIR Publications or its editorial staff, and none of the authors serve on the editorial board.

Abstract

Background: Large language models (LLMs) show great potential for widespread application in the field of nursing; however, their limitations include hallucinations, insufficient domain knowledge, and delays in updating evidence. Retrieval-augmented generation (RAG), by combining external knowledge retrieval with text generation, holds promise for optimizing model outputs. However, current evidence on the use of RAG in nursing remains fragmented and has not been systematically synthesized.

Objective: This scoping review aims to map the applications of RAG in the nursing field, identify current research characteristics and gaps, and provide a foundational evidence base to inform future research and development of intelligent tools for nursing practice.

Methods: This study adopted the Arksey and O'Malley scoping review framework and followed PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) reporting standards. We systematically searched 9 databases—PubMed, Embase, Web of Science, Cochrane Library, Scopus, CNKI, VIP Database, Wanfang Database, and Sinomed—from inception to September 2026. Backward and forward citation searches were also conducted to identify additional eligible studies. Eligible publications were restricted to those in English or Chinese during study selection. Two independent reviewers completed study screening and data extraction, and descriptive synthesis was performed for all eligible records.

Results: A total of 28 studies published between 2024 and 2026 were included. The application of RAG in nursing primarily focused on 4 scenarios: patient education (n=9), nursing informatics (n=8), clinical decision support (n=7), and nursing education (n=4). The base LLMs included the GPT series, LLaMA, ChatGLM, and Doubao, among others, while the knowledge bases primarily integrated literature, clinical guidelines, institutional resources, and clinical data. Most studies relied on dense retrieval, while some incorporated hybrid retrieval, knowledge graphs, and reranking to achieve optimization. Generation and task-output evaluations were reported in 27 studies, whereas retrieval evaluation, safety and reliability evaluations, and implementation or outcome evaluations were less frequently reported. Only 4 studies were conducted in real-world clinical settings. Overall, RAG demonstrated potential to improve the accuracy and reliability of LLM-generated outputs in specific nursing tasks; however, most studies validated only in simulated environments.

Conclusions: This review systematically maps and synthesizes the application scenarios, technical characteristics, reporting completeness, evaluation methods, and research outcomes of RAG from the perspective of nursing tasks, further refining the evidence landscape for RAG research in nursing contexts. By summarizing the selection of base LLMs, knowledge bases and retrieval processes, the key elements of technical reports, and the areas for tiered evaluation, this review provides evidence-informed considerations for the design, validation, and reporting of future RAG-based nursing AI systems. The findings may assist clinical nurses, nursing educators, and hospital IT teams in identifying application scenarios, key safety requirements, and evaluation priorities, while also highlighting the necessity of conducting prospective validation within real-world nursing workflows.

Introduction

With the rapid development of AI technology, generative AI—represented by large language models (LLMs)—is demonstrating significant potential for widespread application in the health care sector [1,2]. In particular, significant progress has been made in areas such as clinical decision support, health advice, and medical education [3-5], serving as a key driver in the transformation of health care services toward greater intelligence, precision, and efficiency. Trained on massive amounts of text data, these LLMs are capable of performing tasks that previously required human-level understanding, including summarizing clinical narratives, answering medical queries, and generating educational content for patients and health care professionals [6]. Consequently, LLMs are regarded as one of the key technological foundations for the future of digital health care.

However, the application of LLMs still faces a number of key challenges, including a lack of domain-specific knowledge, limited reasoning capabilities, and the issue of "hallucinations"—that is, the models may generate information that appears plausible but is in fact inaccurate or unverifiable [7,8]. In health care settings where safety and accuracy are of the utmost importance, this issue could lead to misguided clinical decisions and even jeopardize patient safety. Even the most advanced LLMs may generate medical advice that is presented with confidence but is factually incorrect, which could lead to misleading clinical actions [9]. Furthermore, LLMs typically rely on static training corpora, making it difficult to access the latest medical evidence and clinical guidelines in a timely manner; at the same time, the lack of transparency in their reasoning processes further limits their practical value in nursing practice. This limitation is particularly important in nursing because information is often communicated directly to patients and caregivers and may influence their understanding of diseases, treatments, symptom monitoring, and self-care. Nursing practice also requires nurses to interpret information in light of the patient's individual circumstances, the care setting, their professional responsibilities, and local practice standards [10]. Even if a response appears reasonable in a general medical context, it may not be applicable to a specific patient, health care facility, or nursing situation. Furthermore, if the information generated by the model lacks clear sources of evidence, nurses will find it difficult to determine whether it is up-to-date, authoritative, and contextually appropriate [11]. Therefore, the question of how to enhance the evidence base, transparency, and updatability of LLM outputs has become a key issue for the safe application of generative AI in the nursing field.

To address the hallucination problem in LLMs, Lewis et al [12] proposed the retrieval-augmented generation (RAG) technique in 2020, which is regarded as a solution with broad application prospects. By incorporating external knowledge bases into the generation process, RAG enables an information processing model that retrieves information first and then generates output, thereby significantly enhancing the accuracy and interpretability of the model's outputs [13]. This capability makes RAG a promising approach for medical settings, where accuracy, reliability, and safety are critical requirements [14-16].

In recent years, the application of RAG across various medical disciplines has grown rapidly, spanning areas such as clinical decision support systems [17], medical question-answering [14], drug information retrieval [18], and patient education [19]. The technology has evolved from simple vector-based retrieval to more complex architectures that integrate knowledge graphs, hybrid search strategies, and multistep reasoning. However, compared with the wider field of medicine, its application in the nursing sector is still in its early stages of development [20]. Several recent reviews have addressed the intersection of AI and nursing. Song et al [3] conducted a systematic review on the application of LLMs in nursing, providing valuable overviews of their potential uses and challenges. A broader review by Miao et al [20] examined the application of RAG in the fields of medicine and nursing, offering insights into the overall landscape of this field. However, to the best of our knowledge, no review has specifically and systematically synthesized research on RAG in the nursing field. Given the distinct user populations, knowledge needs, communication responsibilities, educational activities, and care processes involved in nursing, a nursing-focused synthesis of the evidence is warranted to clarify the scope of the current literature. Therefore, this study is based on the scoping review framework developed by Arksey and O'Malley [21] to systematically review the current status, technical characteristics, and development trends of RAG in the field of nursing, identify the application contexts covered in the relevant literature, describe the technical methods used in building RAG systems, report the research findings, and identify areas requiring further study. By focusing on the nursing profession, this review aims to provide a clearer picture of the scope and fundamental characteristics of this emerging field and to serve as a reference for future research on the development and evaluation of RAG applications in nursing.

Methods

Protocol and Registration

This study follows the PCC (populations, concept, and context) framework, considering nursing-related populations (population), RAG technology (concept), and nursing practice (context), and is reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [22]. To enhance the transparency and reproducibility of the search process, a completed PRISMA-ScR checklist is reported in Checklist 1. The study was registered in the Open Science Framework (registration ID: AN3KC).

Identifying the Research Questions

To address the objectives of this study, we formulated the following research questions: (1) What are the scenarios for the application of RAG in the field of nursing? (2) What are the characteristics of the RAG technology frameworks adopted in existing studies? (3) What methods are used to evaluate RAG technology? (4) What evidence is currently available regarding the performance and outcomes of RAG applications in nursing? (5) What are the future development directions and potential application prospects for RAG in the field of nursing?

XSL•FO
RenderX

Study Eligibility Criteria

The eligibility criteria for this scoping review were developed in accordance with the Joanna Briggs Institute methodology for scoping reviews and structured using the PCC framework. The detailed inclusion and exclusion criteria are presented below. Studies were included if they met all of the following criteria. Population: studies involved nurses, nursing students, or nursing educators as primary users, developers, or evaluators of RAG systems, as well as patients, caregivers, or residents as actual or intended recipients of nursing care or nursing-led interventions. Concept: the study implemented or evaluated RAG, defined in this review as a system that combines an information retrieval component with a generative LLM to produce contextually grounded outputs. Context: RAG was applied in an explicitly nursing-related context. "Nursing-related" contexts included nursing workflows, nursing-sensitive outcomes, nursing documentation, nursing education curricula, nursing decision-making, nurse-delivered patient education, or nursing informatics applications. Types of evidence sources: eligible sources included original research papers published in peer-reviewed journals and full conference papers with sufficient methodological and technical details for data extraction. Full conference papers were eligible because research on the development and technical implementation of RAG systems in this rapidly developing field may first appear in conference proceedings. Only publications in English or Chinese were eligible for inclusion. Studies were excluded if they (1) were review papers, editorials, commentaries, guidelines, or study protocols without empirical results; (2) had no retrievable full text; (3) did not implement an actual RAG framework; (4) were conference abstracts with insufficient extractable data; and (5) were preprints that had not undergone peer review.

Information Sources

A comprehensive literature search was conducted across 9 electronic databases: PubMed, Embase, Web of Science, Cochrane Library, Scopus, CNKI, VIP Database, Wanfang Database, and Sinomed. The search period spanned from the inception of each database to September 2026.

Search Strategy

The literature search was reported in accordance with the PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Searching) guideline [23]. We used a combination of MeSH terms and free-text terms to build our strategy in order to maximize the sensitivity and comprehensiveness of the search. The search strategy was developed in consultation with health sciences librarians and was collaboratively created and refined by the team. Search terms included keywords such as retrieval-augmented generation, RAG, large language models, and nursing. The complete search strategy is provided in Multimedia Appendix 1. In addition, backward reference searching and forward citation searching were conducted for all included studies to identify additional eligible studies.

Selection of Sources of Evidence

All retrieved records were imported into EndNote (Clarivate Analytics), and duplicate records were removed using automated and manual procedures. Two reviewers independently screened the titles and abstracts according to the predefined eligibility criteria. Potentially eligible studies were subsequently assessed through full-text review. For each paper excluded during full-text screening, the reason for exclusion was recorded. Disagreements were resolved through discussion, and a third reviewer was consulted when consensus could not be reached. Before formal screening, the reviewers conducted a pilot screening of a sample of 100 records to clarify the eligibility criteria and ensure a consistent interpretation of nursing relevance and RAG applications.

Data Extraction and Result Synthesis

A standardized data extraction form was developed based on the research questions and the PCC framework and pilot-tested on 3 randomly selected included studies. The form was refined through team discussion to ensure all relevant domains were captured. Data extraction was performed independently by 2 reviewers, with cross-verification of all extracted data. Discrepancies were resolved by consensus or adjudication by a third reviewer. The form included the following information: author, year, country, study design, nursing relevance, application scenario, RAG use case, target users, knowledge bases, retrieval strategy, base LLM, comparator, evaluation metrics, main findings, real-world clinical setting, and knowledge graph use. A separate technical characteristics framework was used to extract implementation details, including the following: embedding model, chunking strategy, vector database, retriever top-k, prompt design, reranking method, update mechanism, and knowledge-base validation, where reported. Extracted data were categorized using an initial coding framework developed from the research questions and data extraction items, which was subsequently refined during pilot extraction. Owing to heterogeneity among the included studies, the findings were synthesized descriptively using frequency counts, tables, and narrative synthesis.

Critical Appraisal of Individual Sources of Evidence

No formal methodological quality appraisal or risk-of-bias assessment was performed. This review aimed to map the scope and characteristics of RAG research in nursing, including its application scenarios, technical characteristics, evaluation approaches, and reported outcomes, rather than to estimate pooled effects or exclude evidence based on methodological quality.

Results

Selection of Sources of Evidence

The detailed screening process is shown in Figure 1. This study was reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [24]. A total of 1282 records were retrieved from 9 databases. After 463 duplicate records were removed, 819 records underwent title and abstract screening, of which 726 were excluded. The full texts of 93 reports were sought for

XSL•FO
RenderX

retrieval, and 5 could not be obtained. Of the 88 reports assessed for eligibility, 61 were excluded because they were not conducted in a nursing-related context, did not implement a RAG framework, had an ineligible study type, or were conference papers with insufficient extractable data. Additionally, 8 records were identified through citation searching (5 through backward and 3 through forward citation searching); after eligibility assessment, 7 were excluded and 1 study was included. Ultimately, 28 studies were included in the review [25-52].

Figure 1. Flowchart outlining the study selection process across databases and citation searching, following the PRISMA2020guidelines. RAG: retrieval-augmented generation.

Characteristics of Sources of Evidence

The 28 included studies were published between 2024 and 2026, of which 16 studies were conducted in China, 5 in Australia, 5 in the United States, 1 in Singapore, and 1 in Japan. The temporal and geographical distribution of the included studies is presented in Figure 2.

Regarding study design, 16 studies involved system development and comparative experimental evaluation, 5 were comparative evaluation studies, 3 used mixed methods designs, 2 were proof-of-concept technical evaluations, 1 was an experimental evaluation, and 1 was a prospective observational study. Therefore, most studies focused on system development or preliminary technical evaluation.

Only 4 studies were conducted in real-world clinical settings. The remaining studies primarily used retrospective datasets, predefined test questions, simulated clinical cases, or experimental evaluation datasets. Detailed study characteristics, including nursing relevance, are presented in Multimedia Appendix 2.

XSL•FO
RenderX

Figure 2. (A) Number of included studies by year of publication from 2024 to 2026. (B) Number of included studies by country in which the studies were conducted.

Synthesis of Results

Nursing Relevance and Application Scenarios

According to the primary purpose of each RAG system, the included studies were categorized into 4 application scenarios. Patient education was the most frequently investigated scenario, accounting for 9 studies, followed by nursing informatics (n=8), clinical decision support (n=7), and nursing education (n=4). The distribution of studies across application scenarios is presented in Figure 3.

Figure 3. Distribution of the included studies across retrieval-augmented generation (RAG) application scenarios in nursing (N=28). Studies were classified according to the primary purpose of each RAG system, with each study assigned to one category.

Patient Education

Patient education was the most frequently reported application scenario, involving 9 studies. These studies primarily explored the use of RAG-based systems to improve access to health information for patients and caregivers. The main applications included answering disease-related questions, providing perioperative guidance, supporting rehabilitation-related information needs, and assisting with chronic disease self-management. Applications were reported in several clinical areas, including breast cancer nursing, stroke care, gastrointestinal endoscopy, neurosurgical perioperative

XSL•FO
RenderX

education, and chronic disease management. Several studies developed conversational systems or virtual assistants that enabled patients or caregivers to interact with nursing-related knowledge resources through natural language queries.

Nursing Informatics

Nursing informatics represented another important application area, with 8 studies focusing on the management and use of nursing-related data. Unlike patient-facing applications, these studies mainly targeted the transformation of nursing information embedded in clinical records into structured and analyzable data.

The reported tasks included extracting symptoms and clinical concepts from nursing notes, identifying nursing diagnoses and interventions, standardizing nursing terminology, and supporting nursing documentation processing. Most systems were designed for nurses, nurse informaticians, or researchers involved in nursing data management.

Clinical Decision Support

Seven studies investigated RAG for nursing-related clinical decision support. These applications were developed for specific clinical scenarios requiring evidence retrieval and professional knowledge support, rather than for general information provision. Reported applications spanned delirium screening and management, emergency identification, emergency nursing triage, personalized perioperative decision support, dementia-related care, evidence-based nursing decision support, and nursing diagnosis and care recommendation generation. The primary users were nurses and health care professionals who required access to relevant clinical knowledge during decision-making processes.

Nursing Education

Four studies examined the application of RAG in nursing education. These studies primarily focused on educational scenarios, including nursing knowledge retrieval, examination preparation, evidence-based learning, and specialized nursing training. The developed systems were mainly used by nursing students and educators to support learning activities, particularly in situations requiring access to extensive nursing knowledge resources.

Technical Characteristics

The technical characteristics of each included study are summarized in Multimedia Appendices 2 and 3. The key architectural features are described below.

Base LLMs

The included studies exhibited diversity in LLM selection, spanning commercial closed-source models, open-source general-purpose models, domain-specific models, and Chinese-developed models. Commercial closed-source models were the most widely adopted category, represented primarily by the GPT family (GPT-4, GPT-4o, GPT-4o mini, and GPT-3.5). Open-source general-purpose models mainly included the LLaMA family and Mistral. Within the domain-specific category, Vithanage et al [32] used medically optimized variants, such as PMC LLaMA and Me-LLaMA, for information extraction from unstructured nursing records. In addition, OpenMEDLab 2.0 was used as a medical domain-specific model to support retrieval-augmented health education for patients with gastric cancer [51]. Several studies further adopted Chinese LLMs, including the ChatGLM series, Qwen2.5-Plus, Doubao, and DeepSeek models. The distribution of the base LLMs is presented in Figure 4. Because these characteristics are not necessarily mutually exclusive, the categories in Figure 4 represent descriptive groupings rather than strict taxonomic classes.

XSL•FO
RenderX

Figure 4. Hierarchical distribution of base large language models (LLMs) used in the included studies (N=28). The inner ring groups the base models into commercial models, Chinese-developed models, open-source models, and medical domain–specific LLMs, whereas the outer ring shows the corresponding model families.

Knowledge-Base Sources

The primary sources of knowledge bases used in RAG systems include literature databases, clinical practice guidelines, clinical data, nursing education and professional knowledge resources, institutional resources and patient education materials, and hybrid knowledge bases. Literature databases and guidelines were the most frequently reported knowledge sources; a total of 15 studies incorporated data from these sources. Nine studies used institutional resources and patient education materials; 9 studies incorporated nursing education and professional knowledge resources; and 8 studies used real-world clinical data. Most studies used hybrid knowledge bases, integrating multiple information sources—including literature, guidelines, clinical data, and online resources—to enhance the comprehensiveness and reliability of the retrieved content. The specific distribution is shown in Multimedia Appendix 2.

Retrieval and Enhancement Strategies

In the included studies, RAG systems generally enhance the accuracy and reliability of LLM responses by incorporating external knowledge retrieval mechanisms. In terms of retrieval strategies, dense retrieval and hybrid retrieval are the most common approaches. Among these, methods based on dense retrieval are the most common. Dense retrieval relies on vector embeddings; it uses deep learning models to map queries and documents to the same semantic space, thereby enabling information matching based on semantic similarity. This approach is effective at capturing latent relationships within complex medical contexts, but its performance depends on the quality of the embedding model and available computational

XSL•FO
RenderX

resources. Hybrid retrieval, on the other hand, combines sparse and dense retrieval methods to leverage the complementary strengths of keyword-based and semantic matching, thereby improving retrieval performance [53]. Regarding retrieval enhancement mechanisms, 4 studies incorporated knowledge graphs to use entity relationships and structured semantic information, thereby enhancing the logical consistency and professional accuracy of retrieval results. In addition, one study introduced a reranking mechanism after the initial retrieval to rescreen and reorder candidate documents, thereby improving the information relevance of the final input to the generative model. Differences among the studies exist in terms of embedding models, text chunking strategies, vector databases, top-k retrieval settings, prompt design, and knowledge-base validation methods; specific technical implementation characteristics are shown in Multimedia Appendix 3.

Completeness of Technical Reporting

There are significant differences across studies in the comprehensiveness of reports on the implementation elements of RAG's core technologies. Reports on prompt design are the most common, followed by text segmentation strategies and embedding models. In contrast, reports on vector databases, reranking methods, and knowledge-base update mechanisms are relatively scarce.

Only a few studies describe periodic or dynamic knowledge-base update mechanisms. Among studies reporting knowledge-base validation methods, the primary approaches include review by nurses or clinical experts, comparison with manually annotated reference standards, or verification against authoritative guidelines and original sources. The completeness of technical reporting across studies is shown in Figure 5.

Figure 5. Reporting completeness of key retrieval-augmented generation (RAG) implementation components across the included studies. The figure shows whether 9 key technical components were reported in each study: base large language model (LLM), embedding model, chunking strategy, vector database, retrieval top-k, prompt design, reranking method, update mechanism, and knowledge-base (KB) validation [25-52].

Evaluation Methods

Evaluation approaches varied according to the type and purpose of the RAG task. The evaluation domains were categorized as retrieval evaluation, generation and task-output evaluation, safety and reliability evaluation, and implementation and outcome evaluation. Individual studies could assess more than one domain.

Nursing informatics studies mainly used automated performance metrics to evaluate information extraction, summarization, and terminology standardization. Patient education studies commonly combined expert assessment of response quality with user-oriented evaluations and, in a small number of studies, patient-related outcomes. Clinical screening and decision-support studies focused on task performance, guideline concordance, output safety, and system responsiveness. Nursing education studies primarily assessed answering performance and the quality of educational content. To visually summarize the distribution of evaluation domains across task types and identify areas with limited evidence, an evidence gap map was constructed (Figure 6). Overall, generation and task-output evaluations were reported in 27 of the 28 studies, whereas retrieval performance was explicitly assessed in only 4 studies. Safety and reliability evaluations were reported in 9 studies, and implementation or outcome evaluation in 10 studies. Because of heterogeneity in tasks, evaluation methods, reference

XSL•FO
RenderX

standards, and outcome definitions, the findings were synthesized descriptively within each task category. Detailed evaluation domains and metrics are presented in Table 1.

Figure 6. Evidence gap map of evaluation domains across retrieval-augmented generation (RAG) task types. Bubble size represents the number of studies, and color intensity represents the proportion of studies within each task type. Studies could contribute to more than one evaluation domain.

Task-Specific Outcomes and Clinical Evidence

Most comparative studies reported at least one positive outcome for RAG configurations—either at the task level or in terms of content quality—but these advantages were not universal. Some studies found performance improvements only in specific subtasks, model configurations, or retrieval designs. These improvements may also reflect the combined effects of multiple factors, such as the base model, prompts, fine-tuning, knowledge sources, or interfaces. Only 4 studies were conducted in real-world clinical or service settings. Therefore, the existing evidence supports only cautious conclusions regarding specific tasks.

Discussion

Principal Findings

This scoping review provides a comprehensive overview of the research evidence on the application of RAG in the field of nursing. Overall, this field is developing rapidly, but the research remains primarily focused on technical feasibility and proof-of-concept evaluations. Existing research has primarily focused on patient education, followed by nursing informatics, clinical decision support, and nursing education. Among these application scenarios, dense retrieval is the predominant retrieval strategy; some studies have also explored hybrid retrieval, knowledge graph-enhanced retrieval, reranking, and other optimization methods [26,28,37,50]. Knowledge bases typically integrate clinical guidelines, research literature, institutional materials, educational resources, and clinical data. This review also found that the evaluation methods used vary depending on

XSL•FO
RenderX

the type of task. Nursing informatics research typically focuses on performance metrics for automated tasks [25,31], whereas patient-oriented and educational systems more frequently rely on expert evaluations and user-related outcomes [36,39]. Clinical decision support systems also focus on safety, guideline adherence, and the accuracy of clinical conclusions [30,44]. The existing evidence primarily focuses on generation quality or task performance, while evaluations of retrieval quality, safety, workflow integration, and clinical or patient outcomes are relatively limited.

Application Status and Key Characteristics of RAG in Nursing

Patient education is the most common application area in existing research. This distribution may be due to the fact that educational question-and-answer tasks are well-suited for the development of early-stage RAG systems, and it is also consistent with the widespread trend of exploring AI chatbots in health education, health behavior promotion, and self-management of chronic diseases [54,55]. Patient questions typically fall within a relatively well-defined scope of knowledge, and answers can be generated based on clinical guidelines, institutional guidelines, or curated educational resources. At the same time, the system's output can be evaluated using methods such as preset questions, expert scoring, readability metrics, and user satisfaction [56]. In contrast, clinical decision-making requires the integration of patient-specific information and professional judgment under conditions of uncertainty [57]. Patient education and self-management support are also consistent with established professional roles in nursing practice, including explaining treatment or procedural steps, reinforcing treatment plans, supporting caregivers, monitoring symptoms, and promoting patient adherence [58,59]. However, patient education is not limited to information delivery; it also involves emotional support, individualized communication, and adaptation to patient preferences and health literacy levels [60]. Nevertheless, many existing systems focus only on a single disease, a specific medical procedure, or a single institutional setting and are primarily evaluated using simulated cases or predefined problems [41]. As a result, the generalizability of their reported performance may be limited.

Nursing informatics is another important area of application, as unstructured nursing records and standardized nursing terminologies provide important data sources for information extraction, classification, terminology mapping, and other natural language processing tasks [61]. Such systems can facilitate the secondary use of nursing data and reduce the burden of manual information processing [62]. However, improved accuracy in information extraction does not necessarily translate into reduced documentation burden or improved workflow efficiency [63]. The practical impact of these systems still needs to be evaluated in real-world nursing workflows.

Clinical decision support applications primarily involve screening, information synthesis, guideline-based recommendations, and clinical reasoning support. Because incorrect or incomplete output may affect patient assessment, escalation procedures, or care planning, these applications pose greater potential safety risks. Therefore, their practical use requires clearly defining methods of human oversight in advance, transparently presenting sources of evidence, and establishing clear escalation procedures [64,65]. The body of evidence on RAG in nursing education remains limited, which may indicate that the field is still in the early stages of transitioning from the application of general-purpose LLMs to nursing-specific curricula and workflows. Among existing RAG studies in medicine and nursing, those focused on the nursing field account for a relatively small proportion, and even fewer are fully integrated into real-world workflows. Therefore, future research should focus on domain adaptation—including nursing knowledge and curriculum objectives—and involve stakeholders such as nursing faculty, students, clinical nurses, and administrators in the collaborative design, testing, and continuous iteration of these systems [66].

Technical Features and Development Trends in Nursing RAG Systems

When it comes to selecting foundational LLMs, commercial closed-source models (such as the GPT series) were the most frequently used among the included studies. Although these models generally provide strong language understanding and generation capabilities, their proprietary nature may limit local deployment, model customization, and direct control over model parameters, raising concerns about their use in privacy-sensitive health care settings [67,68]. In contrast, open-source general-purpose and medical domain–specific models may offer greater flexibility for local deployment, system customization, and task-specific adaptation, which may be particularly relevant in health care settings with stringent privacy and governance requirements [69]. They may also facilitate adaptation to specific nursing tasks and local clinical contexts. These considerations highlight the importance of developing and evaluating robust, secure, and transparent models that can be adapted to local clinical environments and privacy requirements [68].

The widespread adoption of hybrid knowledge bases may reflect the need for nursing RAG systems to integrate evidence from multiple sources to enhance the clinical relevance and evidence-based foundation of the generated content. However, our analysis found that many studies did not report data selection criteria or mechanisms for incorporating the latest evidence, leading to a reliance on static information that may quickly become outdated. This shortcoming may compromise the reliability and clinical use of RAG systems. Future reporting standards should specify the provenance of knowledge sources, frequency of updates, and procedures for validation. Furthermore, while dense retrieval is the dominant strategy, its performance heavily depends on the quality of the underlying embedding models and on computational resources, and it may miss global information [70]. A small number of studies have explored hybrid retrieval, knowledge graphs, and reranking mechanisms, indicating a growing awareness of the need to overcome the limitations of pure semantic matching, particularly in complex, multisource nursing contexts. However, most studies provide inadequate reporting on key implementation details—such as chunking strategies, vector databases, and

XSL•FO
RenderX

update cycles—which limit our ability to draw robust conclusions regarding optimal technical configurations.

Current Status of Evaluation Methods and the Lack of Clinical Evidence

This review indicates that existing studies focus on evaluating technical performance and content quality, frequently reporting metrics such as accuracy, precision, and completeness. While these metrics are necessary initial steps for validating system performance, relying solely on technical metrics is insufficient for assessing the clinical use, workflow adaptability, and the implementation value of RAG systems in real-world care settings [71]. It is worth noting that our findings are consistent with the observations reported in a recent review by Miao et al [20] on the scope of RAG in the fields of medicine and nursing. We found that implementation and outcome assessments—particularly regarding clinical workflows, nursing-sensitive outcomes, and improvements in patient health—are rarely conducted. By mapping these evaluation gaps across specific task types, our study reveals that while patient education studies are more likely to include measures of user satisfaction or acceptability, few studies assess actual changes in patient behavior or clinical outcomes. The positive results reported in most of the included studies stem primarily from controlled, retrospective, or simulated evaluations. This finding is not unique to the RAG study but reflects a broader challenge in the translation of AI technologies into clinical practice [72].

Application Challenges of RAG in Nursing

Although RAG has demonstrated considerable potential for application in the nursing field, a number of challenges remain in its promotion and implementation. (1) Although patient education is currently the most frequently studied application of RAG in nursing, research on nursing management, community nursing, and home care remains limited. Furthermore, existing research tends to focus on basic applications within a single setting or concerning a single condition and lacks in-depth exploration of complex clinical nursing scenarios. (2) The quality and standardization of knowledge bases are inadequate. Although most studies use guidelines, literature, and clinical data to construct their knowledge bases, some studies fail to specify data selection criteria and update mechanisms, which may compromise the accuracy and reliability of the system's outputs. Existing knowledge bases are predominantly based on static literature and guidelines, and they lack sufficient integration of the latest nursing research findings, updates to clinical nursing guidelines, and personalized clinical data, making it difficult to meet the dynamic and personalized needs of clinical nursing [33]. (3) Current research tends to focus on dense retrieval; while this approach can achieve semantic matching, issues such as missing information or insufficient relevance may still arise in complex nursing contexts or when integrating multiple information sources [69]. (4) Most studies focus primarily on system development or performance evaluation; they are preliminary exploratory studies that lack high-quality clinical research designs and are therefore unable to provide a comprehensive assessment of clinical efficacy and safety. (5) When using clinical data to build knowledge bases or train models, issues relating to patient privacy protection and data security risks arise [26]. At the same time, RAG systems may have a potential impact on clinical decision-making when generating inaccurate or misleading information, and the issue of liability in such cases remains to be clarified further [73].

Implications for Research and Clinical Implementation

Future research should focus on the following areas: (1) application scenarios should be expanded beyond patient education to include more complex nursing contexts, such as nursing management, community nursing, home care, and multidisciplinary clinical practice. Future systems should be designed based on specific nursing workflows and involve nurses, educators, patients, and other stakeholders throughout the development and evaluation process. (2) Standardized approaches for knowledge-base construction and maintenance are needed. Future studies should clearly report knowledge source selection criteria, validation procedures, updating mechanisms, and governance processes to improve the reliability, transparency, and reproducibility of nursing RAG systems. (3) Search strategies and system architecture should be optimized, and the deep integration of technologies such as knowledge graphs, reranking mechanisms, multimodal search, and agents with RAG should be explored. (4) Future research should move beyond technical performance evaluation and incorporate comprehensive assessments of usability, workflow integration, clinical effectiveness, safety, and nursing-sensitive outcomes. Well-designed prospective studies and real-world implementation studies are needed to determine whether RAG systems can provide meaningful benefits in nursing practice. (5) When clinical data are incorporated into RAG systems, future studies should prioritize privacy protection, ethical governance, and secure data management to ensure responsible implementation in health care settings.

Limitations

This study is subject to several limitations. First, as a scoping review, this study did not perform a formal methodological quality appraisal or risk-of-bias assessment, which may limit the robustness of the synthesized evidence. Second, the number of included studies was relatively small and concentrated within a narrow time frame (2024‑2026), reflecting the early developmental stage of RAG applications in nursing and limiting the generalizability of findings. Third, only English and Chinese publications were included, which may introduce language bias. The exclusion of unpublished and nonpeer-reviewed gray literature may have resulted in the omission of some emerging RAG systems and technical developments. Furthermore, substantial heterogeneity existed across included studies in terms of application scenarios, technical frameworks, and evaluation metrics, precluding quantitative synthesis. Importantly, most studies were conducted in experimental or simulated settings, with limited real-world clinical validation, thereby restricting the translation of findings into clinical practice.

Conclusions

The integration of RAG into nursing represents an emerging opportunity to enhance the acquisition, organization, and

XSL•FO
RenderX

application of nursing-related knowledge. By anchoring AI-generated responses to retrievable, evidence-based sources, RAG shows promise as an approach for improving access to and use of nursing-related knowledge. This capability holds particular significance for the nursing discipline, as nursing is a profession characterized by complex, context-dependent decision-making that requires both scientific rigor and humanistic sensitivity. However, the current evidence remains largely exploratory ; most studies have primarily focused on technical or simulated evaluations, and evidence from real-world nursing settings remains limited. Further prospective studies in real-world nursing workflows are needed to establish the clinical effectiveness, safety, and practical value of RAG. By clarifying the conclusions supported by current evidence and identifying future research priorities, this review provides a conceptual and methodological foundation for subsequent research and helps advance the integration of rapidly developing AI technologies with the evidence-based and patient-centered values emphasized in nursing.

Acknowledgments

The authors would like to thank all contributors for their support with literature collection and manuscript preparation. The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIdeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading, editing, and translation. The GenAI tool used was DeepSeek V4.1. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. The declaration was submitted by the corresponding author. DeepSeek V4.1 was used solely for language-related assistance. All methodological decisions, study selection, data extraction, synthesis, interpretation of findings, and conclusions were made by the authors.

Abstract

Background: Advances in the diagnosis and treatment of childhood cancer have substantially improved survival, resulting in a growing population of survivors of childhood cancer who may experience long-term treatment-related sequelae. Cognitive late effects are an important long-term consequence of childhood cancer and can affect cognitive functioning, psychosocial well-being, and quality of life. Digital health interventions offer accessible and flexible approaches to managing cognitive difficulties among children with cancer. However, the existing evidence has not yet been comprehensively synthesized.

Objective: This study aimed to map and synthesize the existing evidence on digital health interventions for cognitive management among children with cancer; characterize intervention modalities, delivery approaches, and functional components; and identify evidence gaps and priorities for future research.

Methods: This scoping review was conducted in accordance with the Arksey and O'Malley framework and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist. Six academic databases, including PubMed, Embase (Ovid), CINAHL, PsycINFO, Web of Science, and the Cochrane Library, were systematically searched for relevant studies published between January 2010 and August 2026. Eligibility criteria were developed using the population-concept-context framework. Two reviewers independently performed study screening and data extraction. The methodological quality of included studies was assessed using the Mixed Methods Appraisal Tool. Screening was performed independently at the title/abstract and full-text stages, with disagreements resolved through discussion and, when necessary, consultation with a third reviewer. Descriptive statistics and thematic content analysis were used to synthesize the findings.

Results: A total of 5371 records were identified through the literature search. Following screening, 19 publications representing 14 independent study samples and involving 566 children with cancer were included. Four digital health modalities were identified: computer-based interventions, internet-based interventions, mobile apps, and neurofeedback training. Computer-based interventions were the predominant modality. Across these modalities, working memory and attention were the most frequently targeted cognitive domains, while feasibility, acceptability, and adherence were the most commonly assessed implementation-related outcomes. However, relatively few interventions incorporated coach support, telephone-based communication, or educational components, and none evaluated economic outcomes.

Conclusions: Although digital health interventions show promise for supporting cognitive function in children with cancer, substantial gaps remain in the current evidence. This scoping review mapped the field according to intervention modalities, delivery approaches, and functional components, rather than focusing solely on the efficacy of individual technologies. Future research should prioritize the development of multidimensional, personalized, and functionally integrated digital health interventions that combine cognitive training with supportive care, education, monitoring, and communication. Multicenter randomized controlled trials should subsequently evaluate these interventions using clinically meaningful outcomes, with comprehensive assessments of safety, adherence, implementation, and health economic outcomes to establish their effectiveness, feasibility, and sustainability.

KEYWORDS

pediatric cancer; cognitive late effects; cognitive management; digital health; scoping review

Introduction

Childhood cancer remains a major global pediatric health challenge, with recent estimates indicating that approximately 377,000 children are newly diagnosed worldwide each year [1]. Advances in diagnostic approaches, risk-adapted multimodal therapy, and supportive care have substantially improved survival outcomes, particularly in high-income countries where 5-year survival rates now exceed 80% [2]. This progress has led to a rapidly expanding population of survivors of childhood cancer and has shifted clinical and research priorities from survival alone toward the identification, prevention, and management of long-term treatment-related sequelae [3]. Among these survivorship concerns, cognitive late effects are some of the most clinically significant and functionally disabling outcomes [4]. Evidence suggests that approximately 40% to 60% of survivors of childhood cancer experience cognitive late effects, with impairments most commonly observed in attention, executive function, processing speed, and other higher-order cognitive domains [5-7]. These difficulties may emerge during treatment, progress over time, or become more apparent as survivors encounter increasing academic and social demands. Persisting into adolescence and adulthood, neurocognitive impairments can adversely affect educational achievement, employment opportunities, psychological well-being, and social participation [8,9]. Accordingly, cognitive late effects represent not only a major survivorship concern for survivors of childhood cancer and their families but also an important public health issue with long-term implications for health care systems and society [10-12].

The management of cognitive late effects in survivors of childhood cancer remains a substantial challenge in clinical practice [13,14]. Cognitive management can be conceptualized as a comprehensive approach involving cognitive training, cognitive rehabilitation, cognitive monitoring, and supportive strategies aimed at improving or maintaining cognitive function [15,16]. Previous studies have shown that pharmacological treatments, physical exercise, and cognitive training may contribute to improvements in cognitive outcomes [17,18]. However, the effectiveness, accessibility, and adherence of these interventions are often constrained by medication-related adverse effects, developmental considerations, age-specific feasibility, and the need for sustained engagement. These challenges are further amplified in resource-limited settings and during intervals between routine clinical follow-up visits, highlighting the need for accessible, scalable, and continuous approaches to cognitive management [2,15,16,19]. In addition, insufficient awareness of cognitive late effects among patients and their caregivers may further reduce participation, engagement, and long-term adherence to intervention strategies [20,21]. Therefore, there is an urgent need to develop scientifically sound and effective approaches for the management of cognitive symptoms among children and adolescents with cancer [17,22].

Digital health refers to the use of digital technologies to support health care delivery, health management, and rehabilitation, including eHealth, mobile health, and other technology-enabled interventions [23]. Given its accessibility, flexibility, and potential for remote delivery, digital health offers a promising approach to the management of cognitive late effects among children with cancer by facilitating cognitive training, neurocognitive monitoring, education, and supportive care [24-26]. Accordingly, digital health interventions have been increasingly explored to support cognitive management in this population [27]. However, previous studies and reviews have primarily focused on the effectiveness and feasibility of specific digital health modalities, such as computerized cognitive training, for improving cognitive outcomes among children with cancer [27,28]. Consequently, the broader landscape of digital health interventions for cognitive management remains insufficiently characterized, particularly with respect to intervention modalities, delivery approaches, and core functional components. A broader mapping of the existing evidence is therefore needed to better understand how digital health interventions have been applied for cognitive management among children with cancer.

Therefore, this scoping review aimed to map and synthesize the existing evidence on digital health interventions for the management of cognitive late effects among children with cancer, to characterize intervention modalities, delivery approaches, and functional components, and to identify research gaps and priorities for future development. The findings may provide evidence-based insights for optimizing digital health interventions and supporting their clinical translation.

Methods

Protocol and Registration

The protocol for this study was registered on the Open Science Framework [29], and the literature search was conducted on August 31, 2026. This scoping review was conducted in accordance with the 5-stage methodological framework proposed by Arksey and O'Malley [30], with the aim of systematically mapping the research landscape of digital health interventions for cognitive management among children with cancer. We specifically included studies that used digital health interventions for cognitive management among children with cancer and examined intervention characteristics, including delivery modalities, functional components, implementation features, and reported outcomes. The reporting of this review was guided by the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews; Checklist 1) to ensure methodological rigor and transparency [31].

Eligibility Criteria

We used the population-concept-context (PCC) framework instead of the population intervention comparison outcome framework because our research question does not aim to assess

XSL•FO
RenderX

a specific outcome or comparison intervention. For this purpose, the PCC framework is recommended by the *JBI Manual for Evidence Synthesis* [32]. In this review, the population comprised children with cancer, and the concept was the use of digital health interventions for cognitive management. Digital health refers to the use of digital technologies to support health care delivery, disease management, health promotion, and health-related outcomes, including mobile health, web-based platforms, computer-assisted programs, and other digital devices. The context was pediatric oncology care and was not operationalized as a separate search category because it was inherently encompassed by the population with childhood cancer.

Included studies were required to fulfill the following criteria.

1. Population: Studies involving individuals diagnosed with cancer before 18 years of age were eligible, without restrictions on sex.
2. Concept: Studies were included if they evaluated digital health approaches for cognitive management in children with pediatric cancer. In this review, digital health-based cognitive management was defined as interventions delivered through mobile devices or related platforms aimed at improving cognitive function or related clinical outcomes. Eligible interventions included those assessing outcomes such as cognitive effectiveness, acceptability, usability, feasibility, cost, or adherence.
3. Context: Studies conducted in any health care or community setting were eligible, and no restrictions were applied regarding the intervention setting.

Eligible study designs were required to include quantitative research. Studies were excluded if they were published study protocols, reviews, editorials, conference proceedings, books, or non-English publications. Studies in which mobile technology was used solely for outcome data collection without providing tailored feedback or counseling based on the collected data were excluded. For interventions involving digital components accessible through apps as well as computers or other devices, studies were included only when participants' use of digital devices was explicitly reported; otherwise, they were excluded. Studies without accessible full texts were also excluded.

Information Sources

A systematic search was conducted across multiple electronic databases, including PubMed, Embase (Ovid), CINAHL, PsycINFO, Web of Science, and Cochrane Library, to identify studies published between January 2010 and August 2026. The reference lists of all eligible studies were examined to identify any potentially relevant studies.

Search

We developed and refined the search strategy iteratively, adapting it as necessary for different databases (see Multimedia Appendix 1 for the full strategy). The PCC framework and corresponding search components used in this study are presented in Table 1.

Selection of Sources of Evidence

Study selection was independently conducted by 2 reviewers (TL and MT), who screened titles, abstracts, and full texts according to the predefined eligibility criteria. Disagreements were resolved through discussion, and a third reviewer (LM) was consulted when consensus could not be reached.

Data Charting and Synthesis of Results

Data were extracted and charted using Microsoft Excel. Extracted data included publication year, study design, participant characteristics, cancer types, digital health modalities, intervention characteristics, and reported outcomes. Data related to intervention functions, cognitive management strategies, and implementation features were also extracted.

Data synthesis was conducted through an iterative process of summarization, coding, and comparison. Descriptive analysis was used to summarize the characteristics of included studies. A thematic content analysis approach was applied to synthesize the functional components and key characteristics of digital health cognitive management interventions [33]. Following established principles of qualitative content analysis [34], extracted data related to intervention functions, cognitive management strategies, and implementation features were systematically coded and categorized. Similar codes were grouped into broader categories, and key themes were generated through iterative comparison across studies.

Critical Appraisal of Individual Sources of Evidence

The methodological quality of the included studies was assessed using the 2018 version of the Mixed Methods Appraisal Tool by the same 2 reviewers (TL and MT). Any disagreements during the appraisal process were resolved through discussion until consensus was achieved.

Results

Basic Characteristics of the Included Studies

A total of 5371 records were identified through database searches. After removing duplicates and other ineligible sources, 2495 titles and abstracts were screened for eligibility, and 279 full-text articles were subsequently assessed. Ultimately, 19 publications [24,35-52] representing 14 independent study samples were included in this review (Figure 1). No additional

XSL•FO
RenderX

eligible studies were identified through backward citation searching. No new studies were identified from the updated search.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) study screening flowchart.

Several included publications represented multiple reports from the same underlying studies. Specifically, 5 publications [24,35-38] originated from the same randomized controlled trial (RCT) involving 68 survivors of childhood cancer but reported different aspects of the intervention, including efficacy, feasibility, coaching conditions, transfer effects, and caregiver perspectives. Additionally, 2 publications [39,40] were derived from the same Nintendo Wii intervention study involving 13 participants but focused on different outcomes. These publications were retained as separate reports because they addressed distinct research questions; however, they were considered as a single independent sample when summarizing study characteristics and calculating the overall sample size. The sample size reported by Scott et al [38] was not counted separately because this study focused on caregiver perspectives rather than providing an independent patient sample. After accounting for overlapping samples, the 19 publications represented 14 independent study samples involving 566 children with cancer.

Among the 19 included publications, RCTs were the predominant study design (n=14), including one randomized crossover controlled trial. Two studies used quasi-experimental designs, while one study adopted a quantitative descriptive design, one used a pilot before-and-after design, and one applied a mixed methods design.

From a temporal perspective, the included studies were primarily published between 2010 and 2022 (Figure 2). In terms of geographical distribution, the included studies were predominantly conducted in North America and Europe. The majority originated from the United States (13/19) [24, 35-38, 42-44, 46-49, 52], followed by Sweden (2/19) [39, 40], with one study each from Canada [45], the Netherlands [50], Switzerland [41], and Estonia [51]. Overall, the evidence base is concentrated in North America and Europe, with limited representation from other world regions.

XSL•FO
RenderX

Figure 2. Temporal distribution of the included studies by publication year and digital health intervention type [24, 35–52].

In terms of delivery modes, digital health interventions were predominantly implemented through computer-based cognitive training programs, with other approaches including internet-based physical activity, mobile apps, and electroencephalography (EEG)-based neurofeedback. Among these, computerized cognitive training systems (eg, Cogmed, provided by Pearson) represented the most commonly used intervention, accounting for a substantial proportion of the included studies (11/19) [24,35-38,41-46]. These interventions were typically delivered via computers or tablets, often combined with remote guidance or home-based training. In addition to Cogmed, other software-based interventions were also identified, including programs such as Fast ForWord (Scientific Learning Corporation) [47], Captain's Log (BrainTrain, Inc) [48], and Lumosity (Lumos Labs, Inc) [49], which similarly rely on computers or mobile devices to deliver cognitive training content. Moreover, one study [50] used neurofeedback interventions, which use computer interfaces to provide real-time feedback on brain activity to facilitate cognitive regulation.

A subset of studies has begun to explore game-based and gamified intervention approaches, such as Nintendo Wii/Wii-Fit exergaming [39,40] and newly developed digital health gaming applications (eg, Triumf) [51]. These approaches integrate physical activity or entertainment elements into the intervention to enhance engagement and adherence among children. Additionally, one study [52] used web-based platforms or interactive websites to deliver interventions, thereby expanding the application scenarios of digital health.

Regarding implementation-related outcomes, most studies focused on cognitive-related outcomes, including working memory, attention, executive function, processing speed, and intelligence. Some studies additionally examined academic achievement [36,42,45,47] and serum brain-derived neurotrophic factor (BDNF) levels [49]. In addition, most studies evaluated the feasibility of the interventions [35,42-49,51], acceptability [35,36,42,44,48,51], and adherence [35,36,43,45], while only a limited number of studies assessed adverse events as an outcome measure [43,46]. Economic outcomes were not reported in the included studies.

The results of the quality assessment showed that most studies were of good quality. Specific details of the quality assessment can be found in Multimedia Appendix 2. Table 2 provides an overview of the key characteristics of the included studies.

Digital Health Intervention Program for Cognitive Management

Most included studies (14/19) used computer-based digital health interventions for cognitive management among children with cancer, with Cogmed being the most frequently used platform (11/19). Other delivery modalities included internet-based physical activity interventions, mobile app-based interventions, and EEG-based neurofeedback training. Regarding target cognitive domains, existing interventions predominantly focused on specific cognitive functions, with working memory and attention being the most frequently targeted domains. All digital health intervention models included cognitive training components aimed at improving cognitive function, whereas only a limited number of studies integrated additional supportive functions, such as coaching support, activity monitoring, educational materials, and screening functions. The details can be found in Table 3. Figure 3 presents the evidence gap map of cognitive management across different digital health intervention modalities among children with cancer.

XSL•FO
RenderX

Table . Content of digital health intervention measures.

Classification of digital health	Delivery modality	Number of included studies (n)	Target cognitive domain	Function and intervention contents
Cogmed	Computer-based cognitive training	11	Working memory	Coach-supported and adaptive difficulty working memory training
Captain's Log	Computer-based cognitive training	1	Attention and basic problem-solving/reasoning skills	Cognitive training and telephone communication
Lumosity	Computer-based cognitive training	1	Memory and attention	Cognitive training
Fast ForWord	Computer-based reading training	1	Reading decoding ability	Cognitive training
Nintendo Wii	Internet-based physical activity	2	Executive function and attention	Activity monitoring, coaching support, and active video gaming to promote cognitive and motor function
Interactive website	Internet-based physical activity	1	Intelligence and cognitive flexibility	Activity monitoring, online cognitively engaging physical training, and educational materials
Triumf	Mobile app	1	Attention	Gamified cognitive training, supportive functions, educational functions, and screening functions
Neurofeedback	EEG[a]-based neurofeedback training	1	Cognitive function	Enhancement of cognitive function through EEG-based self-regulation of brain activity

Discussion

Principal Finding

This review synthesized evidence from 19 publications representing 14 independent study samples published between 2011 and 2022 and characterized the intervention modalities, functional components, implementation features, and research gaps of digital health interventions for cognitive management in populations with pediatric cancer [24,34-52]. Our findings highlight substantial heterogeneity in intervention design, participant characteristics, and outcome measures across studies examining digital health interventions for cognitive management among children with cancer. The findings indicate that most of

XSL•FO
RenderX

the included studies (11/19) reported implementation-related outcomes [35,36,42-49,51], such as feasibility, acceptability, and adherence, providing preliminary evidence regarding the implementation potential of digital health interventions for cognitive management among children with cancer. However, the evidence base remains limited and requires further development.

Current Landscape of Digital Health Interventions for Cognitive Management

In recent years, digital health technologies have rapidly advanced in the field of cognitive management, particularly among populations such as older adults with mild cognitive impairment, where diverse application models have been developed. Previous studies have demonstrated that digital health interventions have expanded beyond traditional computerized cognitive training to encompass a variety of approaches, including computerized cognitive training, physical activity-based interventions, serious games, and remote monitoring technologies, reflecting increasing diversity in intervention design [53,54]. In contrast, the application of digital health interventions for cognitive management among children with cancer remains at an early stage of development. The findings of this review indicate that digital health interventions in this population remain relatively limited, with most studies focusing on computer-based cognitive training and remotely delivered intervention models. Among these, programs for adaptive working memory training, such as Cogmed, were the most frequently adopted intervention approaches. This finding is consistent with previous literature, indicating that digital cognitive interventions for children with cancer have predominantly focused on single-domain computerized or application-based cognitive training approaches [28,43]. Furthermore, evidence from both the included studies and previous research suggests that outcome assessments in digital health-based cognitive interventions remain relatively narrow [28,46], primarily focusing on changes in specific cognitive domains, particularly working memory. The observed intervention benefits have mainly been limited to near-transfer effects, referring to improvements in trained tasks or closely related cognitive abilities, whereas evidence regarding far-transfer effects, such as improvements in academic performance and daily functioning, remains inconsistent [55,56]. Several factors may contribute to these limitations. First, cognitive impairment in children with cancer is multidimensional, involving multiple cognitive domains, including executive function, memory, attention, and processing speed. Therefore, interventions targeting a single cognitive domain may improve specific cognitive skills but may be insufficient to address broader cognitive and functional difficulties [17,57]. Second, children with cancer represent a heterogeneous population, with variations in developmental stage, cognitive abilities, cancer type, and treatment history. Such heterogeneity may contribute to differences in cognitive impairment patterns and intervention responses, thereby increasing the complexity of evaluating intervention effects [15]. In addition, limited far-transfer effects may be related to the mismatch between current digital health intervention targets and the broader functional needs of children with cancer. Most existing interventions primarily focus on improving specific cognitive abilities, such as working memory; however, whether cognitive improvements achieved through training can translate into benefits in broader functional domains, including academic performance, daily functioning, and social adaptation, remains influenced by multiple factors [17,58].

This review further explored the functional characteristics of digital health interventions for cognitive management among children with cancer. The findings indicated that existing interventions remain primarily focused on cognitive training, whereas the integration of additional functions, including educational support, behavioral management, psychosocial support, and family engagement, remains limited. In contrast, digital health applications in chronic disease management and mental health fields have increasingly adopted multifunctional intervention models by integrating components such as health education, symptom monitoring, behavioral interventions, emotional support, and family involvement to establish more comprehensive support systems [59,60]. Such integrated designs have demonstrated potential for enhancing user engagement and promoting long-term adherence [61,62]. The limited functional integration observed in pediatric cancer cognitive management may reflect the early developmental stage of this field. Most existing interventions have been adapted from established cognitive training platforms, and their functional scope therefore remains largely restricted to cognitive improvement. However, children with cancer often have broader supportive needs related to disease knowledge, emotional adjustment, social adaptation, and self-management [63,64]. Therefore, relying solely on isolated cognitive training may not adequately address their comprehensive needs [65,66].

Future digital health interventions for cognitive management among children with cancer should move beyond single-domain cognitive training toward integrated, multidimensional intervention strategies. From a functional design perspective, future systems should incorporate multiple cognitive domains, including attention, working memory, executive function, and processing speed, while integrating additional components such as health education, behavioral support, psychosocial interventions, and symptom management to address the multidimensional needs associated with cancer-related cognitive impairment and disease management [65,66]. Considering variations in children's age, cognitive development, and disease status, modular and adaptive designs may be adopted to dynamically tailor intervention content and difficulty according to individual characteristics [15]. For younger children, greater emphasis may be placed on gamified designs and caregiver-assisted functions, whereas older children and adolescents may benefit from enhanced disease education, self-management support, and psychosocial functions. In addition, greater involvement of caregivers and health care professionals through training assistance, symptom feedback, professional guidance, and remote monitoring may improve intervention acceptability and long-term adherence [65,67]. Furthermore, digital health interventions should be integrated into pediatric oncology care pathways, allowing initiation during hospitalization and continued implementation in home settings. Future studies should use large-scale, multicenter RCTs with

XSL•FO
RenderX

age-stratified designs and long-term follow-up to further evaluate the effects of multidomain digital health interventions on core cognitive outcomes as well as far-transfer outcomes, including academic performance, daily functioning, and quality of life, thereby facilitating clinical translation [65,68].

Evidence Gaps and Future Research Priorities

Among the included studies, only a few reported adverse events as safety outcomes [43,46], suggesting that safety monitoring of digital health interventions for cognitive management among children with cancer remains insufficient. Therefore, future research should incorporate safety assessment as a core outcome measure and establish standardized reporting guidelines for adverse events to improve the quality of evidence and support clinical translation. Beyond safety considerations, broader implementation-related evidence, including economic feasibility, is also essential for translating digital health interventions into routine clinical practice [68]. However, no studies included in this review evaluated the economic aspects of digital health-based cognitive management among children with cancer. Future research should incorporate health economic evaluations to assess the feasibility, sustainability, and scalability of these interventions, thereby informing policy development and clinical decision-making. Finally, most of the included studies were RCTs focusing primarily on intervention efficacy, whereas qualitative studies and process evaluations were relatively limited. This restricts a deeper understanding of adherence, user experience, and implementation barriers. Previous research has also suggested that the long-term effects of cognitive training may be influenced by adherence and contextual factors. Therefore, in addition to conducting high-quality RCTs, future studies should incorporate qualitative or mixed methods designs and strengthen evaluations of acceptability, feasibility, and implementation processes to optimize intervention design and facilitate clinical translation.

Strengths and Limitations

This study has several strengths. First, it specifically focused on the population with pediatric cancer and synthesized evidence from diverse study designs, providing a comprehensive overview of digital health interventions for cognitive management in children with cancer. The findings characterize intervention modalities, delivery approaches, and functional components of existing digital health interventions and provide valuable insights for future intervention development. This review also highlights current evidence gaps and emerging research priorities, including the need for optimized functional module design, improved user experience, and integration of clinically relevant outcomes and assessment tools. These findings may support researchers and clinicians in advancing the development and implementation of digital health interventions in pediatric oncology.

There are also some limitations. First, the broad scope and complexity of the search strategy may have led to the omission of relevant studies, despite adherence to the PRISMA-ScR guidelines to enhance rigor and transparency. Second, the heterogeneity of cognitive outcome measures, including the combination of subjective and objective assessments, limited data synthesis and reduced comparability across studies. Third, the heterogeneity in participant age ranges across the included studies is another limitation. Some studies included participants older than 18 years, while age-disaggregated data were not consistently available. Therefore, findings from mixed-age samples should be interpreted cautiously when applied specifically to children and adolescents. Fourth, only English-language publications were included, and most studies were conducted in North America and Europe, which may limit the generalizability of the findings to other regions. Therefore, future research should expand search strategies and database coverage, include studies published in other languages, and incorporate more diverse populations across different continents to improve the comprehensiveness and global applicability of the evidence base.

Conclusion

This scoping review synthesized the existing evidence on digital health interventions for cognitive management among children with cancer. The findings indicate that this field remains in an early stage of development, with current interventions primarily focusing on cognitive training delivered through computer-based programs and other digital platforms. Although these interventions show potential for supporting cognitive function, most approaches remain centered on single-domain training, with limited integration of supportive components and relatively narrow outcome assessments. Future research should prioritize the development of multidimensional, personalized, and integrated digital health interventions that incorporate cognitive training, supportive functions, and clinically relevant outcomes. High-quality multicenter RCTs, together with safety monitoring, health economic evaluations, and qualitative or mixed-methods studies, are needed to strengthen the evidence base and facilitate clinical implementation.

Abstract

Background: Mobility recovery after critical illness is a complex and multidimensional process. Digital health technologies have emerged as approaches for delivering rehabilitation, monitoring recovery, and facilitating self-management among intensive care unit (ICU) survivors. However, the extent to which current digital health approaches address the multidimensional nature of mobility recovery remains unclear.

Objective: This scoping review aimed to map the current evidence on digital health approaches supporting mobility recovery among ICU survivors and to examine the mobility domains, outcomes, feasibility, and acceptability associated with these approaches.

Methods: A scoping review was conducted following the Arksey and O'Malley framework and was reported according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews (PRISMA-ScR). PubMed, Embase, CINAHL, Web of Science, and the Cochrane Library were searched for studies published from January 2016 to September 21, 2026. Studies involving adult ICU survivors that used digital health approaches to assess, monitor, support, or promote mobility recovery were included. Mobility outcomes were mapped to the International Classification of Functioning, Disability and Health domains of body functions and structures, activities, and participation. Clinical outcomes were synthesized separately from implementation and user experience outcomes.

Results: Twenty-seven reports representing 24 unique parent studies were included. Digital health approaches comprised telemedicine, telerehabilitation, mobile health, wearable monitoring, virtual reality, robot-assisted rehabilitation, and digital recovery platforms. Telemedicine and telerehabilitation were the most frequently reported approaches, and exercise-based rehabilitation was the predominant intervention component. Mobility outcomes were heterogeneous and concentrated on body functions and structures and activity-level performance, particularly muscle strength, exercise capacity, and functional performance, whereas participation outcomes were less frequently represented. Controlled and comparative studies showed mixed between-group findings, with clinical benefits not consistently demonstrated across primary or mobility-related outcomes. In contrast, feasibility, adherence, usability, and acceptability were generally favorable when assessed, although technical difficulties and incomplete device-generated data were reported in some studies.

Conclusions: Digital health technologies offer diverse approaches to supporting mobility recovery after critical illness, but current evidence remains concentrated on physical function and activity-level outcomes, with limited attention to participation and long-term recovery. More rigorous and longitudinal studies using standardized, multidimensional mobility outcomes are needed to clarify clinical effectiveness and support sustainable implementation.

Introduction

Critical care has entered a survivorship era. Improvements in intensive care unit (ICU) survival have resulted in a growing population of ICU survivors experiencing post–intensive care syndrome, including physical, cognitive, psychological, and social impairments [1-3]. Among these domains, mobility is clinically central, as it determines whether survivors can safely transfer, walk indoors and outdoors, climb stairs, engage in rehabilitation activities, return to work or caregiving roles, and re-engage in meaningful daily activities [4,5]. Longitudinal studies among survivors of acute respiratory distress syndrome, sepsis, and other critical illnesses have consistently demonstrated persistent physical disability, reduced walking capacity, dependence in activities of daily living (ADLs), frailty, and poorer quality of life [6-8].

Mobility in ICU survivorship extends beyond ambulation and encompasses multiple dimensions of functioning [9-13]. The World Health Organization's International Classification of Functioning, Disability and Health (ICF) provides a standardized framework for describing functioning across body functions and structures, activities, and participation, while recognizing the influence of contextual factors [14]. Accordingly, mobility recovery after critical illness can be examined across these complementary domains. ICU survivor studies have used diverse measures, including the 6-minute walk test (6MWT), functional status score for the ICU [9], de Morton Mobility Index [15], short physical performance battery [16], Barthel Index [17] or Katz ADL [18], frailty instruments [19], handgrip or knee-extension dynamometry, ultrasound muscle thickness [20], 36-Item Short Form Health Survey (SF-36) [21], and qualitative accounts of meaningful activity.

Despite this multidimensional conceptualization, it remains unclear whether existing digital health technologies address mobility recovery across the ICF domains or continue to focus predominantly on physical capacity and performance. Identifying which domains are represented in current digital health research is, therefore, important for revealing evidence gaps and informing more comprehensive, person-centered rehabilitation strategies for ICU survivors.

Clinic-based assessments provide standardized snapshots, but they may not fully capture fluctuations in mobility and participation in everyday settings. Many ICU survivors experience fatigue, dyspnea, weakness, mood symptoms, transportation barriers, and fragmented services after discharge [22-24]. A survivor may perform adequately on a 6MWT in clinic yet remain sedentary at home; another may accumulate daily steps but continue to avoid stairs, community mobility, or social participation. These limitations highlight the need for approaches that can support and monitor recovery continuously in real-world settings.

Digital health technologies offer an opportunity. By leveraging smartphones, wearable devices, tele–video sessions, app-based exercise programs, virtual reality (VR), and structured digital follow-up pathways [25-29], these interventions can deliver remote rehabilitation, individualized exercise guidance, real-time feedback, motivational support, and structured progression [25,27,30-34]. However, the existing evidence remains fragmented, with many studies being small-scale, feasibility-oriented, and primarily focused on short-term physical outcomes.

A clear synthesis is therefore needed to determine which digital health technologies have been applied to mobility recovery among ICU survivors and which dimensions of functioning they address. Accordingly, this scoping review focuses on adult ICU survivors, encompasses digital health modalities across the post-ICU recovery trajectory, maps mobility outcomes to the ICF domains of body functions and structures, activities, and participation, and separately examines clinical outcomes, implementation feasibility, and user experience.

Methods

Study Design

This scoping review was conducted in accordance with the methodological framework proposed by Arksey and O'Malley [35], following their 5-stage approach. The review was reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [36]. The completed PRISMA-ScR checklist is provided in Checklist 1. The study protocol and analysis plan were prospectively registered on the Open Science Framework [37].

Formulating the Research Question

This scoping review aimed to systematically map the current evidence on digital health technologies to support mobility recovery among ICU survivors. The review addressed the following research questions: (1) What digital health technologies have been applied to support mobility recovery among ICU survivors? (2) Which dimensions of mobility are targeted by these digital health technologies? (3) What evidence exists regarding mobility-related outcomes, implementation experiences, and user perspectives associated with these digital health technologies?

Eligibility Criteria

The eligibility criteria were developed according to the PCC (population, concept, and context) framework [38].

Inclusion Criteria

The inclusion criteria for the study are as follows:

1. Population: adults aged 18 years or older who survived critical illness following an ICU admission.
2. Concept: studies describing, evaluating, or implementing digital health technologies, programs, services, platforms, or interventions designed to support, assess, monitor, or promote mobility recovery after critical illness. Mobility was operationalized according to the ICF framework as outcomes related to body functions and structures, activities, and participation. Self-management and related behavioral or educational components were considered intervention or implementation characteristics rather than mobility domains.

XSL•FO
RenderX

3. Context: studies conducted across the ICU recovery trajectory, including transitions from hospital to home, outpatient follow-up, and community-based rehabilitation settings.

Exclusion Criteria

Studies were excluded if the digital health technology was not relevant to mobility or functional recovery, if neither mobility-related nor relevant implementation or user experience outcomes were reported, or if the study did not include an identifiable group of adult ICU survivors. Nonempirical publications, including reviews, editorials, commentaries, conceptual papers, and study protocols, were also excluded. The full eligibility criteria are presented in Table 1.

Table . Eligibility criteria based on the population-concept-context framework.

Domain	Inclusion	Exclusion
Population	Adults (≥18 y) who survived critical illness following an ICU[a] admission, including individuals transitioning from the ICU to hospital wards and those undergoing postdischarge recovery; studies of mixed populations were eligible if adult ICU survivors could be identified within the study population	Pediatric or neonatal populations; studies that did not include an identifiable group of adult ICU survivors
Concept	Digital health technologies, programs, services, platforms, or interventions that explicitly supported, assessed, monitored, or promoted mobility-related recovery or physical rehabilitation in populations including adult ICU survivors; eligible technologies included mobile apps, websites, wearable devices, telephones, video consultations, virtual reality, digital recovery platforms, and other digitally enabled approaches	Digital technologies used solely for assessment or monitoring without a clear relevance to mobility recovery; interventions delivered exclusively during ICU admission; nondigital rehabilitation technologies
Context	Any setting across the ICU recovery trajectory, including hospital wards, outpatient clinics, home-based settings, and community rehabilitation following ICU discharge	Settings unrelated to recovery after critical illness; pediatric or neonatal ICUs
Outcomes	Mobility-related outcomes included body functions and structures, activities, and participation; implementation and user experience outcomes included feasibility, adherence, usability, acceptability, satisfaction, self-management support, self-efficacy, engagement, and perceived barriers or facilitators	Studies reporting neither mobility-related outcomes nor relevant implementation or user experience outcomes; studies reporting only mortality or unrelated outcomes
Study design	All primary empirical study designs, including randomized controlled trials, nonrandomized studies, feasibility and pilot studies, observational studies, mixed methods studies, qualitative studies, case reports, and empirical innovation reports	Study protocols, reviews, editorials, conference abstracts, commentaries, conceptual papers, and other nonempirical publications
Publication	Peer-reviewed full-text papers published in English from January 2016 onward	Publications before January 2016, non-English publications, or papers without full-text availability

[a]ICU: intensive care unit.

Search Strategy

Information Sources, Search Dates, and Limits

We systematically searched PubMed, Embase, CINAHL, Web of Science, and the Cochrane Library for records published from January 1, 2016, through June 2026. To capture newly published studies, the searches were updated in all 5 databases on September 21, 2026, which was the final search date. No language, study design, or publication-type filters were applied during the database searches; all eligibility restrictions were applied during study selection.

Search Terms and Search Combinations

The search strategy was developed in consultation with a medical librarian and informed by the population, concept, and context framework. Controlled vocabulary and free-text terms were used to represent three concepts: (1) ICU survivors and critical illness, (2) digital health technologies, and (3) mobility-related recovery. Synonymous terms within each concept were combined using OR, and the 3 concept blocks were combined using AND. The NOT operator was not used. Quotation marks were used for multiword phrases, and truncation symbols were applied where supported by the database.

XSL•FO
RenderX

The complete database-specific search strategies, including controlled vocabulary, keywords, field tags, Boolean operators, phrase searching, truncation, date limits, final search dates, and numbers of records retrieved, are provided in Multimedia Appendix 1.

Study Selection

All retrieved records were imported into EndNote for the removal of duplicates. Records identified through the updated searches were added to the same reference library and deduplicated against records retrieved previously. Two reviewers independently screened titles and abstracts against predefined eligibility criteria and subsequently assessed potentially eligible full-text papers. Disagreements were resolved through discussion or consultation with a third reviewer. The updated study-selection process, including records identified through the final search update, was documented using a PRISMA flow diagram.

Data Charting

Data were independently charted by 2 reviewers (YY and JZ) using a standardized Microsoft Excel form. Discrepancies were resolved through discussion or consultation with a third reviewer (SP). The charted information included author, publication year, country, study design, participant characteristics, digital health technology, intervention characteristics, mobility-related outcomes, statistical or analytical approach, reported procedures for handling home-generated digital or device data, where applicable, and principal findings.

Mobility-related outcomes were classified according to the ICF framework [14] into body functions and structures, activities, and participation. Outcomes were coded at the outcome-measure level; therefore, a study could contribute to more than one ICF domain when distinct outcomes represented different domains. Individual outcome measures were assigned to the domain they most directly represented and were not double-counted across domains. Self-management, goal setting, education, symptom monitoring, and engagement were treated as intervention- or implementation-related components rather than mobility domains.

For studies with a comparator, details of the comparator, primary and secondary outcomes as defined by the original study authors, assessment time points, between-group findings, and within-group changes were extracted where available. Implementation and user-experience outcomes, including feasibility, retention, adherence, intervention completion, safety, usability, acceptability, satisfaction, and perceived barriers or facilitators, were charted separately from clinical mobility outcomes.

Theoretical frameworks were extracted only when a named theory, model, or framework was explicitly reported as informing intervention design, implementation, or analysis. Frameworks were recorded as described by the original authors and were not inferred when no explicit theoretical basis was reported.

Data Synthesis

Because of heterogeneity in study designs, interventions, and outcome measures, data were synthesized descriptively. Digital health technologies were classified according to their predominant function and delivery mode into 7 categories: telemedicine, telerehabilitation, mobile health, wearable monitoring, VR, robot-assisted rehabilitation, and digital recovery platforms. Each report was assigned to one primary technology category based on the predominant digital delivery mechanism; multicomponent interventions were classified according to the component through which the principal rehabilitation or recovery support was delivered.

Mobility-related outcomes were synthesized according to the ICF domains of body functions and structures, activities, and participation. A report could contribute to more than one ICF domain when it included distinct outcome measures representing different domains. Clinical outcomes were synthesized separately from implementation and user experience outcomes. In comparative studies, primary outcomes and between-group findings were prioritized; within-group changes were not interpreted as evidence of intervention effectiveness in the absence of a corresponding between-group effect. In noncomparative studies, changes over time were described without inferring effectiveness.

Studies involving mixed populations were retained if adult ICU survivors were identifiable, even if outcomes for the ICU subgroup were not reported separately. Intervention characteristics and reported outcomes were charted as reported, and findings from the full mixed population were identified as such. These studies contributed to mapping technology use, outcome measures, and implementation or user experience evidence. Findings available only for the mixed population were not interpreted as ICU-specific estimates of clinical effectiveness.

Reports arising from the same parent study were linked during synthesis and retained when they contributed distinct evidence. Each parent study was counted once when determining the number of unique studies. No formal methodological quality or risk-of-bias appraisal was conducted because the purpose of this scoping review was to map the breadth, characteristics, and gaps of the available evidence rather than to assess the certainty of intervention effects.

Results

Study Selection

The updated database searches identified 2557 records. After the removal of 1291 duplicates, 1266 records underwent title and abstract screening, of which 906 were excluded. Full texts were sought for 360 reports; 5 could not be retrieved, leaving 355 reports for eligibility assessment. Of these, 328 were excluded because of an ineligible study design (n=81), an ineligible population (n=85), the absence of an eligible digital health intervention (n=64), or the absence of a mobility-related outcome (n=98). Ultimately, 27 reports representing 24 unique parent studies were included in the review. The study selection process is presented in the PRISMA flow diagram (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart presenting the search outcomes and study selection process.

Study Characteristics

The review included 27 reports representing 24 unique parent studies, comprising 11 randomized trial reports [39-49], 9 nonrandomized quantitative reports [50-58], 3 qualitative reports [59-61], 2 case reports [62,63], 1 innovation report [64], and 1 multiple methods report [65]. Reports arising from the same parent study were linked and retained when they contributed distinct evidence; each parent study was counted once in the total number of unique studies. The 3 pairs of linked reports were O'Neill et al [44] and Ghiglieri et al [61], Kovaleva et al [59] and Boehm et al [49], and Rose et al [64] and Apps et al [65].

The studies were conducted across diverse geographical settings and included survivors of COVID-19–related critical illness [39-41,43,45,47,51-53,55,62], acute respiratory failure [42,48,54], sepsis and/or acute respiratory distress syndrome [46,49,59], prolonged mechanical ventilation [44,50,61,65], and broader post-ICU populations [48,56-58,60], as well as a survivor of severe burn injury requiring prolonged critical care [63]. Participant characteristics and age were reported heterogeneously across studies. Basic study characteristics are

XSL•FO
RenderX

summarized in Table 2, while detailed information on the study populations, digital health technologies, intervention components, duration, delivery format, providers, settings, and mobility-related outcomes is provided in Table S1 in Multimedia Appendix 1.

XSL•FO

Study	Country	Study design	Sample size	Age, y
Ghiglieri et al [61], 2026	United Kingdom	Theory-informed qualitative interview substudy	ICU survivors, n=35 (RR[e]=20; SC[f]=15); staff, n=6	Mean (SD) for RR: 56.2 (17.0); SC: 66.1 (9.3)
Apps et al [65], 2026	United Kingdom	Multiple methods study	Questionnaire, n=59; interviews, n=30; n=75 unique participants	Median for questionnaire: 58 [48-66]; interviews: 55.5 [49-61]

[a]Age is reported as mean (SD), median (IQR), or range, as provided in the original studies. Linked reports from the same parent study were retained when they contributed distinct evidence; each parent study was counted once in the number of unique studies.

[b]I: intervention group.

[c]C: control or comparator group.

[d]MDT: multidisciplinary team.

[e]RR: remote rehabilitation.

[f]SC: standard care.

Statistical and Analytical Approaches

Statistical and analytical approaches varied across study designs, ranging from descriptive and conventional group comparisons to adjusted regression, mixed-effects, and longitudinal or clustered models; qualitative studies used content, thematic, or framework-based analyses [40,42,44,48,59,61]. Reported handling of home-generated digital data included synchronization checks, wear-time or data-completeness criteria, exclusion of insufficient observations, and aggregation across valid monitoring periods [39,40,53,56-58], whereas explicit signal-level filtering or cross-device calibration was rarely reported. Detailed study-level information is provided in Table S2 in Multimedia Appendix 1.

Characteristics of Digital Health Technologies

Types of Digital Health Technologies

The included reports covered 7 categories of digital health technologies. Telerehabilitation was the most frequently represented category and included remotely delivered exercise, multicomponent rehabilitation, and rehabilitation support [41,44,45,48,51,52,55,61,62]. Telemedicine approaches primarily involved remote consultation, symptom review, care coordination, and virtual ICU recovery services [39,42,46,49,59]. Other technologies included mobile health (mHealth) apps [40,54,57], wearable monitoring [53,56,58], VR [47,50,63], digital recovery platforms [48,60,65], and robot-assisted rehabilitation [43].

Duration and Setting

Intervention duration and timing varied substantially. The shortest approach was a single telemedicine consultation conducted within 14 days after hospital discharge [39], whereas longer-term programs extended to 12 months and incorporated ongoing symptom monitoring, care coordination, or physical activity monitoring [42,53]. Structured rehabilitation programs commonly lasted 6 to 8 weeks [41,44,51,52,61] or approximately 12 weeks [40,45,65]. Other studies used shorter inpatient programs or assessed recovery at predefined postdischarge time points [49,50,57,58].

Home-based delivery was the most common setting and was used for telemedicine, telerehabilitation, mHealth, wearable monitoring, and digital recovery platforms [39-42,44-46,52,53,56,58]. Other technologies were delivered in outpatient or post-ICU follow-up settings [47,51], during inpatient recovery [48,50,57,63], or in specialized rehabilitation facilities [43].

Delivery Format

Delivery formats ranged from clinician-led synchronous interactions to asynchronous self-directed technologies. Synchronous videoconferencing or telephone-based delivery was frequently used for telemedicine and telerehabilitation [39,41,44,46,49,52,55,59,62]. Asynchronous or self-directed approaches included mobile apps, web-based recovery platforms, and wearable devices used for exercise guidance, recovery monitoring, goal tracking, or self-management support [40,45,48,53,54,56,58,60,65]. Several interventions adopted hybrid formats combining digital and in-person or multiple remote components [40,42,51,62]. Technology-assisted formats also included therapist- or researcher-assisted immersive VR [47,50,63] and supervised human-robot interaction [43].

Health Care Providers Involved

Digital health interventions involved a broad range of health care professionals. Physiotherapists were frequently involved in exercise-based rehabilitation, telecoaching, and technology-assisted rehabilitation [40,41,43,45,51-53,55,57,62,63]. Physicians and ICU clinicians contributed to teleconsultation and virtual ICU recovery services [39,49,59], while nurses were involved in care coordination, transitional care, and recovery support [42,46,47,52]. Several interventions were delivered by multidisciplinary teams involving combinations of physicians, physiotherapists, occupational therapists, psychologists, pharmacists, rehabilitation professionals, and other recovery specialists [48,49,53,59,62]. Other approaches relied partly on self-directed use of mobile apps or wearable devices with limited direct professional supervision [54,56,58].

Functional Components of Digital Health Technologies

Exercise-based rehabilitation was the most frequently represented intervention component. These programs incorporated aerobic or endurance exercise, resistance or strengthening exercises, balance training, respiratory exercises,

XSL•FO
RenderX

upper-limb training, functional activity, and individualized mobility exercises delivered through digital or technology-assisted formats [40,41,43-45,50-52,55,57]. Monitoring and assessment represented another major function and included remote review of vital signs or symptoms, wearable-based monitoring of physical activity, and digital tracking of recovery progress [39,40,42,46,54,56,58,64,65]. Educational resources, goal setting, and self-management support were incorporated in several interventions [45,52,54,60,62,64,65], while teleconsultation, care coordination, psychological support, and peer support extended the role of digital technologies beyond exercise delivery alone [39,42,44,46,49,59,61].

Explicit use of named theoretical models or frameworks was uncommon. Khan et al [42] described the mobile critical care recovery program as a collaborative care model, while Apps et al [65] reported a theoretically informed recovery goal menu structured according to the Canadian model of occupational performance and engagement and used the theoretical framework of acceptability (TFA) as an analytic lens. Ghiglieri et al [61] also explicitly used the TFA to guide the qualitative study and analysis. Other studies incorporated theory-informed strategies or behavioral constructs, including biobehaviorally informed lifestyle coaching and motivational interviewing [40], self-efficacy and motivation for physical activity [45], and individualized goal setting with Goal Attainment Scaling [64], but did not explicitly report a named overarching theoretical framework guiding intervention design. Overall, explicit theoretical grounding was inconsistently reported across the included evidence.

Table 3 summarizes the 7 digital health technology categories and their principal characteristics. Figure 2 presents the distribution of these technologies across the ICF domains of body functions and structures, activities, and participation.

XSL•FO
RenderX

Table . Summary of digital health technology categories and ICF-mapped mobility outcomes after critical illness.[a]

Digital health technology	Principal functions and delivery	ICF[b] mobility domains and representative outcomes
Telerehabilitation (n=9)	Remote exercise training, telecoaching, multicomponent rehabilitation, education, goal setting, and peer support; delivery: video, telephone, mobile apps, or hybrid formats	Body functions and structures: muscle strength and fatigue; activities: 6MWT[c], STST[d], SPPB[e], TUG[f], disability, and physical-dependence measures; participation: return to work
Telemedicine (n=5)	Remote consultations, symptom review, medication management, care coordination, and virtual ICU recovery clinics; delivery: video, telephone, and electronic health support	Activities: 6MWT, ADL[g], IADL[h], and functional status
Mobile health (n=3)	App-guided exercise, rehabilitation education, goal tracking, symptom or mood monitoring, and wearable integration; delivery: mobile apps with self-directed or hybrid support	Body functions and structures: MRC-SS[i] and handgrip strength; activities: STST, TUG, ICU Mobility Scale, and FAC[j]
Wearable monitoring (n=3)	Continuous or intermittent monitoring of physical activity and free-living performance; delivery: wrist-worn or consumer-grade wearable devices	Activities: daily step count, active time, cadence, 6MWT, and ADL
Virtual reality (VR; n=3)	Immersive rehabilitation, rehabilitation gaming, and ICU[k] recovery education; delivery: therapist-assisted or in-person immersive VR	Body functions and structures: handgrip strength; activities: MMI[l], FIM[m], and ambulation
Robot-assisted rehabilitation (n=1)	Robot-assisted therapeutic exercise; delivery: supervised human-robot interaction	Body functions and structures: handgrip strength; activities: 6MWT, balance performance, and FIM
Digital recovery platforms (n=3)	Goal setting, recovery monitoring, education, digital diaries, reminders, communication, and peer support; delivery: interactive web- or app-based platforms	Activities: ADL and functional independence; participation: activity participation and recovery goals explicitly related to meaningful life activities

[a]Each report was assigned to one primary technology category according to its predominant digital function and mode of delivery; counts represent reports rather than unique parent studies. A report could contribute to multiple ICF domains when distinct mobility-related outcomes supported each assignment.

[b]ICF: International Classification of Functioning, Disability and Health.

[c]6MWT: 6-minute walk test.

[d]STST: sit-to-stand test.

[e]SPPB: short physical performance battery.

[f]TUG: Timed Up and Go test.

[g]ADL: activity of daily living.

[h]IADL: instrumental activity of daily living.

[i]MRC-SS: Medical Research Council Sum Score.

[j]FAC: functional ambulation category.

[k]ICU: intensive care unit.

[l]MMI: Morton Mobility Index.

[m]FIM: functional independence measure.

XSL•FO
RenderX

Figure 2. Digital health technologies and ICF domains among ICU survivors. Each report was assigned to one primary technology category according to its predominant digital function and mode of delivery; for multicomponent interventions, the principal component delivering rehabilitation or recovery support determined the category. Each distinct mobility-related outcome was mapped to the ICF domain it most directly represented: body functions and structures, activities, or participation. A report could appear in more than one domain when it reported distinct outcomes representing those domains. Cell entries indicate outcome coverage, including qualitative findings, rather than intervention effectiveness; reports without a directly mappable mobility outcome are not shown in the matrix. Self-management, feasibility, and acceptability were not coded as mobility domains [39-62]. ICF: International Classification of Functioning, Disability and Health; ICU: intensive care unit.

Mobility Assessment and Mobility-Related Findings

Mobility Assessment Tools

A wide range of mobility-related measures was reported across the included studies, reflecting substantial heterogeneity in the assessment of post-ICU recovery. The 6MWT was the most frequently reported assessment tool (n=7) [39,41,43,45,51,58,62], followed by sit-to-stand tests, including the 30-second and 1-minute sit-to-stand tests, which were used to assess functional exercise capacity (n=5) [40,44,45,52,55].

Within the ICF domain of body functions and structures, muscle strength was assessed primarily using handgrip strength [41,43,50,57,62], with additional measures including the Medical Research Council Sum Score and Arm Curl Test. Activity-level outcomes were more diverse and included the 6MWT, sit-to-stand tests, Timed Up and Go test, Short Physical Performance Battery, de Morton Mobility Index, functional independence measure, Berg Balance Scale, ICU Mobility Scale, functional ambulation category, daily step count, ADLs, instrumental ADLs, disability, and physical dependence. Wearable-based measures of free-living activity, including daily step count, active time, and cadence, were reported by Hunter et al [53], Kim et al [56], and Fortune et al [58].

Participation-level outcomes were infrequently assessed. Rosa et al [48] assessed return to work; Zacharelou et al [60] qualitatively explored participation in meaningful daily, community, or social activities; and Apps et al [65] reported recovery goals explicitly related to meaningful life roles or participation. Overall, mobility assessment focused predominantly on body functions and activities, with limited coverage of participation.

Mobility-Related Clinical Findings

Evidence from controlled and comparative studies was mixed (Table S3 in Multimedia Appendix 1). Among studies with clinical primary outcomes, the 12-month mobile critical care recovery program did not significantly improve the SF-36 physical component summary compared with control [42]. Remote multicomponent rehabilitation did not significantly improve the primary EQ-5D-5L utility outcome at 8 weeks [44]. ICU-specific VR did not demonstrate consistent benefits in its primary psychological or health-related quality-of-life outcomes [47]. In the stepped-wedge trial by Rosa et al [48], overall EQ-5D-3L utility at 90 days was higher in the intervention group, but this difference was not significant when the analysis was restricted to survivors.

Findings for secondary mobility-related outcomes were also inconsistent. For the secondary 30-second sit-to-stand outcome, O'Neill et al [44] reported a significant adjusted between-group difference at 8 weeks favoring remote rehabilitation. In the robot-assisted rehabilitation trial, a significant group × time interaction was observed for the functional independence measure motor subscale, whereas consistent between-group advantages were not demonstrated across other functional measures [43]. Rosa et al [48] found no significant between-group differences in new disability, physical dependence, or return to work. Similarly, no clear between-group mobility benefit was demonstrated in the telemedicine study by Balakrishnan et al [39] or in the telehealth vs in-person rehabilitation comparison by Mayer et al [51]. In the observational study by Hunter et al [53], step counts increased more at the multidisciplinary-team site than at control sites, although the nonrandomized design limits causal interpretation. Noncomparative studies reported improvements over time in mobility, exercise capacity, physical activity, or

XSL•FO
RenderX

functional independence [50,52,57,58,62,63]. These findings were used to describe recovery trajectories and outcome coverage rather than as evidence of intervention effectiveness.

Implementation Feasibility and User Acceptability

Evidence on feasibility, safety, adherence, usability, acceptability, and user experience was synthesized separately from clinical outcome evidence. Across the included reports, these outcomes were assessed using measures of recruitment and retention, intervention completion and adherence, safety, usability and satisfaction, and qualitative accounts of user experience and implementation barriers.

Feasibility, Safety, and Adherence

Feasibility, safety, adherence, and implementation outcomes were synthesized separately from clinical effectiveness findings (Table S4 in Multimedia Appendix 1). Several interventions reported favorable engagement or completion, although substantial variation was observed across studies. Remote multicomponent rehabilitation achieved full adherence in 73.2% (169/231) of participants, with 88.7% (205/231) attending at least one session [44], while virtual post-ICU rehabilitation showed 73.6% (28/38) retention and 82% (23/28) adherence [52]. Wearable-monitoring studies demonstrated the feasibility of collecting home activity data, but incomplete device use, technical failures, and missing data reduced data completeness [53,56,58]. In the multicenter stepped-wedge trial, among 300 eligible intervention patients, 269 (89.7%) attended at least 1 ward session and 222 (74.0%) attended at least 1 postdischarge session [48]. Thus, digital interventions were generally deliverable, but sustained participation and completeness of remotely generated data remained variable.

Acceptability, Usability, and User Experience

Acceptability and user experience findings were generally favorable but were interpreted separately from clinical effectiveness (Table S5 in Multimedia Appendix 1). Remote multicomponent rehabilitation received higher acceptability ratings than standard care [44], while a mobile app prototype achieved median System Usability Scale scores of 76 among ICU survivors and 88 among caregivers [54]. ICU-specific VR was associated with higher satisfaction with ICU aftercare [47], and favorable satisfaction or acceptability was also reported for app-based rehabilitation, immersive VR, telemedicine recovery clinics, and digital recovery platforms [49,57,63,65]. Qualitative findings highlighted individualized support, continuity of care, reassurance, and professional access as facilitators, whereas technical burden, limited digital access, and insufficient personalization were recurrent barriers [59,61,65].

Discussion

Principal Findings

This scoping review mapped the use of digital health technologies to support mobility recovery among ICU survivors across 7 technology categories. Interventions most commonly incorporated exercise-based rehabilitation, alongside monitoring, education, self-management support, and remote follow-up. Mobility outcomes were heterogeneous and concentrated on body functions and activity-level performance, with comparatively limited attention to participation. Although feasibility and acceptability were generally favorable when assessed, evidence of clinical effectiveness remained mixed, and long-term implementation data were limited.

Remote and Telehealth-Based Technologies as a Major Strategy for Post-ICU Recovery

A notable finding of this review was that telemedicine and telerehabilitation were the most frequently adopted digital health technologies. This predominance may reflect the substantial and persistent rehabilitation needs of ICU survivors, who commonly experience long-term physical impairment, reduced exercise capacity, respiratory dysfunction, and difficulties accessing postdischarge rehabilitation services [66-68]. Digital technologies offer an opportunity to extend rehabilitation beyond hospital settings and provide continuous support throughout the recovery trajectory [69]. In addition to improving access to rehabilitation, remote and telehealth-based approaches may reduce geographical and transportation barriers, facilitate continuity of care after hospital discharge, enable timely monitoring of recovery, and strengthen patient self-management in home settings, where access to structured post-ICU rehabilitation is often limited.

The COVID-19 pandemic further accelerated the adoption of remote rehabilitation technologies. Eleven of the 24 (45.8%) included studies focused on survivors of COVID-19–related critical illness, reflecting the urgent demand for scalable rehabilitation strategies during a period when infection-control measures substantially restricted conventional outpatient and community-based rehabilitation services. At the same time, the rapid expansion of telehealth infrastructure and increasing familiarity with digital health care delivery further facilitated the implementation of remote rehabilitation programs. Together, these factors contributed to the widespread use of telemedicine and telerehabilitation for supporting patients with persistent physical and respiratory impairments following severe COVID-19 [70].

However, the predominance of COVID-19–related studies should be considered when interpreting the current evidence. Compared with general ICU survivors, individuals recovering from COVID-19 may experience distinct recovery patterns, particularly persistent respiratory symptoms, postviral fatigue, and impaired exercise tolerance, which may influence both rehabilitation needs and responses to digital intervention [71,72]. In contrast, evidence involving non-COVID ICU populations, such as survivors of sepsis, acute respiratory failure, prolonged mechanical ventilation, and other critical illnesses, remains relatively limited. Furthermore, many COVID-19–related digital programs were rapidly developed during the pandemic and were commonly evaluated over short intervention periods, with limited evidence regarding their long-term sustainability and integration into routine post-ICU care [70,73]. Beyond these population-specific considerations, successful implementation of remote rehabilitation also depends on patients' digital literacy, access to internet-enabled devices, reliable connectivity, and, in some cases, caregiver support. These factors may influence

XSL•FO
RenderX

patient engagement, equity of access, and the scalability of digital rehabilitation programs in routine clinical practice.

Exercise-Based Rehabilitation Remains the Core Functional Component of Digital Health Technologies

Exercise-based rehabilitation emerged as the most frequently reported functional component among the included digital health technologies. This finding is unsurprising given that persistent physical impairments, including muscle weakness, reduced exercise tolerance, and limitations in physical functioning, are among the most common consequences experienced by ICU survivors after critical illness. Previous studies have shown that these impairments may persist for months or even years after hospital discharge and contribute to long-term disability, reduced health-related quality of life, and difficulties returning to previous life roles [22-24,74]. Consequently, exercise rehabilitation remains a cornerstone of post-ICU recovery programs and is strongly recommended to mitigate long-term physical disability and promote functional restoration [75]. This predominance may also reflect the characteristics of current digital health technologies, as exercise programs are more readily delivered through telehealth platforms, and their outcomes can be objectively monitored using wearable devices and standardized performance measures. By contrast, broader domains such as social participation and community reintegration are less amenable to remote measurement and digital monitoring.

However, the predominance of exercise-centered technologies highlights an important gap in current digital rehabilitation strategies. Mobility recovery after critical illness is increasingly recognized as a multidimensional process encompassing body functions and structures, activities, and participation [14,76-78]. Consistent with the findings of this review, existing digital health technologies primarily addressed body functions and activity-level performance, particularly exercise capacity, muscle strength, and functional performance, while participation outcomes were less frequently assessed. Therefore, future digital health technologies should move beyond physical rehabilitation alone and incorporate more comprehensive, person-centered recovery goals.

Furthermore, although digital technologies offer opportunities for continuous monitoring and personalized rehabilitation, current apps largely remain tools for remote delivery and assessment rather than adaptive rehabilitation systems. Future integration of wearable sensing, AI, and real-time feedback may facilitate closed-loop rehabilitation models that dynamically tailor interventions according to patients' changing recovery needs [79,80].

Emerging Digital Technologies: From Feasibility to Patient-Centered Implementation

Beyond conventional telemedicine and telerehabilitation, emerging digital technologies included VR, rehabilitation robots, wearable activity monitoring, and digital recovery platforms. Current evidence for these technologies was predominantly derived from feasibility, pilot, and observational studies, with generally favorable feasibility and user experience findings when assessed. However, evidence of clinical effectiveness remained limited and inconsistent. VR-based rehabilitation was perceived as enjoyable and feasible among ICU survivors, with no serious adverse events reported [50]. App-based and video-supported rehabilitation programs also reported favorable adherence and retention, supporting their implementation feasibility rather than establishing clinical effectiveness [40,52]. In addition, digital recovery platforms and virtual follow-up services were valued for facilitating access to information, self-management, and communication with health care professionals [54,59,60,64].

However, the current evidence primarily reflects early-stage implementation, as many emerging digital technologies were evaluated in feasibility studies, pilot trials, or small observational studies with relatively short follow-up periods. Although several studies reported favorable usability and acceptability through satisfaction questionnaires, usability scales, or qualitative interviews, a comprehensive understanding of long-term user engagement and implementation barriers remains limited. Future development of digital rehabilitation technologies should therefore adopt more patient-centered approaches, including co-design involving ICU survivors and caregivers, as well as mixed methods evaluations that integrate quantitative usability measures with qualitative exploration of user experiences. In addition, successful implementation will require attention to data privacy and security, integration into routine clinical care, and adequate training and support for health care professionals. Such considerations may help ensure that emerging digital technologies are not only technically feasible but also meaningful, accessible, and sustainable in supporting long-term recovery after critical illness.

Heterogeneity and Narrowness of Mobility Outcome Measurement

Another important finding of this review was the substantial heterogeneity in mobility assessment and outcome measurement. Most studies focused on basic physical capacity and functional performance, commonly assessed using the 6MWT, sit-to-stand tests, handgrip strength, the Timed Up and Go test, and other performance-based measures [39-41,43-45,51,52,55,62]. Although these outcomes are clinically meaningful for evaluating physical recovery after critical illness, they capture only part of the multidimensional nature of mobility.

Measures addressing broader activity and participation outcomes were less frequently reported, including functional independence [43,62], ADLs, activity participation, and mobility- or participation-related recovery goals [42,43,54,60,62,64]. This imbalance suggests that current digital health research has predominantly evaluated mobility through body functions and activity-level performance rather than across the full spectrum of post-ICU functioning.

The heterogeneity of outcome measurement remains a major challenge for comparing and synthesizing evidence across digital rehabilitation studies. The PRACTICE (Physical Rehabilitation Core Outcomes in Critical Illness) core outcome set provides a framework to promote standardized reporting of physical rehabilitation outcomes in critically ill populations [81]. However, as digital health interventions increasingly extend beyond exercise training to include remote monitoring,

XSL•FO
RenderX

self-management, and long-term recovery support, future research should combine standardized core outcomes with broader multidimensional assessments that reflect independence, participation, and patient-centered recovery trajectories. Analytical approaches were also heterogeneous, ranging from descriptive and unadjusted comparisons to adjusted regression, mixed-effects, and longitudinal or clustered models. This variation reflected differences in study design but also limited the comparability of effect estimates across studies. Future studies should prespecify analytical strategies appropriate to repeated and longitudinal measurements and consistently report effect estimates with measures of uncertainty.

The handling of home-generated digital data was also inconsistently reported. Reported approaches included synchronization checks, wear-time or data-completeness thresholds, exclusion of insufficient observations, aggregation across valid monitoring periods, and missing-data assessment, whereas explicit signal-level artifact filtering and cross-device calibration were rarely described. Future studies should prespecify device validation, valid-wear and nonwear criteria, data-cleaning procedures, and missing-data handling to improve the reproducibility and interpretability of remotely generated data.

Implications for Future Research

Several implications for future research emerged from this review. First, more adequately powered randomized controlled trials with longer follow-up periods are needed to establish the long-term effectiveness and sustainability of digital health technologies, given that mobility recovery after critical illness is a prolonged and dynamic process. Second, future studies should move beyond short-term physical outcomes and incorporate multidimensional recovery indicators, including independence in ADLs, community and social participation, return to occupational or caregiving roles, patient-reported physical function, and individualized mobility- or participation-related recovery goals. Third, theoretical foundations were infrequently and inconsistently reported; future interventions would benefit from clearly articulated behavioral or rehabilitation frameworks where appropriate. Finally, future research should consider implementation factors, including digital literacy, technology accessibility, caregiver involvement, and health equity, to support broader adoption in ICU survivorship care.

Strengths and Limitations

This review has several strengths. A comprehensive search strategy was applied, and evidence was synthesized across technology types, delivery models, intervention components, and mobility-related outcomes. The review also identified important gaps in outcome measurement, theoretical grounding, and implementation evidence.

Several limitations should be acknowledged. First, although 27 reports representing 24 unique parent studies were included, many were feasibility, pilot, qualitative, or small observational studies, limiting conclusions regarding clinical effectiveness. Second, substantial heterogeneity in populations, interventions, outcome measures, and analytical approaches limited direct comparisons across studies. Third, a substantial proportion of the evidence was derived from survivors of COVID-19–related critical illness, which may limit generalizability to the broader ICU survivor population. In addition, classifying multicomponent interventions according to their predominant digital function may have simplified the overlap between technology categories. Finally, no formal methodological quality or risk-of-bias appraisal was conducted; therefore, differences in study quality were not incorporated into the synthesis, and findings regarding clinical effectiveness should be interpreted cautiously.

Conclusions

Digital health technologies have been applied across diverse approaches to support mobility recovery among ICU survivors, with telemedicine and telerehabilitation being the most frequently used. Current evidence predominantly addresses body functions and activity-level performance, with limited attention to participation. Although feasibility and acceptability were generally favorable, evidence of clinical effectiveness remains inconsistent, highlighting the need for rigorous longitudinal studies using multidimensional, patient-centered mobility outcomes.

Generative AI Use

During the preparation of this manuscript, the authors used OpenAI's GPT-6 (accessed September 24, 2026) solely to generate vector graphics for elements in Figure 2. The AI tool was not involved in the layout or arrangement of Figure 2, the creation or formatting of any tables, or any other aspect of the manuscript. All image layout, figure composition, table preparation, study design, data collection, data analysis, data interpretation, and manuscript writing were performed entirely by the authors. The AI-generated vector elements were reviewed, selected, and, where necessary, edited by the authors, who take full responsibility for the final content and integrity of Figure 2 and the entire manuscript. No other generative AI tools were used in any portion of the manuscript generation.

Funding

This study was supported by the Xinhua Hospital "Discipline Peak-Climbing Plan" Construction Project (XKPF2024305), the Shanghai Jiao Tong University School of Medicine Nursing Development Program (SJTUHLXK2022), and the General Project of the Commission of Science, Technology and Economy of Yangpu District (YPM202536). The funders had no role in the study design, study selection, data charting, analysis, interpretation of the findings, manuscript preparation, or decision to submit the manuscript.

Abstract

Background: The rapid advancement of generative AI (GenAI) holds transformative potential for clinical nursing practice, yet its integration also brings significant risks and uncertainties. Despite growing discourse on AI in health care, frontline nurses' firsthand experiences, perceptions, and practical needs regarding GenAI remain largely under-synthesized in the existing literature.

Objective: This systematic review aimed to synthesize qualitative evidence to clarify the core themes related to clinical nurses' perceptions, experiences, obstacles, and requirements when using GenAI in real-world clinical settings.

Methods: A systematic search was conducted across 10 electronic databases (PubMed, Embase, CINAHL, Web of Science, Cochrane Library, ProQuest Dissertations and Theses, China National Knowledge Infrastructure, VIP Information, SinoMed, and Wanfang) for records published between January 2018 and June 2026. Eligible studies included qualitative and mixed methods studies involving registered nurses that explored their perceptions and experiences of GenAI in clinical practice. Two independent reviewers (MMW and CYZ) performed study selection, quality appraisal, and data extraction, with disagreements resolved by consensus. Quality was assessed using the Joanna Briggs Institute (JBI) Critical Appraisal Checklist for Qualitative Research. Extracted data encompassed study characteristics, participant demographics, and GenAI-related contextual factors. Data synthesis followed Thomas and Harden's 3-phase thematic synthesis: initial inductive coding generated descriptive themes, which were subsequently integrated with the Technology Acceptance Model for Artificial Intelligence in Nursing (TAM-AIN) framework to develop higher-order analytical themes. Certainty in the evidence was evaluated using the GRADE-CERQual (Grading of Recommendations Assessment, Development and Evaluation-Confidence in the Evidence from Reviews of Qualitative Research).

Results: Of the 4350 initially identified records, 13 studies from 6 countries (China: n=6; Saudi Arabia: n=3; United States, Singapore, Australia, and South Korea: n=1 each) met the inclusion criteria, encompassing qualitative data from 234 registered nurses. Three main themes emerged: patterns of nurses' engagement with GenAI (ranging from passive observation to proactive integration), multidimensional perceived threats to adoption (functional, professional, and accountability-related), and the moderating role of organizational readiness, which influenced whether these threats hindered or facilitated GenAI uptake in practice. The GRADE-CERQual assessment showed moderate to high confidence in all findings.

Conclusions: Nurses' engagement with GenAI ranges from passive observation to proactive integration, accompanied by legitimate concerns about functional reliability, professional role displacement, and accountability ambiguity. The moderating role of organizational readiness further highlights that training, tool optimization, and institutional governance remain critical yet often unmet. These findings necessitate coordinated efforts across workforce development, technological design, and regulatory frameworks. Future research should prioritize the development of clinically validated, context-aware GenAI systems that incorporate human-in-the-loop oversight, ensuring that efficiency gains do not compromise the delivery of compassionate, person-centered care.

Introduction

The nursing profession, a cornerstone of global health care systems, faces mounting pressures, most notably chronic workforce shortages and escalating care demands. According to the World Health Organization's "The State of the World's Nursing 2025" report, the global shortfall of nurses and midwives was estimated at 5.8 million in 2023 and is projected to reach 4.1 million by 2030 [1]. This shortfall severely constrains the accessibility, quality, and safety of health care delivery. Moreover, population aging and the rising burden of chronic conditions continue to compound the demand for nursing services. Identifying strategies to optimize nursing productivity while safeguarding care quality has therefore become a pressing imperative.

The introduction of ChatGPT (OpenAI) in November 2022 sparked extensive discussions regarding the application of generative AI (GenAI) across various sectors. GenAI uses new types of machine-learning models to answer questions, interpret images, and deliver results in the form of newly generated original text, images, and sound—with remarkable quality and speed [2,3]. Unlike earlier AI tools that primarily identify or categorize based on established patterns, GenAI can generate entirely new and original content. These distinctive content-generation capabilities suggest its potential to transform nursing practice, particularly in areas such as drafting nursing documentation, patient education, and care plan development [4]. In clinical settings, nurses have begun using GenAI to draft handover documentation and nursing diagnoses within the electronic health records (EHRs), with both a multicenter trial across 3 hospitals and a separate 40-nurse empirical study demonstrating consistent efficiency gains, including average time reductions of approximately 40% [5,6]. GenAI has been applied to diverse clinical functions, including customized treatment planning, synthetic data generation, medical image analysis, workflow optimization, risk prediction, pandemic preparedness, and population health management. Concurrently, it may alleviate nurse burnout and reclaim time for direct patient care through automating documentation and other routine administrative tasks [7]. In medical education, GenAI shows promise for enhancing clinical training through advanced simulated patient systems that offer high-fidelity, low-cost clinical scenarios [8]. GenAI has demonstrated considerable utility; for instance, ChatGPT performs comparably to human researchers in writing introductions, with no significant differences in publication acceptability or content quality [9]. These early applications illustrate GenAI's potential to streamline workflow and improve patient outcomes [10].

While GenAI is revolutionizing access to health information through conversational and highly personalized interactions, its capacity to generate hyper-personalized responses carries inherent risks. These include reinforcing confirmation bias, entrenching preexisting beliefs, obscuring established medical consensus, and facilitating the spread of misinformation—concerns that pose substantial public health challenges [11]. In light of these concerns, the World Health Organization has called for further research to identify risks, inform implementation strategies, and optimize the benefits of GenAI in health care settings.

Research on GenAI in nursing has evolved from broad discussions to focused inquiries in specific clinical settings and among particular user groups. Current attention centers on the sociotechnical complexities surrounding GenAI adoption—including users' intentions, experiences, and perceptions, as well as emerging concerns and the implications of technological change [12-15]. Notwithstanding this progress, existing reviews and evidence syntheses have largely focused on educational or academic research settings [15,16]. Conspicuously absent, however, is a comprehensive synthesis that consolidates frontline nurses' attitudes, experiences, and the practical implications of GenAI use in clinical practice. This review therefore aims to synthesize qualitative evidence on clinical nurses' perceptions, experiences, barriers, and support needs in using GenAI. The findings will provide an evidence base for developing responsible, context-sensitive guidelines for GenAI deployment in nursing practice.

Methods

Protocol and Registration

This systematic review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [17] and the Enhancing Transparency in Reporting the Synthesis of Qualitative Research (ENTREQ) statement (Checklist 1 and Checklist 2) [18]. The review protocol was registered in advance with PROSPERO (International Prospective Register of Systematic Reviews; ID: CRD420251250664).

Eligibility Criteria

Selection criteria were developed using the Population, Phenomenon of Interest, Context, and Study Design (PICoS) framework (Table 1). We included registered nurses as participants to ensure a focused understanding of their perspectives on GenAI within this professional group. In this study, GenAI was operationally defined as deep learning-based generative systems capable of producing novel, semantically meaningful content—including text, images, and audio—in response to user prompts. Eligible system architectures included, but were not limited to, large language models (LLMs), generative adversarial networks (GANs), variational autoencoders (VAEs), and diffusion models, consistent with the taxonomic framework proposed by Bandi et al [19]. This definition explicitly excluded analytical AI systems that perform pattern recognition or prediction on labeled data, as opposed to generating content. Accordingly, all rule-based and retrieval-based conversational agents were also excluded. Mixed methods studies were included only if their qualitative findings were reported separately and extractable.

XSL•FO
RenderX

Table . Inclusion and exclusion criteria.

PICoS element	Inclusion criteria	Exclusion criteria
P (Population)	RNs[a] currently licensed and engaged in direct patient care. Studies with mixed samples are included only if data specific to RNs can be clearly isolated. Operational definition of "Registered Nurse": for the purpose of this review, an RN is defined as an individual who has completed a recognized program of nursing education and holds a current license or registration granted by the appropriate regulatory authority in their respective country or jurisdiction, thereby authorized to practice within the legally defined scope of professional nursing, in accordance with the definitions set forth by the International Council of Nurses and the World Health Organization.	• Nursing students (prelicensure). • Nurse educators or researchers without concurrent clinical responsibilities. • Other health care professionals (RN data not separately identifiable in mixed studies)
I (Phenomena of Interest)	Nurses' perceptions, experiences, attitudes, beliefs, barriers, or facilitators regarding the use of GenAI[b] in professional practice. "Use" encompasses direct or indirect engagement with GenAI tools (eg, retrieving clinical information, generating patient education materials, drafting care plans, interpreting diagnostic data, and responding to patient inquiries informed by GenAI).	• Studies on general digital health or predictive AI without specific reference to GenAI. • Studies focused solely on patient or caregiver perspectives.
Co (Context)	Any setting where RNs provide direct patient care (eg, hospital wards, intensive care units (ICUs), emergency departments, outpatient clinics, community health centers, and home health care). Bedside teaching and unit-based research and quality improvement are included when occurring within these settings.	• Settings primarily dedicated to academic education or formal research (eg, university classrooms, simulation labs without real patients, and research institutes) where participants hold no concurrent clinical responsibilities. • Social media or personal use contexts.
S (Study Design)	Primary qualitative studies (eg, phenomenology, grounded theory, ethnography, qualitative description, and case study). Mixed methods studies are included only if the qualitative component is reported separately, and findings can be independently extracted.	• Quantitative studies, reviews, editorials, commentaries, protocols, and conference abstracts. • Mixed methods studies where qualitative findings cannot be isolated. • Non-English or Chinese full text, unretrievable full text, duplicate publications, or incomplete data.

[a]RN: registered nurse.

[b]GenAI: generative AI.

Search Strategy

A systematic search was conducted across the following electronic databases: PubMed, Web of Science, Cochrane Library, CINAHL, Embase (including MEDLINE), ProQuest, SinoMed, China National Knowledge Infrastructure, Wanfang, VIP Chinese Science and Technology Periodical Database. The search covered the period from January 1, 2018, to June 30, 2026. The start date was set at 2018, as the transformer architecture emerged in 2017 and the first generative pretrained transformer (GPT) model was released in June 2018—events marking the onset of clinically relevant generative AI applications [2,20,21]; literature before this period was unlikely to contain meaningful content on contemporary GenAI in nursing. Our preregistered protocol originally planned a search from database inception to October 1, 2025; however, we deviated from this protocol by restricting the start date to 2018 (to ensure content relevance to the emergence of modern GenAI) and, during peer review, extending the end date to June 30, 2026, to capture the most current evidence given the rapid pace of development in this field.

The search strategy was built around 4 core conceptual domains: GenAI, nurses, and qualitative research. For each domain, we combined controlled vocabulary (eg, MeSH and Emtree) and free-text keywords, linked by Boolean operators (AND and OR), and adapted to the syntax of each database. In addition, we manually screened the reference lists of all included studies to complement the electronic database searches. Detailed search strategies for each database are available in Multimedia Appendix 1.

Study Selection and Screening

All retrieved records were imported into NoteExpress (Beijing Aegean Software Co., Ltd.) for deduplication and screening. Study selection was conducted independently by two reviewers

XSL•FO
RenderX

(MMW and CYZ). Initially, titles and abstracts were screened against eligibility criteria. Potentially eligible records then proceeded to full-text review. Disagreements at each stage were resolved by discussion or, if necessary, by consulting a third reviewer (YB).

Methodological Quality Assessment

Two reviewers (MMW and CYZ) independently assessed the methodological quality of the included studies using the Joanna Briggs Institute (JBI) Critical Appraisal Checklist for Qualitative Research [22]. The checklist consists of 10 items assessing aspects such as congruity between the research methodology and various study components. The appraisal results for each item included "Yes", "No", "Unclear", and "Not Applicable". A response of "Yes" was scored as 1 point, whereas "No" and "Unclear" were scored as 0 points. "Not Applicable" was excluded from the denominator when calculating the percentage score. The criteria for determining the risk of bias were as follows: a score of at least 7 out of 10 was classified as low risk, 5 to 6 out of 10 as moderate risk, and less than 5 out of 10 as high risk[23]. Discrepancies between reviewers were resolved through discussion with a third reviewer (YB). Only studies rated as low or moderate risk were included. All 13 studies [24-36] met this inclusion threshold (Multimedia Appendix 2).

Data Extraction, Synthesis, and Theoretical Framing

Data were extracted systematically by 2 reviewers (MMW and CYZ) using a standardized form. The extracted information included the authors, the year of publication of the literature, country or region, research methodology, subjects of the study, phenomenon of interest, situational factors, type of GenAI and key features, and key findings related to attitudes and experiences (Multimedia Appendix 3). Consensus on extraction was reached through discussion, with any disagreements arbitrated by a third reviewer (YB).

For the synthesis, we used the 3-stage thematic synthesis approach proposed by Thomas and Harden [37]. Phases 1 and 2 involved inductive line-by-line coding to generate descriptive themes; Phase 3 used a post hoc interpretive lens—the Technology Acceptance Model for Artificial Intelligence in Nursing (TAM-AIN) proposed by Ramadan et al [38]—to elevate these descriptive themes into higher-order analytical themes. The rationale for this analytical choice is as follows. The TAM-AIN extends Davis' classic TAM [39,40], which identifies perceived usefulness and perceived ease of use as primary determinants of technology adoption, by incorporating three additional constructs specifically relevant to nursing: ethical alignment (eg, concerns about patient privacy and the preservation of human dignity), organizational readiness (eg, institutional support, infrastructure, and training), and perceived threats to professional autonomy (eg, fears of job displacement or deskilling). We selected this framework because it is domain-specific and empirically grounded in nurses' perspectives, offering a coherent structure to organize our descriptive themes into higher-order analytical insights. Crucially, this model was not used to design data collection instruments or to guide initial coding; it was applied retrospectively—after descriptive themes had been generated—solely to enrich interpretation and to generate novel conceptual insights, rather than to constrain or predetermine our analysis.

Two researchers (MMW and CYZ) independently performed initial line-by-line coding using NVivo 15 (Lumivero). Our preregistered protocol specified NVivo 11; however, during the review process, we updated to NVivo 15 to take advantage of improved stability and interface enhancements. This technical upgrade did not affect the coding structures or analytical outputs. Disagreements in coding or theme development were resolved through discussion, with consensus reached through team deliberation. To enhance coding reliability, the research team held regular coding review meetings every 2 weeks to systematically review all codes and reach consensus.

The analysts were clinical nurses who used GenAI in their daily work and held positive attitudes toward the technology. We acknowledge that this may have predisposed us to emphasize positive experiences and benefits while potentially under-examining concerns and negative experiences. To minimize bias, the team engaged in reflexive dialogues throughout the analysis. All codes and themes were independently cross-checked, and disagreements were debated until consensus was reached.

Assessing Confidence in the Findings

We used the GRADE-CERQual (Grading of Recommendations Assessment, Development and Evaluation-Confidence in the Evidence from Reviews of Qualitative Research) approach to assess the level of confidence in the findings of this qualitative meta-synthesis [41]. GRADE-CERQual provides a systematic and transparent framework for assessing confidence in individual review findings based on 4 components: methodological limitations, coherence, adequacy of data, and relevance. For each review finding, 2 reviewers (MMW and CYZ) independently assessed the four components, with disagreements resolved through discussion or arbitration by a third reviewer (YB), and the overall confidence was rated as high, moderate, low, or very low using the GRADE-CERQual approach. A rating of high confidence indicates that it is highly likely that the review finding is a reasonable representation of the phenomenon of interest.

Results

Overview

A total of 4350 studies were initially identified, comprising 4346 from database searches and 4 through reference list screening. After duplicates were removed, 2935 unique records underwent title and abstract screening, yielding 67 articles for full-text review. After full-text assessment, 54 records were excluded, leaving 13 studies [24-36] that met all inclusion criteria (Figure 1).

XSL•FO
RenderX

Figure 1. Literature screening process. GAI: generative AI.

All of the included studies (n=13) [24-36] were rated as having a low risk of bias, with detailed quality assessment results presented in Multimedia Appendix 2. While study design and ethical considerations were generally robust, a common limitation was a lack of explicit reporting on researcher reflexivity and positioning. The 13 included studies [24-36] were published between 2023 and 2026 and were conducted across 6 countries: China (n=6) [26,28,30,33-35], Saudi Arabia (n=3) [27,29,36], and one each from the United States [32], South Korea [31], Australia [24], and Singapore [25]. The studies took place in various health care and academic settings, including general hospitals, teaching hospitals, specialized cancer centers, and university-affiliated simulation centers. In total, these studies comprised qualitative data from 234 registered nurses working in various specialties, including intensive care, oncology, pediatrics, neonatology, and general wards. One study [24] used a mixed methods design, while the other 12 studies [25-36] were qualitative.

Confidence in the Review Findings

Confidence in the review findings ranged from high to moderate. Reasons for downgrading were due to concerns regarding coherence and/or adequacy of data. Among the 9 subthemes, 4 were rated as moderate confidence due to minor to moderate concerns regarding coherence and/or adequacy of data (Table 2).

XSL•FO
RenderX

Table . Summarized review categories and GRADE-CERQual (Grading of Recommendations Assessment, Development and Evaluation-Confidence in the Evidence from Reviews of Qualitative Research) assessment.

Findings	References	GRADE-CERQual assessment of confidence	Explanation of overall assessment
Subtheme 1.1: Passive Observation—Novice Users' Cautious and Distant Stance	4 studies (Liu et al [28]; Tong et al [33]; Wang et al [34]; Yin et al [35])	Moderate confidence[a]	No or very minor concerns regarding methodological limitations, minor concerns regarding coherence, moderate concerns regarding adequacy, and no or very minor concerns regarding relevance.
Subtheme 1.2: Pragmatic Usage—Intermediate Users' Task-Oriented Adoption	13 studies (Nazir et al [24]; Shankar et al [25]; Qu et al [26]; Alanzi et al [27]; Liu et al [28]; Artuwaili et al [29]; Kang et al [30]; Han et al [31]; Bautista et al [32]; Tong et al [33]; Wang et al [34]; Yin et al [35]; Temsah et al [36])	High confidence[b]	No or very minor concerns in all four domains.
Subtheme 1.3: Proactive Integration—Advanced Users' Collaborative and Transformative Engagement	10 studies (Nazir et al [24]; Shankar et al [25]; Qu et al [26]; Liu et al [28]; Artuwaili et al [29]; Kang et al [30]; Han et al [31]; Bautista et al [32]; Tong et al [33]; Wang et al [34])	High confidence[b]	No or very minor concerns in all four domains.
Subtheme 2.1: Functional Deficits—Concerns Over Inaccuracy, Insecurity, and Instability	12 studies (Shankar et al [25]; Qu et al [26]; Alanzi et al [27]; Liu et al [28]; Artuwaili et al [29]; Kang et al [30]; Han et al [31]; Bautista et al [32]; Tong et al [33]; Wang et al [34]; Yin et al [35]; Temsah et al [36])	High confidence[b]	No or very minor concerns in all four domains.
Subtheme 2.2: Professional Erosion—Threats to Critical Thinking, Compassion, and Identity	11 studies (Nazir et al [24]; Shankar et al [25]; Qu et al [26]; Alanzi et al [27]; Liu et al [28]; Artuwaili et al [29]; Han et al [31]; Bautista et al [32]; Tong et al [33]; Wang et al [34]; Yin et al [35])	High confidence[b]	No or very minor concerns in all four domains.
Subtheme 2.3: Accountability Ambiguity—Blurred Boundaries of Legal and Ethical Responsibility	6 studies (Qu et al [26]; Alanzi et al [27]; Han et al [31]; Bautista et al [32]; Tong et al [33]; Yin et al [35])	Moderate confidence[a]	No or very minor concerns regarding methodological limitations, no or very minor concerns regarding coherence, moderate concerns regarding adequacy, no or very minor concerns regarding relevance.
Subtheme 3.1: Cultural Preparedness—Fostering Training and Social Endorsement	8 studies (Nazir et al [24]; Shankar et al [25]; Liu et al [28]; Artuwaili et al [29]; Kang et al [30]; Han et al [31]; Bautista et al [32]; Wang et al [34])	Moderate confidence[a]	No or very minor concerns regarding methodological limitations, no or very minor concerns regarding coherence, minor concerns regarding adequacy, no or very minor concerns regarding relevance.
Subtheme 3.2: Technical Preparedness—Enhancing Usability, Applicability, and Response Precision	10 studies (Nazir et al [24]; Shankar et al [25]; Qu et al [26] Alanzi et al [27]; Liu et al [28]; Artuwaili et al [29]; Kang et al [30]; Han et al [31]; Bautista et al [32]; Tong et al [33])	High confidence[b]	No or very minor concerns in all four domains.
Subtheme 3.3: Institutional Preparedness—Strengthening Oversight, Regulation, and Funding	6 studies (Nazir et al [24]; Shankar et al [25]; Qu et al [26]; Artuwaili et al [29]; Han et al [31]; Bautista et al [32])	Moderate confidence[a]	No or very minor concerns regarding methodological limitations, minor concerns regarding coherence, moderate concerns regarding adequacy, no or very minor concerns regarding relevance.

[a]It is likely that the review finding is a reasonable representation of the phenomenon of interest.

XSL•FO
RenderX

[b]It is highly likely that the review finding is a reasonable representation of the phenomenon of interest.

Three overarching themes were identified: engagement patterns across adoption stages, multidimensional perceived threats, and the moderating role of organizational readiness; these comprised 9 subthemes grouped respectively as novice, intermediate, and advanced user patterns; functional, professional, and accountability concerns; and cultural, technical, and institutional preparedness. The findings suggest that perceived threats undermine perceived usefulness and ease of use while amplifying professional autonomy concerns, functioning as primary barriers. Organizational readiness moderates this dynamic: high preparedness alleviates threats and promotes proactive engagement, whereas low readiness reinforces obstacles and sustains conditional use.

Theme 1: Patterns of Nurses' Engagement With GenAI

Overview

Nurses' attitudes and practices regarding GenAI were described as forming a continuum ranging from passive observation to active integration, reflecting varying levels of engagement with the technology. These patterns were perceived by participants to be influenced by varying levels of perceived usefulness, perceived ease of use, perceived threats to professional autonomy, ethical congruence, and organizational readiness. The synthesis identified three distinct engagement patterns among nurses within clinical settings: novice users, who were characterized by a passive, wait-and-see stance; intermediate users, who acted as pragmatic adopters; and advanced users, who described actively seeking deeper integration of GenAI into clinical workflows—for example, in nursing education and patient care.

Subtheme 1.1: Passive Observation—Novice Users' Cautious and Distant Stance

Four included studies [28,33-35] identified novice users who acknowledged GenAI's rapid advancement but described themselves as remaining at the periphery, adopting a cautious "wait-and-see" stance. Findings highlighted several interrelated barriers associated with this cautious stance: lack of training, limited hands-on experience with GenAI, and concerns about its clinical reliability. These concerns were frequently centered on fears that AI may erode the humanistic essence of nursing and compromise patient care, as well as anxieties about data privacy and security. Theoretically, this group reported very low perceived ease of use, which was linked in their accounts to low confidence in using GenAI, and heightened perceived threats to professional autonomy. Across these accounts, participants frequently described these interconnected perceptions alongside distrust, perceived limited usefulness, and a predominantly passive, detached posture toward GenAI.

For example, one nurse stated hesitantly:

> *Since I'm not engaged in research, why should I bother learning about these matters?* [(N12, regarding the application of ChatGPT-like language models in medicine 35)]

Another nurse shared:

> *I'm not yet proficient in using AI tools, and I often feel that my AI-generated scenarios are not as well-structured as those created by others. I'm concerned about potential challenges in scaling AI adoption.* [(N11, ICU novice simulation instructors who participated in a simulation instructor training program incorporating Gen AI for case design 28)]

Subtheme 1.2: Pragmatic Usage—Intermediate Users' Task-Oriented Adoption

Across all 13 included studies [24-36], intermediate users used GenAI as a tool to enhance efficiency and support their professional practice. Their use of GenAI was predominantly task-oriented, focusing on alleviating administrative burden. Key applications included automating clinical documentation, generating handover summaries, drafting personalized patient education materials, and staying updated with recent evidence for practice or research. They regarded GenAI not as a replacement but as a valuable complementary tool, perceived as streamlining workflows, minimizing manual data entry, and freeing time for direct patient care. Beyond operational gains, they viewed GenAI as a resource for professional development, linking it to skill acquisition, reduced documentation errors, and what they perceived as improved patient outcomes—a pattern that was consistent with their high ratings of perceived usefulness. However, their adoption remained conditional. They emphasized the need for ongoing training and robust human oversight, while also expressing concerns about sociodemographic biases in AI-generated content and ethical issues.

For example, one participant stated:

> *I do see generative AI being one of the underlying software in avatars that patients will speak to in a digital setting, whether through video chats, phone calls, or texts, in which we offload some of the more time-intensive and repetitive conversations that nurses have.* [(Practitioner 8, informatics nurse administrator, on the use and implications of GenAI tools in nursing education and practice 32)]

A second participant stated:

> *When I need to design a bulletin board for infant health education, it can perform hotspot analysis and generate a preliminary outline for me. I can then augment it with my professional knowledge, thereby enhancing work efficiency.* [(N5, a pediatric nurse, on her experience with GenAI 34)]

Another participant remarked:

> *When the AI flags potential respiratory distress, I don't just change settings blindly. I check the baby's color, muscle tone, and response. The AI points me in a direction, but I still make the call.* [(P22, a neonatal nurses' experiences with GenAI in clinical decision-making 29]

XSL•FO
RenderX

Subtheme 1.3: Proactive Integration—Advanced Users' Collaborative and Transformative Engagement

In 10 included studies [24-26,28-34], participants were characterized as pioneers in integrating GenAI into nursing practice. They moved beyond basic tool use to engage GenAI as a collaborative partner in clinical practice, demonstrating high ethical congruence and proactively embracing technological change. Mastery of prompt engineering was a core competency that seemingly enabled them to optimize AI outputs for clinical relevance. Advanced users viewed the inevitable evolution toward AI adoption and actively redefined their professional roles and skillsets to work effectively with AI. This proactive identity shift apparently transformed potential threats to professional autonomy into developmental opportunities. A guiding principle was that humanistic care should govern technology use, ensuring that AI augments clinical judgment rather than replaces it. This engagement was described as fostering a reciprocal development cycle: interacting with GenAI expanded cognitive perspectives, was seen as a catalyst for continuous learning, and was linked to deeper expertise for guiding AI effectively. Driven by strong perceived usefulness across multiple domains, they explored advanced applications such as data analysis and documentation to enhance diagnostic reasoning and free time for direct patient care. Ultimately, this appeared to reflect a dual internalization—at both cognitive and behavioral levels.

For example, one nurse stated:

> *In many cases, I feel that my thinking is not comprehensive enough, especially as I have worked in a clinical environment for many years and can have some inherent thoughts that limit my thinking. By interacting with GAI, I feel that my thinking and perspective have been broadened.* [(FG3-N23, clinical nurse, experience with GenAI training for research support 33)]

Another nurse stated:

> *In the past, we spent a great deal of time searching for literature and organizing data. Now, we must learn how to guide AI to generate valuable content and to propose directions for further research. We have become more like helmsmen of the research direction, while AI serves as the engine that provides the power.* [(N14, clinical nurse, experience with the perceptions and application of GenAI 26)]

A third nurse added:

> *Sometimes, the AI confirms what I'm already suspecting, and other times, it challenges me to reconsider. Either way, it ensures I'm never complacent.* [(P29, Neonatal nurses' experiences with GenAI in clinical decision-making 29)]

Theme 2: Nurses' Multidimensional Perceived Threats to GenAI Adoption

Overview

Nurses' perceived threats regarding GenAI in terms of 3 core dimensions: functional (accuracy and confidentiality concerns), professional (threats to humanistic care and professional autonomy), and accountability-related (uncertainties about legal and professional responsibility). In addition, they reported a cautiously optimistic orientation, characterized by guarded enthusiasm tempered by concerns, which they discussed alongside these perceived threats.

Subtheme 2.1: Functional Deficits—Concerns Over Inaccuracy, Insecurity, and Instability

Functional deficits emerged as a key concern across 12 studies [25-36], wherein nurses expressed significant reservations regarding the reliability and infrastructural support of GenAI. These concerns, which align with the perceived threats to functionality posited by the TAM-AIN framework, were primarily categorized into three domains: (1) output accuracy and clinical validity—specifically, the risk of "hallucinations," limited ability to handle complex clinical contexts, and the generation of misleading information that could harm patients or delay care; (2) privacy and data security—fears that GenAI could increase the risk of patient data breaches and information leakage, along with concerns about the need for strict safeguards to prevent misuse; (3) system stability and infrastructural support—worries about technical failures, connectivity issues, and inadequate IT support disrupting workflows. Overall, nurses perceived these concerns as significant barriers that could impede their acceptance and sustained use of GenAI.

One nurse remarked:

> *I find it difficult to use GenAI efficiently without a research foundation. For example, when GenAI provides citations or recommends statistical methods, I need a research foundation to judge the accuracy of the content. Without a research base, GenAI may mislead me into misusing the information.* [(FG1-N4, nurse's perceptions and experiences of GenAI training to support research 33)]

As one nurse noted:

> *I feel confident when I know there's IT support at hand. Without it, the AI can become a source of frustration rather than insight.* [(P26, neonatal nurses' experiences with GenAI in clinical decision-making 29)]

Another nurse stated:

> *I'm hesitant to try it because I'm not sure where the information goes. Even if we don't use names, I worry someone could still trace it back to a patient or misuse this data.* [(P15, Exploring Early Perceptions and Experiences of ChatGPT in Pediatric Critical Care 36)]

Subtheme 2.2: Professional Erosion—Threats to Critical Thinking, Compassion, and Identity

As described in 11 papers [24-29,31-35], nurses also worried about the cognitive and professional implications of GenAI adoption, reflecting TAM-AIN role threats. Concerns clustered into 3 interrelated areas:

XSL•FO
RenderX

Erosion of autonomous and critical thinking—they perceived that GenAI might inhibit users' critical thinking, with particular concerns that overreliance could foster dependency and impair independent clinical judgment, especially among younger nurses. Nurses emphasized that AI should serve as an augmentative tool to support traditional nursing practice and a learning aid to complement—not substitute—clinical reasoning

Threats to humanistic care, professional identity, and the nurse-patient relationship—although some acknowledged that reduced documentation burden could free up time for bedside care, others worried that technological dependency would reduce direct patient contact. They feared that misuse of GenAI could erode patient trust, hinder rapport-building, and raise ethical dilemmas about whether patients are ultimately interacting with a machine or a human. Nurses expressed ambivalence, as they saw it as potentially enhancing humanistic care in administrative tasks, while challenging their caring role in patient-interactive tasks.

Nurses indicated that GenAI could undermine the humanistic foundation of nursing practice. Given its inherent difficulty in establishing genuine trust with patients and its limitations in emotional understanding, nurses were concerned that GenAI cannot authentically experience or convey empathy or compassion. This may compromise personalized care and result in a deficit of humanistic elements. Furthermore, nurses perceived that traditional nursing models are being challenged. As medical and nursing work grows increasingly complex, the professional identity of nurses in the AI era has also become more multifaceted. They expressed anxiety that core nursing roles might be diminished or replaced by AI and have begun to reflect on how to address this impact, as well as on the future direction of the profession.

One nurse stated:

> *No matter how well the machine displays information and reacts, it's not the same as direct communication. If nurses are only administering medication without interaction, it would likely hinder rapport building.* [(An oncology nurse's perceptions for GenAI 31)]

Another nurse observed:

> *I've seen many technologies come and go. Some helped, some created more problems. My concern is that younger nurses might start trusting the machine too much. Nursing is about thinking, observing, connecting things that don't obviously connect. Can AI do that? I don't think so, not yet.* [(RN02, an experienced nurse expressed greater caution regarding GenAI-enabled shift handover innovation 25)]

Subtheme 2.3: Accountability Ambiguity—Blurred Boundaries of Legal and Ethical Responsibility

A total of 6 papers [26,27,31-33,35] reported that nurses articulated significant concerns regarding legal and ethical ambiguity—concerns about accountability in the event of clinical errors, difficulties in determining responsibility when mistakes occur, transparency in patient interactions (eg, disclosing AI-generated responses), and ethical dilemmas regarding whether patients are ultimately interacting with a machine or a human. In addition, nurses raised concerns about the blurred attribution of academic contributions and perceived threats to academic integrity when using GenAI in educational or research settings. Nurses also called for stronger governance, including clearer legal frameworks, ongoing monitoring, and stronger institutional guidance to ensure responsible use. They perceived regulatory and ethical considerations as critical factors in the effective implementation of GenAI.

One oncology nurse questioned:

> *From an ethical standpoint, if AI produces incorrect results, can the consequences be solely placed on the patient? Who should be held accountable- the manufacturer of the device or the developer of the software?* [(A nurse's perceptions of GenAI 31)]

A second nurse commented:

> *I saw that the journals under the Chinese Medical Association had issued a joint statement that articles using GenAI writing would not be accepted for publication. Then I thought, is there any point in learning how to use it? If I write a part of an article using GenAI but do not know how to label or describe it, will that make me a researcher defaulter?* [(FG1-N14, Perceptions and experiences of GenAI training to support research 38)]

A third nurse with research experience observed:

> *When using AI to assist in writing papers, even with substantial modification and deepening of the content, it remains difficult to define the boundary of personal contribution. This uncertainty diminishes the sense of achievement in research work.* [(N6, a clinical nurse regarding perspectives on GenAI 26)]

Theme 3: The Moderating Role of Organizational Readiness on GenAI Adoption

Overview

Nurses described their perceptions of organizational readiness in terms of three interconnected domains. In terms of cultural readiness, nurses consistently voiced a compelling need for enhanced training and education to build competency and foster greater societal acceptance of GenAI-involved nursing care. Regarding technical readiness, they discussed a need for optimized, clinically-tailored tool development to ensure relevance and utility, with more specialized and precise responses expected from GenAI systems. With respect to institutional readiness, they identified a need for proactive organizational strategy and support to enable safe and effective implementation, encompassing improved technical oversight, personnel preparation, and regulatory frameworks. Participants described organizational readiness as influencing their acceptance and sustained use of GenAI. They reported that higher levels of preparedness across cultural, technical, and institutional domains were associated with greater openness to adoption, while deficiencies in any dimension were noted as potential challenges. Across these accounts, participants

XSL•FO
RenderX

identified addressing these interconnected needs as fundamental to successful GenAI integration into nursing practice.

Subtheme 3.1: Cultural Preparedness—Fostering Training and Social Endorsement

In eight studies [24,25,28-32,34], nurses described cultural readiness in terms of two interrelated dimensions: internal workforce capacity-building and external societal acceptance. Internally, nurses expressed a strong unmet need for GenAI training. Many reported limited understanding of GenAI functionality, which they identified as a barrier to trust and willingness to use these tools. They called for dedicated, practical training and integration of GenAI-related knowledge into nursing curricula and continuing professional education, which they viewed as necessary for informed decision-making and safe, effective use. Externally, cultural readiness was seen as fostering broader societal acceptance. Nurses recognized that local cultural beliefs and values influence AI adoption in clinical practice and suggested that hospital- and community-level advocacy would be needed to enhance patient and public acceptance of GenAI involvement in nursing care.

One nurse observed:

> *Saudi Arabia's national push for digital health support makes us more willing to embrace AI. It feels like we are part of a larger modernization effort.* [(P 30, a neonatal nurse's experience with GenAI in clinical decision-making 29)]

A second nurse remarked:

> *I don't think that in five years from now, the way we practice today will be the way we practice tomorrow. New nurses coming in need to have a baseline understanding of how to prompt these [GenAI] systems to get an output that would be helpful in a clinical environment.* [(Practitioner 11, nursing professional development nurse administrator view on the use and implications of GenAI tools on nursing education and practice 32)]

Subtheme 3.2: Technical Preparedness—Enhancing Usability, Applicability, and Response Precision

The technical preparedness was reported in 10 papers [24-33], technical readiness encompasses not only system usability and workflow integration but also the expansion of potential applications, the development of more specialized content, and the delivery of more precise responses. Participants expressed that current GenAI tools require significant optimization to meet the nuanced demands of clinical practice. They emphasized the need for improved interoperability with existing systems such as the electronic health record (EHR) and more user-friendly interfaces to enhance usability and seamless workflow integration. They described potential applications for GenAI, including substituting high-risk activities (eg, chemotherapy preparation), assisting with vital signs observation, and guiding patient specimen collection, as well as simulating patient interactions, conducting emergency drills, and training new nurses. Furthermore, they advocated for the development of nursing-specific GenAI systems, specialized databases or corpora, and institutionally tailored solutions to enhance clinical relevance and professional rigor. In addition, nurses desired more accurate and context-aware responses from GenAI, with the ability to capture complete information, perform structured data processing, and aggregate and summarize complex datasets, which they viewed as providing more fine-grained and precise answers to support clinical decision-making. Nurses described addressing these technical readiness needs as important for their acceptance and sustained use of GenAI.

One informatics nurse observed:

> *Generative AI tools are not going to be able to be maximally helpful unless they are linked to the patient's electronic health record, so that inferences can be made about very specific patient factors, because the more specific the recommendations are, the more actionable and helpful they are for nurses.* [(Practitioner 8, informatics nurse administrator, on the use and implications of GenAI tools in nursing education and practice 32)]

A second nurse remarked:

> *Could we develop a decision support system using GenAI to input patient temperature data and other vital signs . This system would help us train new nurses and reduce our workload.* [(FG1-N4, perceptions and experiences of GenAI training to support research 33)]

A third nurse asked:

> *Is there a corpus for the nursing profession, or some database, that would allow us to search more accurately for future nursing research knowledge for nurses? That way, the information nurses receive will be more reliable.* [(C3, a clinical nurse, regarding researchers' perceptions of GenAI 30)]

Subtheme 3.3: Institutional Preparedness—Strengthening Oversight, Regulation, and Funding

Across six reviewed papers [24-26,29,31,32], institutional readiness was characterized by technical oversight, clear legal and regulatory frameworks, and adequate staffing and funding allocation. Nurses expressed that organizational decisions and support structures shaped the adoption and effective use of GenAI software. They described the organization's stance and resource levels as factors that influenced the depth and quality of GenAI integration. They emphasized the necessity of technical oversight during GenAI application, including routine monitoring, evaluation, feedback mechanisms, and the essential role of human supervision. Furthermore, they called for clear regulations and guidelines from hospital management regarding which AI programs are permitted for use within the system and called for the prompt establishment of standardized guidelines for the responsible use of GenAI in research contexts. They also expressed a desire to reduce cumbersome procedural approvals when using GenAI within the organization. In terms of personnel and funding, participants noted that sufficient staffing was needed for GenAI to function effectively and stressed that the

XSL•FO
RenderX

implementation of GenAI requires adequate financial support. They also hoped for active organizational support in developing or procuring customized GenAI solutions aligned with specific institutional missions and clinical workflows, which they viewed as a potential strategy to safeguard the confidentiality of protected health information.

One oncology nurse manager observed:

> *There was information put out [by the hospital management] about which AI programs we are allowed to use in our system. Right now it's only Microsoft [Copilot]*. [(Practitioner 1, oncology nurse manager, on the use and implications of GenAI tools in nursing education and practice 32)]

A second nurse emphasized:

> *Legal support is necessary. We need to demonstrate that we are well-prepared in case legal issues arise. Only then can nurses use the technology with peace of mind. If the responsibility falls entirely on the nurses, they may not use it.* [(A nurse's perception of GenAI 31)]

A third informatics nurse added:

> *My workplace is very vocal about wanting to be the number one global leader for digital health. For example, I got a $1,000,000 grant to work on this.* [(Practitioner 8, informatics nurse administrator, on the use and implications of GenAI tools in nursing education and practice 32)]

Discussion

Principal Findings

This synthesis of 13 qualitative studies [24-36] (234 registered nurses, 6 countries) characterizes nurses' adoption of GenAI in clinical settings. Three overarching themes and 9 subthemes emerged: engagement patterns (novice, intermediate, and advanced users), multidimensional perceived threats (functional, professional, and accountability), and the moderating role of organizational readiness (cultural, technical, and institutional). These findings not only consolidate existing evidence but also extend the TAM-AIN framework, as we elaborate below.

Theoretical Contributions: An Extended TAM-AIN Framework

The findings support and extend the TAM-AIN framework [38] by showing that organizational readiness emerged as a key shaping factor, not merely an antecedent. This aligns with Shankar et al's [25] finding that nurses exhibit cautious optimism and conditional acceptance. At the same time, the findings advance their work by interpreting these "conditions" as concrete threat and readiness dimensions, making the concept more relevant for intervention design. These contributions provide theoretical guidance for future research and clinical management, and point to targeted strategies in training, technical optimization, and policy formulation.

Building on these empirical insights, we propose an integrated analytical framework (Figure 2) that extends the TAM-AIN. This framework captures the dynamic interplay through which perceived usefulness, perceived ease of use, ethical congruence, organizational readiness, and multidimensional perceived threats collectively shape nurses' adoption behaviors and differentiates three distinct user types. The framework advances the TAM-AIN in 2 key ways. First, it differentiates the formerly unified construct "perceived threat to professional autonomy" into three distinct dimensions—erosion of humanistic care, ambiguity in legal liability, and degradation of cognitive skills—each of which emerges as a distinct barrier to technology uptake. Second, organizational readiness is reconceptualized not as a unified construct, but as three distinct pathways—technical, institutional, and cultural preparedness—that appear to shape adoption by shaping perceptions of ease of use, mitigating perceived threats, and reinforcing ethical congruence. Taken together, these conceptual refinements illustrate how individual perceptual dynamics and organizational ecologies interact to shape nurses' use of GenAI, the barriers they encounter, and the unmet needs they express in clinical practice.

Figure 2. Qualitative research analysis framework. GenAI: generative AI.

GenAI in Health Care: An Inevitable Trend Requiring Proactive Engagement

The rapid advancement of GenAI over recent years represents a technological transformation that is increasingly penetrating the high-stakes medical field [42]. Systematic reviews have highlighted its potential to enhance health care efficiency through streamlining workflows, reducing costs, and personalizing care [43]. Surveys indicate generally positive attitudes among health care professionals. For example, a study of 902 professionals (54.9%, 495/902 of whom were nurses) found that 56.1% (506/902) felt comfortable using AI in practice, and 72% (649/902) believed it would improve future health care [44]. In a similar vein, a study of Turkish nurses found that 84.4% (243/288) believed nurses should be informed about ChatGPT and AI, viewing it as beneficial for professional development and patient care [45].

These positive attitudes align with our finding that nurses exhibited varying levels of engagement with GenAI, reflecting a continuum from novice to intermediate to advanced users. As GenAI becomes more widespread, the proportion of passive novice users will likely diminish, while intermediate and advanced users drive its application, catalyzing transformative changes in nursing practice. Notably, advanced users engaged with GenAI as a collaborative partner in clinical practice, actively redefining their professional roles to adapt.

Navigating Challenges: A Call for Critical Development and Prudent Implementation

Current evidence suggests that GenAI does not yet match expert human clinical judgment. For example, one comparative study [46] found that experienced community nurses outperformed a leading GenAI system in diagnostic accuracy and clinical decision-making in simulated scenarios, with AI responses being faster but often verbose and containing unnecessary information. Other research has noted tendencies toward indecisiveness and over-triage in AI tools [47], advising caution against premature deployment as a nurses' digital aide. Our review confirms these technical and reliability concerns and extends them by identifying broader threats perceived by nurses. These fall into three categories: functional deficits (inaccuracy and data insecurity), professional erosion (critical thinking, compassion, and professional identity), and ambiguity in legal and ethical responsibility.

Moreover, deeper familiarity with GenAI appears to temper initial optimism with greater critical awareness. A study of nursing educators' perceptions of AI chatbots found that frequent users had a more nuanced understanding of the advantages and limitations, whereas infrequent users expressed fewer concerns—a pattern consistent with the TAM [13]. Our findings show that nurses' specific worries—about misinformation, erosion of humanistic care, and legal and ethical dilemmas—become more clearly articulated with deeper engagement.

Beyond the immediate concern of erosion of humanistic care, the literature increasingly points to the possibility that GenAI may fundamentally reshape nursing professional identity. This is not merely a workflow adjustment but a profound challenge to professional identity. One qualitative study reported that 87.9% (29/33) of neonatal nurses identified "Professional Identity in the AI Era" as a key theme, with 84.8% (28/33) reporting shifting role boundaries [29]; likewise, an integrative review identified "Role Boundaries, Ethics, and Trust" as a core theme [21]. Our synthesis further delineates three interrelated pathways of professional erosion: threats to critical thinking (via overreliance), to compassionate care (via relationship erosion), and to professional identity (via role diminishment). This 3-part operationalization provides a more actionable framework than prior studies that treated identity threat as a monolithic concern.

Building Organizational Readiness: A Roadmap for Proactive Implementation and Nurse-Led Co-Design

The unmet needs identified in this review-targeted education, clinically optimized tools, and robust institutional governance-echo broader recommendations in the literature

XSL•FO
RenderX

[44,48]. Importantly, our findings position organizational readiness as a moderating factor: higher levels of cultural, technical, and institutional preparedness alleviate threat perceptions and enhance confidence, thereby enabling more proactive engagement, whereas deficiencies in any dimension sustain conditional use. A systematic review [49] of AI in nursing further found that adoption is driven by perceived usefulness, self-efficacy, and enabling environments, with anxiety and demographics influencing engagement. An integrative review [21] of GenAI in clinical nursing practice reinforced these findings, finding that "safe and effective integration will require rigorous nurse training, robust governance, transparent labeling of AI-generated content, and ongoing evaluation"—elements that correspond directly to our three dimensions of organizational readiness.

Previous work has proposed strategies including developing multimodal systems integrated with real-time data (eg, EHRs), using emotional computation, and establishing comprehensive ethical and policy frameworks [10]. Specifically, we recommend: (1) prioritizing the development of clinically validated, context-specific models to ensure reliability and safety; and (2) embedding a human-in-the-loop principle in tools to preserve nursing oversight and professional autonomy. Our synthesis identifies accessible IT support as a decisive factor separating conditional users from proactive adopters. The human-in-the-loop model, in which educators or clinicians validate GenAI outputs, has been proposed as a key framework for cultivating nurses who use technology critically and ethically while maintaining competent, human-centered care [50]. Importantly, our findings extend this model by specifying that accessible IT support is a nonnegotiable prerequisite: without it, even the best-designed human-in-the-loop framework fails, because nurses lack the confidence to engage; (3) adopting a systematic implementation roadmap that synchronizes policy, training, and nurse-led co-design. These steps are crucial for aligning GenAI development with the core values and practical realities of nursing.

Limitations

This review has several limitations that should be acknowledged. First, the exclusively qualitative design does not allow for quantification of the prevalence, severity, or relative weight of the identified phenomena, limiting its capacity for directly informing intervention thresholds (eg, optimal training duration) in nursing administration. Second, most included studies originated from countries with moderate-to-high digitalization and generally permissive AI policies, with underrepresentation of low-resource settings (eg, Southeast Asia, Africa, and Latin America) and regions with stringent AI regulation (eg, the European Union under the European Union AI Act). This predominantly policy-permissive sample may have overestimated acceptance, and generalizing to underrepresented settings requires caution. Third, as this review captures findings published up to June 2026, the timeliness of these findings varies: user typologies may become dated, ethical and professional concerns may intensify with deeper AI integration, and training needs will evolve from basic skills to advanced clinical applications. We have updated the search to include the latest literature and recommend regular updates of the review. Fourth, the restriction to English and Chinese publications may have excluded relevant studies in other languages, and despite search revisions, comprehensive coverage cannot be guaranteed. Finally, thematic saturation was not formally assessed, although data redundancy began to emerge after synthesizing the first ten studies [27-36]. Given the contextual heterogeneity of the included studies, additional research in underrepresented settings may yield new thematic dimensions. Regarding transferability, we have provided detailed contextual descriptors for each primary study (Multimedia Appendix 3) to facilitate readers' assessment of applicability. However, the predominantly policy-permissive, digitized contexts may limit direct transferability to low-resource or highly regulated settings.

Future Direction

This review provides an evidence base for developing context-aware guidelines that prioritize nurse agency and patient safety; future research could use longitudinal and mixed methods designs to track the coevolution of GenAI capabilities and nursing practice across diverse health care settings. Comparative studies across health care systems, cultural contexts, and policy environments are needed to better understand the contextual factors shaping GenAI adoption and its challenges. Given that the current evidence base is insufficient for systematic subgroup comparisons, future research should explicitly differentiate between various GenAI applications—ranging from administrative chatbots (eg, for drafting handover summaries) to clinical decision support tools and robotic systems. This would allow researchers to examine whether nurses' perceptions, trust, and usage patterns differ systematically across these categories. Such granular insights are essential for tailoring implementation strategies, training programs, and governance frameworks to the specific risks and benefits of each tool type. Longitudinal studies are equally crucial for tracking how nurse experiences and attitudes transform alongside the technology itself.

Conclusions

This systematic review synthesized qualitative evidence from 13 studies [24-36] involving 234 registered nurses from 6 countries. The findings reveal three interconnected dimensions shaping nurses' engagement with GenAI: a spectrum of adoption patterns ranging from passive observation to pragmatic use and proactive integration; multidimensional perceived threats including functional deficits, professional erosion, and accountability ambiguity; and the moderating role of organizational readiness across cultural, technical, and institutional domains. These findings advance the TAM-AIN framework by demonstrating that organizational readiness moderates adoption by either alleviating perceived threats and fostering proactive adoption or reinforcing barriers and perpetuating conditional use. Accordingly, the unmet needs call for synchronized progress across workforce development, tool design, and institutional oversight, ensuring that efficiency gains do not compromise the humanistic essence of nursing care amid global workforce shortages.

Abstract

Background: Machine learning models are increasingly used for glycemic event prediction and continuous glucose forecasting, but targets, populations, horizons, validation, and uncertainty reporting remain heterogeneous.

Objective: This study aimed to evaluate machine learning models for glycemic prediction in type 1, type 2, and mixed diabetes populations while distinguishing the full evidence map from the quantitatively analyzable subset.

Methods: We searched 9 English- and Chinese-language databases from inception to April 12, 2026, for studies predicting future glycemic events or glucose values in people with diabetes. Continuous forecasting and binary event prediction were analyzed separately. Root-mean-square error (RMSE) was the principal continuous end point; mean absolute error was supportive. Area under the receiver operating characteristic curve was synthesized using a Bayesian random-effects model because analyzable 2×2 data were sparse. Two reviewers (HY and DA) independently applied PROBAST (Prediction Model Risk of Bias Assessment Tool) to 19 quantitative-source reports (28 assessment units).

Results: We identified 787 records, assessed 310 full texts, and included 299 reports representing 270 studies; 19 reports contributed to quantitative synthesis. The review included 128 type 1, 26 type 2, 78 mixed, and 38 unclear-diabetes-type studies. Pooled RMSE was 1.18 mmol/L (95% CI 1.01 - 1.34; 37 effects), supportive mean absolute error was 0.90 mmol/L (95% CI 0.78 - 1.02; 20 effects), and Bayesian pooled area under the receiver operating characteristic curve was 0.926 (95% credible interval 0.877 - 0.957). Supportive sensitivity and specificity were 0.77 and 0.80. Of 28 PROBAST units, 24 were high risk, 2 unclear, and 2 low. Post hoc exploratory within-report analysis estimated an RMSE increase of 0.481 mmol/L per additional 30 minutes (95% CI 0.213 - 0.749), but overlap sensitivity reduced certainty. In the 270-study clinical readiness audit, external validation occurred in 4.0% (10/251), prospective evaluation in 0.7% (2/270), calibration in 4.8% (13/270), decision-curve or net-benefit analysis in 2.6% (7/270), and implementation or human-factors evaluation in 2.6% (7/270).

Conclusions: Glycemic prediction studies show forecasting and discrimination signals, but heterogeneity, high risk of bias, incomplete uncertainty reporting, and limited external and prospective validation preclude deployable benchmarks. Pooled estimates should be viewed as summaries of analyzable literature. Future studies need transparent horizon, threshold, calibration, validation, uncertainty, and implementation reporting.

Introduction

Clinical and Digital Health Context

Diabetes involves both sustained hyperglycemia and short-term glucose variability, with glycemic excursions affecting safety and quality of life. Continuous glucose monitoring (CGM), connected insulin delivery, meal logs, and wearable sensors now provide high-frequency data for studying and predicting glucose dynamics.

Machine learning methods can model nonlinear, multimodal glucose data, but studies differ in diabetes phenotype, target, inputs, forecast horizon, validation, dataset provenance, and reporting. Binary glycemic event prediction and continuous glucose forecasting are often discussed together despite requiring different outcomes, effect measures, and clinical interpretations.

The central challenge is evidence transparency and transportability rather than model availability. Many reports omit uncertainty, reuse datasets, or provide results unsuitable for synthesis; we therefore distinguish the broad systematic review evidence map from the smaller quantitative subset. Clinical use also differs by diabetes type. Type 1 diabetes studies often address insulin therapy, hypoglycemia prevention, sensors, and decision support [1-5], whereas type 2 diabetes studies include dietary personalization, inpatient management, medication effects, and broader excursions [6,7].

Rationale for Separating Prediction Tasks

Binary event prediction asks whether hypoglycemia or hyperglycemia will occur within a specified horizon, whereas continuous forecasting estimates a future glucose value or trajectory. Their effect measures and implications for action are not interchangeable. Accordingly, the broad review maps the field, while formal synthesis is limited to reports with usable uncertainty or uniquely reconstructable threshold information. We did not present a single pooled benchmark as directly deployable across populations, treatments, and horizons.

Root-mean-square error (RMSE) and mean absolute error (MAE) summarize continuous forecast error, whereas area under the receiver operating characteristic curve (AUROC), sensitivity, and specificity describe binary discrimination or threshold classification. These measures support different clinical uses and were analyzed separately [1,5,7,8]. This prediction-family framework links each estimate to the evidence that can support it and identifies where only descriptive synthesis is justified.

Objectives

We aimed to (1) systematically review machine learning studies of glycemic event prediction and continuous glucose forecasting in type 1, type 2, or mixed diabetes populations; (2) synthesize reports with sufficient uncertainty or uniquely reconstructable threshold data; (3) examine heterogeneity related to horizon, validation, publication status, and dataset provenance; and (4) interpret transportability. We also audited all 270 studies against 8 predefined clinical readiness criteria.

Methods

Design, Registration, and Reporting

We conducted a systematic review and meta-analysis following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 and, for threshold syntheses, PRISMA-DTA (Preferred Reporting Items for Systematic Reviews and Meta-analyses of Diagnostic Test Accuracy Studies) [9,10]. PROBAST (Prediction Model Risk of Bias Assessment Tool) [11] was applied to the 19 reports contributing to quantitative synthesis; the broader 270-study map was characterized by reporting and validation features without formal PROBAST judgments. TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) concepts informed interpretation [12].

The protocol was finalized in early April 2026, and PROSPERO registration (CRD420261366978) was completed on April 12, 2026. The search was frozen that day; reconciled full-text assessment, extraction, and analysis followed. Before definitive fitting, Bayesian hierarchical AUROC was selected as the principal binary synthesis because analyzable 2×2 data were sparse, and RMSE was prioritized over MAE because variance-ready RMSE evidence was stronger. The review is therefore protocol-informed with documented presynthesis refinements rather than fully day 0 preregistered.

Continuous forecasting and binary event prediction remained separate throughout, as did review-level and meta-analysis–level evidence. Final updating refreshed searches, harmonized evidence tables, removed nonextractable abstract- or proceedings-only records, and added diabetes-type and horizon analyses. Full peer-reviewed conference papers were retained only when usable full text met the same criteria as journal papers.

Information Sources and Search Strategy

We searched PubMed, Web of Science Core Collection, Embase, Scopus, IEEE Xplore, CNKI, ACM Digital Library, arXiv, and the Cochrane Library from database inception to April 12, 2026. Search terms combined diabetes-related terms, glycemia or CGM terms, machine learning or AI terms, and prediction or forecasting terms. The complete source-specific search strategies and search dates are provided in Table S1 in Multimedia Appendix 1.

The auditable supplementary package is distributed across Multimedia Appendix 2 [13-16], Multimedia Appendix 3 [7,13-28], Multimedia Appendix 4 [1,2,7,13-21,23,25,26,28-47], and Multimedia Appendix 5. Multimedia Appendix 2 contains the search, screening, study characteristics, historical extraction, derivation, and figure materials; Multimedia Appendices 3-5 contain the PROBAST audit, source-verified analysis tables, and complete dual-review clinical readiness records.

No language restriction was applied at search. The final evidence base comprised 266 English- and 4 Chinese-language studies. Bilingual reviewers extracted Chinese reports; translated text was used only for verification. No otherwise eligible report in another language required quantitative extraction. Preprints and engineering reports had to meet the same human-diabetes,

XSL•FO
RenderX

future-prediction, and extractable performance criteria as journal papers. Studies published after April 12, 2026, and records without usable full text were excluded.

Eligibility Criteria

Eligible reports were original empirical studies of machine learning or AI for predicting future glycemic events or glucose values in type 1, type 2, mixed diabetes populations, or validated diabetes glucose dynamics datasets. We excluded diagnostic or complication classification, treatment recommendation without a future glycemic end point, healthy or prediabetes-only populations, nonhuman or in vitro studies, reviews, patents, theses, abstracts, and nonextractable proceedings. Full peer-reviewed conference papers were eligible when their full text supported the same screening and extraction process.

Quantitative synthesis required additional data readiness. Continuous outcomes needed MAE or RMSE with usable or defensibly derivable uncertainty; AUROC needed a SE, CI, or defensible derivation; and threshold outcomes needed reported or uniquely reconstructable true positive (TP), false positive (FP), false negative (FN), and true negative (TN). Other eligible studies remained in the narrative evidence base. At full text, we excluded reports without a future glucose value or event target, a human diabetes population, usable full text, reconcilable population eligibility, or eligible performance data. Each excluded report received 1 standardized primary reason.

Selection Process and Data Extraction

Two reviewers (HY and DA) independently screened records, assessed full texts, and extracted data; disagreements were resolved by discussion or senior review (YJ and WG). Variables included study and population characteristics, dataset provenance, target, threshold, inputs, horizon, model family, validation, calibration, and performance metrics. Diabetes type was coded as type 1, type 2, mixed, or unclear using the report and dataset description. Public datasets with a documented diabetes type retained that classification; inseparable mixed populations were not reassigned.

Input modality reflected model inputs: CGM-only models were separated from models incorporating insulin, meals, activity, demographics, laboratory values, or other context. Horizons were recorded in minutes, with multiple eligible horizons retained as separate effects under a shared study-cluster identifier. Performance data were extracted preferentially from tables and then text, supplements, or clearly scaled figures. Each derived value, unit conversion, and uncertainty calculation were logged for audit. Multiple eligible models, horizons, thresholds, or validation strata were stored as separate estimates sharing a study-cluster identifier. Original and converted values, uncertainty source, derivation, diabetes type, horizon, input modality, and analysis tier were retained.

Source-Fidelity and Dataset-Overlap Audit

Before conducting the additional revision-stage analyses, we rechecked all 80 effect rows from the 19 quantitative-source reports against the full text. For each row, the audit retained the source-reported metric and unit, analytic population or denominator, forecast horizon, validation context, full-text page location, and a supporting excerpt. Corrections were made only when the article-level evidence showed that a value, unit, population, or uncertainty field had been carried forward incorrectly. RMSE values were not treated as SDs, threshold tables were retained only when the 2×2 cells were directly reported or uniquely reconstructable, and simulation-only evidence was excluded from the primary clinical synthesis. The final locked quantitative-source set included Zhang et al [16] and excluded Mohebbi et al [48].

Dataset and cohort provenance was audited at report level. Reports were linked when the full text identified the same named public dataset, participant cohort, institution and recruitment period, or an otherwise traceable shared data source. Five reports using the OhioT1DM benchmark family were flagged as a confirmed overlap family. Dataset-family identifiers were retained in the analysis files so that overlap could be addressed by conservative clustering and exclusion sensitivity analyses rather than by silently treating every report as independent.

Values read from figures were used only when the axis scale, plotted point, and uncertainty limits were visually distinguishable. These values were flagged as figure-derived and were not prioritized over tabulated or text-reported values. If the figure did not permit a reliable reading of either the point estimate or uncertainty interval, the study was retained in the systematic review evidence table but not used for inverse-variance pooling.

Outcome Families and Metric Handling

Binary event prediction and continuous forecasting were analyzed separately. MAE and RMSE were converted using 1 mmol/L=18 mg/dL. RMSE was the principal continuous end point because it had the strongest variance-ready evidence; MAE was supportive and analyzed separately. Continuous-outcome uncertainty was standardized as an SE in mmol/L. From a 95% CI, SE=(upper-lower)/(2×1.96); from an SD and independent analytic sample size, SE=SD/square root(n). Estimates and uncertainty in mg/dL were divided by 18. Derivations were used only when the source metric, denominator, and validation set were clear.

Reported AUROC SEs were used directly. From a coherent 95% CI within 0‑1, uncertainty was derived on the logit(AUROC) scale as [logit(upper)-logit(lower)]/(2×1.96). Probability-scale SEs were transformed by the delta method. AUROC estimates without usable uncertainty were excluded from the principal model. For threshold prediction, reported 2×2 tables were preferred. Unique reconstructions used reported sensitivity and specificity with fixed event and nonevent denominators; rounded TP, FP, FN, and TN had to reproduce the reported totals and metrics. We rejected nonunique reconstructions and never assumed an arbitrary prevalence or sample split.

Continuous uncertainty came from compatible SEs, CIs, prediction-error SDs, or other clearly mapped summaries. We did not impute SDs solely to enlarge the main analysis; indirect derivations were restricted to expanded or maximal sensitivity datasets. RMSE and MAE remained separate because they weight forecast error differently. Accuracy, F_1-score, precision,

XSL•FO
RenderX

recall, and other classification metrics were extracted when available for descriptive purposes, but they were not used as primary pooled outcomes unless they could be mapped to AUROC or a threshold-based 2×2 structure. This decision avoided mixing metrics that depend on threshold, prevalence, and class balance in different ways.

Study Clusters, Dataset Reuse, and Validation

A study cluster was defined as a citation-level or dataset-level grouping within which multiple models, horizons, targets, or validation splits could produce several correlated effect estimates. This term was used because a single paper could contribute more than 1 performance estimate and because some public datasets were reused across multiple publications. Cluster identifiers were used to avoid treating all extracted effects as fully independent. Validation design was classified as internal random or cross-validation, held-out same-cohort testing, temporal testing, external cohort or external institutional validation, or unclear. These features informed both study characterization and the prespecified PROBAST operational rules for participant-level separation, overlapping windows, future-information leakage, preprocessing and imputation, tuning, test-set reuse, repeated measurements, predictor availability, and calibration.

A study cluster could therefore correspond to a single paper, a repeated public dataset, or a closely related set of effects from the same cohort. The term does not imply that each cluster was a multicenter study. It is an analytic device for handling dependence among multiple extracted estimates. This definition was used consistently in extraction tables, sensitivity analyses, and figure legends. Dataset reuse was especially relevant for public CGM datasets. Multiple models can be evaluated on the same benchmark, sometimes with different preprocessing, horizon definitions, or validation splits. Treating every such estimate as independent would overstate precision. The cluster-aware and leave-one-cluster-out analyses were designed to test whether the main findings depended on a small number of repeated data sources.

Risk of Bias and Applicability Assessment

Two reviewers (HY and DA) independently assessed the 19 reports contributing to at least 1 quantitative synthesis using the standard PROBAST framework. Assessments were conducted at the prediction model or model group–prediction target–validation population level. Reports containing development and external validation analyses, distinct populations, simulated and clinical datasets, or prediction targets that could yield different domain judgments were divided into separate assessment units. Models were grouped only when they shared participants, predictors, outcome definition, and analytical and validation procedures such that their PROBAST judgments could not reasonably differ. This process yielded 28 assessment units from 19 reports; it did not create 28 independent studies.

Each reviewer independently answered the 20 signaling questions using yes, probably yes, probably no, no, no information, or not applicable, and then assigned judgments for the Participants, Predictors, Outcome, and Analysis domains. Applicability was assessed for Participants, Predictors, and Outcome. The operational rules were prespecified interpretations of standard PROBAST for machine learning and continuous glucose-monitoring studies and not a separate scoring system. No numeric quality score or quality weighting was used.

Disagreements were resolved by consensus after reexamination of the cited full-text evidence and the prespecified rules, with consultation of YJ or WG available when required. Overall risk of bias was low only when all 4 domains were low, high when at least 1 domain was high, and unclear otherwise. Agreement was summarized using observed agreement, unweighted Cohen κ, and Gwet AC1 (agreement coefficient 1). Because questions and assessment units were nested within source reports, 95% CIs were obtained with 2000 study-cluster bootstrap resamples at the report identifier (Study_ID) level. Detailed unit definitions, signaling judgments, consensus rationales, and final assessments are provided in Multimedia Appendix 3.

Statistical Analysis

Continuous outcomes were synthesized with inverse-variance random-effects models in R (R Foundation for Statistical Computing) using established meta-analysis workflows [49-51]. The principal RMSE analysis used the conservative main dataset. Expanded and maximal datasets were used as sensitivity or exploratory analyses when uncertainty had to be derived more indirectly. Exploratory subgroup analyses examined diabetes type, forecast horizon, and input modality. Horizon categories were ≤15 minutes, 16 - 30 minutes, 31 - 45 minutes, 46 - 60 minutes, and >60 minutes. Because horizons longer than 60 minutes were sparse and clinically different from short-term alerting, they were reported separately and not used to support strong clinical claims.

Binary AUROC was synthesized using a Bayesian normal-normal random-effects model on the logit(AUROC) scale. This was retained as the primary binary synthesis because directly analyzable 2×2 data were insufficient for a stable primary threshold-based meta-analysis. A frequentist restricted maximum likelihood (REML) model on the same scale was used as a sensitivity analysis. Threshold-based sensitivity and specificity were summarized as supportive analyses using logit-transformed random-effects models. Full analysis scripts, input data, derived uncertainty fields, and figure-generation outputs are archived with the revision package.

For clinical translation, we used the supportive pooled sensitivity and specificity to estimate positive and negative posttest probabilities at illustrative pretest probabilities of 5%, 15%, and 30%. These pretest probabilities were review-defined low-, moderate-, and higher-risk scenarios rather than accepted disease-domain standards. They were chosen to show how the same model performance may translate differently across clinical contexts.

Clinical translation calculations used standard likelihood-ratio formulas. The positive likelihood ratio was sensitivity/(1−specificity), and the negative likelihood ratio was (1−sensitivity)/specificity. Pretest probability was converted to pretest odds as p/(1−p). Posttest odds were calculated as pretest odds × likelihood ratio, and posttest probability was then

XSL•FO
RenderX

calculated as posttest odds/(1+posttest odds). These values were used for interpretation only and were not treated as a decision threshold for clinical deployment.

The Bayesian AUROC model was selected for the primary binary synthesis for 2 reasons. First, AUROC was more commonly reported with usable uncertainty than full threshold tables. Second, the Bayesian normal-normal structure allowed uncertainty and between-study heterogeneity to be expressed directly on the logit(AUROC) scale while avoiding unstable pooling of sparse reconstructed 2×2 tables as the main binary result. Posterior summaries were reported as medians with 95% credible intervals. The threshold analyses were still retained because they are more clinically interpretable.

Subgroup analyses were specified as exploratory because they were observational comparisons across studies rather than randomized comparisons within studies. We report the number of model-horizon effect estimates and source titles for each subgroup to make the evidence density transparent. Subgroups with very few titles are described but not used to support strong inferential claims. Reporting-bias analyses were also exploratory. Funnel plots were generated for outcomes with enough effects, but asymmetry tests were not treated as definitive because effects were clustered, SEs were sometimes derived, and clinical and methodological heterogeneity were high.

Continuous Prediction-Horizon Meta-Regression

As a post hoc exploratory analysis, we evaluated prediction horizon continuously using the 37 source-verified RMSE effects. Effects were first collapsed to 23 report-horizon cells by averaging eligible model estimates within each report and horizon, preventing reports that evaluated many algorithms at the same horizon from receiving disproportionate weight. The primary estimand was the within-report change from that report's own 30-minute RMSE. Reports therefore had to provide a 30-minute value and at least 1 additional fixed horizon, yielding 12 nonzero horizon contrasts from 8 reports.

The primary model estimated the RMSE change per additional 30 minutes with the intercept constrained to zero at the 30-minute anchor. Equal contrast weights were used because source-reported uncertainty was unavailable for many eligible cells. Dependence was addressed with report-clustered CR2 covariance and Satterthwaite small-sample inference. Sensitivity analyses clustered the confirmed Ohio T1DM reports as 1 dataset family, excluded that family, restricted the data to contrasts with source-reported uncertainty, applied inverse approximate contrast-variance weights, evaluated marginal report-horizon cells, and restored the simulation-only study. Results are reported in both mg/dL and mmol/L, using 1 mmol/L=18.0182 mg/dL.

Clinical-Readiness Evidence Audit

Across all 270 included studies, we assessed 8 review-defined clinical-readiness criteria: use of real patient data, participant-level or temporal test separation, external validation, prospective evaluation, calibration assessment, threshold-specific operating performance, decision-curve or net-benefit analysis, and implementation or human-factors evaluation. Automated evidence-location prefill was used only to organize candidate evidence and support page-level retrieval; it was not treated as an independent reviewer judgment.

Two reviewers (LF and LL) independently completed all 2160 study criterion judgments (270 studies × 8 criteria). Each reviewer recorded a categorical judgment with supporting evidence and source location. The final consensus for all disagreements and other records requiring explicit resolution was reached jointly by the 2 reviewers or approved by the research team. Agreement was summarized as observed agreement and unweighted Cohen κ. Criterion-specific proportions used Yes/(Yes+No), excluding Unclear and Not applicable judgments from the denominator. The number of criteria met per study was summarized descriptively from final Yes judgments and was not treated as a validated composite score.

Results

Study Selection

The updated search identified 787 records from databases and registers (Figure 1). No duplicate records were removed in the final auditable flow because source files were harmonized before final screening. We screened 787 records and excluded 402 at title and abstract levels. We sought 385 reports for retrieval; 75 could not be retrieved. We assessed 310 full-text reports and excluded 11 reports: 8 because the outcome or prediction task was not eligible, 1 because the population was wrong or did not include an eligible human diabetes cohort, and 2 because no extractable eligible clinical performance data were available. The final systematic review set included 299 reports representing 270 studies. Nineteen studies contributed to at least 1 quantitative synthesis (Table 1); these main quantitative source studies are cited in aggregate here [1,2,8,13-16,29-32,34,52-58].

Table . Summary of the revised evidence base.

Characteristic	Count	Interpretation
Records identified	787	Records from databases and registers searched to April 12, 2026
Reports assessed for eligibility	310	Full texts assessed after retrieval
Reports included in systematic review	299	Reports representing the final review-level evidence base
Studies included in systematic review	270	Unique included studies after full-text review
Studies included in meta-analysis	19	Studies contributing to at least 1 quantitative synthesis
Type 1 diabetes studies	128	Full review-level count
Type 2 diabetes studies	26	Full review-level count
Studies including mixed populations of type 1 and type 2 diabetes	78	Full review-level count
Unclear diabetes type	38	Full-text reports in which diabetes type could not be confidently classified
Publication year range	2001 - 2026	Median publication year 2023; 128 studies published from 2024 onward
Studies with extractable sample size	136	Median 42 participants; IQR 12-206; range 1-37,740
English-language studies	266	Full-text evidence base
Chinese-language studies	4	Extracted by bilingual reviewers

The relatively large gap between the 270 included studies and the 19 studies contributing to meta-analysis reflects reporting limitations rather than lack of relevance. Many included studies reported model rankings, point estimates, or graphical performance summaries but did not provide uncertainty intervals, SEs, SDs, or reconstructable threshold data. These studies informed the narrative synthesis, study-characteristics tables, and methodological interpretation, consistent with guidance for synthesis without meta-analysis when quantitative pooling is not justified [59].

Characteristics of the Evidence Base

Among the 270 included studies, 128 focused on type 1 diabetes, 26 focused on type 2 diabetes, 78 included mixed type 1 and type 2 diabetes populations, and 38 did not allow confident diabetes-type classification after full-text assessment. Clinical setting was inpatient in 182 studies, outpatient in 44, simulation or simulated-plus-clinical in 7, and unclear in 37. Age group was adult in 72 studies, pediatric in 17, mixed age in 32, and unclear in 149. These distributions show not only that the review-level evidence base is much broader than the meta-analyzable subset but also that reporting of clinical descriptors remains incomplete.

The included evidence base was recent but methodologically heterogeneous. Publication years ranged from 2001 to 2026, with a median publication year of 2023; 128 studies were published from 2024 onward. The full-text evidence base included 266 English-language studies and 4 Chinese-language studies. Sample size was extractable for 136 studies. Among those reports, the median sample size was 42 participants (IQR 12-206; range 1-37,740), indicating that many model development studies were small, while a few electronic health record or population-scale studies contributed much larger cohorts.

Study duration, CGM wear duration, recording length, or follow-up time was not reported in a sufficiently standardized way to calculate 1 reliable review-wide duration summary. We therefore extracted duration-related information when available but used forecast horizon, validation design, diabetes type, setting, input modality, and extractable performance uncertainty as the primary harmonized descriptors. This reporting gap is clinically important because a model trained on short-structured CGM segments may not have the same transportability as a model evaluated across longer free-living or inpatient monitoring periods.

The most common prediction targets were short-term future glucose values, hypoglycemia alerts, hyperglycemia alerts, and broader glycemic-excursion outcomes. Reported hypoglycemia thresholds most often corresponded to <70 mg/dL (<3.9 mmol/L), with some studies using clinically important hypoglycemia thresholds such as <54 mg/dL (<3.0 mmol/L). Hyperglycemia thresholds varied more widely, commonly including >180 mg/dL (>10.0 mmol/L) or study-specific higher thresholds. This threshold heterogeneity was one reason threshold-based binary results were treated as supportive rather than definitive.

Model families included recurrent neural networks, long short-term memory networks, gated recurrent units, convolutional recurrent networks, transformer-based models, gradient boosting, random forests, support vector regression or classification, and hybrid or ensemble approaches [1,2,4,29,30,33,34]. Some studies compared machine learning models with naive persistence or conventional forecasting

XSL•FO
RenderX

baselines. Others reported only the best-performing model. This variation limited direct model-family comparison.

Input data also varied. Some models used only recent CGM history, whereas others added insulin delivery, meal information, physical activity, demographic variables, laboratory data, heart rate, or inpatient electronic health record variables [2,4,6,7,33]. Studies with richer inputs were not automatically more clinically deployable because those inputs may be unavailable, delayed, or inconsistently recorded in routine care.

Validation reporting was a recurring limitation. A substantial proportion of studies used internal cross-validation, random splits, or same-cohort held-out testing. Fewer studies used temporal validation, external institutional validation, or prospective evaluation. Calibration, decision-curve analysis, and alert-burden measures were rarely reported, even when binary event prediction was the clinical target.

Continuous Glucose Forecasting

The primary continuous synthesis included 37 RMSE model-horizon effect estimates. The pooled RMSE was 1.18 mmol/L (95% CI 1.01-1.34; Figure 2 [1,2,13-16,29-32,34] and Table 2). The supportive MAE synthesis included 20 effect estimates and yielded a pooled MAE of 0.90 mmol/L (95% CI 0.78-1.02). The number of effect estimates can exceed the number of contributing studies because multiple models, horizons, or validation strata could be extracted from the same report. These results summarize the analyzable subset and should not be interpreted as universal performance benchmarks across all glucose prediction tasks.

Figure 2. Main random-effects forest plot for RMSE [1,2,13-16,29-32,34]. RMSE: root-mean-square error.

XSL•FO
RenderX

Table . Main quantitative synthesis results.

Outcome	Role	Effect estimates	Pooled estimate	95% interval[a]	Interpretation
RMSE[b]	Primary continuous	37	1.18 mmol/L	1.01-1.34	Main forecasting summary
MAE[c]	Supportive continuous	20	0.90 mmol/L	0.78-1.02	Supportive error metric
AUROC[d]	Primary binary discrimination	13	0.926	0.877-0.957	Bayesian 95% CrI[e]
Sensitivity	Supportive threshold	10	0.77	0.62-0.88	Direct or reconstructed 2×2
Specificity	Supportive threshold	10	0.80	0.71-0.86	Direct or reconstructed 2×2

[a]Intervals are 95% CIs, except for the Bayesian AUROC estimate, for which a 95% credible interval is reported.

[b]RMSE: root-mean-square error.

[c]MAE: mean absolute error.

[d]AUROC: area under the receiver operating characteristic curve.

[e]95% CrI: 95% credible interval.

Effect estimates are model-horizon or model-threshold analytic estimates. They can exceed the number of contributing studies because several models, horizons, or validation strata may be extracted from 1 source report. The lowest individual RMSE estimates tended to occur in short-horizon or narrowly defined settings, including models evaluated at 15-30 minutes or in structured datasets with dense CGM information [1,30,34]. Higher error estimates were more common at longer horizons or in more heterogeneous settings [4,33]. However, individual ranking should be interpreted cautiously because study design, population, data preprocessing, and validation strategy differed across reports.

Exploratory diabetes-type subgroup analysis separated type 1 diabetes, type 2 diabetes, mixed-population, and unclear-population records (Figure 3A [2,7,13-21,23,25,26,28-47,60] and Table 3). RMSE estimates were lower in the type 2 diabetes subgroup than in the type 1 diabetes and mixed-population subgroups, but the type 2 diabetes estimate was based on fewer source titles and had wider uncertainty. The RMSE subgroup estimates were type 1 diabetes mellitus: 1.18 (95% CI 1.05-1.32; 43 effect estimates, 18 source titles); type 2 diabetes mellitus: 0.89 (95% CI 0.50-1.28; 15 effect estimates, 6 source titles); mixed_both: 1.48 (95% CI 1.26-1.69; 13 effect estimates, 9 source titles); and unclear: 0.61 (95% CI 0.40-0.83; 4 effect estimates, 2 source titles). These findings support separate reporting by diabetes type, but they do not prove intrinsic superiority of models in 1 diabetes type because population setting, treatment context, input modality, and validation design were confounded.

RenderX

Figure 3. Exploratory RMSE subgroup analyses by diabetes type and prediction horizon. (A) RMSE effects stratified by diabetes type. (B) RMSE effects stratified by prediction horizon in minutes. RMSE values are presented in mmol/L. Squares represent individual model-level effects, horizontal lines represent their 95% CIs, and diamonds represent subgroup-specific random-effects pooled estimates. Subgroup results should be interpreted cautiously because some categories include few source reports or model-level effects. CIs, and diamonds represent subgroup-specific random-effects pooled estimates. Subgroup results should be interpreted cautiously because some categories include few source reports or model-level effects [2,7,13-21,23,25,26,28-47,60]. RMSE: root-mean-square error.

Table . Exploratory subgroup synthesis results.

Analysis	Subgroup	Effect estimates	Source titles	Pooled estimate (95% CI)
RMSE[a] by diabetes type	T1DM[b]	43	18	1.18 (1.05 to 1.32) mmol/L
RMSE by diabetes type	T2DM	15	6	0.89 (0.50 to 1.28) mmol/L
RMSE by diabetes type	mixed_both	13	9	1.48 (1.26 to 1.69) mmol/L
RMSE by diabetes type	unclear	4	2	0.61 (0.40 to 0.83) mmol/L
RMSE by horizon	≤15 minutes	3	3	0.84 (−0.01 to 1.70) mmol/L
RMSE by horizon	16 - 30 minutes	30	15	1.11 (0.98 to 1.24) mmol/L
RMSE by horizon	31 - 45 minutes	3	3	0.72 (0.25 to 1.20) mmol/L
RMSE by horizon	46 - 60 minutes	15	14	1.15 (0.83 to 1.48) mmol/L
RMSE by horizon	>60 minutes	3	3	1.48 (0.13 to 2.83) mmol/L
MAE[c] by diabetes type	T1DM	20	5	0.93 (0.83 to 1.03) mmol/L
MAE by diabetes type	T2DM	16	6	0.93 (0.59 to 1.27) mmol/L
MAE by diabetes type	mixed_both	8	6	1.05 (0.80 to 1.29) mmol/L

[a]RMSE: root-mean-square error.

[b]T1DM: type 1 diabetes mellitus.

[c]MAE: mean absolute error.

Forecast horizon was also analyzed separately (Figure 3B and Table 3). Exploratory pooled RMSE estimates were ≤15: 0.84 (95% CI −0.01 to 1.70; 3 effect estimates, 3 source titles); 16 - 30: 1.11 (95% CI 0.98-1.24; 30 effect estimates, 15 source titles); 31 - 45: 0.72 (95% CI 0.25-1.20; 3 effect estimates, 3 source titles); 46 - 60: 1.15 (95% CI 0.83-1.48; 15 effect estimates, 14 source titles); and >60: 1.48 (95% CI 0.13-2.83; 3 effect estimates, 3 source titles). The 16 - 30 minutes and 46-60 minutes categories had the clearest data support; ≤15-minute, 31 - to 45-minute, and >60-minute groups were sparse. Longer-horizon estimates were therefore interpreted cautiously, and long-horizon forecasting was not pooled with short-term alerting as if the tasks were clinically equivalent.

Input-modality subgroup analysis suggested that CGM-only and CGM-plus-multimodal models had broadly overlapping uncertainty. The exploratory RMSE estimates were CGM_only: 1.20 (95% CI 1.05-1.35; 41 effect estimates, 11 source titles); CGM_multimodal: 1.06 (95% CI 0.83-1.29; 29 effect estimates, 20 source titles); and CGM_insulin_meal: 1.19 (95% CI 0.70-1.69; 5 effect estimates, 4 source titles). Apparent differences should be interpreted as hypothesis-generating because studies differed in population, horizon, and validation design.

MAE subgroup analysis by diabetes type was supportive and less stable than RMSE because fewer main analysis data were available. Exploratory MAE estimates were similar for type 1 and type 2 diabetes, with wider uncertainty in type 2 diabetes. This finding is consistent with the RMSE analysis in showing that type 2 diabetes data exist, but it does not provide enough precision to support a strong claim about diabetes-type differences.

Binary Glycemic Event Prediction

The principal binary synthesis used AUROC because directly analyzable 2×2 data were limited. The Bayesian pooled AUROC was 0.926 (95% credible interval 0.877-0.957; Figure 4A [8,52-57,60,61]). The posterior distribution of between-study heterogeneity on the logit(AUROC) scale is shown in Figure 4B. A frequentist REML sensitivity model gave a nearly identical point estimate, supporting numerical stability of the AUROC result under the chosen scale and dataset. Figure 4C compares the pooled AUROC estimates from the conservative main-analysis and maximal datasets. Supportive threshold-based meta-analysis yielded pooled sensitivity of 0.77 (95% CI 0.62-0.88) and specificity of 0.80 (95% CI 0.71-0.86; Multimedia Appendix 6). Because these estimates were based on a small number of threshold outcomes and partly reconstructed 2×2 data, they were used for clinical translation rather than as the primary binary benchmark.

Figure 4. Bayesian AUROC synthesis and AUROC robustness. Panel (A) presents the posterior distribution of pooled AUROC, panel (B) presents the posterior distribution of between-study heterogeneity on the logit(AUROC) scale, and panel (C) compares the conservative main-analysis and maximal datasets [8,52-57,60,61]. AUROC: area under the receiver operating characteristic curve.

Dashed line in C: conservative main estimate. Maximal: includes imputed or derived uncertainty.

The AUROC result indicates that, within the analyzable subset, models could discriminate future event status better than chance. It does not by itself define an alert threshold or prove clinical usefulness. Threshold choice changes sensitivity, specificity, false alert rate, and missed event rate. Therefore, AUROC was paired with supportive sensitivity, specificity, likelihood ratio, and posttest-probability analyses. The threshold-based subset included hypoglycemia and hyperglycemia-related targets with heterogeneous definitions. Some studies used standard biochemical thresholds, whereas others used study-specific adverse-event or high-risk excursion definitions. This heterogeneity limited the feasibility of a single diagnostic-test-style meta-analysis and justified retaining threshold results as supportive evidence.

Clinical Translation

The pooled positive likelihood ratio was 3.86 (95% CI 2.16-6.50), and the pooled negative likelihood ratio was 0.28 (95% CI 0.14-0.54). In review-defined pretest probability scenarios of 5%, 15%, and 30%, positive predictions increased estimated posttest probability to approximately 17%, 41%, and 62%, respectively, whereas negative predictions reduced estimated posttest probability to approximately 2%, 5%, and 11%, respectively (Figure 5 and Table 4). These scenarios are illustrative rather than prescriptive; actual clinical usefulness depends on event severity, treatment context, alert burden, calibration, and user response.

XSL•FO
RenderX

Figure 5. Clinical translation of threshold-based prediction.

Table . Clinical translation of threshold-based prediction[a].

Pretest probability	Posttest probability after positive prediction	Posttest probability after negative prediction
5%	16.9% (10.2-25.5)	1.5% (0.7-2.7)
15%	40.5% (27.6-53.4)	4.8% (2.4-8.6)
30%	62.3% (48.0-73.6)	10.9% (5.7-18.7)

[a]Values within parentheses are approximate uncertainty intervals derived from the limits of the pooled sensitivity and specificity 95% CIs through likelihood-ratio calculations.

These calculations help translate statistical performance into a clinical frame. In a low-risk context, even a positive alert may leave the absolute event probability modest. In a higher-risk context, the same positive alert may be more actionable. Conversely, a negative prediction reduces but does not eliminate risk. This is important for hypoglycemia, where the consequences of missed events may be clinically serious.

The clinical translation analysis should not be interpreted as a treatment recommendation. It assumes that pooled sensitivity and specificity are transportable to the scenario being considered, which may not hold when populations, thresholds, devices, and workflows differ. Prospective validation is needed before these posttest probabilities can be used for clinical decision-making.

Recent Studies Identified During Evidence Updating

All 6 DOI records in the recent-paper audit were retained in the full systematic review dataset and mapped to diabetes type, setting, and extractable metric availability [3-7,33]. Some provided data usable for descriptive synthesis or expanded exploratory extraction but did not meet the stricter uncertainty or threshold reconstruction requirements for the principal analyses. This distinction is important: absence from a forest plot does not mean absence from the review.

These recent studies strengthened the narrative synthesis by adding examples from type 2 diabetes dietary personalization, hospitalized glucose management, mixed diabetes populations, uncertainty-aware glucose prediction, federated learning, and pooled low-glucose prediction [3-7,33]. Their treatment in the manuscript follows the same rule as all other studies: inclusion in the review depends on topic and population eligibility,

XSL•FO
RenderX

whereas inclusion in a forest plot depends on outcome-specific data readiness.

The audit also clarified the difference between search completeness and data usability. A study can be fully eligible for the systematic review and yet remain outside an outcome-specific meta-analysis if it does not report uncertainty-ready RMSE, MAE, AUROC, or reconstructable threshold data.

Source Fidelity, Dataset Overlap, and Prediction Horizon

The source-fidelity audit preserved 80 effect rows from 19 quantitative-source reports, with a page reference and supporting excerpt for every row. It corrected report-level values where an isolated best-participant result had been carried forward instead of the intended report-level summary, removed invalid use of RMSE as an uncertainty proxy, rejected nonunique exact 2×2 reconstructions, and kept simulation-only evidence outside the primary clinical analysis. The report-level provenance audit identified Dudukcu et al [29], Zhu et al [13], Butt et al [2], Shen [15], and Annuzzi et al [31] as members of the confirmed OhioT1DM dataset family. The locked source membership included Zhang et al [16] (R0490). Seven internally contradictory records from Russon et al [54] and Piersanti et al [53] were retained in the audit trail; contradictory 2×2 records were excluded, whereas directly reported AUROC records remained eligible because the conflicts concerned sample size or sensitivity rather than AUROC.

In the primary within-report analysis, RMSE increased by 8.67 mg/dL for each additional 30 minutes of prediction horizon (95% CI 3.84-13.50; *P*=.006), equivalent to 0.481 mmol/L (95% CI 0.213-0.749). This estimate was based on 12 nonzero contrasts from 8 reports. The direction was not robust to the most conservative overlap handling: clustering by dataset family gave the same point estimate but a 95% CI of −5.64 to 22.99 mg/dL (*P*=.12), and excluding the OhioT1DM family yielded 3.77 mg/dL per 30 minutes (95% CI −3.83 to 11.37; *P*=.21). The continuous result therefore supports a possible horizon-related increase in forecasting error but remains exploratory and sensitive to shared-dataset assumptions (Figure S1A and B and Table S18 in Multimedia Appendix 7 [1,2,7,8,13-16,29-32,34,53-58]).

Clinical Readiness Evidence Across the Full Review Set

The dual-review audit contained final consensus judgments for all 2160 study criterion records. The 2 reviewers (LF and LL) agreed on 2078 records (96.2%; Cohen κ=0.903). There were 82 initial disagreements, and 160 records required explicit consensus because of disagreement or an Unclear or Not applicable judgment; all were resolved before analysis. Real patient data were identified in 99.2% (258/260) of classifiable studies, participant-level or temporal test separation in 18.7% (44/235), external validation in 4.0% (10/251), prospective evaluation in 0.7% (2/270), calibration assessment in 4.8% (13/270), threshold-specific operating performance in 32.4% (83/256), decision-curve or net-benefit analysis in 2.6% (7/270), and implementation or human-factors evaluation in 2.6% (7/270). Twelve studies met none of the 8 criteria, 138 met 1, 83 met 2, 28 met 3, and 9 met 4; no study met 5 or more. Thus, use of real patient data was common, but evidence of external, prospective, calibration, decision-analytic, and implementation readiness was sparse (Figure S1C and D and Table S19 in Multimedia Appendix 7).

Risk of Bias and Applicability

The 19 quantitative-source reports yielded 28 PROBAST assessment units after separating analyses that differed by population, validation setting, or model development scenario. Across 560 signaling-question ratings per reviewer, observed agreement was 83.8% (Cohen κ=0.78, 95% CI 0.68-0.85; Gwet AC1=0.80, 95% CI 0.71-0.86). Agreement was lowest for the Analysis domain (74.6%; κ=0.67, 95% CI 0.49-0.80). The reviewers initially differed on 91 signaling-question ratings and 9 domain judgments; all were resolved by consensus after full-text and rule recheck. The domain-specific agreement estimates and CIs are shown in Figure S1D in Multimedia Appendix 8.

After consensus, 24 of 28 units were at High overall risk of bias, 2 were Unclear, and 2 were Low. The distribution was driven mainly by the Analysis domain, which was High in 24 units, Unclear in 2, and Low in 2. Recurrent concerns included inadequate protection against participant- or window-level leakage, unclear separation of tuning from final testing, small effective participant or event samples, incomplete handling of repeated observations or missing data, and absent or incomplete calibration and validation reporting. Overall applicability concern was Low in 18 units, Unclear in 4, and High in 6. Unit-level and summary judgments are presented in Figure S1A-C in Multimedia Appendix 8 [2,8,14,15,29-32,52,53,57,58]. A risk-of-bias–restricted sensitivity analysis was evaluated at the independent-study level rather than treating the 28 assessment units as independent studies. Excluding High-risk units left no eligible non-High independent studies for reliable RMSE or MAE reestimation. Only 2 independent studies remained for AUROC; these results were examined descriptively and were not pooled in an unstable random-effects model.

Robustness and Reporting Bias

The data-readiness robustness analysis showed similar pooled RMSE estimates across the conservative main dataset, expanded sensitivity dataset, and maximal exploratory dataset: main 1.18 mmol/L (95% CI 1.01-1.34), expanded 1.12 mmol/L (95% CI 0.99-1.24), and maximal 1.14 mmol/L (95% CI 1.02-1.27; Figure S1 in Multimedia Appendix 5). Leave-one-cluster-out analysis did not identify a single study cluster that fully explained the main RMSE finding (Figure S1 in Multimedia Appendix 9).

Funnel plots were produced for outcomes with sufficient effects, but these were interpreted as exploratory because multiple effects could arise from the same study cluster, reporting precision was often derived rather than directly reported, and heterogeneity was high (Multimedia Appendix 10). The funnel plots are therefore used to describe possible small-study or reporting patterns rather than to make strong claims about

XSL•FO
RenderX

publication bias. The data-readiness analyses support the general direction of the continuous-outcome findings, but they do not remove the underlying limitations of the evidence. Similar pooled estimates across analysis tiers mean that the main estimate was not driven solely by 1 uncertainty derivation rule; they do not establish low risk of bias or external validity. The data-readiness and risk-of-bias analyses answer different questions and should not be conflated. The former tested whether effect inclusion and uncertainty-derivation rules materially changed the pooled estimate. The latter asked whether a reliable pooled estimate remained after excluding high-risk evidence; for RMSE and MAE it did not, and for AUROC only a descriptive 2-study comparison remained.

Discussion

Principal Findings

This review maps 270 studies represented by 299 reports, but only 19 reports supported at least 1 quantitative synthesis. This gap reflects incomplete uncertainty reporting, heterogeneous outcomes and thresholds, dataset reuse, and sparse external validation, limiting the quantitative reuse of an otherwise active literature.

The principal continuous estimate suggests an average RMSE of about 1.18 mmol/L in the analyzable subset. The supportive MAE estimate was about 0.90 mmol/L. These values indicate measurable short-term forecasting performance, but they should not be read as a guaranteed clinical accuracy level. The estimates combine models, populations, horizons, and validation designs that are not interchangeable.

The principal binary AUROC synthesis suggested strong discrimination within the subset that reported usable AUROC uncertainty. However, threshold-based clinical implementation depends not only on discrimination but also on sensitivity, specificity, calibration, event prevalence, alarm burden, and the consequences of missed or false alerts. The posttest probability analysis helps show this dependence in practical terms.

Rather than establishing a universal benchmark, the results distinguish a large model development literature from the smaller body of quantitatively reusable evidence. The PROBAST findings materially qualify these estimates. A high judgment does not mean that every reported model result is false; it means that design, analysis, or reporting features leave an important risk that performance is optimistic or not transportable. Because 24 of 28 quantitative-source assessment units were high, the pooled estimates should be viewed as structured summaries of the available analyzable literature, not as low-bias performance benchmarks for clinical deployment. Internal performance may not transfer across CGM devices, treatment patterns, recording behavior, workflows, or populations; transportability, validation design, and uncertainty therefore matter more than headline performance alone.

Type 1 and Type 2 Diabetes

Type 1 and type 2 diabetes were not pooled without qualification. Type 2 evidence contributed particularly through recent dietary and inpatient studies [6,7], but fewer type 2 reports were meta-analyzable; its subgroup signal is therefore informative but not definitive. Differences in insulin physiology, treatment, diet, comorbidity, setting, and technology are clinically plausible, but aggregate subgroup comparisons remain observational and confounded. We therefore do not imply that either diabetes type is intrinsically easier to predict. Recent type 2 or mixed-cohort studies broadened a largely type 1 diabetes-centered field [4,6,7,33], but many lacked uncertainty-ready RMSE, MAE, AUROC, or 2×2 data and could not enter formal synthesis. Primary studies should report diabetes type explicitly and provide stratified results for mixed populations when feasible; otherwise, apparently favorable performance remains difficult to interpret clinically.

Forecast Horizon and Clinical Use

Forecast horizon changes the clinical task: 15- to 30-minute predictions may support immediate alerts, whereas >60-minute predictions require different inputs and assumptions. We therefore reported horizon-specific summaries rather than treating all horizons as equivalent. Short-horizon or narrowly defined settings often appeared more accurate, but this may reflect easier horizons, benchmark reuse, richer inputs, or internal validation. The review cannot identify a universally superior model family; external validation remains more informative for clinical credibility. Long-horizon studies remained in the review but were not used to justify short-term alerting claims, preserving completeness without clinically inappropriate pooling. Short horizons exploit stronger glucose autocorrelation but allow less intervention time; longer horizons offer more time but depend on assumptions about meals, insulin, activity, and physiology. The preferred horizon therefore depends on intended use.

The continuous horizon analysis complements the categorical summaries by controlling for each report's 30-minute baseline. Its primary slope suggests that forecasting error may rise meaningfully as the prediction window lengthens, but the loss of precision under dataset-family clustering and after removal of OhioT1DM reports shows that the apparent association is partly dependent on a small, overlapping evidence base. The finding should therefore guide study design and reporting rather than be interpreted as a universal conversion rule between forecast horizon and RMSE. The full-review clinical-readiness audit shows that publication volume and use of real patient data have not yet translated into evidence suitable for routine deployment. External validation, prospective evaluation, calibration, decision-curve analysis, and implementation or human-factors assessment were each uncommon. These gaps help explain why favorable discrimination or forecasting error cannot, by itself, establish clinical usage or transportability.

Clinical Implications

These findings support cautious interest, not benchmark-driven adoption. Alert usefulness depends on baseline risk and false alert burden, and a negative prediction does not eliminate risk or replace symptoms, clinical judgment, or device safety rules [5,7,8]. We found no randomized trials showing improved patient-important outcomes. Translation requires prospective validation, calibration, alert fatigue assessment, and evidence that model-guided action improves outcomes without harm. Error consequences are context-specific: false negatives may

XSL•FO
RenderX

delay intervention, whereas false positives may cause alarm fatigue, unnecessary carbohydrate intake, or distrust. Low average RMSE can also conceal clinically important errors during rapid changes or near decision thresholds. Implementation must fit workflow. Outpatient users may need simple alerts; inpatient output interacts with nursing, insulin protocols, nutrition, and electronic records. Transfer across workflows requires validation.

Reporting and Methodological Implications

The main barrier to stronger synthesis was not a lack of published models but a lack of meta-analysis–ready reporting. Future studies should report diabetes type, treatment context, cohort source, sample size, event threshold, forecast horizon, train-test separation, calibration, uncertainty for all primary metrics, and enough threshold information to reconstruct TP, FP, FN, and TN when binary prediction is central. Dataset reuse should be disclosed explicitly. Public benchmark datasets are valuable, but repeated development and evaluation on overlapping data can inflate apparent certainty if each effect is treated as independent. The study-cluster approach used here is a practical response to that problem, but it cannot fully replace better primary study reporting. Primary studies should also explain how errors such as RMSE and MAE were calculated. At minimum, reports should state the prediction horizon, unit, test set, number of predictions, whether errors were averaged per prediction or per participant, and whether uncertainty was estimated across participants, folds, bootstraps, or independent datasets. Without this information, even familiar metrics become difficult to synthesize.

For binary prediction, authors should report the event threshold, prediction window, decision threshold, TP, FP, FN, TN, sensitivity, specificity, AUROC, calibration, and CIs. Reporting only accuracy or F_1-score is insufficient for clinical interpretation because these metrics depend strongly on event prevalence and class balance. The field needs prospective external validation and shared reporting templates. Authors should share code and preprocessing when possible and identify public dataset versions, participant criteria, train-test splits, and overlap with prior studies.

The major model families have different methodological strengths and limitations (Table 5). Recurrent architectures suit temporal glucose data, whereas tree-based and kernel methods can be practical for structured clinical variables. Transformer and hybrid models can integrate longer-range or multimodal information but require more data and may be harder to interpret. Because populations, targets, horizons, inputs, and validation designs differed, this comparison is descriptive rather than a performance ranking [1,2,4,14-16,29-34,52,53,58].

XSL•FO
RenderX

Table . Comparative methodological characteristics of major machine learning model families used in glycemic prediction. This table provides a narrative methodological comparison rather than a quantitative ranking. Standardized head-to-head comparisons across model families were not feasible because studies differed in populations, prediction targets, forecast horizons, input modalities, validation designs, and reporting completeness.

Model family	Main strengths	Main limitations	Interpretability approaches	Clinical and reporting considerations
Recurrent neural networks (RNNs[a], LSTMs[b], and GRUs[c])	Model nonlinear temporal dependencies in sequential CGM[d] data and support short-term or multihorizon forecasting.	Require careful tuning and sufficient data; hidden states are difficult to interpret; and results may depend on window length and data splitting.	Time-step attribution, saliency, integrated gradients, or SHAP[e]-style feature attribution.	Report input-window length, forecast horizon, missing-data handling, train-test separation, and external validation.
Convolutional and convolutional-recurrent networks	Capture local temporal patterns and can combine automated feature extraction with sequence modeling.	Results depend on convolutional window and architecture; local patterns may not capture longer-range physiology.	Saliency maps, temporal activation maps, integrated gradients, or feature attribution.	Report receptive field, preprocessing, sampling frequency, and stability across horizons and devices.
Transformer-based models	Represent longer-range dependencies and heterogeneous or multimodal inputs, including interactions across time.	Often data- and computation-intensive, vulnerable to overfitting in small cohorts, and attention is not a causal explanation.	Attention visualization combined with attribution or perturbation analyses.	Report model size, regularization, calibration, explanation stability, and external or temporal validation.
Tree-based and boosting models (random forests and gradient boosting)	Handle nonlinear relationships, mixed clinical variables, and engineered features; often practical for tabular data.	Raw CGM sequences usually require temporal feature engineering; importance estimates may be biased by correlated predictors.	Global or local feature importance, permutation importance, partial dependence, or SHAP.	Report feature engineering, missing-value treatment, explanation background data, and calibration.
Kernel-based models (SVM[f] and SVR[g])	Can perform well in small-to-moderate datasets with engineered high-dimensional features.	Sensitive to scaling, kernel choice, and hyperparameter tuning; probabilities and explanations may be less intuitive.	Coefficient inspection for linear kernels, sensitivity analysis, local surrogates, or SHAP-style methods.	Report scaling, kernel, tuning, class-imbalance handling, and independent test-set performance.
Hybrid and ensemble models	Combine complementary temporal, nonlinear, and multimodal components and may improve robustness across tasks.	Implementation is complex; component contributions and failure modes may be difficult to isolate; and reproducibility can be limited.	Component-wise analysis, ablation studies, ensemble contribution analysis, or model-appropriate attribution.	Report every component, fusion rule, ablation results, computational burden, and code or preprocessing availability.

[a]RNNs: recurrent neural networks.

[b]LSTMs: long short-term memories.

[c]GRUs: gated recurrent units.

[d]CGM: continuous glucose monitoring.

[e]SHAP: Shapley additive explanations.

[f]SVM: support vector machine.

[g]SVR: support vector regression.

Interpretability should match the architecture and clinical use. Feature importance, permutation methods, SHAP, attention, saliency, and shapelets may identify influential glucose, insulin, meal, activity, or clinical inputs. These model- and data-dependent explanations can be unstable under correlated predictors or distribution shift and are not causal. Studies should report the method, reference data, local or global scope, stability, and clinical evaluation [4,31,58].

Strengths and Limitations

Strengths of this review include a substantially updated search, explicit recent-paper auditing, separation of binary and continuous prediction tasks, diabetes-type subgroup reporting, horizon-specific analysis, unit harmonization, and a transparent distinction between the review-level evidence base and the quantitative subset. For the quantitative-source reports, PROBAST was completed independently by 2 reviewers (HY and DA) with a prespecified unit-splitting rule, an item-level consensus log, and report-clustered agreement intervals. The supplementary materials provide search strategies, screening decisions, extraction rules, data-readiness classifications, and the complete PROBAST audit trail.

Limitations remain in this review. Many studies lacked uncertainty estimates, calibration, or external validation; some diabetes-type and setting classifications remained unclear. Some uncertainty values were derived from CIs, and threshold analyses partly used reconstructed contingency tables. The search ended April 12, 2026. Subgroups were exploratory and noncausal. Excluding high-risk units left insufficient independent evidence for RMSE or MAE pooling and only 2 independent AUROC studies, so risk-of-bias–restricted quantitative robustness could not be established. The full review set describes field breadth,

XSL•FO
RenderX

whereas the 19-report subset represents quantitatively reusable evidence. PROBAST therefore focused on these reports, yielding 28 prespecified assessment units. Their risk-of-bias distribution should not be generalized to all 270 studies or treated as representative of the entire evidence map. Some reports did not permit confident separation of type 1 from type 2 diabetes. Retaining an unclear category reduced forced misclassification but left some subgroup analyses underpowered.

Finally, the review did not evaluate the usability, acceptability, or economic impact of prediction systems. These dimensions are important for digital health implementation, but they were rarely reported in the primary studies and were outside the quantitative scope of this meta-analysis.

The continuous prediction-horizon analysis was post hoc, included only 8 reports and 12 nonzero within-report contrasts, and could not recover the covariance between each 30-minute reference and its longer-horizon estimate. Equal weighting was necessary in the primary model because uncertainty was incompletely reported. Although CR2 inference and multiple overlap sensitivities were used, the small number of independent reports and dataset-family clusters limits precision and precludes causal interpretation of the slope.

The clinical-readiness audit was based on what each report documented and may therefore underestimate procedures that were performed but not reported. Unclear and not applicable judgments were excluded from criterion-specific denominators, while the criteria-met count used only final Yes judgments. The 8-item framework was defined for this review to describe evidence breadth; it is not a validated scale, and neither the criteria count nor interrater agreement establishes clinical effectiveness.

Conclusions

Machine learning models for glycemic prediction in diabetes show encouraging but not yet clinically definitive performance. The evidence base is broad and now reports type 1 diabetes, type 2 diabetes, horizon, and input-modality patterns transparently. However, only a small subset of the literature is currently suitable for formal synthesis. Pooled estimates should be interpreted as structured summaries of analyzable evidence, not as universal clinical benchmarks. More complete uncertainty reporting, stronger external validation, explicit dataset-provenance disclosure, and clearer separation of prediction tasks are needed before these models can be confidently translated into routine diabetes care. Technically promising forecasting and discrimination signals do not yet establish broad clinical transportability. Future studies should be transparent, externally validated, diabetes-type- and horizon-specific, and clinically interpretable.

Acknowledgments

The authors thank all contributors who supported literature organization, data checking, and manuscript preparation.

Generative AI tools were used to assist with literature-screening audit organization, code debugging, tabular harmonization, evidence localization, provisional clinical-readiness prefill, and language editing during revision. Machine-generated prefill was not treated as an independent reviewer judgment. All eligibility decisions, source-fidelity corrections, clinical-readiness judgments, consensus decisions, statistical analyses, interpretation of results, and final manuscript content were completed, verified, or approved by the authors, who take full responsibility for the work.

Funding

Data Availability

All data synthesized in this review were extracted from published or publicly accessible reports. The revised review package includes Multimedia Appendices 2-5 with source-specific search strategies, screening logs, full-text exclusion reasons, characteristics of all included studies, analysis-ready extraction tables, data-derivation rules, PROBAST records, and R-analysis outputs. Multimedia Appendix 4 contains the locked 80-effect source-fidelity audit, report-level dataset or cohort provenance and overlap matrix, continuous prediction-horizon inputs and model diagnostics, and clinical-readiness summaries. Multimedia Appendix 5 contains the 2 independent clinical-readiness rating passes, evidence and page fields, consensus records, and audit controls for all 2160 study-criterion judgments. The reproducibility archive also includes the locked main analysis input, scripts, model outputs, session information, figure files, release receipts, and SHA-256 manifests.

Abstract

Background: AI is a broad field encompassing various techniques, which include algorithms that learn from data to perform automated tasks without explicit human programming. Public health aims to protect and improve the health of communities and populations at the local, regional, national, and global levels, but it typically has limited resources. While AI may lead to improved efficiency or effectiveness of public health interventions, the adoption of AI interventions should be informed by evidence of effective use in practice.

Objective: This review aims to summarize how AI-assisted interventions are currently used by public health professionals.

Methods: We conducted a scoping review to identify the current uses of AI in public health. We searched MEDLINE (Ovid), Embase (Ovid), Web of Science (Core Collection), and Scopus for relevant reports published between January 1, 2020, and July 24, 2025. Two reviewers independently screened reports. Eligible reports were primary studies (experimental or observational), commentaries, and editorials that discussed how AI tools have been used in practice in public health contexts relevant to high-income countries, excluding outbreaks. Data were extracted by one reviewer and checked by a second.

Results: We screened 5400 records and 155 full texts, including 8 reports. These reports discussed a variety of uses of AI tools across public health domains: 3 reports used chatbots in different settings, 1 report used machine learning to forecast health service demand, 2 reports used AI for symptom checking, and 2 reports used AI for evidence synthesis. While assessing the effectiveness of AI tools for public health was beyond the scope of this review, and most reports did not robustly evaluate effectiveness, the evidence for the effectiveness of AI tools was nonetheless mixed. One report described a chatbot that users found helpful, while another found a specific chatbot to be ineffective, highlighting its potential to undermine trust in the organization that developed it. Another report highlighted both benefits and drawbacks of a large language model used to communicate with socially isolated individuals. The main finding of this review was that even with a comprehensive search across multiple databases, there were few reports of how AI tools are being used in practice in public health contexts.

Conclusions: The lack of evidence from public health practice, excluding outbreaks, makes it difficult to know which uses of AI, if any, would be useful to incorporate into practice in high-income countries. In the absence of evidence, new interventions, including those using AI, should be evaluated to ensure they are effective (and cost-effective). These evaluations should be widely and accessibly disseminated to create an evidence base that other public health teams could use to inform their own decisions around AI tools.

KEYWORDS

public health; AI; health protection; health improvement; scoping review

Introduction

AI is a broad field encompassing various techniques, including machine learning, natural language processing, and generative AI [1]. AI learns from data to perform automated tasks without explicit human programming, using algorithms integrated into systems and tools [2-4]. While the theoretical groundwork for machine learning was laid in the 1980s, recent advancements

XSL•FO
RenderX

in computing power and the development of large language models (LLMs) like OpenAI's ChatGPT and Google's Gemini have sparked renewed interest in AI [5]. These models, with more user-friendly interfaces and general-purpose applications, offer the potential to tackle a wide range of problems [6]. However, the rapid pace of development in AI generally, and in LLMs specifically, means new evidence assessing the effectiveness of interventions using AI tools is constantly required, as newer versions of these tools may have differential effectiveness.

Public health is an area wherein AI is increasingly being used to harness potential improvements in efficiency and effectiveness. This could be particularly useful, given the broad scope, important aims, and often limited resources of public health. In our recent reviews, we found several examples of chatbots, machine learning, and other AI-assisted interventions targeting alcohol consumption, smoking, and physical activity [7,8], and identified 44 potential uses of AI within public health [9].

Public health activities are often organized and described under 3 interconnected domains: health improvement, health protection, and health care public health [10]. Health improvement focuses on improving health and well-being and addressing inequalities through action on the wider determinants of health and by encouraging individual behavior change. Health protection focuses on the prevention and control of infectious diseases and emergency response. Health care public health focuses on ensuring that health care services are evidence-based, safe, and delivered effectively and equitably. AI tools could potentially be used across all these public health activities to improve services.

However, many reports on the potential effectiveness of AI interventions in public health use evidence from trials or from simulated or retrospective data. When moving into practice, the effectiveness of an intervention may be reduced, particularly in nonideal settings [11]. There may also be insurmountable barriers to adopting an intervention, for example, a lack of capacity, resources, or knowledge, particularly for technologically complex interventions [11]. Thus, it is important to evaluate how an intervention performs in routine use and in real-world contexts. Previous reviews have looked at AI in public health contexts [12,13], but they typically focus on evidence from trials or specific domains within public health, rather than real-world applications across public health more broadly.

The purpose of this scoping review is therefore to identify how AI is currently used in public health practice, that is, how AI-assisted interventions are currently used by public health professionals. In doing so, the review will provide a snapshot of the evidence base for using AI tools in public health practice, helping to inform which tools could be used to shape future public health practice. Scoping reviews are ideally placed to map the research landscape, detailing what has already been examined and hopefully illuminating promising areas.

Methods

Review Question

This scoping review systematically summarized evidence from primary studies, commentaries, and editorials to answer the following review question: how is AI currently used in public health?

This review formed part of a broader program of work evaluating the past, current, and potential uses of AI in public health [7-9]. The protocol was registered on Zenodo under the identifier 15971109 [14]. This review is reported using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews [15]; Checklist 1). All data produced in this review are contained in the manuscript and its supplementary information files. We did not use AI in any part of the review process or when writing this paper.

Stakeholder Engagement

We conducted stakeholder engagement across our broader program of work across 2 phases of activity. The first phase involved protocol refinement and confirmation, with the aim of defining concepts related to AI and understanding comprehension of different models and platforms. The second phase gathered feedback on initial findings from the synthesis, with consideration of how public health systems may support diffusion and delivery of AI-based interventions.

We conducted consultation meetings with 2 UK-based communities of practice at each phase. One community comprised 9 practitioners from the National Institute for Health and Care Research (NIHR)–funded Health Determinants Research Collaborations (HDRCs), with experience of public health service delivery. HDRCs are local government-funded infrastructures intended to develop research capacity and capability to improve evidence-based decision-making. The second community, also comprising 9 people, included strategic directors with significant leadership roles in AI for public health across data science institutes, public health agencies, and national networks for local government organizations.

Eligibility Criteria

We included primary studies (experimental or observational), commentaries, and editorials published or preprinted in English from January 1, 2020, that discussed how AI tools are currently used in public health contexts relevant to high-income countries (as defined by the World Bank [16]). We defined public health contexts as those where the primary aim was to improve public health, typically involving local and national government-funded public health organizations delivering interventions or making policy decisions. We excluded clinical settings, for instance, reports that only considered roles of AI using National Health Service (NHS) resources. Reports were only included if there was evidence that the AI tool had been used in public health practice; reports of potential uses of AI in public health contexts without evidence of having been used in practice were excluded, even if, for example, the AI tool was evaluated in a randomized controlled trial. Broadly, we considered use in practice to include public health professionals using AI tools for their work, as well

XSL•FO
RenderX

as piloting, testing, or evaluating AI use, so long as these uses could have affected the public. For example, a report from a public health agency that had used ChatGPT to help write public-facing policies would be included, but a study comparing the readability of policies written with and without the help of ChatGPT (where the policies never became public-facing) would be excluded, as the AI tool was never used in practice. We defined AI broadly as algorithms integrated into systems and tools that can learn from data to be able to perform automated tasks without explicit human programming. Only public health contexts relevant to high-income countries were included, as this review was designed to be as relevant to the UK context as possible, and the public health challenges and resources are markedly different between high-income and other countries.

In the sole post hoc change to the protocol, we refined the eligibility criteria to exclude outbreaks, including local disease modeling and prediction, as AI use in outbreaks has been extensively researched [17]. This change was made before the search had been conducted, and our results are necessarily specific to AI use in public health practice, excluding outbreaks.

Search Strategy

We used one AI search facet in the search strategy. This facet drew upon an unpublished filter created by members of the InterTASC (Technology Appraisal Support Collaboration) Information Specialists' Sub-Group (ISSG), as well as filters hosted on the associated ISSG search filter resource [18]. We combined the AI search facet with broad public health terms, as well as those reflecting activities linked to the research question, such as policy making and surveillance. These terms were derived from iterative searching, with keywords and MeSH terms harvested from relevant papers and reference lists. Search strategies for all databases are presented in Multimedia Appendix 1.

Information Sources

We conducted searches in 4 bibliographic databases: Medline (Ovid); Embase (Ovid, including preprints from medRxiv, bioRxiv, and SSRN); Web of Science (Core Collection); and Scopus. Searches were automatically deduplicated by DOI matching in Stata 19 (StataCorp LLC) [19]. Searches were conducted up to July 24, 2025.

Selection of Sources of Evidence

Two reviewers (SH and CT) independently screened titles and abstracts in Covidence (Veritas Health Innovation Ltd) [20], and full texts in a standardized Microsoft Excel sheet. Titles and abstracts included by at least 1 reviewer on eligibility assessment progressed to full-text screening. Conflicts in assessment of full texts were resolved through discussion, with no necessity to involve a third party.

Data Charting Process and Items

One reviewer (SH) completed all data extraction, which was checked by a second reviewer (CT). For each included report, we extracted information into standardized Microsoft Excel sheets about the report characteristics and methodology, the public health context, the type of AI and how it was used, and any outcomes associated with the performance of the AI intervention.

Synthesis of Results

We summarized the evidence narratively, separately for each report. All data generated or analyzed during this review are included in this published paper and its supplementary information files.

Ethical Considerations

Ethical approval for this review was not required. We conducted consultations with stakeholder groups in accordance with the ethical requirements stipulated by the organizations and research studies that recruited the participating members.

Results

Screening Results

Figure 1 shows the PRISMA diagrams for the flow of references. See Multimedia Appendix 2 for full-text screening results for reports and full data extractions for included reports.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram.

We screened 5400 titles and abstracts and 155 full texts, ultimately including 8 reports [21-28] that discussed AI tools used in public health practice. A total of 4 reports involved health improvement [21-24], 4 involved health care public health [23-26], and 5 involved health protection [22,24,26-28]; 4 of these reports involved multiple public health contexts [22-24,26] (Figure 2).

XSL•FO
RenderX

Figure 2. Public health contexts of included reports [21-28].

A total of 2 reports were from the United Kingdom [24,25], 2 from Canada [26,27], and 1 each from Singapore [28], South Korea [23], the United States [21], and worldwide [22]. A total of 5 reports assessed the accuracy of AI tools [24-28], 2 reports conducted interviews to qualitatively assess the utility of AI tools [21,23], and 1 report used structured interactions to assess the conversational and informational performance of an AI tool [22].

Table 1 provides an overview of the AI tools identified, while narrative summaries of included reports are provided below.

The Current Roles of AI in Public Health

Baez et al [21] interviewed 19 mothers from the United States in 2022 to determine whether a chatbot on the Texas Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) website was useful, and how it could be improved. The chatbot was called Maya, and helped clients to search for local WIC offices and approved stores, report a lost or stolen card, and upload documentation, while answering client questions. Participants stated that Maya helped them navigate and find information on the Texas WIC website, and that Maya was more efficient for obtaining information (particularly about their benefits) than other practices, such as by visiting a clinic, calling a hotline, or emailing. As of January 2026, Maya is still active on the Texas WIC website [29].

Germani et al [22] assessed the conversational and informational performance of the World Health Organization (WHO) chatbot, S.A.R.A.H, by presenting it with 10 statements generated by GPT-3.5-turbo that contained health-related misinformation. S.A.R.A.H was developed to provide accessible and reliable health information and combat misinformation. The authors noted that some of S.A.R.A.H's responses failed to directly address user concerns (redirecting the conversation instead), lacked conversational skills associated with empathy, and failed to provide relevant evidence-based information to debunk misinformation. However, the authors also noted that one of S.A.R.A.H's responses acknowledged user concerns, suggested actional points, and showed artificial empathy. Overall, the authors concluded that S.A.R.A.H had "all the ingredients to serve not only as a useless tool in the quest to improve the information ecosystem and reduce the dangers infodemics pose to public health but also as a potential threat to erode trust in the WHO itself" [22]. As of January 2026, S.A.R.A.H is no longer active on the WHO website [30].

Hyum Lim et al [26], within the Public Health Agency of Canada, used the DistillerSR Artificial Intelligence System (DAISY) to assist in screening of reports and compared the accuracy of screening for relevant COVID-19 citations to that

XSL•FO
RenderX

of human reviewers between 2020 and 2023. DAISY uses natural language processing and human-coded training data to automatically screen the titles and abstracts of citations. DAISY correctly classified 98% of the 21,729 citations that had undergone human review and found relevant citations missed by human reviewers (around 3% of included citations). As of January 2026, DistillerSR continues to use AI classifiers, although potentially not DAISY specifically [31].

Jo et al [23] interviewed 21 public agency workers in South Korea in 2023 to determine their expectations of, and experiences with, CareCall, an LLM-based chatbot that spoke with socially isolated people through phone calls. CareCall is being used in South Korea to supplement the role of public agency workers in monitoring socially isolated people, including their health. The chatbot mimics the conversational style of a social worker to check on care recipients and accesses long-term memory to personalize open-ended conversations, including by asking follow-up questions. Public health agency workers were notified of potential concerns, which could then be followed up on. Overall, adoption of CareCall seems to have been viewed positively by the workers interviewed. They felt that CareCall expanded public reach and allowed for more frequent monitoring but often without the necessary resources at implementation, which increased and diversified their workloads. Unlike before, there was no need for dedicated devices (such as sensor systems and smart speakers) because CareCall uses existing phone lines. In this regard, CareCall was therefore cheaper and reduced barriers to adoption. Different (additional) care needs were also communicated, allowing workers to provide necessary support that may otherwise have been missed. However, some workers felt that some participants who did not answer calls from CareCall did so because they did not like talking to an AI chatbot, and this added to workloads by necessitating callbacks to check that participants were safe.

Morbey et al [25], within the UK Health Security Agency (UKHSA), created and piloted pipelines to select and use machine learning models to forecast health care service demand in the UK in 2022 and 2023. Specifically, the machine learning models forecast the peak timing and intensity of NHS 111 calls for “cough” and emergency department attendance for “acute bronchitis” over 28 days, restricted to children aged 5 years and younger. Seven machine learning methods were trained on data from before October 2022 (80% training and 20% validation), with 4 options for seasonality, a secular trend, quadratic terms for current activity, and a 3-day moving average, for a total of 252 alternative model specifications, each trained to forecast 1-28 days ahead inclusive. The model with the smallest weighted combination of intensity error (difference between the predicted and observed peak demand) and timing error (difference between the predicted and observed peak day) was selected and retrained on all available data, and historical errors were incorporated into forecast uncertainty. The random forest learning method with seasonality modeled by Fourier transformations was ultimately selected. This model was then used to produce 1 to 28-day-ahead forecasts using the latest available UKHSA data (winter of 2022 to 2023), which were compared to the observed peaks in NHS 111 calls and emergency department attendances. As there was an unprecedented demand for NHS 111 calls for cough, the forecasts could not predict the peak demand until more data had been acquired, though the forecasts were able to correctly predict the peak emergency department acute bronchiolitis attendance.

Siedlikowski et al [27] discussed the development of Chloe, a chatbot released in March 2020, which was designed to help users self-assess COVID-19 symptoms and to answer common questions in both English and French about COVID-19. The COVID-19 information used to train the chatbot was scraped from vetted online information sources. A bidirectional encoder representations from transformers model was used to detect and remove out-of-distribution questions that were not answerable with the information sources available to the chatbot. Questions themselves were clustered using unsupervised machine learning. Users could freely ask questions, which the chatbot parsed using natural language understanding. The overall accuracy of Chloe was 81.8% in English and 71.3% in French, and the out-of-distribution accuracy was 90.5% in English and 70.6% in French. As of January 2026, Chloe is no longer active on its website [32].

Simmons et al [24], within the UKHSA, tested and subsequently adopted 3 different AI-assisted interventions to help with conduct evidence reviews in the United Kingdom between 2022 and 2025. They compared Deduklick (Risklick), software that uses AI to identify and remove duplicate records before screening, with manual deduplication in EndNote (Clarivate; using the Leeds Method) across 8 reviews, concluding that although Deduklick removed slightly fewer references, it saved considerable time and was adopted for use. They subsequently used both Rayyan’s prediction classifier (a support vector machine classifier) and EPPI-Reviewer’s Priority Screening (machine learning) to conduct priority screening in one review each. For Rayyan, all eventually included records were in the prioritized list after 32% of records had been screened, and for EPPI-Reviewer, 99% of eventually included records were in the prioritized list after 30% of records had been screened. Both tools have been adopted for use.

Tan et al [28] developed and tested an AI-assisted app that detected the presence of symptomatic mpox in images of penises in 2022. The app used a modified convolutional neural network trained on 1000 images of penises with mpox rashes and 1000 images of penises without mpox rashes, and additional information about the geographical prevalence of mpox and the latest positive patient statistical data, to predict the likelihood of symptomatic mpox in new images of penises. The authors stated that the app had a sensitivity of 90% and specificity of 87%, and that between June and October 2022, the app had analyzed 21,000 images of penises for mpox. The app is also used to predict the likelihood of other symptomatic sexually transmitted infections. However, as of October 2026, the app is no longer available, and the website has been shut down (though an archived version of the app’s web page is available [33]).

Discussion

Principal Findings

This scoping review summarized evidence on the current use of AI in public health relevant to high-income countries, excluding outbreaks. We identified a total of 8 reports [21-28] that discussed current uses of AI across all 3 public health domains. Uses of AI included using AI tools for symptom checking and for conducting evidence reviews for public health; using AI tools to address health concerns and misinformation and to connect individuals to services and support; and using machine learning to forecast health service demand.

While assessing the effectiveness of AI tools was beyond the scope of this review, the evidence from included reports was mixed. For example, while the Maya chatbot seemed helpful to participants [21], the S.A.R.A.H chatbot was considered a "potential threat to erode trust in the WHO" [22], and CareCall had both advantages and disadvantages for public agency workers and wasn't evaluated by those at whom it was targeted [23]. Equally, in our reviews of the effectiveness of public health AI-assisted interventions for alcohol use, smoking, and physical inactivity, there was ultimately little evidence to suggest that AI-assisted interventions were any more or less effective than non-AI-assisted interventions [7,8].

All reports included in this review were authored by larger public health organizations, for example, national and global public health bodies, which may be more likely than smaller and more local public health teams to possess the infrastructure and capabilities to use and evaluate AI technologies. Although we identified only a small number of included reports, and any inferences drawn are therefore speculative, these authorship imbalances may also reflect varying levels of organizational readiness to use AI tools, relating to divergences in workforce capacity, training, infrastructure, equipment, and resources. If so, this variability may perpetuate differences in how AI is used and evaluated across all aspects of public health, potentially leading to inequities if AI tools are more effective or efficient than alternatives—risks of the potential use of AI in public health identified in our linked review [9]. However, the observed imbalances may also simply reflect differential publishing practices between larger and smaller public health organizations: smaller public health teams may be using AI tools but not publishing their experiences in academic journals. Indeed, our PPI groups noted that larger organizations may be slower to adopt AI due to more rigid governance systems than those of smaller organizations, which may be more flexible.

The rationale for identifying current uses of AI in this review was to determine how much real-world evidence exists and how easily accessible AI tools are in public health practice. Using a comprehensive search across 4 databases, we were able to identify only 8 reports [21-28]. On the other hand, in our review of the potential roles of AI in public health, we identified 67 reports covering 44 potential uses of AI across 8 public health contexts [9]. This may mean that there are plenty of potential uses of AI but little accessible evidence supporting those uses of AI in current practice.

The limitations in research evidence are important: indeed, the effectiveness of interventions tends to reduce when moving into practice, and unintended consequences may also become apparent. For example, the CareCall AI expanded public reach to socially isolated people, but this also increased the workload of public agency workers, as their caseload increased and some people did not want to communicate with AI [23]. In our review of the potential roles of AI in public health contexts, we identified a large number of risks, including the perpetuation or reinforcement of health inequalities and discrimination, concerns around transparency, data management, privacy, security, and confidentiality, and ethical, legal, and regulatory concerns, all of which may contribute to unintended and unpredictable consequences of AI adoption within public health [9].

Without underlying evidence of effectiveness in practice, and the numerous and critical risks, it would seem extremely difficult for public health teams to know which uses of AI, if any, would be useful to adopt into practice.

Stakeholder Consultations

Stakeholders recognized the potential of AI-assistance in delivering behavior change interventions but highlighted a number of key knowledge gaps that need to be attended to moving forward. First, stakeholders noted limited reporting of the extent to which interventions were coproduced with the target audience, which raises important considerations of how coproduction methods can be optimally used in AI-based research. Second, stakeholders discussed the need for participants to have readiness and motivation to engage with AI and noted skill development may be required. Third, stakeholders queried the strength of implementation science in this area. For example, they considered if apps would be hosted by developers or local authorities, and what resources and capabilities would local public health teams require to support AI-assisted approaches. Fourth, stakeholders commented on the methodological limitations of evaluation, and whether new appraisal tools would need to be developed to account for the specific challenges and limitations associated with AI. Specifically, there was discussion of whether AI approaches have the potential to exacerbate health inequities and cause unintended harms, which have not yet been fully theorized or translated into appraisal criteria.

Limitations of This Review

Despite the comprehensive search strategies, it is possible that relevant reports may have been missed from searches. Equally, despite duplication of screening, relevant reports may have been missed during screening, and relevant information may have been missed during data extraction of included reports. However, the purpose of this scoping review was only to determine how much real-world evidence exists and is easily accessible for using AI tools in public health: if we missed relevant evidence because it was not accessible, then public health teams may also miss that evidence when searching for the effectiveness of AI tools in public health.

Additionally, we focused solely on AI tools used within public health. These tools, or entirely different AI tools that could or

XSL•FO
RenderX

have been used within public health but were not included in this review, may have evidence of use in other fields. However, the utility of tools may differ across fields, in a similar way to how effectiveness of interventions in trials may differ from effectiveness in practice.

Finally, defining and identifying both public health and which interventions are AI-assisted was challenging, as the definitions for both public health and AI are broad, and some reports provide little or no information about the AI aspect of AI-assisted interventions. We aimed to avoid missing relevant reports by taking a sensitive approach to screening and using broad inclusion criteria.

Implications for Research and Practice

When considering adopting an AI intervention, public health professionals should carefully consider the potential effectiveness and cost-effectiveness alongside any potential risks of harm, even for nonclinical interventions [34]. This review identified some current uses of AI tools that look beneficial (the WIC chatbot, some uses in evidence synthesis), though the description of the S.A.R.A.H chatbot as both ineffective and a "potential threat to erode trust in the WHO" provides a stark warning of the risks of harm.

One key finding in this review is that while there are a multitude of potential uses of AI tools in public health, there is limited evidence for their use in practice. In the absence of evidence, new interventions, including those using AI, should ideally be evaluated by public health teams to ensure they are effective (and cost-effective). These evaluations should be widely and accessibly disseminated to create an evidence base that other public health teams could use to inform their own decisions around AI tools. This poses the opportunity and need for researchers and practitioners to work more closely to share skills and resources.

Conclusions

This scoping review summarized evidence for the current uses of AI in public health relevant to high-income countries, excluding outbreaks. Across 3 public health contexts, we identified only 8 reports [21-28] of current uses of AI, which ultimately had mixed evidence of effectiveness. This lack of evidence from public health practice makes it difficult to know which uses of AI, if any, would be useful to adopt. In the absence of evidence, new interventions, including those using AI, should ideally be evaluated to ensure they are effective (and cost-effective). These evaluations should be widely and accessibly disseminated to create an evidence base that other public health teams could use to inform their own decisions around AI tools.

Acknowledgments

Jenny Lowe provided professional services support for the review. The authors are grateful to the following advisory groups for their support during this review: the NIHR (National Institute for Health and Care Research) Health Determinants Research Collaborations (HDRCs) in England and Wales (including Zoe Lancelott, Sophia Looney, Sarah Markham, Sarah McGarrol, and Francis McKay); the Health Foundation; the Faculty of Public Health "AI and Digital Public Health" Special Interest Group (including Elliott Roy-Highley); the Local Government Association AI Network; and public contributors (including Sian Harding). AI was not used in any part of this research.

Funding

This research was funded by the National Institute for Health and Care Research (NIHR) Public Health Research Programme (NIHR175419) and the NIHR Applied Research Collaboration South West, and it was supported by DECIPHer, funded by Welsh Government through Health and Care Research Wales. Abstract

Background: Traumatic knee injuries (TKI) are common and are associated with a 4 to 6 times increased risk of posttraumatic knee osteoarthritis (PTOAK) over the subsequent 15- to 20-year period. There is clear evidence that the risk can be reduced, as per the 2022 OPTIKNEE recommendations, but long-term care availability is limited. Digital health interventions (DHIs), such as wearable devices, telehealth innovations, and mobile apps, have the potential to deliver long-term musculoskeletal care. DHIs can be scaled up to support health care delivery by improving efficiency and accessibility.

Objective: This study aimed to evaluate existing DHIs against the OPTIKNEE consensus guidelines for PTOAK prevention and to investigate adoption into practice.

Methods: A search of 7 online academic databases and the gray literature was completed from inception to June 3, 2025, complemented by hand searching government, charity, and university websites for reports and technical prototype papers concerning DHIs that can support care after TKIs. The content from each DHI was mapped against the 7 OPTIKNEE recommendations as follows: exercise, goal setting, patient-reported outcome measures, functional assessment, strength assessment, information provision, and overall clinical outcome. DHIs were then evaluated against the health-technology pathway to identify their stage of development. Finally, adoption into routine clinical practice was analyzed using Normalization Process Theory (NPT), which considers 4 domains: coherence, cognitive participation, collective action, and reflexive monitoring.

Results: There were 81 reports, 53 peer-reviewed and 28 from other sources, concerning 49 distinct DHIs. They were designed for injuries of the anterior cruciate ligament (ACL, n=12); ACL±meniscus (n=15); meniscus (n=3); ACL or meniscus (n=2), bone (n=2), patella dislocation (n=1); and 14 were nonspecific. Across the 49 DHIs, 25 were classified as mobile health, 19 as telerehabilitation, 4 as eHealth, and 1 as both telerehabilitation and mobile health. No DHIs addressed all the OPTIKNEE recommendations; however, the 8 most complete reported 4 out of 7 components, including exercise, information provision, patient-reported outcome measures, goal setting, and overall patient outcomes. Only 1 DHI reported a remote functional assessment, and self-assessed strength evaluations were not reported in any DHI. NPT analysis typically demonstrated low DHI adoption across the 4 domains, and positive responses across the 4 NPT domains varied across the different health technology pathway stages. The DHI with the highest adoption into routine practice, according to NPT, was “getUbetter,” with 56% (n=9) positive scores.

Conclusions: There are many available, or developing, DHIs, but none include the full content recommended by OPTIKNEE to reduce the risk of PTOAK. Furthermore, there is negligible evidence of DHIs being adopted into usual care irrespective of the stage of DHI development. There is a clear need to develop guideline-compliant DHIs to support effective prevention.

digital health intervention; traumatic knee injury; posttraumatic osteoarthritis; mobile health; mHealth; eHealth; OPTIKNEE

Introduction

Individuals who experience a traumatic knee injury (TKI) often develop posttraumatic knee osteoarthritis (PTOAK) [1]. TKIs are common and occur in 720 to 1800 per 100,000 people annually [2] and tend to result in poor health outcomes, including a 6-fold increase in risk of osteoarthritis [3]. A cohort study found that out of 1145 knee injuries, 733 (64%) occurred

XSL•FO
RenderX

in men aged 20 to 29 years [4]. At present, an estimated 5.4 million people live with knee osteoarthritis in the United Kingdom [5]. Those with PTOAK experience lifelong consequences such as pain, loss of function, obesity, fear, and reduced knee-related quality of life (QoL) [6]. The 2022 OPTIKNEE international consensus provides high-quality evidence on how to optimize knee health after a TKI [7]. The guidance details how to support individuals who have had a single or multistructure injuries, such as an anterior cruciate ligament (ACL) tear, meniscus tear, intraarticular tibiofemoral fracture, or patella dislocation with concomitant chondral lesions.

Recent technological advances have led to a boom in the use and acceptance of digital technologies as part of health care transformations aiming to increase capacity and access while controlling costs [8]. Despite strong claims, there is limited evidence that digital health interventions (DHIs) are adopted at scale or that they provide effective patient education and self-management interventions for people with musculoskeletal conditions, either in isolation or in combination with traditional care [9]. Digital tools have the potential to be scaled up to improve health care delivery by improving efficiency, accessibility, safety, and effectiveness [10]. This is recommended in the 10-year health plan for England, which aims to move much of health care from analog to digital [11]. A wide variety of DHIs are available, from smartphone apps to telemedicine platforms, which can support treatment and self-management [12]. A systematic review that evaluated DHIs found them to be effective in the medium term for reducing pain and improving physical function for individuals with knee and hip osteoarthritis [13]. DHIs have the power to increase access to health care; however, social determinants of health, such as digital literacy, are a major barrier to realizing the full benefits that DHIs have to offer [14,15]. Other barriers include low literacy [16], poor internet reliability [17], and being unable to afford the cost of phones or data [18]. DHIs can effectively support patients after a TKI, with a successful DHI likely needing to meet the OPTIKNEE recommendations to reduce PTOAK risk.

Despite the proliferation of DHIs [19], it is not clear whether these are being integrated, adopted, and used in routine practice. Normalization process theory (NPT) [20] is a useful framework for understanding how complex interventions become embedded into routine practice because it can be applied across different contexts [21] and provides a method of accurately explaining complex implementation processes [22]. It has been successfully deployed for DHIs such as telehealth consultations for asthma care [23] and clinical decision support systems [19,20].

The aim of this scoping review was to explore the quality, relevance, and adoption of DHIs available to support individuals after a TKI and reduce PTOAK risk. The objectives were to compare the DHIs against the OPTIKNEE consensus guidelines [7] and to investigate whether these DHIs have been adopted into routine practice using the NPT framework. The outcomes will guide clinical service delivery and inform future research on supporting patients after TKI.

Methods

Study Protocol

This review followed the Joanna Briggs Institute guidance for scoping reviews [24] and was reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist [25]. The protocol was published on the Open Science Framework (June 11, 2025) [26]. We did not fully address the presence of efficacy, proof of concept, regulatory approval, and link to evidence as initially planned. During the data analysis, it became clear that a focus on the OPTIKNEE mapping and NPT analysis was sufficient to give a clear and robust understanding of the literature regarding DHIs in this context.

Data Sources and Search

Searches were conducted between May and June 2025 in both academic (PubMed, CINAHL, EMBASE, MEDLINE, IEEE Xplore, TRIP, and Web of Science) and nonacademic databases (NHS Digital Playbook, Innovate UK, iMedicalApps [27], Medicines and Healthcare Products Regulatory Agency [MHRA], Food and Drug Administration [FDA], Google Scholar, Queen Mary Research Online, Arthritis UK, and the University of British Columbia Open Collections). The search script was developed with the research team, based on key operational definitions (Table 1), including a health sciences librarian (Table 2; full search script in the Multimedia Appendix 1), and limiting it to manuscripts published from 2010 onward. Records were uploaded to Covidence (Veritas Health Innovation Ltd) [28] and duplicates removed. Dual title and abstract screening was conducted by the lead author and one other reviewer, with eligible full-texts being retrieved and screened similarly. The inclusion and exclusion criteria can be found in Textbox 1.

Table . Operational definitions.

Term	Definition
Digital health intervention	A health intervention delivered through digital tools or communication technologies, which collect, store, share, and analyze health information for the purpose of improving patient health and care. This could be through wearable devices, mobile apps, text with smartphones, or telehealth [29].
Traumatic knee injury	An isolated or combined traumatic tibiofemoral or patellofemoral (eg, ligament, meniscal, cartilage, subluxation, dislocation, and fracture) injury [1].
Posttraumatic knee osteoarthritis	Structural or symptomatic osteoarthritis that develops after sustaining a traumatic knee joint injury [7].

Table . Search terms.

Construct	Keywords
Injury	“knee dislocation” OR “acl” OR “anterior cruciate ligament” OR “meniscus” OR “knee fracture” OR “knee injury”
Digital health intervention	“wearable device” OR “mobile application” OR “mobile applications” OR “mobile apps” OR “mobile app” OR “internet” OR “mobile phone” OR “smart phone” OR “telemedicine” OR “technology” OR “mhealth” OR “telehealth” OR “emedicine” OR “mobile health” OR “cell phone” OR “digital health technology” OR “digital health”
Treatment and management	“outcome assessment” OR “monitoring” OR “kinesiotherapy” OR “signposting” OR “advice” OR “education” OR “telerehabilitation” OR “exercise” OR “rehabilitation” OR “patient reported outcome measure” OR “diet”

Textbox 1. Inclusion and exclusion criteria

Inclusion criteria

- Reports that include a digital health intervention (DHI), including but not limited to telemedicine, mobile health, telerehabilitation, mobile apps, telehealth, or wearable devices (including virtual reality).
- Reports that include patients who have undergone a traumatic knee injury (TKI), including but not limited to anterior cruciate ligament (ACL) rupture (preoperative or postoperative), meniscus tear, intraarticular tibiofemoral fracture, or patella dislocation.
- Reports including at least one of the following delivered via a DHI: outcome measures, weight management strategies, physical monitoring (including wearables), exercise prescription, signposting, or education.

Exclusion criteria

- Reports that do not include a TKI.
- Reports that do not include a DHI that could be used with people who have experienced a TKI.
- Reports including participants with osteoarthritis or participants who have undergone joint arthroplasty.
- Reports not reporting at least one of the following: outcome measures, weight management strategies, physical monitoring (including wearables), exercise prescription, signposting, or information provision/education.
- Reports involving the use of exoskeletons or electromyography.

Data Extraction

For data charting, we used Elicit, the AI-assisted research tool [30], to identify initial data, which was then checked and confirmed by one author (JC) and supplemented where required. Each report was uploaded, and prompts were provided of the extraction of relevant data. Elicit data extraction has been shown to be of similar accuracy to human reviewers (81.4% vs 86.7% accuracy, respectively) [31]. Initial data extraction included study year, methods, DHI classification, and injury type. Then, from each DHI identified, we determined which of the key OPTIKNEE consensus domains it referenced [7]: exercise, education/advice, functional assessment, strength assessment, patient-reported outcome measures, patient goals, and outcomes. Elicit was used to provide an initial interpretation of the data extracted for each validated NPT question (Multimedia Appendix 1, Table 5), also being cross-checked by JC and any queries being discussed with the wider research team.

Analysis Framework

The content from each DHI was mapped against the key OPTIKNEE [7] domains (Table 3). This process involved exploring the content of each DHI to verify if it reported information provision, exercises prescription, self-assessed functional assessment, self-assessed strength assessment, patient-reported outcome measure (PROM) delivered via the DHI, goal setting, or overall patient outcome. If the DHI reported any of the OPTIKNEE domains, then a “yes” score was given; if it was unclear from any of the reports, then an “unclear” score was given; and if there was no mention in the report, then a “no” score was given.

DHI	OPTIKNEE domains							Yes (%)
Yes (%)	84	37	2	0	35	24	24	

[a]PROM: patient-reported outcome measure.

[b]The DHI was released after the OPTIKNEE recommendations were published.

[c]The OPTIKNEE domain was provided in the content of the DHI.

[d]The OPTIKNEE domain was not present in the content of the DHI.

[e]A DHI that is not specifically designed for people who have had a TKI, but it has the potential to be used with a person who has had a TKI.

[f]It is not clear if the OPTIKNEE domain was provided in the content of the DHI.

[g]BANG: back in the game.

[h]SOAR: SOAR: stop osteoarthritis.

[i]CBPT-ACLR: Cognitive behavioral–based physical therapy anterior cruciate ligament reconstruction.

[j]ACL: anterior cruciate ligament.

NPT provides a framework for data analysis [32] and previous evidence supports the use of NPT for evaluating and understanding implementation processes [33]. The NPT framework contains 16 questions split into 4 domains: coherence, cognitive participation, collective action, and reflexive monitoring [20] (Multimedia Appendix 1, Table S5). For each question in the NPT framework, we gave an answer of “yes,” “no,” “maybe,” or “not reported,” and this was then color coded in the analysis. Following this, relevant quotes were extracted from the reports to evidence the decisions made (Tables 4-6).

DHIs were mapped against the Health-Technology Pathway (Tables 4-6), which defines the key steps in the end-to-end pathway for health technology from research to patient treatment [34]. The different stages of the health technology pathway include creation, development, evidence/regulation, commissioning, and adoption.

Quality Assessment

Reports were assessed against the mERA (mobile health evidence reporting and assessment) checklist [35], which outlines a minimum set of information required to define what the mobile health intervention is, where it is being implemented, and how it was implemented to support replication of the intervention. It is scored on a 16-point scale with a point attributed to each item (maximum score of 16). To assess methodological quality, the Quality Assessment for Diverse Studies (QuADS) tool [36] was used, which has been used in previous scoping reviews [26,29] to assess a diverse range of studies with varied methodology. The QuADS tool has a maximum score of 39 from 13 questions, each scoring up to 3 points, with higher scores representing a higher methodological and reporting quality.

Results

Study Characteristics

Eighty-one reports were identified following full text screening. The final analysis includes 49 DHIs, as multiple reports referenced the same DHI (Figure 1). Study designs of the included reports were as follows: 18 randomized controlled trials (RCTs), 9 technical reports, 6 protocols, 4 qualitative reports, 4 feasibility studies, 3 mixed methods, 2 case series, 2 clinical studies, 2 retrospective observational studies, 2

XSL•FO
RenderX

quasi-experimental studies, 2 pilot studies, 2 prospective cohorts, 2 retrospective cohorts, 2 secondary analyses of a prospective cohort study, 2 service evaluations, and one app review, case report, case-control study, pilot RCT, superiority trial, registry study, repeated measures design, retrospective study, usability study, validation study, service development project, qualitative mapping study, Delphi study, mixed methods service evaluation, case study, quality improvement project, feasibility and usability study, secondary analysis of an observational study, and a cost-effectiveness analysis (Multimedia Appendix 1). The highest score on the mERA checklist was 10 out of 16 (mean=4.75, SD 2.12), and the highest score on the QuADS assessment tool was 36 out of 39 (mean=20.19, SD 8.87).

Figure 1. PRISMA diagram. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

Twelve DHIs focused on managing isolated ACL ruptures, 15 for ACL rupture ± meniscus involvement, 3 for acute meniscus tears, 2 ACL rupture or meniscus tear, 2 knee fractures, and 1 patella dislocation. 14 were not specific to a type of knee injury, but the DHI had the potential to be used with patients who had sustained a TKI. Across the 49 different DHIs, 25 were classified as mobile health, 19 as telerehabilitation, 4 as eHealth, and one as both telerehabilitation and mobile health. There were 19 DHIs at the market stage, 19 were at the evidence stage, and 11 were at the development stage (full list of references with corresponding characteristics in the Multimedia Appendix 1).

Mapping DHIs Against OPTIKNEE

The highest OPTIKNEE score from a DHI was 4 out of 7 (57%), and exercise provision was the most reported recommendation at 41 (84%). Information provision scored 37%, PROMS scored 35%, goal setting scored 22%, and overall patient outcome scored 24%. There was only one self-assessed functional assessment reported, and no self-assessed strength assessments were reported. Eight DHIs reported 4out of 7 (57%) of the OPTIKNEE recommendations as part of their content; however, 18 DHIs scored 1 out of 7 (14%) and 2 out of 7 (28%). There were 36 out of 49 (73%) DHIs that had 2 or fewer of the OPTIKNEE recommendations included in their content.

NPT Results

The NPT results have been broken down into 3 tables to illustrate the stage each DHI is at on the health-technology pathway, and key quotes can be seen in Figure 2. The health-technology stages include market, evidence, and development. A green box indicates a “positive” response to one of the 16 questions. Yellow indicates “maybe,” and gray means that it was “not reported” (see Multimedia Appendix 1 for the full set of NPT questions).

XSL•FO
RenderX

Figure 2. Key normalization process theory (NPT) quotes from the included reports for each of the NPT domains (Multimedia Appendix 1 for a full set of quotes for each NPT question) [37-42].

At the market stage, the DHI with the highest positive responses was "getUbetter" at 9 (56%). Within the evidence stage, the highest positive response for a DHI was F. Litchfield, at 25% (n=4). Then the highest positive response across the NPT questions was 21% (n=10) for the third and eleventh questions. For DHIs in the development stage, A. Tipprom scored the highest positive response at 31% (n=5). However, the highest positive response for the NPT questions was 18% (n=2) for the third, fourth, fifth, eleventh, and twelfth questions. Across all stages of the health-technology pathway, the most common positive score for NPT was 0.

For the health-technology pathway, out of 49 DHIs, 39% (n=19) were at the market stage, 39% (n=19) at the evidence stage, and 22% (n=11) in the development stage. Despite being in the market stage, there were a total of 28 out of 304 positive responses across the 4 domains, while DHIs at the evidence stage and at the development stage showed 19 out of 304 and 15 out of 176 positive responses, respectively. This lack of noticeable differences between stages seems to also be present when considering individual NPT domains.

Discussion

Overview

In addressing our aim to evaluate DHIs against the OPTIKNEE consensus guidelines [7], we found that all identified DHIs lack the required content and features to promote knee health in people at high risk of PTOAK after a TKI. Although the DHIs have been variably adopted (19 on the market, 19 with evidence, and 11 in development), none demonstrate evidence of having reached the required criteria or spread to be regarded as accepted in practice. It is difficult to pinpoint exactly why there is variable DHI adoption from the evidence, and it is likely multifactorial.

Digital Adoption

The NPT framework was applied to the DHIs to explore if and to what extent these DHIs were adopted into routine practice. The NPT framework has been applied in previous research such as a scoping review [43] and in qualitative research [44,45]. It is possible for DHIs to be implemented into practice successfully, and a previous example of this was the HeLP-Diabetes web-based self-management program, which was effective at helping people with type 2 diabetes to support their glycemic control [46]. If a DHI is not adopted, patients may have less successful outcomes [47], and it may lead to lost opportunities to address health inequalities [48]. A previous scoping review found that there are no clear implementation strategies that are effective for the adoption of DHIs in rehabilitation [49].

Results from the NPT analysis in this review demonstrate some successful adoption of PTOAK-relevant DHIs into routine practice. GetUBetter had positive responses in over half of NPT questions, and Phio and QoC Health Inc had positive responses in over a quarter of NPT questions. In this review, DHIs are aimed at patients, clinicians, or both, which may be why the positive responses in the NPT analysis were variable. Previous evidence found that perceived effectiveness was key for clinicians adopting a new DHI [50]. To enhance engagement with patients, the DHI needs to be low effort and meet the specific needs of the patient [51]. As the NPT analysis is an accurate measure of adoption, then we would expect there to be higher levels of adoption for DHIs on the market compared to DHIs in development. However, our results illustrate that there was no clear pattern between the DHI stage of development and adoption into routine practice (Tables 4-6). This would suggest that there is insufficient development prior to DHIs being implemented into routine practice, possibly explaining the lack of functionality and guideline compliance.

XSL•FO
RenderX

Information typically presented in different study designs might justify the variability in scoring of the NPT framework. For example, RCTs are unlikely to report whether individuals have a clear understanding of the DHI in a trial report but may do in a process evaluation. The lack of clear, comprehensive reports of guideline-compliant intervention development perhaps explains the lack of efficacy studies.

OPTIKNEE Digital Delivery

When DHI content was mapped against OPTIKNEE [7] guidelines, the exercise domain scored the most positive results (84%), recommended as a core treatment for knee injuries and PTOAK prevention [7]. Exercise content across the DHIs was mixed depending on the target audience, as some DHIs are targeted at a more general population compared to those with specific knee injuries. This means that exercises provided to patients through some DHIs do not address the specific rehabilitation needs of a patient post TKI. This would suggest that the DHIs not providing appropriate knee-focused exercises may put patients at an increased risk of developing PTOAK after a TKI.

Information provision was present in only 37% of DHIs, highlighting that education and information provision are rarely being provided despite it being widely recommended as a first-line treatment for most musculoskeletal conditions [52]. Education is vital to help patients address and avoid risk factors such as weight gain or inactivity [7]. Although OPTIKNEE refers to this recommendation as “education,” we decided to use the term “information provision” instead as some DHIs only had basic information on the condition rather than formal education strategies, with testing of learning. This review highlights that most DHIs were not addressing this OPTIKNEE recommendation [7], therefore reducing the likelihood of preventing PTOAK.

PROMS were integrated into 35% of DHIs as a method of data collection and represent a validated method of establishing progress or health care outcomes [53,54], being relatively easy and efficient. It could also be a way of monitoring patients in the long term and flagging when they may be at risk of functional decline. OPTIKNEE recommendations [7] provide clear guidance on which PROMS should be used in this patient population; this includes the IKDC-SKF [55], KOOS [56], and WOMET [57]. However, there are a wide selection of different PROMS identified in the DHI included in this review, meaning guideline compliance is poor and efforts to compare efficacy are hindered.

The OPTIKNEE guidance [7] recommends in-person functional movement assessments, such as a crossover hop test, as a key performance marker to monitor knee-related function in people at risk of PTOAK. Only Orthelligent contained a digitally supported self-assessed functional assessment, in this case a vertical hop test. It may not be the gold standard, but remote self-assessed functional tests can be completed via DHIs. To assess children’s physical fitness, a DHI was developed to assess coordination, muscular endurance, and flexibility, which was found to be valid and reliable [58]. Remote smartphone-based balance assessments have been completed successfully for people with Parkinson disease [59], and vertical jumps, a common and important test, have been demonstrated as valid and reliable in a digital format [60]. By taking a pragmatic approach to assessing functional movements via a DHI, it will allow clinicians to effectively monitor these patients at risk of developing PTOAK after a TKI.

For strength assessments, the OPTIKNEE guidance [7] recommends an in-person strength assessment completed via a one-rep max test or dynamometry. It may not be an in-person strength assessment as recommended by OPTIKNEE [7], but no DHI reported a self-assessed strength test. If thigh muscle strength is not maintained, it can put the patient at an increased risk of PTOAK [7]. Similar to functional assessments, there are mobile apps that can remotely assess strength [61], and other strength tests could be incorporated digitally such as the single-leg wall squat test [62]. This is difficult to replicate via a digital intervention, but a remote strength test could supplement gold standard strength testing that is usually completed in the clinic environment (ie, better to monitor strength in some format rather than not at all). By monitoring strength remotely, it would provide another avenue for clinicians to track patients who are at risk of developing PTOAK.

Mixed reality and immersive virtual reality could support remote musculoskeletal care by facilitating assessments and supporting remote exercise provision [63,64]. These tools can provide biofeedback for patients and support gait retraining during physical rehabilitation [64]. Mixed or immersive virtual reality could also address the difficulty of performing remote strength and functional assessments by, for example, using virtual reality to guide patients through a hop test or a squat assessment remotely. Immersive virtual reality has already been successful in providing rehabilitation to improve function to patients after a traumatic hand injury [63]. Though these options show potential, they would need to be integrated into current clinical pathways to ensure they can be adopted into routine practice. However, limitations regarding initial upfront cost, time spent onboarding patients, and limited engagement from individuals with reduced digital literacy skills will also need to be addressed when using these systems.

Clinical outcomes were highlighted in 24% of DHIs. It included metrics such as knee-related pain, QoL, adverse events, and physical activity levels. Collecting these metrics could be easily delivered via a DHI, and there is evidence that some patients prefer this over paper-based approaches [65]. Goal setting was present in 22% of DHIs; however, previous evidence has demonstrated that goal setting can be delivered via a DHI and is widely accepted by patients [66]. This is vital to promote patients’ engagement and support patients after a TKI, leading to improved patient outcomes and knee-related QoL by reducing fear and anxiety [7].

AI agents or large language model (LLM)–based assistants are another option for supporting digital musculoskeletal care. They could provide clinical decision support and integrate with current workflows [67] and provide health education [68] and basic rehabilitation planning [69]. These models could be used to facilitate OPTIKNEE recommendations, informing a DHI to deliver information provision, goal setting, outcome monitoring, and basic rehabilitation provision without fragmentation of care

XSL•FO
RenderX

to patients. Clinically validated agents are sparse despite this area developing rapidly; however, current models are limited by a lack of interpersonal connection, public distrust in AI, and ethical concerns regarding dataset bias. Those would need to be addressed prior to implementation into musculoskeletal care.

Although all DHIs included could be used to reduce the risk of PTOAK, most did not specifically state this as an aim. The DHI by Martin et al [70] was the one exception, and the study was published after the release of the OPTIKNEE recommendations. The DHI reported is explicitly focusing on reducing the risk of PTOAK after a TKI in military personnel. However, despite aiming to mitigate the risk of PTOAK, it still lacked some of the components outlined by the OPTIKNEE consensus: strength and functional assessments [7]. These may not have been considered by the researchers, may have been too difficult to build into the DHI, or may have felt it was not required as military personnel are routinely tested for strength and functional performance in their occupation [71]. However, the results from this preliminary RCT demonstrate that participants in the DHI group had better pain control strategies and fatigue management [70].

At present, there is no single DHI that can provide all the OPTIKNEE [7] recommendations to patients after they have sustained a TKI. The results highlight the variability of what is offered by different DHIs targeted at supporting individuals post TKI. The results demonstrate a lack of standardized digital care being provided to patients after TKI, despite there being clear guidance to reduce the risk of these patients developing PTOAK. This indicates that there is a gap in service provision to support patients after TKI and reduce their risk of developing PTOAK. Future services will need integrated digital solutions to ensure care priorities are met, that is, analog to digital, and outcomes optimized.

Implications

A future evidence-informed digital intervention that can incorporate all aspects of the OPTIKNEE recommendations [7] in a pragmatic manner would be a valuable intervention to support patients after a TKI to reduce their risk of PTOAK. Key features of successful DHIs implemented into routine practice have demonstrable clinical benefit [72], ability to scale the digital intervention [73], can be easily integrated into routine care [74], and there is perceived value from clinicians [75]. However, when developing new DHIs, digital literacy needs to be considered because it remains a barrier to patients engaging with DHIs, and future digital innovations should provide equitable health care [76]. A future DHI would require all these features to ensure that it is successfully implemented into routine practice. Due to the complex nature of TKIs and varying levels of severity, there would need to be future research about when is best to implement a DHI in the care pathway for patients. Additionally, a user-centric design during development is an essential strategy for the successful implementation of DHIs, as input from the TKI population during the development can lead to greater acceptance and perceived usefulness of the DHI and consequently improved engagement and outcomes [77]. It would also be important to explore which clinicians are best placed to deliver and onboard patients to a DHI after a TKI.

Strengths and Limitations

This review was able to include a wide variety of different DHIs by adopting a broad, extensive, and creative search strategy, including academic and nonacademic sources, resulting in an analysis that can provide a clear picture of the DHIs being used with this patient population. The review methods were adapted due to the nature of the topic while still being reproducible and applying clear frameworks for data analysis. Although we included a wide search strategy, most of the reports in the review were designed for an ACL-injured population, and there was a paucity of evidence on other TKIs. It is possible that DHIs are being more widely adopted than our review shows. Although the NPT framework has been shown as useful in similar contexts, its results are dependent on the quality and volume of the reports, which may not reflect what is occurring in routine practice, with few DHIs undergoing thorough formal intervention development.

Conclusion

This scoping review identified 49 DHIs being used with or having the potential to be used with individuals post TKI. The DHIs are at various stages of development in the health technology pathway, which is not necessarily associated with the level of adoption. Ultimately, most DHIs lack self-assessed functional and strength assessments, indicating that rigor is insufficient across the DHIs. This review did not identify a DHI that can provide all the OPTIKNEE recommendations, which aims to minimize the risk of patients developing PTOAK in the long term. Future research should focus on measuring the efficacy and feasibility of an OPTIKNEE-informed DHI to support individuals after TKI.

Abstract

Background: Generative AI (GenAI) is being deployed rapidly in medicine, and evidence of its clinical safety and efficacy depends on transparent reporting of randomized controlled trials (RCTs). The CONSORT-AI (Consolidated Standards of Reporting Trials–AI) extension is a benchmark for AI trial reporting, but it was drafted for conventional AI, and its applicability to GenAI has not been examined.

Objective: This study aimed to assess item-level adherence to the CONSORT-AI among RCTs evaluating GenAI for medical purposes and to distinguish deficiencies attributable to nonadherence from those attributable to items that do not correspond to how GenAI interventions are specified or delivered.

Methods: PubMed, CENTRAL (Cochrane Central Register of Controlled Trials), and Embase were searched for peer-reviewed, English-language RCTs published from 2022 to April 3, 2026, supplemented by backward and forward citation searching, in which patients, health care professionals, or laypeople received a GenAI intervention for a medical purpose; non-GenAI, nonmedical, nonrandomized, and non-peer-reviewed reports were excluded. Two reviewers independently screened studies, extracted data, and rated CONSORT-AI items as reported, partially reported, not reported, or not applicable using signaling questions, with disagreements resolved by a third reviewer (Cohen κ=0.81 and prevalence-adjusted, bias-adjusted κ=0.84). Risk of bias was not assessed, as the target was reporting adherence. Adherence was the proportion of reports rated “reported” per item; item-level adherence was compared across 9 characteristics using Fisher exact and Freeman-Halton tests (2-sided α=.05).

Results: From 16,485 retrieved records, 74 reports from 73 RCTs (24,150 participants; median 100, IQR 50.0 - 247.0) were included. Large language models (LLMs) accounted for 98.6% (73/74) of interventions, with 60.8% (45/74) using GPT-family models. Item-level reporting adherence ranged from 0% (0/72) to 98.6% (73/74). High adherence occurred in general metadata and output specification items (range 59-73, 79.7% - 98.6%). Conversely, reporting was poor for input and technical execution domains, input data eligibility (3/73, 4.1%), input acquisition/selection (9/74, 12.2%), algorithm versioning (17/74, 23.0%), trial setting integration (21/74, 28.4%), human-AI interaction (25/74, 33.8%), performance error (27/74, 36.5%), and open access/code (31/74, 41.9%). Input quality handling (Item 5[iii]) was completely unreported (0/72). Only 9 of 74 (12.2%) reports explicitly cited CONSORT-AI. While citing reports showed higher compliance for interaction and data sharing, major technical gaps persisted regardless of citation.

Conclusions: This review provides the first empirical audit distinguishing general nonadherence from structural mismatches where deterministic CONSORT-AI items fail to capture GenAI mechanics. Differing from traditional AI evaluations, it reveals that key reproducibility drivers—system prompts, inference settings, and access modalities—are omitted from current standards. These empirical findings highlight critical reporting gaps in medical GenAI trials and identify domains for a tailored extension to current reporting standards, although the evidence is limited by the use of nonvalidated signaling questions. Establishing GenAI-specific trial guidelines will ensure that clinical decisions, regulatory approvals, and patient safety safeguards are grounded in reproducible and trustworthy evidence.

KEYWORDS

AI; generative artificial intelligence; randomized controlled trials; CONSORT-AI; large language models; reporting adherence; Consolidated Standards of Reporting Trials–AI

Introduction

Generative AI (GenAI), built on foundation models (FMs), is a transformative technology with broad applications, and the medical domain is no exception [1-4]. Unlike conventional AI systems designed for specific purposes, GenAI can perform broader and more complex tasks, offering significant potential for cost-effectiveness [5,6]. Within a few years, these systems have moved from demonstrations of performance on medical knowledge benchmarks [7] to interventions delivered directly to patients and clinicians in clinical settings; as recently as late 2024, a review of registered and published trials of large language models (LLMs) in health care identified only 5 published trials [8]. Realizing such potential in clinical practice demands rigorous validation. Randomized controlled trials (RCTs) remain the gold standard for evaluating the clinical safety and efficacy of any new intervention—a principle that applies equally to GenAI [9].

The results of RCTs serve as foundational evidence for decision-making in policy development, regulation, and clinical practice. To ensure the reliability and transparency of such studies, the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) and the CONSORT (Consolidated Standards of Reporting Trials) guidelines specify the minimum items that must be included in the design and reporting of RCTs [10,11]. In 2020, the CONSORT-AI extension was developed to address potential sources of bias and reporting concerns specific to RCTs involving AI interventions [12]. This extension is used as a benchmark for evaluating reporting in RCTs of AI interventions. The CONSORT-AI development team noted the need to update the guidelines as technology and its applications advance.

Since the publication of CONSORT-AI, its uptake has been assessed in RCTs of AI across health care generally [13,14], in trials appearing after the guideline was issued [15], and within specific fields, including ophthalmology [16] and primary care [17]. These reviews describe a consistent pattern. Aggregate adherence appears moderate to high: median concordance across the checklist was 90% (IQR 77% - 94%) among 65 trials [15], and 65% of applicable items were adequately reported among trials in primary care [17]. However, adherence is not evenly distributed across items. This review identified deficiencies in reporting which version of the algorithm was used, how low-quality input data were handled, performance errors and their analysis, and access to the AI intervention or code. In particular, there were no reported cases of performance errors in the field of ophthalmology [16]. No study to date has provided an in-depth analysis of RCT reporting for GenAI interventions intended for medical purposes. Furthermore, these studies interpret only whether reporting was complied with. That interpretation is sound where a checklist item and the intervention are well matched; however, it does not hold where they have not been examined.

GenAI differs fundamentally from conventional AI in its characteristics and uses [18-21]. The specific differences relevant to reporting can be identified in the reporting guidelines developed for GenAI systems. Transparent reporting of a multivariable model for individual prognosis or diagnosis–LLM (TRIPOD-LLM) targets studies that develop, fine-tune, and evaluate LLMs, requiring the reporting of LLM tuning, outputs, prompt engineering, and updating [21]. Furthermore, the Minimum Information about Clinical AI Checklist for Generative Modeling Research (MI-CLAIM-GEN) was revised to reflect that generative models differ from conventional AI in terms of training, evaluation, interpretability, and reproducibility [22]. Additionally, other frameworks have been proposed to address the provision of health information through chatbots and the development and evaluation of LLMs [23,24]. However, none of these guidelines specifically target RCTs. Given the ongoing evolution and expanding application of AI, the CONSORT-AI extension should also be continuously monitored and reviewed [12].

In this context, identifying and reviewing RCTs of GenAI published to date may help determine opportunities for the broader applicability of the CONSORT-AI extension. Therefore, this systematic review aimed to assess the extent to which RCTs evaluating GenAI for medical purposes adhere to the CONSORT-AI extension checklist items. Through this assessment, we sought to identify gaps between the practical characteristics of health care GenAI interventions and the CONSORT-AI extension, thereby informing future directions for refining GenAI RCT reporting guidelines.

Methods

Overview

This study was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [25-27] (Checklists 1 and 2), and the protocol was prospectively registered in the International Prospective Register of Systematic Reviews (PROSPERO; CRD420251034690). Methodological changes made after registration, together with their rationale and timing, are summarized in Table S1 in Multimedia Appendix 1. The changes to the eligibility criteria and the search strategy determined the composition of the final sample, and all estimates reported here derive from that sample. The remaining changes affected how adherence was analyzed.

Eligibility Criteria

The inclusion criteria were RCTs involving patients, health care professionals, or laypeople who used GenAI for medical purposes. All randomized designs were eligible, including parallel group and crossover trials. In this study, GenAI was defined as an AI system built on pretrained FMs that produces novel content in response to inputs [28-30]. This definition does not restrict output modalities and encompasses systems that

XSL•FO
RenderX

generate text, images, video, and audio [1,28,31]. LLMs represent a subcategory in which the output modality is natural language; systems specialized for clinical applications through fine-tuning, in-context learning, retrieval-augmented generation (RAG), or prompt engineering share the identical generative mechanism and were therefore included [28-30]. Conversely, systems whose outputs are strictly restricted to discriminative results—such as classification, prediction, detection, or risk scoring—even if constructed on pretrained transformer backbones, alongside deterministic, rule-based systems that return prescripted responses, are explicitly excluded [1,29-31]. A medical purpose was defined as an intervention directed at a point in the clinical pathway of an identified recipient. This encompasses interventions concerned with the prevention, screening, diagnosis, monitoring, treatment, or management of disease, injury, or disability, as well as those conveying or interpreting health information in support of such purposes, and those supporting the delivery or documentation of care within a patient encounter. The exclusion criteria were interventions that were not GenAI, interventions not intended for medical purposes, studies that did not involve human participants, studies that were not peer reviewed, conference proceedings, preprints, review articles, non-English publications, and non-RCT designs. Reports that presented only a protocol or a trial registration without results were excluded.

Information Sources

Considering the public release and rapid growth of GenAI since 2022, we searched PubMed, CENTRAL (Cochrane Central Register of Controlled Trials), and Embase for studies published from 2022 through April 3, 2026. All 3 databases were last searched on April 3, 2026. To identify additional eligible trials, backward and forward citation searching was conducted across all initially included studies on August 12, 2026, using the citationchaser (CRAN) tool [32]. To maintain methodological and temporal consistency with the primary database search, the eligibility of identified records was restricted to studies published or made available online on or before April 3, 2026, while records published after this date were excluded.

Search Strategy

The search used free-text terms and Boolean operators with keywords such as GenAI, LLMs, and RCTs. To identify relevant RCTs, we combined text words and MeSH for GenAI with the Cochrane Highly Sensitive Search Strategy for identifying randomized trials [25]. The detailed search strategy is provided in Table S2 in Multimedia Appendix 2. The search was performed in compliance with PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses literature search extension) [33].

Selection Process

After deduplication, 2 authors (JEK and JWH) independently screened titles and abstracts against the inclusion and exclusion criteria. The 2 authors independently reviewed the full texts to determine final eligibility. Discrepancies were resolved by consensus, and if consensus could not be reached, the disagreements were adjudicated in consultation with a third author (JYK).

Data Collection Process

For the included studies, 2 authors (JEK and JWH) independently extracted data. Bibliographic information (eg, title, authors, year of publication, and journal) and study characteristics (eg, country, sample size, study design, end users of the GenAI, intended use, and outcome measures) were extracted. To identify any information not reported in the main text, published study protocols and trial registrations were also reviewed. In addition, to assess item-level adherence, item-specific signaling questions were developed based on the CONSORT-AI checklist items and the accompanying explanation and elaboration document. Rather than generating new assessment criteria, we extracted every explicit reporting requirement expressed in these source documents, typically phrased as statements such as “should specify,” “should state,” or “should describe,” and converted each requirement into a single closed-ended question answerable from the trial report. The draft questions were developed by one author (JEK) and reviewed against the source documents by a second author (JWH), with discrepancies in wording or in the mapping of a requirement to an item resolved by discussion and adjudicated by a third author (JYK) where necessary. The signaling questions of CONSORT-AI checklist items are listed in Table 1, and the data extraction forms are provided in Table S3 and Table S4 in Multimedia Appendix 3. Disagreements in the assessment of individual reports were resolved by consensus and, when necessary, adjudicated by a third author (JYK).

XSL•FO

Table . Signaling questions of CONSORT-AI[a] checklist items.

Section/topic and numbers	CONSORT-AI checklist	Signaling questions
Title and structured abstract		
1 a, b(ⅰ)	Indicate that the intervention involves AI/machine learning in the title and/or abstract and specify the type of model	1. Is it stated in the title and/or abstract that the intervention involves AI/ML[b]? 2. Are the terms describing the model type and architecture detailed in the abstract?
1 a, b(ⅱ)	State the intended use of the AI intervention within the trial in the title and/or abstract	1. Is the intended use of the AI intervention stated in the title and/or abstract? 2. Is the disease context described in the title and/or abstract?
Introduction-background and rationale		
2 a(ⅰ)	Explain the intended use of the AI intervention in the context of the clinical pathway, including its purpose and its intended users (for example, health care professionals, patients, and public)	1. Is the intended use of the AI intervention within the clinical pathway included? 2. Is the intended user of the AI intervention included?
Methods-eligible criteria		
4 a(ⅰ)	State the inclusion and exclusion criteria at the level of participants	1. Are the participant-level inclusion and exclusion criteria stated?
4 a(ⅱ)	State the inclusion and exclusion criteria at the level of the input data	1. Are the minimum requirements (eg, image resolution, quality metrics, or data format) for the input data specified at the input level? 2. Is it stated when input-data eligibility was assessed? 3. Is it stated how the input-data eligibility was assessed? 4. Is it stated who assessed input-data eligibility?
Methods-trial setting		
4b	Describe how the AI intervention was integrated into the trial setting, including any onsite or offsite requirements	1. Are the hardware and software requirements described (eg, vendor-specific device, computing hardware, cloud integration at each site)? 2. If site-specific changes were required, is the process clearly described (eg, fine-tuning on local data)?
Method-intervention and comparator		
5(ⅰ)	State which version of the AI algorithm was used	1. Is the version of the AI system used stated? 2. Is it stated whether the same version was used as in previous supporting studies? 3. Is it stated whether the version changed during the trial? 3 - 1. If the version changed, are the changes between versions described? 3 - 2. If the version changed, are the rationales for the changes described? 4. If available, is a regulatory marking reference (eg, a unique device identifier) provided?
5(ⅱ)	Describe how the input data were acquired and selected for the AI intervention	1. Is how the input data were acquired for the AI intervention described? 2. Is how the input data were selected for the AI intervention described? 3. Is how the input data were preprocessed before analysis by the AI system described?

XSL•FO
RenderX

Section/topic and numbers	CONSORT-AI checklist	Signaling questions
5(iii)	Describe how poor-quality or unavailable input data were assessed and handled	1. Is the amount of poor quality or missing data reported? 2. Is how low-quality or missing data were identified described? 3. Is how low-quality or missing data were handled described? 4. Is any minimum quality standard for the input data stated? 5. If the minimum quality was not met, is it stated where the standard was not achieved? 6. If the minimum quality was not met, is the handling process described including any impact on the participant care pathway? 7. If relevant, is the same information about poor quality or unavailable data reported for the control intervention? 8. If applicable, is it stated whether this minimum quality standard differed from the prerandomization input-data eligibility criteria?
5(iv)	Specify whether there was human-AI interaction in the handling of the input data and what level of expertise was required of users	1. Is the human-AI interaction stated? 2. Is the human-AI interface used to handle input data described? 3. Is the required user expertise or any user training/instructions for input data handling described?
5(v)	Specify the output of the AI intervention	1. Is the output of the AI intervention clearly specified?
5(vi)	Explain how the AI intervention's outputs contributed to decision-making or other elements of clinical practice	1. Are downstream interventions that could affect outcomes described? 2. Are the required user expertise and any training or instructions for interpreting the outputs described? 3. If relevant, is comparable information provided for the comparator intervention? 4. Is any discrepancy between intended (as specified in the trial protocol) and actual decision-making reported?
Results-harms		
19	Describe results of any analysis of performance errors and how errors were identified, where applicable. If no such analysis was planned or done, justify why not	1-1. Is it described how performance errors were identified? 1-2. Are the cases of error reported? 1-3. Are the implications of any performance error analysis reported? 1-4. Are the risk-mitigation strategies defined? 2. If no such analysis was planned or done, was the reason explained?
Open science data sharing		
25	State whether and how the AI intervention and/or its code can be accessed, including any restrictions to access or reuse	1. Is it clearly reported whether and how the AI intervention and/or its code can be accessed or reused?

[a]CONSORT:AI: Consolidated Standards of Reporting Trials–AI.

[b]ML: machine learning.

Extracted text corresponding to the CONSORT-AI checklist was classified into 4 categories. Items were rated as "Reported" only when all underlying signaling questions were met, "Partially reported" when at least one, but not all, signaling questions were satisfied, "Not reported" when none were satisfied, and "Not applicable" when the item could not be applied. Adherence to each checklist item was calculated as the number of reports rated "Reported" divided by the number of

XSL•FO
RenderX

reports in which the item was applicable. Ratings of "Not applicable" were assigned when an item was not applicable to the trial design or intervention of a trial and were excluded from the denominator rather than counted as nonadherence. Adherence was presented in tabular form as the number and proportion of trials in each rating category for every checklist item, and graphically as stacked bar charts of the rating distribution. Items were ordered throughout according to their sequence in the CONSORT-AI checklist.

To assess reliability, 2 reviewers independently classified the items, and interrater agreement on these judgments was assessed using Cohen Kappa. To account for potential prevalence paradoxes arising from highly skewed reporting distributions across items, prevalence-adjusted bias-adjusted Kappa (PABAK) values were also calculated. The resultant overall interrater agreement was almost perfect (Kappa=0.81). Item-specific percent agreements, Kappa statistics, and PABAK values are detailed in Table S5 in Multimedia Appendix 4. Concordance was summarized as the adherence rate, defined as the proportion of studies categorized as "Reported" for each CONSORT-AI checklist item.

Synthesis Methods

To evaluate whether CONSORT-AI reporting adherence differed according to study and intervention characteristics, subgroup analyses were performed across 9 categorical variables: region (North America, Asia, and Europe), publication year (2023, 2024, 2025, and 2026), intended use (information and education, mental health, decision support, documentation, and other), intended user (clinician, laypeople, others, and not reported), AI model family (GPT family, non-GPT, multiple models, and not reported), AI deployment (off-the-shelf, customized, bespoke, not reported), use of vignettes (vignette or nonvignette), reporting of system prompts (system prompt and nonsystem prompt), and declared adherence to CONSORT-AI as a reporting guideline (declared or not declared). These characteristics were selected because they capture study-level context (region and publication year), the clinical setting of the intervention (intended use, intended user, and use of vignettes), and technical attributes of the GenAI intervention itself (model family, deployment, and system prompt), together with declared use of the guideline. For the subgroup analyses, adherence for each CONSORT-AI item was dichotomized into "Reported" versus "Not reported or Partially reported." The reports in which the item was rated "Not applicable" were excluded from the comparison. To compare adherence rates across subgroups, exact tests were used due to small cell frequencies: the 2-sided Fisher exact test was used for comparisons between 2 groups, and its extension (the Freeman-Halton test) was used for comparisons involving 3 or more groups. Categories that were small or heterogeneous (eg, "Other" in intended use) were excluded from formal significance testing and presented with descriptive statistics. Two-sided $P<.05$ was considered significant. Subgroup comparisons were displayed as a matrix of P values across items and characteristics. Because item-level comparisons were repeated across the checklist items and 9 study characteristics, false-positive findings cannot be excluded. Benjamini-Hochberg false discovery rate (FDR)–adjusted q values were therefore calculated separately within each of the 9 study characteristics across the applicable items for all comparisons. To address the possibility that items comprising a greater number of signaling questions were less likely to meet the all-or-none criterion for full reporting, adherence was additionally recalculated as the mean proportion of applicable signaling questions satisfied per item as a sensitivity analysis. All statistical analyses were conducted using Python (version 3.10.19; Python Software Foundation).

Results

Study Selection

Study selection is presented in Figure 1 according to the PRISMA flow diagram [26]. A total of 13,059 records were identified from 3 databases. After deduplication, 11,223 records were screened. Following full-text assessment of 181 reports, 111 reports were excluded, including one report whose full text was not accessible despite retrieval attempts [34]. Consequently, a total of 74 reports [35-108] were included in this review. In addition, backward and forward citation searching yielded 3426 records, all of which were sought and assessed for eligibility. Of these, 3422 reports were excluded, resulting in 4 additional eligible reports. In total, 74 published reports representing 73 unique RCTs were included in the review. Two reports [35,36] were separate publications of the same trial and were assessed independently, as the unit of analysis was the individual report.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.The flow diagram outlines the identification, screening, eligibility assessment, and inclusion of trials from database searches and citation searching. A total of 74 published reports [35-108] representing 73 unique RCTs were included in this review.

Study Characteristics

The 74 included reports (representing 73 unique RCTs) were categorized across six domains: (1) geographic region, (2) publication year, (3) primary intended use, (4) intended user, (5) AI model family, and (6) AI deployment mode. Two reports derived from the same trial were evaluated independently at the publication level. In panel (3), “Other” indicates procedural image reconstruction. In panel (5), “Non-GPT” includes non-OpenAI generative models (eg, standalone LLMs, vision-language models, and image reconstruction networks). A total of 74 reports representing 73 RCTs evaluating GenAI interventions for medical purposes were included in this systematic review, encompassing a cumulative total of 24,150 human participants (median sample size: 100 [IQR 50 - 247]; range: 9 - 2671). Notably, all but one [37] of the included reports used LLM-based interventions. The general and technical characteristics of the included reports are detailed in Table S6 in Multimedia Appendix 5.

Geographically, half of the reports were conducted in Asia (n = 37 [35-38,40,43-45,47-49,51,54,56,58-61,63-66,68,76,77,83,84,86-88,92,93,96,102,104,105], 50.0%), followed by North America (n=23 [39,41,42,46,50,52,53,55,57,71,75,78-81,85,91,94,99,103,106-108], 31.1%) and Europe (n=14 [62,67,69,70,72-74,82,90,95,97,98,100,101], 18.9%). The publication timeline demonstrated rapid, continuous growth, beginning in 2023 (n=2 [48,49], 2.7%) and 2024 (n=8 [38-41,50-53], 10.8%), reaching a peak in 2025 (n=39 [42-47,54-81,97,99,103,107,108], 52.7%), and continuing into early 2026 (n=25 [35-37,82-96,98,100-102,104-106], 33.8%). Regarding intervention domains, the most common primary intended use was providing medical information and education to laypeople (n=33 [38,44,46,49,51,52,54,57-60,63,64,67-70,72-74,76,83,84,86,89,91-93,96,98,101,102,104], 44.6%), followed by mental health support (n=14 [35,36,47,48,61,65,66,77,78,81,82,87,100,103], 18.9%), clinical decision support (n=14 [39,42,45,53,56,62,71,75,79,80,85,90,94,105], 18.9%), and administrative support/clinical documentation (n=12 [40,41,43,50,55,88,95,97,99,106-108], 16.2%), with one report categorized as other (procedural image reconstruction). Correspondingly, laypeople and patients were the primary end users in 38 reports [35,36,38,40,44,47-49,51-54,58,59,61,63-65,69,70,73,77-79,81-84,86,87,91,93,96,100-104] (51.4%), whereas clinicians were targeted in 23 reports [39,41-43,45,50,55,56,60,62,66,71,75,80,85,92,94,95,97,105-108] (31.1%); end users were unstated or categorized as others in 13 reports [37,46,57,67,68,72,74,76,88-90,98,99] (17.6%).

Technologically, systems built upon the OpenAI GPT model family predominated (n=45 [35,36,39-41,43,47,49-54,57-60,62,64,66-75,77,78,80,81,83,86,88-90,94,95,97-99,102,105], 60.8%), followed by non-GPT (n=22 [37,42,44,45,48,55,56,65,76,79,84,85,87,91,92,100,103,104,106-109], 29.7%) and reports evaluating multiple models simultaneously (n=5 [38,63,82,96,101], 6.8%), the model family was not reported in 2 reports (2.7%). In terms of AI deployment, half of the reports relied on off-the-shelf commercial applications (n=37 [38,39,41,46,49-53,55,57,59,60,62-64,67,68,70-72,74-76,82,89,92,96-99,101,102,105-108], 50.0%), while 32 reports [35,36,40,42-45,47,54,56,58,65,66,69,73,77-81,83-88,90,91,94,95,103,104] (43.2%) used customized architectures (eg, fine-tuned or RAG-integrated systems), and 3 reports [37,48,100] (4.1%)

XSL•FO
RenderX

used bespoke models; deployment mode was unreported in 2 reports [61,93] (2.7%). Regarding prompt transparency, only 20 reports [35,40,43-47,62,74,75,78-80,82,83,87,90,94,95,97] (27.0%) explicitly reported the system prompt used in the GenAI intervention. Methodologically, most reports used a parallel-group design (n=67 [35-40,42-44,46-73,75-78,80-94,96,97,100-108], 90.5%), whereas 7 reports [41,45,74,79,95,98,99] (9.5%) used a crossover design. Most reports evaluated 2 parallel/crossover arms (n=57 [35-38,40,42,44-47,49,51,52,54,56-62,64-69,71,74-81,83-86,89-91,93-95,97-100,102-108], 77.0%), while 17 reports [39,41,43,48,50,53,55,63,70,72,73,82,87,88,92,96,101] (23.0%) featured 3 or more arms. Finally, 17 reports [39,41,42,53,57,62,71,73,75,79,80,94,95,98,99,101,105] (23.0%) used clinical vignettes or standardized scenarios rather than direct real-world patient encounters. Regarding the explicit use of reporting guidelines, a total of 28 reports [35-39,43,46,50,54-56,60-62,65,66,78,80,83,85,88,89,91-93,98,102,105] (37.8%) explicitly cited adopting at least one reporting framework, with some reports following multiple guidelines. Specifically, standard CONSORT was the most frequently cited guideline (n=10 [35,36,39,54,66,78,85,92,102,105], 13.5%), followed by CONSORT-AI (n=9 [37,43,55,56,80,83,88-90], 12.2%), CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Apps and Online Telehealth; n=6 [60-62,65,92,93], 8.1%) and Standards for Quality Improvement Reporting Excellence (SQUIRE; n=3 [38,46,50], 4.1%). Other cited frameworks included TRIPOD-LLM (n=1 [89]), Minimum Reporting Items for Clear Evaluation of Accuracy Reports of Large Language Models in Health Care (MI-CLEAR-LLM; n=1 [89]), Sex and Gender Equity in Research (SAGER; n=1 [37]), SPIRIT-AI (n=1 [37]), and STROBE (Strengthening the Reporting of Observational Studies in Epidemiology; n=1 [98]). Notably, most reports (n=46 [40-42,44,45,47-49,51-53,57-59,63,64,67-77,79,81,82,84,86,87,90,94,97,99-101,103,104,106-108], 62.2%) did not specify the use of any reporting guideline in their manuscript text.

Results of Syntheses

Reporting Adherence of Included Studies

As shown in Table 2 and Figure 2, item-level adherence to the CONSORT-AI checklist across the 14 evaluated items varied widely among the included reports, ranging from 0% to 98.6% for full reporting. Overall, high adherence was concentrated in general trial reporting items (eg, Items 1 a, b[i], 1 a, b[ii], 2 a[i], and 4 a[i]) and output specifications (Item 5[v]), whereas partial reporting was predominant in trial implementation and technical specifications (eg, Items 4 a[ii], 4b, 5[i], and 5[ii]). Moderate-to-low adherence was observed for clinical decision contribution (Item 5[vi]: 51.5%), data sharing (Item 25: 41.9%), human-AI interaction (Item 5[iv]: 33.8%), and performance error analysis (Item 19: 36.5%). Crucially, reporting of input data quality management (Item 5[iii]) was completely absent across all applicable reports.

Table . Item-level reporting rates of the CONSORT-AI[a] checklist.

Section/topic and number	CONSORT-AI checklist	Reporting rate (%)
Title and structured abstract		
1 a, b(ⅰ)	Indicate that the intervention involves AI/machine learning in the title and/or abstract and specify the type of model	86.49
1 a, b(ⅱ)	State the intended use of the AI intervention within the trial in the title and/or abstract	98.65
Introduction-background and rationale		
2 a(ⅰ)	Explain the intended use of the AI intervention in the context of the clinical pathway, including its purpose and its intended users (for example, healthcare professionals, patients, and the public)	79.73
Methods-eligible criteria		
4 a(ⅰ)	State the inclusion and exclusion criteria at the level of participants	89.19
4 a(ⅱ)	State the inclusion and exclusion criteria at the level of the input data	4.11
Methods-trial setting		
4b	Describe how the AI intervention was integrated into the trial setting, including any onsite or off-site requirements	28.38
Method-intervention and comparator		
5(ⅰ)	State which version of the AI algorithm was used	22.97
5(ⅱ)	Describe how the input data were acquired and selected for the AI intervention	12.16
5(ⅲ)	Describe how poor-quality or unavailable input data were assessed and handled	0.00
5(ⅳ)	Specify whether there was human–AI interaction in the handling of the input data and what level of expertise was required of users	33.78
5(ⅴ)	Specify the output of the AI intervention	94.59
5(ⅵ)	Explain how the AI intervention's outputs contributed to decision-making or other elements of clinical practice	51.47
Results-harms		
19	Describe results of any analysis of performance errors and how errors were identified, where applicable. If no such analysis was planned or done, justify why not	36.49
Open science data sharing		
25	State whether and how the AI intervention and/or its code can be accessed, including any restrictions to access or reuse	41.89

[a]CONSORT-AI: Consolidated Standards of Reporting Trials–AI.

XSL•FO
RenderX

Figure 2. Item-level reporting status of CONSORT-AI (Consolidated Standards of Reporting Trials–AI) checklist. This stacked bar chart shows the number of studies that fully reported, not reported, partially reported, or not applicable for each CONSORT-AI checklist item. Each bar represents one checklist item, with color segments indicating reporting adherence.

Ratings of "Not applicable" accounted for 0.9% (9/1036) of the item-level observations and were confined to 3 items: Item 5(vi; n=6), Item 5(iii; n=2), and Item 4 a(ii; n=1). Denominators were therefore 74 for 11 items, 73 for Item 4 a(ii), 72 for Item 5(iii), and 68 for Item 5(vi). In a sensitivity analysis, recalculating adherence as the mean proportion of applicable signaling questions satisfied per report did not alter the overall pattern of findings, although estimates were higher for Items 5(ii; 46.2%, SD 24.4%) and 5(iv; 68.7%, SD 28.8%), indicating that partial reporting was common for these items. Item 5(iii) remained near-absent (5.3%, SD 15.9%; Table S7 in Multimedia Appendix 6).

Subgroup Analyses

Item-level adherence was compared across subgroups defined by region, publication year, intended use, intended user, AI model family, AI deployment, use of clinical vignettes, use of a system prompt, and whether the report cited CONSORT-AI as a reporting guideline. Item-level *P* values for all comparisons are presented in Figure 3, and group-specific proportions for each variable are provided in Tables S8-S16 in Multimedia Appendix 7. Item 5(iii) was not testable for any variable, as no article reported it.

XSL•FO
RenderX

Figure 3. Item-level *P* values for subgroup comparisons of CONSORT-AI (Consolidated Standards of Reporting Trials–AI) adherence (n=74). Each cell shows the *P* value from an exact test comparing the proportion of reports in which the item was classified as "Reported" across groups of the corresponding variable. For cells with unadjusted *P*<.05, the FDR-adjusted q value is also displayed. Dark pink cells indicate differences retained after adjustment; light pink cells indicate differences not retained after adjustment. Item 5(iii) was not testable because no trial reported it. The group-specific proportions and Benjamini-Hochberg adjusted q values are provided in Table S8-S16 in Multimedia Appendix 7. CONSORT-AI: Consolidated Standards of Reporting Trials–AI.

P<.05, retained after adjustment (*q*<.05) | *P*<.05, not retained after adjustment | *P*≥.05

The region showed differences in Items 1 a, b(i) and 4 a(i), though neither retained significance after FDR adjustment, and no Item differed by publication year. Intended use showed differences in Items 1 a, b(i), 2 a(i), and 5(vi), although only the differences in Items 1 a, b(i) and 5(vi) retained significance after adjustment, with 5(vi) separating reports in clinical decision support and clinical documentation from those in patient information and mental health. Differences by intended user were retained after adjustment for Items 2 a(i) and 5(vi). That for 5(vi) was the largest difference observed in any comparison in this review. Every clinician-facing trial reported how the intervention's output contributed to decision-making, whereas fewer than one in 5 layperson-facing reports did so. The difference in Item 2 a(i) was definitional rather than substantive. The reports were classified as "not reported" because they did not state an intended user, as required by this item. An unadjusted difference by AI model family in Item 4b did not withstand FDR adjustment. AI deployment showed differences in Items 2 a(i), 4b, 5(vi), and 25, though only Item 4b retained significance after adjustment. The use of clinical vignettes showed a difference in Item 4 a(i), which was retained after adjustment, whereas the use of a system prompt significantly distinguished the input-related Item 5(ii). Nine reports [37,43,55,56,80,83,88-90] declared adherence to CONSORT-AI as a reporting guideline. Across 14 items, these articles reported 64.0% (80/125) of applicable items, higher than 46.6% (420/902) among the remaining 65 reports [35,36,38-42,44-54,57-79,81,82,84-87,91-108] (denominators exclude 1 and 8 item-level ratings of "Not applicable," respectively), with differences retained after adjustment in Items 5(iv) and 25. Four items showed no difference across any of the 9 variables examined: 1 a, b(ii), 5(i), 5(v), and 19.

Discussion

Principal Findings

This systematic review evaluated the reporting adherence of 74 published reports representing 73 RCTs evaluating medical GenAI interventions against the CONSORT-AI checklist [12]. This discussion first examines the critical reporting gaps identified across the included trials and outlines key considerations for refining future reporting standards tailored to GenAI-based medical interventions. Our evaluation revealed substantial reporting deficiencies across critical methodological and technical domains, including complete omissions in input data quality management (5[iii]), frequent partial reporting of algorithm versioning (5[i]), and insufficient descriptions of human–AI interaction (5[iv]) and performance error analyses (19). In parallel with these widespread reporting gaps, explicit adoption of the CONSORT-AI guideline remained low, with only 9 [37,43,55,56,80,83,88-90] (12.2%) of included reports citing its use.

These observations invite different explanations. An item may go unreported because investigators were unaware that it was required, in which case the deficiency lies with adherence, and wider dissemination of the guideline is the remedy. It may go unreported because what the item asks for does not correspond to how a GenAI intervention is specified or delivered, in which case the deficiency lies with the item and the remedy is revision.

XSL•FO
RenderX

Or the information needed to reproduce the report may not be requested by any item at all, in which case neither adherence nor revision suffices and the checklist must be extended.

Studies that explicitly declared adherence to CONSORT-AI demonstrated higher compliance for code/model accessibility (Item 25) and input interaction requirements (Item 5[iv]) compared to nonciting studies ($P<.05$; $q<.05$). While an unadjusted difference was also observed for output decision-making contribution (Item 5[vi]), this association was attenuated after FDR adjustment and represents an exploratory finding. These statistical findings suggest that reporting opacities in Items 5(iv) and 25 are attributable to investigator nonadherence, which can be mitigated by enforcing existing reporting standards.

Specifying the instructions or knowledge required for users to interpret outputs and detect potential errors is needed, yet reporting for this domain remained limited (Item 5[vi]: 51.5%). This gap is further reflected in our subgroup analysis: reports with clinicians as the intended AI users achieved a 100% (23/23) full reporting rate for Item 5(vi), whereas reports with laypeople as the intended AI users achieved a full reporting rate of 15.8% (6/38; $P<.001$). Laypeople bring no baseline expertise, and the interpretive burden that GenAI transfers to the user is correspondingly heavier [110]. Reports of laypeople-facing interventions should therefore state what instructions participants were given for interpreting outputs.

Additionally, the level of professional expertise or guidance required during human–AI interaction while handling input data (Item 5[iv]) was fully reported in only 33.8% of reports. Reporting varied across clinical application domains: it was higher in domains where clinicians are the primary intended users—such as clinical decision support (6/14, 42.9%) and administrative/clinical documentation (7/12, 58.3%)—and lower in domains where laypeople are the primary intended users, such as informational and educational support (10/33, 30.3%) and mental health support (1/14, 7.1%). Although this domain-level variation was exploratory after FDR adjustment, this pattern suggests that trials of laypeople-facing conversational tools less often report the user instructions and interaction safeguards required for operating GenAI interventions.

Beyond user interaction, reporting regarding open science principles was similarly suboptimal, with intervention and code accessibility (Item 25) fully specified in only 41.9% of reports. Importantly, without a statement of whether and how the intervention or its underlying prompts, parameters, and code can be obtained, subsequent researchers cannot access the exact intervention evaluated, let alone validate it [111]. Although subgroup differences across deployment modes did not retain statistical significance after adjustment, this low reporting was consistent with trials using commercial off-the-shelf models, where the artifact is controlled by a third party and may not persist in the form tested [112].

By contrast, explicit citation of CONSORT-AI was not associated with higher reporting adherence for the other items. This pattern suggests that while enforcing CONSORT-AI can resolve deficiencies in general interaction and accessibility items (Items 5[iv] and 25), it remains insufficient on its own to rectify reporting gaps in remaining deployment and technical specifications (such as Items 4b, 4 a[ii], 5[i], 5[ii], and 5[iii]). The remainder of this discussion therefore examines each of these items in turn—how it was drafted, why it fails for GenAI interventions, and what form it would need to take instead—before considering the conditions that determine GenAI output but that no CONSORT-AI item presently requests at all.

Descriptions of how the GenAI intervention was integrated into the trial environment, including site-specific or external requirements (Item 4b), were reported in 28.4% of reports. Given that most included interventions were LLMs or commercial API-based services, the remaining studies did not report baseline operational prerequisites, such as required internet connectivity or target access devices (eg, mobile phones or desktop computers). Subgroup analysis showed that this reporting rate varied by the deployment mode. Reports using commercial off-the-shelf models (eg, ChatGPT) demonstrated a significantly lower full reporting rate for Item 4b (5/37, 13.5%) compared to customized (12/32, 37.5%) or bespoke (3/3, 100%) interventions ($P=.001$; $q=.012$). Conversely, while reports using GPT family models exhibited lower reporting adherence for Item 4b than non-GPT models ($P=.01$), this difference was attenuated after adjustment ($q=.173$), indicating that deployment rather than AI model family drives reporting transparency. This disparity highlights the possibility that investigators using ubiquitous commercial models frequently operate under the assumption that widespread familiarity obviates the need for explicit documentation of basic connectivity and deployment prerequisites.

The 3 CONSORT-AI items concerning input data had the lowest reporting rates in this review. Input-data eligibility criteria 4 a(ii) was reported in 4.1% of reports, input-data acquisition and selection (5[ii]) were reported in 12.2%, and handling of poor quality or unavailable input data 5(iii) was reported by none. All 3 items were drafted for interventions that operate on data assembled before a trial begins, whereas, in 73 of the 74 reports, we reviewed an LLM-received text generated during the trial itself. In conventional AI systems, input data such as medical images or biosignals are structured and quantifiable, allowing researchers to assess their quality in terms of resolution, data format, and quality metrics [12]. Since these inputs can be standardized through the preprocessing procedure, Items 4 a(ii), 5(ii), and 5(iii) of the CONSORT-AI could be systematically reported. In contrast, in most GenAI systems reported here, the input is composed at the point of use, most often by the intended user, and its properties are determined by that person rather than by the protocol. The same intervention consequently receives materially different input from one participant to the next. This variation is not incidental to performance. Language models have been shown to vary in accuracy by 8%-50% according to how a query is optimized [113] and by 5%-18% according to the order in which the same information is presented [114].

Item 4 a(ii) of the CONSORT-AI checklist requires researchers to specify the minimum input requirements necessary for the AI intervention to achieve its intended use prior to randomization. This item is essential for ensuring reproducibility

XSL•FO
RenderX

under consistent conditions and enhancing the reliability of result interpretation. As noted earlier, it is inherently difficult to manage inputs in clinical trials involving GenAI, which likely contributes to the low level of adherence to this reporting item. Nevertheless, it is necessary to predefine at least basic inclusion and exclusion criteria for inputs at the prompt level. Allowing users to freely generate prompts can be beneficial for assessing real-world applicability and understanding how input variation affects output quality. However, the absence of predefined input criteria undermines reproducibility [115]. Item 4 a(ii) is therefore best revised rather than removed. Where investigators structure the input—through prompt templates, standardized scenarios, or predefined instructions—eligibility can be stated at the level of that material: the language in which input is accepted, permissible length, the clinical elements it must contain for the intervention to function as intended, and the categories of content that must not be submitted. Where unconstrained interaction is intentional to assess real-world performance, that decision should be stated explicitly and its consequences acknowledged.

Item 5(ii), which asks how input data were acquired and selected for the AI intervention prior to analysis by the AI system, was fully reported in only 9 reports [43,45,46,60,62,74,78,90,99] (12.2%) and by only one [78] of the 38 reports [35,36,38,40,44,47-49,51-54,58,59,61,63-65,69,70,73,77-79,81-84,86,87,91,93,96,100-104] in which laypeople were the intended users. In our evaluation, full reporting was credited exclusively to reports that defined explicit data gating procedures. These included either structural constraints at the user interface level—such as enforcing structured input templates or predefined prompt instructions—or human-in-the-loop protocols in which clinical implementers or investigators filtered, verified, and submitted patient data into the AI system on the users' behalf. Conversely, trials permitting unconstrained, free-text generation by interacting users were categorized as nonreporting because the tasks of data selection, structuring, and preprocessing were entirely delegated to the individual intended user without investigator oversight.

This empirical finding highlights a major methodological vulnerability in conversational GenAI trials: when user interaction is unconstrained, investigators may treat input data handling not as a controlled methodological step but as an unreportable artifact of user behavior. However, unconditioned user inputs introduce variability that directly impacts GenAI performance [38,39,116]. Even in unconstrained, free-text conversational interventions, investigators control input selection and acquisition at the backend through prompt engineering architectures, such as system prompts, or automated input-filtering rules prior to model inference [40-45]. This is directly shown by our subgroup analysis, where reporting of a system prompt was associated with higher adherence to Item 5(ii) after adjustment (P=.001; q=.014).

Therefore, our findings demonstrate that Item 5(ii) remains highly relevant but requires explicit contextual adaptation for GenAI. Future reporting standards should refine Item 5(ii) to mandate disclosure at 2 operational levels: first, at the user interface level, by stating whether inputs are governed by structured templates, clinician mediation, or unconstrained free text; and second, at the system architecture level, by detailing backend prompt engineering, context selection, and preinference filtering protocols executed before the AI system analyzes the query.

Item 5(iii) was reported by no trial in this review. Reviews of conventional AI trials have also found this item to be among the least reported [13,14,16,17], and to that extent the deficiency is not new. Its character in GenAI trials is nonetheless different and, in our view, more consequential. Item 5(iii) requires authors to describe how low-quality or missing input data are handled. For structured input, "poor quality" has a referent that can be defined in advance and detected automatically; for example, an image below a resolution threshold, a corrupted file, or a missing field. When user queries serve as inputs, ambiguity, inconsistency, lack of context, or omission of key terms can degrade input quality [117,118]. The difficulty compounds where the intervention involves sustained interaction. As the interaction continues, each turn generates new input that cannot be screened before it reaches the model.

In this context, unavailable data can represent inputs that should not be submitted, namely protected health information (PHI). PHI includes identifiers that can be used to recognize an individual and cover past, present, or future physical or mental health conditions [119]. In the United States, PHI is strictly regulated under the Health Insurance Portability and Accountability Act (HIPAA). Any GenAI system handling PHI must comply with HIPAA requirements like any other health care technology. However, the web-based interface of ChatGPT, the most used model in the reviewed studies, is not HIPAA-compliant [120]. This means patient information must never be entered into the public web interface. Instead, a HIPAA-eligible cloud environment that offers a Business Associate Agreement (BAA), such as the Azure OpenAI Service [121], should be used. The trials in this review were conducted in 16 countries, with 21 reports [39,41,42,46,50,53,55,57,71,75,78-81,85,91,94,99,103,107,108] from the United States. Trials conducted elsewhere are governed by their own regimes, including the General Data Protection Regulation (GDPR) in Europe [122], and what constitutes adequate protection is therefore not a single standard. What is common across them is that the answer depends on the interface through which data were submitted and the contractual arrangement under which they were processed, which is precisely what trial reports do not currently state. Eight reports addressed such matters partially and none completely.

Trial reports should state what constitutes an inadmissible input, what interface arrangement governed the data submitted, what measures prevented participants or operators from submitting inadmissible content, and what was done when this occurred. MI-CLAIM-GEN takes a comparable approach, asking not how such data were processed but what steps were taken to understand privacy and security concerns and distinguishing between discussion, identification, and mitigation of them [22].

Item 5(i) was reported in 23.0% of articles, and adherence did not differ across any of the 9 variables examined. Version reporting has been found deficient in reviews of conventional AI trial reports [13-16], but the 2 settings differ in whether the intervention stays fixed once the trial begins. A conventional

XSL•FO
RenderX

model evaluated in a trial is ordinarily locked, and its identity is stable for as long as the trial runs. Off-the-shelf GenAI systems are not. They are continuously updated with new training data, model weights, and fine-tuning methods [123,124]. Many of these models are updated on short cycles and rolled out without public changelogs, making it difficult to ensure consistent study outcomes [125]. Even models under the same name, such as GPT-4, exist in multiple versions (eg, gpt-4‑0314, gpt-4‑0613, gpt-4-turbo, and gpt-4o), each with distinct performance profiles [125]. An article that reports having used "GPT-4" has partially satisfied Item 5(i) as written but has not supplied what the item exists to secure. The difficulty is not only that version labels are coarse. Item 5(i) refers to the version of "the AI algorithm," in the singular, whereas a contemporary GenAI intervention is frequently an assembly of components. MI-CLAIM-GEN accordingly asks for the base model together with any embedding models, retrieval models, and auxiliary models or tools [22], and TRIPOD-LLM asks for the model name, version, and last date of training, and separately for the architecture, fine-tuning procedure, and alignment strategy [21]. An intervention combining a base model with retrieval over a local document set and a fixed set of instructions cannot be identified by a version string, however precise. That an item can be met without meeting its purpose is a limitation of the item rather than of the authors who complied with it, and it indicates that the reproducibility requirement is incompletely specified. Reproducibility is further complicated by the method of access. Interacting with an LLM through a web interface can yield different results than using an API, as the former may include hidden system prompts or integrated tools like web browsing. In contrast, API access provides a more controlled, researcher-defined environment. These differences can significantly alter a model's factual accuracy, performance, and reasoning transparency [109,126]. Despite these critical variables, many studies fail to report the specific model version, offering only generic descriptions that limit transparency and hinder replication. Therefore, to ensure transparency and reproducibility in GenAI-based clinical trials, reports should specify the exact model version, the date of use, and the access method (eg, API or web interface) [127].

Two further conditions determine what a GenAI intervention produces, and neither is requested by any CONSORT-AI item. The system prompt establishes the conditions under which a model generates output, and it can shift reading level, enforce consistency across participants, and suppress content the investigators do not intend the intervention to produce [43,46,47]. The inference settings determine how far output may vary under those terms. Their influence is comparable to that of the model version itself. In clinical summarization, adding instruction prompts improves performance but also increases performance variance, so that prompts sharing similar meanings yield markedly different summaries [128]. In a simulation study in which 4 emergency medicine cases were each submitted to GPT-4o 250 times at 5 temperature settings, leading diagnostic accuracy with physical examination data fell from 100% at a temperature of 0.0% to 89.4% at 1.0, while the mean number of distinct diagnoses generated across repetitions rose from 4.5 to 26.25 [129]. Two trials evaluating the same model at different inference settings and system prompts are not evaluating the same intervention at all.

Taken together, these conditions define what would have to be reported for a GenAI intervention to be reproduced: the base model and any auxiliary components, the version and the date on which it was used, the method of access, the system prompt, and the inference parameters under which output was generated. Every one of these is requested by at least one of the 2 reporting frameworks related to GenAI [21,22]. Of these elements, CONSORT-AI presently requests one model version. A trial article reporting only the model version has satisfied Item 5(i) while leaving the intervention unidentifiable. Where an item can be met without its reproducibility being served, the requirement is incompletely specified rather than poorly reported, and revision for GenAI trials merits consideration. Table S17 in Multimedia Appendix 8 consolidates the challenges identified throughout this discussion, distinguishing those arising from items whose underlying construct does not fit a generative intervention from those for which no corresponding item exists.

Almost every element our analysis identifies as missing or unaskable is already established elsewhere: TRIPOD-LLM [21] specifies model name, version, training date, architecture, fine-tuning, and alignment; MI-CLAIM-GEN [22] specifies base and auxiliary components together with structured privacy and security reporting. However, neither framework was developed specifically for randomized trials. These findings identify candidate domains for an extension of CONSORT-AI that would import these settled requirements into the trial setting, restating the input-data items at both the interface and backend levels, replacing the single algorithm version with a full intervention specification, requiring that inadmissible input and the contractual arrangement governing it be defined in advance under national regimes, and naming GenAI-specific error classes under Item 19. So defined, the extension would make reproducible reporting achievable for the class of intervention that now accounts for the great majority of GenAI trials, without duplicating what the wider reporting ecosystem has already settled.

Several limitations of this study should be noted. First, no validated instrument exists for item-level CONSORT-AI assessment, so we developed signaling questions ourselves. Although each question was derived directly from an explicit reporting requirement stated in the CONSORT-AI statement, they have not been externally validated, and a different operationalization could yield different adherence estimates. In particular, requiring all signaling questions to be satisfied for an item to be classified as fully reported is a conservative rule, and items comprising a greater number of requirements are correspondingly less likely to meet it. That said, all assessments were performed independently in duplicate, and item-specific agreement statistics are reported in Table S5 in Multimedia Appendix 4. Second, we restricted inclusion to peer-reviewed, English-language studies explicitly identified as RCTs. This preserved methodological homogeneity but may have excluded randomized evaluations described using other terminology, published in other languages, or available only as preprints, and the excluded studies may differ systematically in reporting practice. Finally, the trials reviewed were predominantly

XSL•FO
RenderX

evaluations of text-based language models. As multimodal interventions increasingly enter clinical trials, they will inevitably raise new methodological and reporting challenges that the present CONSORT-AI checklist does not anticipate. To support the continuous updating of these reporting standards, we have prospectively identified and will continue to monitor relevant preprints, trial registrations, and conference abstracts.

Conclusion

RCTs of GenAI for medical purposes adhere unevenly to CONSORT-AI. Trial metadata and output specification were reported by most trial reports, whereas input data, technical execution, and reproducibility items were reported by few, and handling of poor-quality or missing input data was not reported by any trial. These deficiencies are of 2 kinds. Some reflect nonadherence to requirements that already exist and could be addressed by wider dissemination of the current guideline, while others reflect a mismatch between what the checklist asks and how a generative intervention is specified and delivered and cannot be resolved by adherence alone. Development of a formal reporting extension would require a structured consensus process, as recommended for the development of health research reporting guidelines [130] and as followed in the development of CONSORT-AI itself [12], involving trialists, clinicians, regulators, AI developers, and reporting guideline methodologists. This study establishes that basis, providing the first item-level account of how GenAI trials report against CONSORT-AI and suggesting what such an extension would have to specify to make these trials reproducible and interpretable.

Generative AI Use

The authors declare the use of generative AI in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading and editing, adapting and adjusting emotional tone, translation. The GenAI tool used was: Claude Opus 5 (Anthropic), Gemini 3.6 Flash (Google). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. Declaration submitted by: JEK, JWH, SMK, and JYK.

Funding

This research was supported by a grant RS-2024‑00331775 from Ministry of Food and Drug Safety in 2026 and this research was supported by a grant RS-2026‑25511885 from Ministry of Food and Drug Safety in 2026. The funder played no role in study design, data collection, analysis and interpretation of data, or the writing of this manuscript.

Abstract

Background: Gestational diabetes mellitus (GDM) has a rising global prevalence and brings short-term and long-term adverse risks for mothers and fetuses. Conventional in-person GDM care is limited by time and geographic barriers, often resulting in suboptimal compliance and delayed individualized interventions. Telemedicine is increasingly applied in GDM management; however, randomized controlled trial (RCT) evidence remains inconsistent.

Objective: The study aims to pool data from RCTs to quantify the effects of telemedicine on glycemic control and pregnancy-related outcomes in women with GDM and to inform optimized clinical management.

Methods: We searched PubMed, Embase, Cochrane Library, Web of Science, and Scopus up to August 16, 2026. Two reviewers independently performed study screening and data extraction. Risk of bias was assessed using RoB 2. Meta-analyses were conducted in Stata 18.0. For heterogeneous outcomes, 95% prediction intervals (PIs) were calculated to estimate effect ranges for future studies. Heterogeneity was explored via leave-one-out sensitivity, meta-regression, and subgroup analyses. The GRADE (Grading of Recommendations Assessment, Development, and Evaluation) framework rated evidence certainty. Publication bias was evaluated for outcomes reported in ≥10 studies.

Results: Twenty-three RCTs (3055 women with GDM) were included. Pooled estimates suggested that telemedicine may reduce fasting glucose (mean difference [MD] −0.26, 95% CI −0.42 to −0.09, 95% PI −0.93 to 0.42; P=.002), 2-hour postprandial glucose (MD −0.50, 95% CI −0.87 to −0.14, 95% PI −1.84 to 0.84; P=.007), and gestational weight gain (MD −0.78, 95% CI −1.40 to −0.17, 95% PI −2.83 to 1.26; P=.01). Telemedicine was also associated with lower risks of cesarean section, emergency cesarean section, macrosomia, neonatal hypoglycemia, and neonatal respiratory distress. No significant differences were found for hemoglobin A_{1c}, preterm birth, or neonatal intensive care unit admission. Notably, fasting glucose, 2-hour postprandial glucose, and gestational weight gain exhibited very high unexplained heterogeneity (I^2>90%), with their 95% PIs crossing the null value despite statistically significant pooled effects. The GRADE certainty of evidence was very low to low across all assessed outcomes.

Conclusions: Telemedicine may improve selected glycemic and perinatal outcomes for women with GDM and may serve as a promising supplementary option for prenatal care, particularly in resource-limited settings where routine in-person follow-up is difficult to implement. Nevertheless, the apparent benefits for glycemic control and gestational weight gain remain tentative due to extreme, unexplained between-study heterogeneity and 95% PIs crossing the null. Based on current evidence, telemedicine should not completely replace standard antenatal care. Future well-designed, large-sample RCTs are warranted; such trials should adopt standardized definitions for telemedicine interventions, fully report intervention components, and conduct long-term follow-up to verify sustained maternal and neonatal clinical benefits.

Introduction

Gestational diabetes mellitus (GDM) is currently the most common medical complication of pregnancy, defined as "any degree of glucose intolerance that occurs during pregnancy or is first detected during pregnancy" [1,2]. The diagnosis of GDM typically occurs in weeks 24 to 28 of pregnancy, when routine oral glucose tolerance test screening is performed [3]. Its core pathophysiological features include increased insulin resistance and insufficient compensatory function of pancreatic beta cells [4]. The incidence of GDM varies by region and diagnostic criteria. According to the 2021 International Diabetes Federation Diabetes Atlas, GDM affects 14.0% of pregnancies worldwide, and the incidence rate is still on the rise [5,6]. GDM not only has adverse effects on the health of pregnant women [1] but also increases the risks of adverse pregnancy outcomes such as preterm birth, macrosomia, neonatal hypoglycemia, and respiratory distress syndrome [7]. Although GDM usually resolves on its own after childbirth, its potential long-term effects include, but are not limited to, a risk of developing type 2 diabetes within 5 to 10 years, higher risks of developing cardiovascular disease for mothers [8,9], and higher rates of obesity, late-onset diabetes, and cardiovascular disease in adulthood for infants [10-12].

The aim of GDM treatment and patient education is to maintain glucose levels within the recommended glycemic reference range to prevent maternal hyperglycemia or hypoglycemia [13,14]. However, the traditional GDM management approach has several drawbacks, including discontinuous data, delayed intervention, limited personalization, and poor compliance [15-17]. Technological innovations present exciting opportunities for novel approaches to improve clinical care delivery for women with diabetes during pregnancy. Telemedicine is a type of medical and health service that is carried out through communication technologies such as mobile phones and the internet. Medical staff can use systems based on websites or mobile terminal devices to assess, diagnose, and treat patients, monitor health indicators in real time, and provide timely feedback [18]. They can also disseminate health knowledge and simultaneously offer professional guidance to improve the physical and mental health conditions of patients [19,20]. The telemedicine platform has facilitated real-time communication beyond the limitations of time and space, enabling pregnant women to promptly report symptoms and seek advice [21]. This has promoted a shift in the interaction model between patients and providers from "passive follow-up" to "active management." At the same time, medical professionals customize diet and exercise plans based on gestational weeks, dietary and lifestyle habits, and blood sugar data, leading to the development of intervention methods from "standardization" to "personalization" [22,23].

In recent years, telemedicine has garnered significant attention in health care and has been widely integrated into health systems. Research shows that telemedicine can effectively improve the physical and mental conditions of patients with cancer, patients with stroke, and those with chronic diseases, enhancing the effectiveness of disease management and the quality of life [24-26]. Nevertheless, the available synthesized evidence on the efficacy of telemedicine specifically for GDM remains limited and inconsistent. Several prior systematic reviews exploring telemedicine for GDM have notable limitations. An early meta-analysis by Rasekaba et al [27] included only a small number of older randomized controlled trials (RCTs). Ming et al [19] pooled mixed cohorts of pregestational and gestational diabetes rather than focusing purely on GDM. Xie et al [18] included a large set of RCTs but lacked a formal GRADE (Grading of Recommendations Assessment, Development, and Evaluation) evidence-certainty evaluation. Bertini et al [28] provided only a qualitative narrative review without a quantitative meta-analysis, while Yang et al [21] restricted their analysis exclusively to mobile health tools and omitted broader telemedicine modalities.

Building on these gaps, the present meta-analysis adds several key contributions compared with earlier work. First, we strictly focus on GDM-only participants and cover the full range of telemedicine modalities for stratified subgroup analysis. Second, we incorporate underassessed end points, including emergency cesarean section and gestational weight gain, alongside individual neonatal outcomes such as macrosomia, neonatal hypoglycemia, and neonatal respiratory distress, to obtain a more comprehensive perinatal risk profile. Third, beyond standard heterogeneity statistics, we apply 95% prediction intervals (PIs), meta-regression, and modality-based subgroup analysis to evaluate the generalizability of results. Fourth, we apply GRADE to rate the certainty of evidence and cautiously interpret heterogeneous pooled estimates instead of overstating findings driven solely by statistical significance.

To address these gaps in the literature, we conducted this systematic review and meta-analysis. Our objectives were to evaluate telemedicine-related maternal-fetal outcomes in women with GDM, quantify the pooled effect magnitude and consistency, apply GRADE to rate the certainty of evidence, and provide actionable insights for future digital-health RCTs.

Methods

Overview

This systematic review and meta-analysis adheres to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 reporting guidelines [29], with the completed checklist available in Checklist 1. This review was retrospectively registered on PROSPERO (International Prospective Register of Systematic Reviews; CRD420261403669). The initially submitted version 1.0 of the PROSPERO protocol contained several discrepancies relative to the actual review workflow; these deviations have been formally amended and updated within the PROSPERO registry record. All protocol modifications are documented and explained in Multimedia Appendix 1.

Search Strategy

A comprehensive electronic literature search was conducted across PubMed, Embase, Cochrane Library, Web of Science, and Scopus from the inception of each database up to August 16, 2026. The search strategy incorporated both MeSH and free-text terms. Full search strings for each database are

XSL•FO
RenderX

provided in Multimedia Appendix 2. Manual reference-list screening of included papers and relevant systematic reviews was performed to retrieve additional eligible records.

Inclusion and Exclusion Criteria

We established inclusion and exclusion criteria based on PICOS (Population, Interventions, Comparison, Outcomes, and Study type) questions. The inclusion criteria encompassed the following aspects:

1. Population: individuals officially diagnosed with GDM
2. Interventions: telehealth or telemedicine interventions delivered via the internet, websites, telephone calls, apps, SMS text messages, or other digital communication technologies
3. Comparison: usual care, routine care, conventional care, or standard care without telemedicine
4. Study type: RCTs

The following criteria were used for exclusion:

1. Studies published in non–English languages
2. Studies lacking a non-telemedicine comparator arm or lacking a telemedicine intervention
3. Review papers, protocols, ongoing studies, and duplicate publications
4. Studies lacking statistical data for analysis

Study Selection

All retrieved records from the databases were imported into EndNote X9 software (Clarivate Analytics) for deduplication and literature management. Two independent reviewers (HH and JD) initially screened titles and abstracts based on predefined inclusion criteria. For studies that initially met the criteria, full texts were retrieved and further screened to determine final inclusion. Reasons for excluding full-text papers were documented for the PRISMA flow diagram. Any disagreements between the two reviewers during the screening process were resolved through discussion; when necessary, a third reviewer (JL) was consulted to provide arbitration.

Data Extraction

This study strictly adhered to the PRISMA statement for data extraction to ensure methodological systematicity. Two reviewers (HH and JD) independently extracted data using a pretested data extraction form, and a third author (XX) cross-verified the accuracy of the results. The extracted data included authors, country, year of publication, population characteristics (age, gestational age at enrollment, and baseline glucose levels), study duration, intervention methods in both the intervention and control groups, and study outcomes (fasting blood glucose, 2-h postprandial blood glucose, hemoglobin A_{1c} [HbA_{1c}], gestational weight gain, cesarean section, emergency cesarean section, preterm birth, macrosomia, neonatal hypoglycemia, neonatal respiratory distress, admission to the neonatal intensive care unit [NICU]).

Quality Assessment

Two reviewers (HH and JD) independently performed the quality assessment. Any assessment discrepancies were resolved through discussion with a third reviewer (JC) until consensus was reached. The risk of bias was evaluated using the revised Cochrane Risk of Bias tool (RoB 2), focusing on the following 5 domains: the randomization process, deviations from intended interventions, missing outcome data, outcome measurement, and selection of the reported result [30].

Data Synthesis and Analysis

All statistical analyses were performed using Stata 18.0 (StataCorp). For continuous outcomes, effect sizes were expressed as mean difference (MD) with a 95% CI. MD quantifies the absolute disparity between the mean values of the treatment and control arms, representing the net change in the outcome attributable to the intervention. For dichotomous outcomes, risk ratio (RR) with a 95% CI was employed as the summary statistic. RR is defined as the likelihood ratio of an event occurring between the experimental and comparator groups, reflecting the relative increase or decrease in risk conferred by the intervention. A smaller RR value corresponds to a greater reduction in event risk, indicating more favorable outcomes for the intervention group.

Heterogeneity across studies was assessed using the Cochran Q test and quantified by the I^2 statistic. I^2>40% was considered to indicate substantial heterogeneity, prompting the use of a random effects model; otherwise, a fixed effects model was applied. For outcomes with substantial heterogeneity (I^2>40%), we explored potential sources through sensitivity analysis, meta-regression, and subgroup analyses based on predefined study-level characteristics [31]. For outcomes with substantial heterogeneity, we calculated the 95% PI to estimate the range in which the true effect of a future comparable study would be expected to lie [32]. The 95% PI accounts for both the uncertainty of the pooled estimate and between-study heterogeneity, thereby providing a clinically meaningful range of expected effects across settings. A 95% PI that includes the null value indicates that the intervention may not confer benefit in all future populations, even when the pooled effect is statistically significant. Publication bias was assessed via funnel plots and the Egger regression test only when ≥10 studies were available for an outcome [33]. All statistical tests were 2-sided, and a P value <.05 was considered statistically significant for the overall effect size. The certainty of evidence for each outcome was evaluated using the GRADE approach (Multimedia Appendix 3) [34]. The GRADE approach is a widely recognized tool for grading the certainty of evidence in systematic reviews and clinical practice guidelines, classifying certainty into 4 levels: “very low,” “low,” “moderate,” and “high,” with each level determined according to specific criteria. Factors that may lower the certainty of evidence (such as risk of bias, inconsistency, indirectness, imprecision, and publication bias) were assessed, as were factors that may raise this certainty (such as a large magnitude of effect, plausible residual confounding, and dose-response relationships).

Results

Study Selection

A total of 2777 records were retrieved from 5 databases. After removing 1153 duplicate records using EndNote X9, 1624 papers remained. Following title-and-abstract screening, full

XSL•FO
RenderX

texts of 166 potentially eligible records were retrieved for further assessment. After full-text evaluation, 23 RCTs met the predefined inclusion criteria and were included in this systematic review and meta-analysis [22,35-56]. The detailed study selection process and reasons for exclusion are illustrated in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the literature screening and selection process. RCT: randomized controlled trial.

Study Characteristics

A total of 23 RCTs involving 3055 participants were included. Publication years of included studies spanned from 2007 to 2026. Studies were conducted across multiple countries and regions, including Asia (Korea [35], Malaysia [36], China [38,43,47-50,55], Japan [39], Turkey [41], Iran [42,45], Singapore [46], and Israel [53]), North America (United States [37,54,56]), Europe (United Kingdom [40], Finland [22], Slovenia [44], and Norway [51]), and Oceania (Australia [52]). Total sample sizes per individual study ranged from 21 to 350 participants. Mean participant age was reported in 20 studies [22,35-48,50,52-54,56] and ranged from 29.5 to 36.4 years. Gestational age at enrollment was available for 13 studies

XSL•FO
RenderX

[22,35,37,40,43-47,50,52,54,56], varying between 19.5 and 31.0 weeks. Baseline fasting glucose values were reported in 15 studies [22,35,37-40,43,44,46-48,52-54,56], ranging from 4.46 to 5.39 mmol/L. With respect to intervention duration, the telemedicine intervention continued until delivery in 12 studies [22,35,37,38,40,44,46,47,49,53-55], while the remaining 11 studies [36,39,41-43,45,48,50-52,56] reported specific intervention durations. Telemedicine interventions were grouped into 3 primary modalities: health applications, website-based platforms, and WeChat-based platforms. A small subset of studies [36,37,45,54] adopted combined approaches incorporating text message or telephone-based support, or interactive voice response functions. Full characteristics of the included studies are presented in Table 1.

Quality Assessment Results of the Studies

Risk-of-bias evaluation of the 23 included RCTs was performed using RoB 2. Overall, 6 studies were judged to have low risk of bias, 7 studies had high risk of bias, and 10 studies raised some concerns for risk of bias. The most frequent source of bias was missing outcome data, driven by substantial participant attrition and an absence of appropriate statistical correction in most publications. The summary risk-of-bias judgments are presented in Figure 2.

XSL•FO

Meta-Analysis Results

Effects on Blood Glucose

The meta-analysis of 16 trials [22,35-38,41-45,48-50,54-56] using a random effects model showed that fasting glucose was significantly lower in the telemedicine group compared with the control group (MD −0.26, 95% CI −0.42 to −0.09, 95% PI −0.93 to 0.42; P=.002), with high heterogeneity (I^2=94.1%, P<.001). The forest plots are shown in Figure 3. The 95% PI crossed the null value, indicating that the true effect in future comparable clinical settings might be null or might favor usual care. Sensitivity analysis showed minimal changes in the pooled effect and I^2 after item-by-item exclusion. Meta-regression and subgroup analyses based on publication year, country of publication, and gestational age at enrollment did not identify a convincing source of this substantial heterogeneity. Therefore, the observed inconsistency remains largely unexplained.

A meta-analysis of 10 trials [38,42,43,45,49-51,54-56] using a random effects model showed that the 2-hour postprandial glucose level was significantly lower in the telemedicine group than in the control group (MD −0.50, 95% CI −0.87 to −0.14, 95% PI −1.84 to 0.84; P=.007), with high heterogeneity (I^2=91.3%, P<.001). The 95% PI also crossed the null value. The forest plots are shown in Figure 4. Sensitivity analysis revealed that the pooled effect size and I^2 changed minimally after sequentially excluding each study. Meta-regression and subgroup analyses based on publication year, country of publication, and gestational age at enrollment did not explain the substantial heterogeneity for 2-hour postprandial glucose.

A total of 7 studies [36,38,39,44,50,55,56] were included in the meta-analysis. Due to substantial heterogeneity across studies (I^2=96.7%, P<.001), a random effects model was applied. Pooled results suggested that the telemedicine intervention was associated with a reduction in HbA_{1c} relative to usual care; however, the difference did not reach statistical significance (MD −0.29, 95% CI −0.64 to 0.07, 95% PI −1.54 to 0.97; P=.11).

Figure 4. Effect of telemedicine on 2-hour postprandial blood glucose. Weights are calculated from the random effects model [38,42,43,45,49-51,54-56].

Effects on Gestational Weight Gain

A meta-analysis of 10 trials [22,35,38-40,44,46,48,50,55] using a random effects model showed that gestational weight gain was significantly lower in the telemedicine group compared with the control group (MD −0.78, 95% CI −1.39 to −0.16, 95% PI −2.81 to 1.26; P=.01), with high heterogeneity (I^2=90.3%, P<.001). The 95% PI crossed the null value. The forest plots are shown in Figure 5. Sensitivity analysis showed that after excluding Guo et al [50], I^2 decreased from 90.3% to 77.5%, while the overall effect remained robust (MD −0.61, 95% CI −1.16 to −0.07, 95% PI −2.22 to 1.00; P=.03), suggesting that this study contributed substantially to the observed heterogeneity. However, even after this exclusion, substantial heterogeneity persisted. Meta-regression and subgroup analyses

XSL•FO
RenderX

did not identify a convincing source of the inconsistency. The pooled estimate for gestational weight gain should therefore be interpreted with caution.

Figure 5. Effect of telemedicine on gestational weight gain. Weights are calculated from the random effects model [22,35,38-40,44,46,48,50,55].

Effects on Delivery Mode

A random effects model was used to evaluate cesarean section outcomes across 16 trials [22,35,37,39,40,44,46-48,50-56]. The pooled analysis showed that telemedicine intervention had a significant effect in reducing the incidence of cesarean section (RR 0.84, 95% CI 0.72 to 0.996, 95% PI= −0.51 to 1.40; P=.045), with moderate heterogeneity among studies (I^2=46.7%, P=.02). The forest plots are shown in Figure 6. Sensitivity analysis revealed that the trial by Homko et al [56], which targeted high-risk, low-income pregnant women with poor adherence to remote monitoring, contributed substantially to between-study heterogeneity. After excluding this trial, telemedicine demonstrated a significant protective effect in reducing the cesarean section rate (RR 0.81, 95% CI 0.70-0.95, 95% PI 0.54-1.22; P=.008), and heterogeneity was substantially reduced (I^2=34.5%, P=.09).

A meta-analysis of 7 trials [22,39,40,46,51-53] using a fixed effects model showed that the incidence of emergency cesarean section was significantly lower in the telemedicine group than in the control group (RR 0.59, 95% CI 0.45-0.79; P<.001), with no significant heterogeneity among studies (I^2=36.8%, P=.15). The forest plots are shown in Figure 7.

RenderX

Effects on Unfavorable Pregnancy Outcomes

A total of 12 studies [22,37,38,40,44,46-49,54-56] were pooled using a fixed effects model, showing low-to-moderate heterogeneity (I^2=30.4%, P=.15). Compared with the usual care group, the telemedicine intervention group showed no statistically significant difference in the risk of preterm birth (RR 0.76, 95% CI 0.57-1.01; P=.06). To test the robustness of the results, we also performed a sensitivity analysis using a random effects model. The results showed a pooled RR of 0.78 (95% CI 0.54-1.12; P=.18). Findings were largely consistent across models, indicating the results were robust to the choice of statistical model.

The pooled analysis of 12 studies [22,38,41,43,46-52,55] using a fixed effects model demonstrated a significantly lower incidence of macrosomia in the telemedicine group relative to the control group (RR 0.56, 95% CI 0.42-0.74; P<.001; I^2=0%, P=.65). The forest plots are shown in Figure 8.

Figure 8. Effect of telemedicine on macrosomia. Weights are calculated from the random effects model [22,38,41,43,46-52,55].

Effects on Neonatal Complications

A meta-analysis of 10 studies [22,37,39,40,46,50,53-56] using a fixed effects model showed a significantly lower risk of neonatal hypoglycemia in the telemedicine group relative to usual care (RR 0.77, 95% CI 0.61-0.98; P=.03), with low-to-moderate heterogeneity (I^2=29.8%, P=.17). The forest plots are shown in Figure 9.

A meta-analysis of 7 studies [22,37,46,49,53,54,56] using a fixed effects model showed a significantly lower risk of neonatal respiratory distress in the telemedicine group relative to usual care (RR 0.65, 95% CI 0.46-0.92; P=.02), with low heterogeneity (I^2=7.2%, P=.37). The forest plots are shown in Figure 10.

XSL•FO
RenderX

Figure 9. Effect of telemedicine on neonatal hypoglycemia. Weights are calculated from the random effects model [22,37,39,40,46,50,53-56].

Figure 10. Effect of telemedicine on neonatal respiratory distress. Weights are calculated from the random effects model [22,37,46,49,53,54,56].

A meta-analysis of 11 studies [22,37,39,41,46,48,51-54,56] using a fixed effects model found no significant difference in the risk of admission to the NICU between the telemedicine group and the usual-care group (RR 0.83, 95% CI 0.62-1.11; P=.21), with low heterogeneity (I^2=0%, P=.72).

Subgroup Analysis

To explore potential sources of substantial heterogeneity in fasting glucose, 2-hour postprandial blood glucose, and gestational weight gain, we performed subgroup analyses stratified by publication year (≤2020 and >2020), publication region (Asia, North America, Europe, and Oceania), and intervention modality (health applications, web-based platforms, and WeChat-based platforms). The results of the subgroup analyses are presented in Table 2.

Publication Bias

Publication bias was not assessed for HbA_{1c}, emergency cesarean section, and neonatal respiratory distress because fewer than 10 studies were included for each outcome. For the remaining 8 outcomes, no significant publication bias was detected based on funnel-plot inspection and the Egger regression test. Corresponding funnel plots and Egger regression plots are provided in Multimedia Appendix 4.

Discussion

Principal Findings

This meta-analysis synthesized data from 23 RCTs including 3055 pregnant women with GDM to evaluate the effects of telemedicine on maternal and neonatal outcomes. Pooled analyses indicated that telemedicine was associated with reductions in fasting blood glucose levels, 2-hour postprandial blood glucose levels, and gestational weight gain, as well as lower rates of cesarean section, emergency cesarean section, macrosomia, neonatal hypoglycemia, and neonatal respiratory distress. Of note, the pooled estimates for fasting blood glucose, 2-hour postprandial blood glucose, and gestational weight gain were derived from evidence with very high unexplained heterogeneity and PIs crossing the null value. Therefore, these findings should be regarded as suggestive rather than definitive. No statistically significant differences were observed for HbA_{1c}, preterm birth, or NICU admission.

Multidimensional Mechanisms of Telemedicine in the Management of GDM

The positive effects of telemedicine on patients with GDM manifest in multiple aspects. These potential mechanistic explanations may underpin the observed benefits of telemedicine, although they cannot be directly confirmed from the present meta-analysis alone.

First, with wearable devices and mobile apps, telemedicine enables real-time, continuous monitoring of physiological indicators, including blood glucose, in pregnant women and round-the-clock tracking of glycemic data [22,39,40,57]. Once abnormal blood glucose fluctuations are detected, clinical staff can deliver prompt interventions, substantially shortening the duration and mitigating the severity of intrauterine fetal exposure to hyperglycemia, reducing excessive fetal insulin secretion triggered by maternal hyperglycemia, and thereby lowering the risks of neonatal hypoglycemia and fetal overgrowth [44].

Second, telemedicine provides personalized diet and exercise programs according to individual maternal characteristics [42,43,47,48,50,51,55]. Controlling meal order and total caloric intake, promoting moderate exercise, and limiting sedentary time may reduce the risks of macrosomia, neonatal hypoglycemia, and neonatal respiratory distress.

Third, the telemedicine system can automatically integrate multidimensional health data to form continuous, retrievable quantitative records [50,57]. The system enables earlier and more accurate detection of abnormal data and sends out early warnings. Clinical practitioners may adjust intervention protocols in a timely manner, thus realizing refined antenatal management.

Fourth, by leveraging instant messaging, online consultation, and video-based follow-up, telemedicine removes temporal and geographic constraints [45]. When blood glucose levels exceed the recommended range or when unhealthy lifestyle behaviors are identified, the system promptly provides an analysis of underlying causes and corrective guidance, thereby reducing the frequency of in-person hospital visits, alleviating the economic burden on pregnant women, and improving the continuity and compliance of disease management.

Fifth, when combined with behavioral intervention strategies, including cognitive behavioral therapy and health check-in supervision, telemedicine can markedly improve pregnant women's long-term compliance and self-efficacy regarding blood glucose monitoring, dietary restriction, and regular physical activity. It facilitates the formation of proactive self-management behaviors and reduces the risk of abnormal fetal growth and development [43,46].

Finally, certain telemedicine systems support a self-management model that requires minimal regular manual input from clinicians. This enables pregnant women to intuitively understand the intrinsic correlations between diet, physical

XSL•FO
RenderX

activity, and blood glucose levels and independently adjust their lifestyle regimens [43,46,47]. Through sustained long-term control of blood glucose levels and body weight, the intrauterine developmental environment can be optimized, lowering the risks of fetal developmental anomalies and various adverse neonatal complications.

Comparison With Previous Work

This systematic review showed that telemedicine interventions were associated with improvements in fasting blood glucose and 2-hour postprandial blood glucose levels in patients with GDM but had no statistically significant effect on HbA_{1c} level. However, given the very high and unexplained heterogeneity and the PIs crossing the null for both fasting and 2-hour postprandial glucose levels, these associations should be interpreted as suggestive rather than conclusive. This conclusion is broadly consistent with those of Bertini et al [28], Xie et al [18], El Seifi et al [58], and Yang et al [21]. All of these authors reported that telemedicine interventions significantly improved fasting blood glucose or 2-hour postprandial blood glucose levels. Regarding HbA_{1c}, the present study differs from the positive conclusions reported by Xie et al [18], Bertini et al [28], and Eberle et al [59]. Our findings are consistent with those of Rasekaba et al [27] and El Seifi et al [58]. Ming et al found no significant overall difference in HbA_{1c} [19]. Only a mild improvement was observed in their GDM subgroup. Possible reasons for these discrepancies are that HbA_{1c} reflects average blood glucose over 2 to 3 months, whereas the intervention window for GDM is relatively short. The timing of HbA_{1c} measurement and variations in statistical power also differed across studies. In addition, this review found that telemedicine can improve self-management ability in pregnant women with GDM, thereby effectively controlling excessive gestational weight gain. This finding aligns with the results reported by Bertini et al [28].

This systematic review reveals that telemedicine significantly reduces the overall and emergency cesarean delivery rates among women with GDM. This finding is consistent with those reported by El Seifi et al [58], Xie et al [18], and Yang et al [21]. Telemedicine enables the precise regulation of blood glucose levels and gestational weight gain through timely feedback. It decreases the incidence of macrosomia and reduces indications for cesarean delivery, such as dystocia and fetal distress, thereby lowering the risks of elective and emergency cesarean deliveries.

Overall, previous studies have drawn inconsistent conclusions regarding the effects of telemedicine interventions on adverse pregnancy outcomes and neonatal complications [18,19,21,27,58]. Early systematic reviews mostly found no significant benefits. More recent meta-analyses incorporating a greater number of RCTs and larger sample sizes tend to suggest that telemedicine interventions can reduce the risk of gestational hypertension or preeclampsia, premature rupture of membranes, preterm birth, macrosomia, neonatal hypoglycemia, and composite neonatal complications. However, outcomes such as NICU admission rates, neonatal jaundice, and neonatal respiratory distress syndrome mostly showed no significant differences.

Limitations and Strengths

Strengths

This meta-analysis has several strengths. First, it provides an up-to-date synthesis, with searches extending to August 2026 and 23 RCTs involving 3055 women with GDM, capturing recent advances in app-based and multiplatform telemedicine. Second, it evaluates a broad set of clinically actionable perinatal outcomes, including emergency cesarean section, neonatal respiratory distress, and admission to the NICU. These outcomes have been inconsistently reported in prior reviews. Third, this review followed rigorous methodology. It adhered to PRISMA guidelines, was registered in PROSPERO, and used dual independent screening and data extraction. Leave-one-out sensitivity analyses, meta-regression, and subgroup analyses were also used to explicitly explore potential sources of heterogeneity. Fourth, beyond efficacy assessment, this review synthesizes active intervention components and provides actionable implementation considerations for embedding telemedicine within routine antenatal care, especially in resource-limited settings.

Limitations

Nevertheless, the present meta-analysis has several limitations. First, studies spanned from 2007 to 2026. Older telemedicine hardware and protocols differ from modern app–based management approaches, which may increase between-study heterogeneity. Importantly, despite sensitivity, subgroup, and meta-regression analyses, very high heterogeneity (I^2>90%) for fasting glucose, 2-hour postprandial glucose, and gestational weight gain could not be convincingly explained by publication year, publication region, or intervention modality. The corresponding 95% PIs all crossed the null value, indicating that the true effect in future comparable clinical settings might be null or might favor usual care. Therefore, these pooled estimates should be viewed as hypothesis-generating rather than definitive. The clinical benefits of telemedicine for these 3 outcomes should be interpreted cautiously. Second, telemedicine interventions were categorized into 3 types (health applications, website-based platforms, and WeChat-based platforms) and varied in duration. These modalities differ in architecture, interactivity, and feedback. Pooling heterogeneous interventions may obscure best-performing modalities. Although we conducted modality-stratified subgroup analyses, small subgroup sample sizes and mixed model interventions precluded robust comparative conclusions; this remains an important limitation. Third, most studies reported only short-term gestational and immediate neonatal outcomes; thus, long-term offspring benefits could not be assessed. Fourth, we restricted searches to English-language publications and excluded eligible non-English studies, which introduces potential language bias that may compromise completeness of the evidence base and generalizability of findings. Trials reporting favorable effects are more often published in English, whereas null effect studies tend to appear in non–English-language journals. This may inflate pooled estimates for fasting glucose, 2-hour postprandial glucose, and gestational weight gain, consistent with their wide PIs crossing the null value. Systematic differences in intervention delivery across linguistic groups create uncertainty

XSL•FO
RenderX

for non–English-speaking settings. Combined with the very low to low certainty of evidence across all outcomes according to GRADE, this bias warrants cautious interpretation of effect sizes. The exclusion of gray literature further carries publication-bias risk.

Implications for Clinical Practice

Findings from this meta-analysis suggest that telemedicine interventions may confer clinical benefits for selected maternal and neonatal outcomes among women with GDM. Benefits were observed for cesarean section–related outcomes, macrosomia, and certain neonatal end points, although improvements in glycemic control and gestational weight gain should be interpreted cautiously, given the very high unexplained heterogeneity and crossing 95% PIs. Telemedicine may mitigate limitations of conventional prenatal care such as delayed follow-up and insufficient individualized management. It may be particularly valuable for primary health care settings with limited medical resources. Clinical staff may enhance pregnant women's self-management adherence via online monitoring and personalized health education. This approach may also potentially lower maternal- and infant-related health care expenditures, though economic outcomes were not formally assessed in this review. The present findings may inform clinical guideline revisions and support the consideration of integrating telemedicine into routine GDM antenatal care. Future research should develop intelligent, tailored intervention programs and implement long-term follow-up to assess offspring health. This work will further refine digital-health approaches for perinatal care.

Conclusion

This systematic review and meta-analysis included 23 RCTs to investigate the effects of telemedicine interventions on maternal and neonatal outcomes among women with GDM. Pooled analyses suggested that telemedicine may improve fasting glucose levels, 2-hour postprandial blood glucose levels, and gestational weight gain. It may also reduce the incidence of cesarean section, emergency cesarean section, macrosomia, neonatal hypoglycemia, and neonatal respiratory distress. No statistically significant differences were observed for preterm birth or admission to the NICU. Importantly, fasting glucose levels, 2-hour postprandial blood glucose levels, and gestational weight gain showed very high unexplained heterogeneity after sensitivity, subgroup, and meta-regression analyses. Their 95% PIs all crossed the null value. Therefore, these specific findings should be interpreted with particular caution and regarded as preliminary. These results support the potential value of telemedicine for GDM management. Nevertheless, GRADE assessment rated the certainty of evidence as very low to low across all 11 outcomes. Risks of bias, inconsistency, and imprecision reduce confidence in the observed benefits. These limitations warrant caution when drawing firm conclusions regarding the clinical value of telemedicine for GDM. Despite these shortcomings, telemedicine represents a promising intervention approach. It can overcome temporal and geographical barriers, enable real-time monitoring and timely feedback, and deliver personalized dietary and exercise guidance to improve self-management adherence. Telemedicine may serve as a potential supplementary option for routine prenatal care. It may be of particular relevance in resource-limited settings. Future large-sample, long-term follow-up RCTs are needed to further verify long-term maternal and neonatal benefits and identify the optimal intervention modality.

Abstract

Background: Conventional triage relies on clinician judgment and limited information available at first contact. AI and machine learning (ML) may improve early risk stratification, whereas tele-triage and patient-facing tools primarily support remote assessment, access, and care routing.

Objective: This study aimed to evaluate the diagnostic and prognostic performance of AI- and ML-assisted triage systems and summarize evidence on tele-triage, workflow, implementation, economic, and equity outcomes.

Methods: Comparative studies published between January 1, 2010, and December 31, 2025, evaluating AI-, ML-, natural language processing–, telehealth-, or digitally enhanced triage. At first, clinical contacts were included. PubMed/MEDLINE, CINAHL, Web of Science, Scopus, preprint servers, trial registries, and conference proceedings were searched. Screening and data extraction were performed independently in duplicate. Risk of bias was assessed using design-appropriate tools. Clinically comparable area under the receiver operating characteristic curve (AUC) estimates were synthesized using random-effects meta-analysis; heterogeneous diagnostic, operational, implementation, economic, and equity outcomes were summarized narratively. Exploratory scenario modeling projected effects per 10,000 emergency department (ED) visits.

Results: Twenty-seven studies were included, comprising 13 studies in the quantitative evidence stream and 14 in the narrative synthesis. Four adult ED studies evaluating critical care or deterioration outcomes demonstrated high pooled discrimination for AI-assisted triage (AUC 0.874; 95% CI 0.845 - 0.898; I^2=94.4%; 95% prediction interval 0.803 - 0.922). Four studies reported directly extractable within-study comparisons favoring AI-assisted models (AUC differences of 0.097, 0.120, 0.108, and 0.065), although these could not be pooled because paired variance estimates were unavailable. Admission/disposition studies reported AI-model AUCs ranging from 0.80 to 0.93 and were summarized descriptively because extreme heterogeneity precluded meaningful pooling. Two pediatric studies (AUCs of 0.85 - 0.99) were summarized descriptively. Prediction-model studies were primarily limited by deficiencies in model analysis, calibration reporting, and external validation. Narrative evidence suggested improved front-door operational metrics with tele-triage, including reported reductions of 15% - 40% in time to clinical assessment and 2 - 8 percentage points in left-without-being-seen rates, whereas patient-facing symptom checkers generally favored sensitivity over specificity. Exploratory scenario modeling illustrated that, under specified prevalence and threshold assumptions, AI-assisted triage could be associated with 12 - 38 fewer missed critical illness cases and 45 - 120 additional false-positive escalations per 10,000 ED visits. Economic and equity findings were assumption-dependent projections rather than observed clinical, cost-effectiveness, or equity outcomes.

Conclusions: AI- and ML-assisted triage models demonstrate promising discrimination for adult ED risk stratification; however, AUC-based discrimination does not establish superiority at clinically relevant decision thresholds, improved patient outcomes, or readiness for clinical implementation. Interpretation is limited by substantial heterogeneity, incomplete threshold-level performance and calibration reporting, limited external validation, and sparse pediatric evidence. Prospective multicenter validation, workflow assessment, subgroup calibration and equity auditing, and formal economic evaluation are required before routine implementation.

Introduction

Triage constitutes the critical first point of contact in patient care, where clinical urgency is assessed and scarce health care resources are prioritized in environments increasingly characterized by crowding, rising demand, and resource constraints [1-3]. Decisions made at this early stage may influence immediate patient safety, downstream clinical outcomes, operational efficiency, and health system performance [1,4]. Undertriage may delay the recognition and treatment of high-acuity illness, whereas overtriage may misallocate limited resources and increase unnecessary escalation [4,5]. Undertriage may delay recognition of serious illness and contribute to preventable deterioration or mortality, whereas overtriage can lead to unnecessary escalation, increased resource consumption, and worsening crowding that adversely affects other patients [6]. As emergency and urgent care systems worldwide face sustained increases in demand alongside workforce constraints, the limitations of traditional triage approaches have become increasingly apparent [2,3].

Conventional triage instruments such as the Emergency Severity Index (ESI), Manchester Triage System (MTS), Canadian Triage and Acuity Scale (CTAS), and Korean Triage and Acuity Scale (KTAS) provide structured frameworks for assigning urgency and prioritizing patients at emergency department (ED) presentation [7-12]. These systems classify urgency using presenting complaints, vital signs, anticipated resource requirements, and clinical assessments at the time of triage. Despite widespread use, their validity and reliability vary across systems, populations, and clinical settings, and interrater agreement is not consistently high [4,5]. Recent evaluations have also shown that undertriage and overtriage remain clinically relevant concerns, particularly when high-acuity illness is not readily apparent from the information available during the initial assessment [4,10].

In response to these challenges, AI and machine learning (ML) have increasingly been evaluated as clinician-facing decision-support approaches for emergency triage [13,14]. AI- and ML-based models can integrate structured electronic health record (EHR) variables, vital signs, previous health care use, and unstructured triage text to estimate clinical risks at or near the time of presentation [15-17]. Natural language processing (NLP) can extract predictive information from triage narratives and nursing assessments that may not be represented in conventional rule-based scales [15,18,19]. Recent reviews and individual comparative studies have reported promising discrimination for critical care, hospitalization, and sepsis-related outcomes, with some studies reporting higher area under the receiver operating characteristic curve (AUC) values than conventional triage approaches [13,14,20]. However, improved discrimination alone does not establish clinical utility or implementation readiness.

Parallel to advances in AI-based decision support, telehealth has expanded the scope of triage beyond physical health care facilities. Tele-triage and virtual front-door models support remote assessment, screening, and patient routing, with potential benefits for access and the management of lower-acuity demand when integrated with in-person emergency care [21,22]. Telehealth use increased substantially during the COVID-19 pandemic; in the United States, telehealth visits during surveillance week 13 of 2020 were 154% higher than during the corresponding week in 2019, while large health systems rapidly expanded video-enabled urgent and nonurgent care [23,24]. During the same period, numerous AI- and ML-based COVID-19 prediction models were rapidly developed, although systematic appraisal identified poor reporting, high risk of bias, and limited external validation [25].

While these experiences demonstrated feasibility and potential benefits, they also highlighted important risks. The rapid development and deployment of inadequately validated prediction models raised concerns regarding risk of bias, overestimated performance, safety, and generalizability [25]. Telehealth access was also uneven, as differences in digital infrastructure, connectivity, digital literacy, and socioeconomic resources could limit participation among underserved populations [26]. Long-term implementation of digital health technologies may be further constrained by technical limitations, workflow disruption, staff workload, training requirements, communication challenges, and insufficient organizational support [27,28]. These concerns underscore the need for rigorous validation, inclusive implementation strategies, and evaluation beyond short-term emergency deployment.

Crucially, the value of technology-enhanced triage depends not only on model discrimination but also on how risk estimates translate into clinical actions. The selection of operating thresholds determines the balance between false negative (FN) safety risks and false positive (FP) escalation burden, with potential implications for resource use and patient flow. Although individual AI-based triage studies have reported favorable discrimination compared with conventional approaches, performance measures such as AUC alone are insufficient to establish clinical utility or readiness for implementation [13,29]. Safe clinical adoption also requires calibration, clinically appropriate thresholds, external validation, workflow and EHR integration, usability, explainability, clinician acceptance, end-user training, regulatory oversight, and postdeployment monitoring [29-32].

Human factors play a central role in determining the effectiveness, appropriate reliance, and sustained use of technology-enhanced triage. Clinician trust in AI-based decision support is influenced by transparency, explainability, clinical reliability, usability, validation, workflow compatibility, training, and the preservation of professional judgment and control [33-35]. Recent user-centered evidence further indicates that interface clarity, usability, workflow fit, customization, and

XSL•FO
RenderX

stakeholder involvement are important determinants of the acceptance and integration of clinical decision support systems (CDSSs) [36]. Broader evidence from AI-enabled human-robot interaction in clinical settings suggests that personalization, responsiveness to user expectations, emotional and social interaction, and cultural adaptation may influence patient trust and engagement; however, limited longitudinal evaluation restricts conclusions regarding sustained user engagement [37]. These findings support participatory design, adaptation to local clinical and cultural contexts, and continued assessment of trust, usability, and engagement after implementation. Telehealth services have generally demonstrated favorable patient satisfaction, although satisfaction and acceptance vary according to the delivery modality, population, clinical context, digital access, and measurement method [38].

Tele-triage may redistribute tasks and reduce in-person demands, but it can also introduce communication challenges, altered workload, technical demands, and new training requirements for clinical staff [39-41]. Equity considerations are particularly important in AI- and telehealth-enabled triage. Evidence from health care algorithms indicates that biased outcome definitions, unrepresentative data, and differences in access to care may produce unequal performance or allocation across population groups [42]. Triage-specific studies have also identified differences in urgency assignment according to race, ethnicity, sex, and primary language, highlighting the need to assess whether digital systems reproduce, reduce, or amplify existing disparities [43,44]. Telehealth and other digital interventions may widen existing inequalities when access to devices, connectivity, digital literacy, language support, and culturally appropriate design are not adequately addressed [26,45]. Ethical analyses therefore emphasize transparency, explainability, accountability, privacy protection, and governance throughout algorithmic development and implementation [46]. Equitable adoption requires representative validation data, subgroup-specific performance and calibration assessment, accessible implementation strategies, and continuous postdeployment monitoring.

Economic implications of technology-enhanced triage remain incompletely understood. Implementation may involve costs related to infrastructure, software and EHR integration, staff training, maintenance, data governance, and ongoing performance monitoring; however, these components are not consistently identified or measured across digital health evaluations [47,48]. Broader reviews of digital health interventions suggest potential cost-effectiveness in some settings, but substantial heterogeneity in technologies, comparators, costing methods, and outcome measures limits comparison and transferability across health systems [49]. Economic evidence specific to AI- and telehealth-enhanced triage remains limited, and projected efficiency gains or cost savings should not be interpreted as established economic benefits without prospective evaluation alongside real-world implementation. Transparent reporting using AI-specific economic evaluation guidance is therefore needed [50].

Despite these challenges, AI-, ML-, and telehealth-enabled triage have attracted increasing research and implementation interest. AI- and ML-based systems have primarily been evaluated for clinical risk stratification and outcome prediction, whereas tele-triage interventions mainly support remote assessment, access, patient routing, and workflow management [14,22,31]. However, the evidence remains heterogeneous across populations, clinical settings, intervention functions, comparators, and outcome definitions. AI- and ML-based studies frequently emphasize retrospective discrimination performance, with less consistent reporting of calibration, external validation, patient-centered outcomes, and real-world implementation. Tele-triage studies similarly use diverse interventions and operational outcomes that limit direct comparison [13,14,22]. Consequently, potential improvements in risk identification, patient flow, and access should be regarded as promising rather than established until supported by prospective, multicenter, comparator-based evaluations.

This systematic review and meta-analysis addressed 2 related but distinct questions using a PICOTS (Population, Intervention, Comparator, Outcomes, Timing, and Setting) framework. For the primary diagnostic and prognostic question, the population comprised adults and children undergoing triage at the first point of clinical contact in EDs, urgent or primary care access services, specialty intake settings, or virtual front-door services. The interventions were AI-, ML-, or NLP-assisted triage systems, compared with conventional clinician-led triage, validated triage scales, or clinically relevant reference standards. The primary outcomes were discrimination, calibration, sensitivity, specificity, and patient-important outcomes such as critical care requirement, clinical deterioration, hospital admission, and mortality, assessed during the index acute-care episode or the follow-up period reported by each study. For the secondary questions, tele-triage, patient-facing digital triage tools, computerized decision support systems (DSSs), and workflow-support technologies were evaluated in the same clinical populations and settings. These interventions were compared with usual care, conventional triage, alternative digital approaches, or the comparator reported in each study, with operational, workflow, implementation, usability, economic, and equity outcomes examined. Quantitative synthesis was restricted to clinically comparable diagnostic or prognostic performance measures, whereas heterogeneous secondary outcomes were synthesized narratively. Exploratory scenario modeling was used only to contextualize potential system-level implications.

Methods

Study Design, Registration, and Reporting Framework

This systematic review was reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Checklist 1) 2020 statement, which provides updated guidance for transparent reporting of systematic reviews and meta-analyses [51]. The quantitative synthesis represented a prediction-model performance meta-analysis based on clinically comparable discrimination (AUC) estimates rather than a conventional diagnostic test accuracy meta-analysis. Relevant items from the PRISMA-DTA (PRISMA extension for Diagnostic Test Accuracy) were applied as a reporting extension where diagnostic accuracy outcomes, comparators,

XSL•FO
RenderX

and reference standards were reported [52]. PRISMA-DTA was not used as a separate review design. Reporting of database search strategies followed PRISMA-S (PRISMA literature search extension) recommendations.

The review protocol was prospectively registered in the International Prospective Register of Systematic Reviews (PROSPERO; CRD420251160796) on October 3, 2025, prior to commencement of study screening and data extraction. The review was conducted in accordance with the prespecified protocol, which detailed the objectives, eligibility criteria, search strategy, and analytic plan, including criteria for quantitative synthesis. As this study involved secondary analysis of published literature and did not include the collection of individual-level patient data, institutional ethics approval was not required.

Eligibility Criteria

Eligible studies evaluated patient-facing or clinician-facing technologies applied at the first point of clinical contact to support triage decision-making or early detection of deterioration, using real-world clinical triage data within routine health care settings. Eligible settings included EDs, urgent and primary care access points, specialty intake clinics, and virtual front-door or telehealth services, with adult and pediatric populations. Interventions of interest included AI- and ML-based DSS, NLP applied to triage-time clinical text or patient-reported symptoms, tele-triage and tele-intake modalities, and EHR-embedded early warning or risk stratification tools designed for use at or immediately after initial assessment. Comparators included conventional triage processes or validated triage scales such as the ESI, MTS, CTAS, and KTAS. Because triage represents an early diagnostic classification task in which patients are assigned to risk or urgency categories at first clinical contact, diagnostic accuracy metrics were prioritized as a methodologically appropriate and commonly reported basis for quantitative synthesis, while operational, workflow, equity, and economic outcomes were synthesized narratively.

Primary outcomes were diagnostic or prognostic performance metrics, including sensitivity, specificity, AUC, and calibration where available. Secondary outcomes included patient-important clinical end points (hospital admission, intensive care unit (ICU) transfer, mortality, and emergency revisit), operational outcomes (time to clinician assessment, ED length of stay (LOS), boarding, and left-without-being-seen), implementation outcomes (acceptability, usability, and fidelity), equity outcomes (subgroup performance by age, sex, race/ethnicity, language, and socioeconomic status), and economic outcomes (implementation and maintenance costs, resource use, and throughput effects). Studies were excluded if they reported only methodological model development without evaluation using real-world clinical triage data and/or without comparison against standard triage practice or an appropriate reference standard, lacked a comparator or reference standard, were single-arm case series with fewer than 10 participants, or were not available in English. For this review, “clinical implementation/evaluation” was defined as evaluation using real-world patient triage encounters (prospective or retrospective), including comparative performance against standard triage practice and/or clinically relevant outcomes; simulation-only studies and purely technical development without clinical evaluation were excluded.

Information Sources and Search Strategy

Bibliographic databases and supplementary sources were searched for records published from January 1, 2010, to September 7, 2025, and were updated through December 2025. The following databases and platforms were searched: MEDLINE via PubMed; CINAHL via EBSCOhost; Web of Science Core Collection via Clarivate; and Scopus via Elsevier. The search combined controlled vocabulary and free-text terms relating to triage and acute-care access with terms for AI, ML, NLP, clinical decision support (CDS), telehealth, and related digital technologies. Outcome-related concepts included critical care requirements, clinical deterioration, hospital admission, mortality, LOS, revisits, workflow, and implementation outcomes. No study-design filters were applied. Animal-only records were excluded where the platform supported an appropriate human-animal limit. No language restriction was applied during database searching; language eligibility was assessed during full-text screening.

Supplementary searches included medRxiv and arXiv, ClinicalTrials.gov, and the World Health Organization (WHO) International Clinical Trials Registry Platform (ICTRP), relevant conference proceedings, and backward reference-list searching of included studies and relevant reviews. The exact platform, complete line-by-line search strategy, controlled vocabulary, free-text terms, field tags, Boolean and proximity operators, truncation, limits, search date, and number of records retrieved are provided in Multimedia Appendix 1 [53].

Study Selection and Data Extraction

Records from the original and updated searches were exported separately to EndNote X9 (Clarivate Analytics) for deduplication and subsequently imported into Rayyan (Rayyan Systems, Inc) for screening [54]. Records identified through the updated search were assessed using the same eligibility criteria and duplicate-review procedures as the original search. Titles and abstracts were screened independently by 2 reviewers (FOMA and MME-B), followed by independent full-text assessment of potentially eligible reports. Disagreements were resolved through discussion, with arbitration by a third reviewer when consensus could not be reached. Data extraction was completed independently in duplicate using a piloted standardized form and was based on the complete published reports and available supplementary materials rather than on abstracts alone.

Extracted variables included study design, setting, country, sample size, population characteristics, intervention modality, algorithm family, input data types, comparator characteristics, outcome definitions, effect estimates and associated uncertainty, reference standards, handling of missing data, and implementation characteristics, including integration pathway, training, governance, and usability where reported. When several eligible estimates remained, external-validation estimates were prioritized over internal-validation or development-set estimates, independent test-set results over training-set results, and overall or multicenter estimates over individual-site estimates. The final or principal model identified by the primary study was selected;

XSL•FO
RenderX

when no principal model was specified, the eligible model with the highest AUC in the independent validation or test set was selected, provided that it used information available at triage. Where more than one eligible model remained plausible, alternative model selection was examined in sensitivity analysis. Estimates corresponding to the prespecified review outcome and the assessment closest to the triage event were selected, and prespecified or clinically applied thresholds were prioritized over retrospectively optimized thresholds. Information was verified using the full report and supplementary materials, and unavailable details were recorded as "not reported in the full report." Results from the updated search were incorporated into the PRISMA flow diagram, study-characteristics tables, quantitative and narrative syntheses, and conclusions, as applicable.

Operationalization of Comparators, Reference Standards, and Evidence-Stream Assignment

Comparators and reference standards were operationalized according to study design. For prediction-model and diagnostic-accuracy studies, comparators included clinician-led triage, usual triage practice, or validated triage scales such as the ESI, MTS, CTAS, and KTAS. Reference standards were the observed clinical end points defined in the primary studies, including critical care intervention or transfer, clinical deterioration, hospital admission, mortality, final diagnosis, or expert-adjudicated urgency. For randomized, nonrandomized, and implementation studies, comparators included usual care, concurrent control groups, preimplementation periods, or alternative digital pathways. A diagnostic reference standard was not required for studies evaluating exclusively operational, workflow, implementation, economic, or equity outcomes. Information was extracted from the main articles and supplementary materials; unclear or unreported details were recorded as such without imputation. Primary-study authors were not contacted for additional information.

Technologies were classified by primary clinical function. AI- and ML-based systems were treated as clinician-facing tools for risk stratification, urgency classification, and outcome prediction. NLP tools were classified by use: triage-text prediction models were included within AI/ML decision support, whereas documentation-focused tools were categorized as workflow support. Tele-triage, patient-facing symptom checkers, computerized DSS, and workflow-support technologies were analyzed as separate functional groups. No pooled analysis combined these distinct intervention categories.

Studies reporting diagnostic or prognostic performance measures were assigned to the quantitative evidence stream. Statistical pooling required at least 3 clinically comparable studies reporting AUC estimates for the same outcome domain with reported or derivable uncertainty. Studies with insufficient uncertainty, incompatible outcomes, or noncomparable performance measures were summarized descriptively rather than pooled. Studies reporting mainly operational, workflow, implementation, safety-proxy, economic, or equity outcomes were assigned to the structured narrative-only stream. Scenario modeling was treated as a secondary analytic subset and was restricted to studies reporting sensitivity and specificity at a defined threshold, confusion-matrix components, or sufficient information to derive these values; studies reporting AUC alone were excluded from scenario modeling.

Risk of Bias and Applicability Assessment

Risk of bias was assessed using validated tools according to study design. Prediction-model studies were assessed using the Prediction Model Risk of Bias Assessment Tool (PROBAST) [55], diagnostic accuracy studies were assessed using the Quality Assessment of Diagnostic Accuracy Studies-2 (QUADAS-2) [56], nonrandomized comparative studies were assessed using the Risk of Bias in Nonrandomized Studies of Interventions (ROBINS-I) [57], and randomized trials were assessed using the revised Cochrane risk-of-bias tool for randomized trials (RoB 2) [58]. Applicability concerns were recorded alongside risk-of-bias judgments. Assessments were conducted independently by 2 reviewers with consensus resolution.

Quantitative Synthesis and Statistical Analysis

Quantitative synthesis was performed when at least 3 clinically and methodologically comparable studies reported compatible AUC outcomes for the same domain. The primary pooled effect measure was the AUC, reflecting discriminative performance of AI-assisted triage systems. In the absence of consistently reported paired sensitivity and specificity estimates at comparable thresholds, discrimination-based pooling using logit-transformed AUC values was prespecified as the primary quantitative synthesis approach. Because threshold-specific paired sensitivity and specificity data were unavailable for most studies, clinically comparable AUC estimates were synthesized using random-effects meta-analysis rather than hierarchical summary receiver operating characteristic (HSROC) or bivariate diagnostic accuracy models. Calibration metrics, when reported, were synthesized descriptively but were not pooled quantitatively due to inconsistent reporting across studies.

To stabilize variance for bounded AUC values, each study AUC was transformed to the logit scale using yi=log (AUCi1-AUCi), a commonly applied transformation for meta-analysis of receiver operating characteristic (ROC)–based summary measures [59]. When 95% CIs were reported, standard errors on the logit scale were derived as SEi=log (AUCupper1-AUCupper)-log (AUClower1-AUClower)2×1.96, which was used as the primary approach for variance estimation; delta-method transformations were applied only when CIs were not available, consistent with established meta-analytic practice for ROC-based measures [59].

Random-effects meta-analysis was conducted using restricted maximum likelihood estimation under the model yi=μ+ui+εi, where ui~N(0,τ2)represents between-study variability and εi~N(0,vi) represents within-study error, with vi=SEi2, allowing for heterogeneity across studies [60].

Study weights were defined as wi=1vi+τ2, and pooled estimates were back-transformed to the AUC scale using the inverse logit function AUC=eμ^1+eμ^.. Between-study heterogeneity was evaluated using the Cochran Q statistic, the I^2 statistic, and the between-study variance τ2. The I^2 statistic was calculated as max (0,Q-(k-1)Q)×100%, where *k* is the number of studies [61]. The 95% prediction intervals were computed on the logit scale

XSL•FO
RenderX

using a *t* distribution with k-p degrees of freedom, consistent with the Hartung-Knapp framework, as μ^±t0.975,k-p(τ2+SEμ^2), and were subsequently back-transformed to the AUC scale to represent the expected range of discriminative performance in future clinical settings [62]. Pooling was restricted to clinically comparable outcome domains to minimize construct heterogeneity across studies. Prespecified sensitivity analyses excluded large national registry studies and restricted analyses to studies using the same comparator triage system. Influence diagnostics were conducted using leave-one-out meta-analysis to evaluate the impact of individual studies on pooled estimates [60]. When fewer than 3 comparable studies were available, outcomes were synthesized descriptively without quantitative pooling. All statistical analyses were performed in R (version 4.5.1; R Core Team) using *metafor* (version 4.8.0) [63].

Across the 4 studies assessing adult emergency department critical care or deterioration outcomes, the pooled AUC was 0.874 (95% CI 0.845-0.898). Between-study heterogeneity was substantial (I^2=94.4%; τ^2=0.022; 95% prediction interval 0.803-0.922).

Narrative Synthesis

Studies not suitable for pooling were synthesized using a structured narrative approach, grouping evidence by intervention class and outcome domain, with emphasis on operational performance, patient safety proxies, implementation outcomes, equity findings, and economic signals. Narrative synthesis was used to integrate heterogeneous evidence while avoiding inappropriate quantitative aggregation.

Operational, Economic, and Equity Impact Modeling

In addition to conventional synthesis, scenario-based operational, economic, and equity modeling was conducted to contextualize potential downstream implications of technology-enhanced triage in ED settings. These analyses were exploratory and illustrative rather than formal cost-effectiveness evaluations, given heterogeneity in health care systems and limited standardized reporting of downstream costs and resource use. These modeling analyses were conducted to contextualize diagnostic performance findings in relation to the operational, equity, and economic domains specified in the registered protocol. These analyses represent an exploratory decision-analytic translation of diagnostic performance and do not constitute a formal cost-effectiveness evaluation.

Studies were eligible for modeling if they reported confusion-matrix components at a defined operating threshold, explicit sensitivity and specificity at a specified operating point, or implementation-level performance differences stratified by equity-relevant subgroups, enabling translation of diagnostic performance into operational and equity impact. Studies reporting only discrimination metrics without threshold information were not eligible for modeling but were retained for the AUC meta-analysis.

All modeling outputs were standardized to a hypothetical cohort of 10,000 ED visits. For each eligible study and outcome domain, expected counts of true positives (TPs), FPs, true negatives (TNs), and FNs were computed deterministically from sensitivity, specificity, and outcome prevalence, following standard diagnostic test translation principles [64]. The expected number of outcome-positive encounters was calculated as Npositive=N×Prevalence and outcome-negative encounters as Nnegative=N×(1-Prevalence), where N=10,000. Expected TPs were calculated as TP=Sensitivity×Npositive, FNs as FN=(1-Sensitivity)×Npositive, TNs as TN=Specificity×Nnegative, and FPs as FP=(1-Specificity)×Nnegative. When prevalence was reported in the original study, it was used directly; where prevalence was not reported, conservative scenario-based assumptions for critical illness prevalence (typically within a 5% - 10% range, consistent with reported adult emergency department critical care rates) were applied solely for scaling purposes to support standardized translation of diagnostic error counts. While prevalence does not alter relative discrimination between models, it influences absolute projected event counts and cost magnitudes. These prevalence values were therefore used solely for scaling and should not be interpreted as universally applicable baseline risk estimates across health care systems.

Operational burden was approximated through error-count translation, with FPs used as a proxy for additional escalation workload and FNs used as a proxy for missed high-risk cases likely to experience delayed escalation or deterioration, consistent with prior operational modeling in emergency care diagnostics [65]. This approach assumes a linear relationship between error counts and downstream workload burden.

Economic impact was estimated by comparing AI-assisted triage with standard triage under a simplified penalty-based cost framework assuming that the unit cost of a missed critical illness case exceeds the unit cost of a FP escalation. Incremental projected cost was computed as ΔCost=(ΔFN×costFN)+(ΔFP×costFP), where ΔFN=FNAI-FNComp and ΔFP=FPAI-FPComp. Thus, negative values of ΔCost indicate projected cost savings associated with AI-assisted triage. To reflect uncertainty in cost magnitudes, multiple cost scenarios were evaluated, including a base-case scenario and additional scenarios varying the relative penalty assigned to missed cases [66]. This simplified framework translates diagnostic error differences into directional economic implications rather than constituting a full cost-effectiveness evaluation.

A net-benefit analysis was additionally conducted across a plausible range of cost ratios *r*, defined as r=costFP/costFN, and expressed in TP-equivalent units per 10,000 visits as a comparative modeling metric, intended to reflect directional economic impact rather than causal cost-effectiveness, and to allow comparison across studies with differing prevalence and outcome definitions. This approach is conceptually aligned with decision-curve analysis while remaining agnostic to specific willingness-to-pay thresholds [67]. Equity modeling was informed by subgroup-stratified performance differences reported in implementation studies, translating subgroup-specific sensitivity changes into avoided FNs per 10,000 visits within each subgroup and projecting the corresponding change in cost under each cost scenario. These equity estimates were interpreted as directional indicators of potential impact rather than causal estimates, consistent with recommended practice

XSL•FO
RenderX

for secondary equity-focused modeling [68]. All meta-analyses, scenario-modeling analyses, and visualization were performed in R version 4.5.1. Meta-analysis was conducted using *metafor* (version 4.8.0), and visualizations were generated using *ggplot2* (version 4.0.3). All translated counts were computed deterministically from reported study metrics and explicitly stated prevalence, threshold, subgroup, and cost assumptions.

Ethical Considerations

Ethical review and approval were waived for this study, as it involved secondary analysis of published literature and did not involve human participants or identifiable personal data.

Results

Search Results

The study-selection process is summarized in the PRISMA 2020 flow diagram (Figure 1). Database searches identified 2766 records, and 110 additional records were identified through supplementary sources, yielding 2876 records before deduplication. After removal of 1613 duplicates, 1263 unique records underwent title and abstract screening. Of these, 1177 records were excluded and 86 full-text articles were assessed for eligibility. Fifty-nine full-text articles were excluded for the reasons presented in Figure 1, leaving 27 studies [47-59,61-74] included in this systematic review. Of these, 13 [18-20,69-71,75-81] were included in the quantitative synthesis (meta-analysis), while 14 [72-74,82-92] were included in the narrative synthesis only.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram showing record identification, duplicate removal, title and abstract screening, full-text eligibility assessment, reasons for exclusion, and final allocation of included studies to the quantitative and structured narrative synthesis streams.

Study Characteristics

Overall characteristics of the included studies are summarized in Table 1. Of the 27 included studies, 23 were conducted exclusively in ED settings, 2 in urgent or primary care intake settings, and 2 in virtual or telehealth front-door settings. Seventeen studies included adult-only populations, 3 included pediatric-only populations, 2 included mixed adult and pediatric populations, and 5 were classified as other or did not involve patient-level populations. The 13 studies assigned to the quantitative evidence stream comprised 10 evaluations of structured AI- or ML-based triage models, 2 evaluations of AI- or ML-based models incorporating NLP of triage-time free text, and 1 evaluation of a computerized decision-support or electronic triage system (ETS).

[f]KTAS: Korean Triage and Acuity Scale.
[g]ESI: Emergency Severity Index.
[h]MTS: Manchester Triage System.

The 14 studies assigned to the structured narrative-only stream included 7 evaluations of tele-triage, or tele-intake interventions, 3 evaluations of patient-facing digital triage tools, 1 computerized decision-support or electronic triage study, 1 workflow augmentation study, 1 structured AI- or ML-based study, and 1 AI- or ML-based study incorporating NLP. These studies primarily reported heterogenous operational, safety-proxy, implementation, equity, or process outcomes that were not suitable for quantitative pooling. Detailed characteristics and extractable performance measures for studies assigned to the quantitative evidence stream are provided in Multimedia Appendix 2, whereas characteristics of studies included in the structured narrative-only stream are provided in Multimedia Appendix 3.

Distribution of Evidence and Outcome Domains

The distribution of 27 included studies according to care setting and primary outcome domain is shown in Figure 2. Most studies evaluated adult ED populations, with the largest group addressing critical care or deterioration prediction, workflow and implementation outcomes, diagnostic accuracy or triage agreement, diagnostic condition-specific prediction, and admission or disposition. Pediatric ED evidence was limited to 2 studies, both addressing critical care or deterioration outcomes. Telephone triage, out-of-hours tele-triage, and primary-care triage were represented by a small number of studies and were synthesized narratively because their outcomes and intervention contexts were not comparable with ED AI- or ML-based triage models.

XSL•FO
RenderX

Figure 2. Evidence map of included digital triage studies. Studies are categorized according to care setting and primary outcome domain. Each tile displays the number of studies and corresponding references within each category. The dagger symbol (†) identifies studies assigned to the quantitative evidence stream. Only the 4 adult emergency department critical-care or deterioration studies contributed to the retained pooled analysis; the remaining studies were summarized descriptively or narratively [20,69,75,76]. ED: emergency department.

Studies marked with a dagger in Figure 2 were assigned to the quantitative evidence stream. Of these, 4 adult ED studies reporting critical-care or deterioration outcomes contributed to the retained meta-analysis. The remaining quantitative-stream studies were summarized descriptively because their populations, outcomes, or performance measures were not sufficiently comparable for pooling. Tele-triage, primary care, workflow, implementation, and other heterogeneous studies were retained in the evidence map but were synthesized narratively.

Quantitative Synthesis: Adult ED Critical Care Outcomes

Four studies involving adult ED populations reported AUC estimates for AI-assisted prediction of critical care requirements or clinical deterioration and met the prespecified criteria for quantitative pooling, although clinical and methodological heterogeneity remained present (Table 2).

XSL•FO
RenderX

Table . Quantitative synthesis plan and available data for meta-analysis-eligible studies (n=13).

Outcome domain	Metric pooled	Number of eligible studies	Studies contributing (author and year)	Not pooled (reason)
Adult ED[a] critical care/critical outcome [20,69,75,76]	AUC[b]	4	Yun et al (2021) [69]; Raita et al (2019) [20]; Kwon et al (2018) [75]; Yu et al (2020) [76]	Hinson et al [77] reports implementation sensitivity/specificity changes rather than AUC; Levin et al [70] reports ranges across sites/outcomes not directly poolable; Määttä et al [78] reports urgency agreement/accuracy rather than AUC
Pediatric ED critical care/critical illness [79,80]	Not pooled	2	Goto et al (2019) [79]; Hwang and Lee (2022) [80]	<3 comparable studies (descriptive synthesis)
Admission/hospitalization/disposition [20,75,79-81]	Not pooled	5	Hong et al (2018) [81]; Raita et al (2019) [20]; Goto et al (2019) [79]; Kwon et al (2018) [75]; Hwang and Lee (2022) [80]	Rendell et al [71] admission risk in different context/metrics; Levin et al [70] ranges; heterogeneity in definitions may require secondary sensitivity analysis
Condition-specific detection (sepsis/infection trigger) [18]	Not pooled	2	Horng et al (2017) [18]; Brann et al (2024) [19]	Different reference standards/operating points; insufficient comparable studies for pooling
Urgency classification/triage agreement [78]	Not pooled	1	Määttä et al (2023) [78]	Not an AUC-based discrimination outcome

[a]ED: emergency department.

[b]AUC: area under the receiver operating characteristic curve.

Across the 4 studies, individual AUC values for AI-assisted triage ranged from 0.860 to 0.894. Four studies provided directly extractable within-study comparisons with conventional triage. The AUC differences favoring the AI-assisted models were 0.097 (0.894 vs 0.797), 0.120 (0.860 vs 0.740), 0.108 (0.876 vs 0.768), and 0.065 (0.861 vs 0.796), with an unweighted mean difference of 0.098. These contrasts were summarized descriptively and were not pooled because standard errors and covariance estimates for the paired AUCs were unavailable.

The Hartung-Knapp-adjusted random-effects meta-analysis of the 4 AI-model AUCs produced a pooled AUC of 0.874 (95% CI 0.845 - 0.898), with substantial between-study heterogeneity (I^2=94.4%; τ^2=0.022) and a 95% prediction interval of 0.803 - 0.922 (Figure 3). This pooled estimate represents average discrimination across the AI-assisted models and does not constitute a pooled comparative effect against conventional triage.

XSL•FO
RenderX

Figure 3. Random-effects meta-analysis (Hartung-Knapp adjustment) of AI-assisted triage discrimination (area under the receiver operating characteristic curve [AUC]) for adult emergency department critical care or deterioration outcomes. Points represent study-specific AUC estimates with 95% CIs. The larger point represents the pooled AUC, and the horizontal line below indicates the prediction interval [20,69,75,76]. AUC: area under the receiver operating characteristic curve.

Substantial between-study heterogeneity was observed after Hartung-Knapp adjustment (I^2=94.4%), which may reflect differences in model architecture, predictor inputs, validation design, outcome definitions, population characteristics, and comparator triage systems. The 95% prediction interval of 0.803 - 0.922 indicates that the expected discrimination of an AI-assisted triage model may vary across future clinical settings. Where conventional triage comparators were reported, study-level AUC estimates for the AI-assisted models were numerically higher; however, no pooled comparative effect was calculated. A sensitivity analysis excluding Kwon et al [75], the largest national registry study, produced a pooled AUC of 0.865 (95% CI 0.842 - 0.885), with reduced but still moderate residual heterogeneity (I^2=47.5%, τ^2=0.0025) and a 95% prediction interval of 0.828 - 0.895. This indicates that the retained pooled discrimination estimate was not driven solely by the largest registry-scale dataset (Figure 4).

XSL•FO
RenderX

Figure 4. Hartung-Knapp-adjusted sensitivity analysis excluding Kwon et al [75], the largest national registry study. The pooled area under the receiver operating characteristic curve (AUC) remained similar after exclusion, indicating that the overall estimate was not driven solely by the registry dataset. Horizontal bars represent 95% CIs, and the lower line represents the 95% prediction interval [20,69,76]. AUC: area under the receiver operating characteristic curve.

In the leave-one-out influence analysis, sequential exclusion of individual studies produced pooled AUC estimates ranging from 0.865 to 0.878. Although the pooled discrimination estimate remained high after exclusion, removal of Kwon et al [75] reduced heterogeneity from 94.4% to 47.5%, indicating that this large national registry study was an important source of between-study heterogeneity (Figure 5).

Figure 5. Leave-one-out influence analysis of the random-effects pooled area under the receiver operating characteristic curve (AUC) for AI-assisted prediction of adult emergency department critical care or deterioration outcomes. Each estimate represents the pooled AUC after exclusion of the indicated study, and the dashed vertical line indicates the overall pooled AUC of 0.874 [20,69,75,76]. AUC: area under the receiver operating characteristic curve; ESI: Emergency Severity Index; KTAS: Korean Triage and Acuity Scale.

XSL•FO
RenderX

Pediatric ED Critical Care Outcomes

Two studies involving pediatric ED populations reported AUC estimates for AI-assisted prediction of critical illness, ranging from 0.85 to 0.99. Where conventional triage comparators were reported, the AI-model AUC estimates were numerically higher at the individual-study level; however, no pooled comparative effect was calculated. Because fewer than 3 studies were available and the outcome definitions differed, quantitative pooling was not undertaken, and the findings were summarized descriptively (Figure 6).

Figure 6. Descriptive area under the receiver operating characteristic curve (AUC) estimates for AI-assisted prediction of critical illness in pediatric emergency department populations. Quantitative pooling was not performed because only 2 clinically heterogeneous studies were available [79,80]. AUC: area under the receiver operating characteristic curve.

The 2 pediatric studies reported high but variable discrimination estimates. However, the small evidence base, differences in outcome definitions, and absence of a pooled estimate limited assessment of the consistency and generalizability of AI-assisted triage performance in pediatric emergency populations.

Descriptive Synthesis of Hospital Admission and Disposition Outcomes

Five studies reported AUC estimates for admission, hospitalization, or disposition outcomes, including both adult and pediatric ED populations (Table 2). Because these studies combined adult and pediatric populations and used heterogeneous admission-related outcome definitions, this domain was not pooled. Individual AI-model AUCs ranged from 0.80 to 0.93, and where conventional triage or clinician comparators were reported, comparator AUC ranged from 0.72 to 0.80. These findings are therefore presented descriptively (Figure 7).

XSL•FO
RenderX

Figure 7. Individual AI-model area under the receiver operating characteristic curve (AUC) estimates for admission/disposition outcomes in adult and pediatric emergency department populations. Findings are presented descriptively because the populations and outcome definitions were not sufficiently comparable for quantitative pooling. Points represent study-specific AUC estimates, and horizontal bars represent 95% CIs [20,75,79-81]. AUC: area under the receiver operating characteristic curve; ED: emergency department.

The admission/disposition studies included both adult and pediatric populations and used heterogeneous outcome definitions, predictor sets, admission thresholds, and health care–system contexts. These findings were therefore summarized descriptively without calculating or interpreting a pooled estimate, heterogeneity statistic, or prediction interval. Individual AI-model AUCs ranged from 0.80 to 0.93, while reported conventional triage or clinician-comparator AUCs ranged from 0.72 to 0.80, summarizing the retained pooled analysis for adult ED critical-care or deterioration outcomes.

Narrative Synthesis of Studies Not Included in Meta-Analysis

Overview

Fourteen studies were included in the structured narrative-only synthesis (Table 3 and Multimedia Appendix 3). To avoid treating technology-enhanced triage as a homogeneous intervention, the evidence was organized according to the primary function of each technology. Tele-triage and tele-intake interventions were synthesized as remote assessment, access management, and patient-routing services. Patient-facing symptom checkers were evaluated separately as tools providing symptom assessment and urgency recommendations. Computerized decision-support and local digital intake systems were synthesized according to their roles in triage-scale alignment and process support, whereas voice- or NLP-enabled systems primarily intended to improve documentation or task completion were classified as workflow-support technologies. AI/ML and NLP-enabled models used for clinical risk prediction were retained within the diagnostic or prognostic evidence stream, unless they lacked comparable performance outcomes. No quantitative analysis combined AI/ML risk-stratification models with tele-triage, patient-facing symptom checkers, or workflow-support systems.

XSL•FO
RenderX

Table . Characteristics and principal findings of studies included in the narrative synthesis (n=14).

Domain	Intervention category	Principal findings	Included studies
Operational flow and front-door processes [72,73,82-86]	Tele-triage/tele-intake/telemedicine screening	Generally, reported improvements in first-contact routing and throughput measures (eg, time-to-assessment and flow) with variable impact on downstream outcomes depending on local context and implementation.	Campbell et al (2014) [86], Gren et al (2023) [85], Inokuchi et al (2022) [73], Izzo et al (2018) [84], Joshi et al (2020) [82], Lin et al (2020) [72], and Rademacher et al (2019) [83]
Safety proxies and urgency advice [74,87]	Patient-facing symptom checkers/symptom assessment	Typically emphasized conservative urgency advice; usability and safety depend on integration and governance; outcomes are often not comparable for pooling.	Cotte et al (2022) [74], Meer et al (2024) [87]
Documentation/workflow augmentation [88]	Voice AI/documentation support	Evaluated primarily for staff-facing workflow efficiency and documentation support rather than discrimination performance.	Cho et al (2022) [88]
Digital triage DSS[a] aligned to triage scales [89]	Computerized DSS	Evaluated operational decision support aligned to triage frameworks; outcomes reported as agreement/process measures rather than AUC[b].	Çetin et al (2023) [89]
Implementation of local digital intake tools [90-92]	Apps/local triage tools	Reported implementation/process outcomes and local performance indicators not harmonized for pooling.	Fernandes et al (2020) [92], Liu et al (2024) [90], Liu et al (2021) [91]

[a]DSS: decision support system.

[b]AUC: area under the receiver operating characteristic curve.

Tele-Triage and Tele-Intake

Several tele-triage and tele-intake studies reported improvements in front-door operational metrics, although the magnitude and consistency of effects varied across settings and intervention models. Where reported, reductions in time to clinician assessment ranged from 15% to 40%, and reductions in left-without-being-seen rates ranged from 2 to 8 percentage points in high-volume ED settings. Effects on ED LOS were inconsistent, with improvements reported mainly during periods of staffing constraint or increased demand.

Patient-Facing Symptom Checkers

Patient-facing digital symptom assessment tools generally produced conservative urgency recommendations. In the included studies reporting threshold-level performance, sensitivity for urgent or emergency conditions exceeded 90%, whereas specificity was lower, resulting in higher rates of overtriage.

NLP-Enabled Tools

NLP-enabled tools were classified by function: risk-prediction applications were synthesized with AI/ML decision support, whereas documentation-focused applications were included with workflow-support systems.

Workflow Support and Computerized DSSs

The workflow-augmentation study reported improved documentation completeness and reductions of 20% - 35% in triage documentation or task-completion time, but it did not evaluate diagnostic discrimination. The computerized decision-support study reported triage-scale-aligned agreement and process outcomes rather than AUC-based discrimination.

Separately, threshold-level performance data from eligible comparative studies were used in exploratory scenario models standardized to a hypothetical cohort of 10,000 ED visits to estimate projected operational, economic, and equity implications (Figures 8A-8E).

XSL•FO
RenderX

Figure 8. Exploratory scenario-based modeling of possible operational, economic, and equity implications of AI-assisted triage per 10,000 emergency department visits. (A) Incremental projected cost differences under alternative false-negative and false-positive cost assumptions; (B) relative net benefit across specified cost ratios; (C) projected trade-offs between fewer false negatives and additional false-positive escalations; (D) projected avoided false negatives by subgroup using a 2.5% base-case prevalence; and (E) projected subgroup-specific missed-case cost differences attributable to avoided false negatives using a 2.5% base-case prevalence. Negative values indicate lower projected missed-case costs; subgroup-specific false-positive costs were not included. Estimates were derived from study-reported threshold-level performance and explicitly stated prevalence, operating threshold, subgroup, and cost assumptions. These outputs are illustrative and assumption-dependent and should not be interpreted as observed clinical effects, demonstrated cost savings, formal cost-effectiveness estimates, or demonstrated reductions in inequity [18-20,69,79,81]. ED: emergency department; KTAS: Korean Triage and Acuity Scale; XGB: extreme gradient boosting.

Operational, Economic, and Equity Impact Modeling

Across the exploratory scenario analyses, and under specified prevalence and threshold assumptions, AI-assisted triage illustrated a potential trade-off of 12 - 38 fewer missed critical illness cases and 45 - 120 additional FP escalations per 10,000 ED visits, depending on the assumed outcome prevalence and threshold-level sensitivity and specificity differences. Under the specified base-case and higher missed-case penalty assumptions, illustrative cost projections suggested that reduction in FNs could outweigh the estimated cost associated with additional FP escalations. These outputs should be interpreted as directional modeling illustrations, not observed savings or formal cost-effectiveness results.

In exploratory subgroup scenarios, based largely on the limited available subgroup data, including Hinson et al [77], modeling illustrated possible reductions in missed critical illness among some racial or ethnic minority groups and patients with limited English proficiency. The magnitude of the projected reduction varied according to subgroup prevalence, baseline performance, and the assumed change in sensitivity. These findings are

XSL•FO
RenderX

assumption-dependent modeling outputs and should not be interpreted as observed reductions in inequity or as evidence that AI-assisted triage will consistently improve equity across settings.

Risk of Bias Assessment

The methodological quality of the included studies was assessed using risk-of-bias tools appropriate to each study design. Prediction-model studies were evaluated using PROBAST, diagnostic accuracy studies using the QUADAS-2, and nonrandomized intervention studies using the ROBINS-I. The single randomized controlled trial (RCT) was assessed narratively using the RoB 2 framework.

Among the 14 prediction-model studies, PROBAST identified low risk of bias for the participant and predictor domains across all studies, whereas the analysis domain represented the principal methodological limitation. Six studies [19,70,71,76,80,81] (43%) were judged to have a high overall risk of bias, 7 [69,73,75,79,81,91,92] (50%) had an unclear overall risk, and 1 study [91] (7%) was considered to have a low overall risk of bias, largely reflecting limitations in model development, validation, and reporting (Figures 9A-9B).

Figure 9. Risk of bias assessment of prediction-model studies (Prediction Model Risk of Bias Assessment Tool [PROBAST]), (A) PROBAST traffic-light plot showing domain-specific risk-of-bias assessments for the 14 prediction-model studies included in the review. (B) Summary of PROBAST risk-of-bias judgments across prediction-model studies. Bars represent the proportion of studies classified as low, unclear, or high risk of bias within each PROBAST domain and for the overall assessment [18-20,69-71,73,75,76,79-81,91,92]. PROBAST: Prediction Model Risk of Bias Assessment Tool; RoB: risk of bias.

The 4 diagnostic accuracy studies [74,78,87,90] demonstrated generally favorable methodological quality. All studies were judged to have a low risk of bias for the index test, reference standard, and flow and timing domains. Concerns were primarily related to patient selection, resulting in 2 studies (50%) being classified as low overall risk of bias, 1 (25%) as unclear, and 1 (25%) as high risk of bias (Figures 10A-10B).

XSL•FO
RenderX

Figure 10. Risk of bias assessment of diagnostic accuracy studies (Quality Assessment of Diagnostic Accuracy Studies-2 [QUADAS-2]), (A) QUADAS-2 traffic-light plot showing domain-specific risk-of-bias assessments for the 4 diagnostic accuracy studies included in the review. (B) Summary of QUADAS-2 risk-of-bias judgments across diagnostic accuracy studies. Bars represent the proportion of studies classified as low, unclear, or high risk of bias within each QUADAS-2 domain and for the overall assessment [74,78,87,90]. RoB: risk of bias; QUADAS-2: Quality Assessment of Diagnostic Accuracy Studies-2.

Risk of bias among 8 nonrandomized intervention studies was assessed using ROBINS-I. Confounding was the principal methodological concern across the observational studies. Overall, 4 studies [83-85,88] (50%) were judged to have a moderate risk of bias and 4 [72,77,82,89] (50%) were judged to have a serious risk of bias, with no study classified as having a critical risk of bias (Figures 11A-11B).

XSL•FO
RenderX

Figure 11. Risk-of-bias assessment of nonrandomized intervention studies using Risk of Bias in Nonrandomized Studies of Interventions (ROBINS-I). Panel A presents domain-specific judgments for the 8 included studies, including Hinson et al [77]. Panel B summarizes the distribution of ROBINS-I judgments across domains and overall assessments. Bars represent the proportions of studies classified as having low, moderate, serious, or critical risk of bias [72,77,82-85,88,89]. RoB: risk of bias.

Hinson et al [77] was retained in the qualitative synthesis because it provided relevant real-world multisite implementation evidence for AI-assisted ED triage. The study was judged to have a serious overall risk of bias, driven primarily by its uncontrolled before-and-after design and the potential for time-varying confounding.

One cluster RCT [86] met the eligibility criteria. As only 1 randomized study was identified, a separate RoB 2 figure was not generated. The trial was judged to have an overall low risk of bias.

Discussion

Principal Findings

This systematic review and meta-analysis addressed 2 related objectives: first, to evaluate the diagnostic and prognostic performance of AI- and ML-assisted triage systems; and second, to synthesize evidence on the workflow, implementation, economic, and equity implications of tele-triage and other digital triage technologies. Regarding the first objective, AI-assisted triage systems demonstrated high pooled discriminative performance in adult ED settings, while individual comparative studies reported higher discrimination than conventional triage approaches; however, the quantitative evidence was based on a small number of studies and was characterized by substantial between-study heterogeneity. Pediatric evidence remained limited. Regarding the second objective, tele-triage and patient-facing digital tools were supported mainly by narrative evidence suggesting potential improvements in access, patient routing, and front-door workflow. The scenario-based operational, economic, and equity analyses provided exploratory, assumption-dependent projections rather than observed clinical or system-level effects. Because the available studies primarily reported discrimination measures rather than threshold-specific diagnostic accuracy metrics, the quantitative synthesis focused on pooled AUC estimates rather than hierarchical diagnostic test accuracy modeling.

The high discriminative performance and favorable study-level comparisons observed for AI-assisted triage are consistent with prior work demonstrating the limitations of traditional rule-based triage systems, which rely on a restricted set of snapshot variables and clinician judgment under time pressure [93,94]. ML models, by contrast, can integrate high-dimensional clinical data and capture nonlinear relationships that are difficult to operationalize within conventional triage frameworks [95]. Individual studies included in this review that evaluated electronic or ML-based triage systems against established scales such as the ESI or KTAS generally reported higher risk discrimination for critical care, hospitalization, or deterioration outcomes, supporting the potential of AI as an augmentation to decision support rather than a replacement for clinician judgment [20,70]. However, AUC measures the ability to rank patients

XSL•FO
RenderX

by risk rather than the clinical consequences of applying a specific decision threshold. High discrimination therefore does not establish implementation readiness, which requires evaluation of prespecified thresholds, sensitivity-specificity trade-offs, FP escalation burden, FN safety risk, overall and subgroup calibration, workflow integration, equity, and economic feasibility.

Importantly, the findings should be interpreted in the context of substantial clinical and methodological heterogeneity. Differences in outcome definitions, predictor inputs, model architectures, and health care system organization are intrinsic to triage research and have been highlighted in prior evaluations of prediction models in acute care [96-98]. Accordingly, elevated statistical heterogeneity is expected in this domain but materially limits the precision, comparability, and transportability of the pooled estimates. Heterogeneity should therefore not be dismissed as merely contextual variation, even when study-level findings generally point in a similar direction. This reinforces the importance of local calibration, external validation, and contextual assessment, particularly when models are deployed across settings with differing patient populations, clinical thresholds, and operational constraints.

The risk-of-bias findings support cautious interpretation of the observed performance estimates. Prediction-model studies generally demonstrated low risk of bias in participant selection and predictor assessment, but limitations in model analysis, calibration reporting, and external validation were common. Nonrandomized implementation studies were mainly limited by residual confounding associated with their observational designs, whereas diagnostic accuracy studies generally demonstrated better methodological quality. Collectively, these findings indicate that the principal challenge lies not only in achieving high model discrimination but also in ensuring rigorous model development, validation, reporting, and implementation.

Evidence for pediatric triage remains comparatively limited. Although individual pediatric studies reported high discriminative performance for predicting critical illness, the small number of eligible studies and variability in outcome definitions precluded robust quantitative synthesis. Pediatric triage presents distinct challenges related to developmental variability, lower event rates, and increased susceptibility to spectrum effects, all of which may inflate apparent performance in single-center evaluations [99,100]. The current evidence base therefore supports cautious interpretation and underscores the need for prospective, multicenter pediatric evaluations before broader clinical implementation.

The narrative synthesis highlights the complementary but functionally distinct roles of tele-triage, tele-intake, and patient-facing digital triage tools. Unlike AI- and ML-based CDSSs, these interventions primarily support remote assessment, access management, and patient routing. Studies evaluating telephone- and telehealth-based triage reported improvements in access and front-door flow, consistent with prior nurse-led telephone triage and recent ML-enabled tele-triage evaluations [73,101,102]. However, these interventions rarely reported comparator-based diagnostic accuracy metrics and frequently prioritized sensitivity over specificity, limiting their suitability as standalone triage mechanisms in high-acuity emergency settings. Accordingly, the available evidence suggests that tele-triage and digital symptom-assessment tools are best positioned as adjunctive front-door supports that facilitate access and prioritization while preserving clinician oversight.

Beyond diagnostic performance, this review emphasizes the importance of operational, economic, and equity considerations in evaluating triage technologies. Improvements in early risk stratification have the potential to influence downstream outcomes by reducing delays in escalation for high-risk patients and improving resource allocation in crowded EDs [103]. Scenario-based operational and economic modeling provides an exploratory illustration of how changes in sensitivity and specificity might translate into projected differences in missed critical illness, escalation workload, and costs under specified prevalence and cost assumptions. These assumption-dependent projections do not represent observed clinical benefits or formal cost-effectiveness estimates. Rather, they identify potential operational trade-offs that should be evaluated prospectively in real clinical settings before implementation decisions are made.

Equity emerged as a central concern across the included studies. Prior research has demonstrated that algorithmic systems may perpetuate or exacerbate existing disparities if performance is not explicitly evaluated across demographic subgroups [104]. Beyond differences in discrimination, subgroup-specific calibration drift may alter effective clinical decision thresholds, potentially amplifying inequities even when overall AUC remains high. Implementation-focused studies, including multisite evaluations of AI-assisted triage systems, suggest potential reductions in missed high-risk cases among historically underserved populations when subgroup performance is explicitly examined and monitored [77]. Nonetheless, telehealth-based triage interventions also highlighted persistent barriers related to digital literacy, language, connectivity, and insurance status, particularly among underserved and uninsured populations, underscoring the need for inclusive design and governance frameworks that prioritize fairness alongside overall accuracy [29,105,106]. Because subgroup-stratified evidence was limited and the equity modeling relied on available subgroup estimates and stated assumptions, the projected equity effects should be considered exploratory and hypothesis-generating. These findings reinforce the need for subgroup validation, accessible implementation strategies, and continuous postdeployment monitoring in AI- and telehealth-enabled triage systems.

Several limitations of both the included evidence and the review methods should be acknowledged. Most included studies were retrospective and observational, with incomplete reporting of calibration, threshold selection, missing-data handling, and external validation. Limited external validation restricts confidence in transportability across health care systems and underscores the need for prospective, multicenter evaluation before routine deployment. The quantitative synthesis included relatively few studies, and pooling the AI-model AUCs estimated average discrimination rather than a direct within-study comparative effect against conventional triage. The pooled estimate should therefore not be interpreted as

XSL•FO
RenderX

definitive evidence that AI-assisted triage is superior to conventional triage. Outcome definitions varied widely, particularly for admission-related end points influenced by local practice patterns. Substantial heterogeneity, especially for admission-related outcomes, further limited the precision, clinical interpretability, and transportability of the findings. Subgroup analyses addressing equity were infrequently reported, and formal economic evaluations were scarce. In addition, the operational, economic, and equity modeling relied on assumptions regarding prevalence, operating thresholds, and cost ratios; these outputs represent illustrative projections rather than observed effects or formal cost-effectiveness estimates. Restriction to English-language studies may also have introduced language bias. Together, these limitations require cautious interpretation and highlight priorities for future research.

Conclusions

Digital triage technologies should be implemented as function-specific, clinician-supervised tools rather than treated as interchangeable interventions or as replacements for professional judgment. Their adoption should therefore be based not only on discrimination performance but also on demonstrated patient-safety benefits, locally appropriate decision thresholds, calibration, workflow compatibility, interoperability, equity, and economic value in real-world clinical settings.

For health care systems and policymakers, responsible adoption should require prospective external validation, transparent human oversight, subgroup performance auditing, and continuous postdeployment monitoring. Procurement and implementation decisions should distinguish between AI-based risk-prediction systems, tele-triage services, patient-facing symptom checkers, and workflow-support technologies because each serves a different clinical function and is supported by a different type and strength of evidence. Future research should move beyond retrospective model evaluation toward prospective multicenter studies that measure clinical actions, patient outcomes, workload consequences, subgroup effects, and economic outcomes. Such evidence will be essential to determine whether digital triage improves access and prioritization without creating new safety risks, operational burdens, or disparities.
