## Abstract

**Background:** COVID-19 became a global pandemic not long after its identification in late 2019. The genomes of SARS-CoV-2 are being rapidly sequenced and shared on public repositories. To keep up with these updates, scientists need to frequently refresh and reclean data sets, which is an ad hoc and labor-intensive process. Further, scientists with limited bioinformatics or programming knowledge may find it difficult to analyze SARS-CoV-2 genomes.

**Objective:** To address these challenges, we developed CoV-Seq, an integrated web server that enables simple and rapid analysis of SARS-CoV-2 genomes.

**Methods:** CoV-Seq is implemented in Python and JavaScript. The web server and source code URLs are provided in this article.

**Results:** Given a new sequence, CoV-Seq automatically predicts gene boundaries and identifies genetic variants, which are displayed in an interactive genome visualizer and are downloadable for further analysis. A command-line interface is available for high-throughput processing. In addition, we aggregated all publicly available SARS-CoV-2 sequences from the Global Initiative on Sharing Avian Influenza Data (GISAID), National Center for Biotechnology Information (NCBI), European Nucleotide Archive (ENA), and China National GeneBank (CNCB), and extracted genetic variants from these sequences for download and downstream analysis. The CoV-Seq database is updated weekly.

**Conclusions:** We have developed CoV-Seq, an integrated web service for fast and easy analysis of custom SARS-CoV-2 sequences. The web server provides an interactive module for the analysis of custom sequences and a weekly updated database of genetic variants of all publicly accessible SARS-CoV-2 sequences. We believe CoV-Seq will help improve our understanding of the genetic underpinnings of COVID-19.

**KEYWORDS**

COVID-19; SARS-CoV-2; bioinformatics; genetics; genome; virus; sequence; data sets; programming; web server

## Introduction

Since its identification in late 2019, the novel coronavirus SARS-CoV-2 has caused an outbreak of viral pneumonia and has become a global pandemic. Despite efforts to contain its spread, as of late September 2020, SARS-CoV-2 had infected nearly 33 million patients and caused nearly 1 million deaths worldwide [1]. To understand its evolution and genetics,

scientists have sequenced SARS-CoV-2 genomes from patients across different age groups, genders, ethnicities, locations, and disease stages [2]. These genomic sequences are being shared on public repositories at a rapid pace, with thousands of new sequences every week [3-5]. To keep up with the latest developments, scientists need to frequently download and clean new data sets, which is an ad hoc and time-consuming process. Furthermore, scientists with limited knowledge of bioinformatics

or programming may experience difficulty in analyzing SARS-CoV-2 genomes.

We developed the CoV-Seq toolkit to address these challenges. CoV-Seq consists of several components: a data analysis pipeline that takes FASTA sequences and generates variant callsets in variant call format (VCF) and open reading frame (ORF) predictions. The pipeline automatically filters low-quality sequences, removes duplicate sequences, performs sequence alignment, and identifies and annotates genetic variants. We provide a web server [6] to enable the rapid analysis of custom sequences without any programming. The web interface includes an interactive genome visualizer and tabulated displays of genetic variants and ORF predictions. All results can be downloaded for downstream analysis. Further, we provide a command-line interface to allow high-throughput processing in local environments. To facilitate data sharing, we aggregate SARS-CoV-2 sequences from the Global Initiative on Sharing Avian Influenza Data (GISAID) [3], National Center for Biotechnology Information (NCBI) [4], European Nucleotide Archive (ENA) [5], and China National GeneBank (CNGB).

## Methods

### Data Collection

The majority of publicly available SARS-CoV-2 genomic sequences are deposited into the following databases: GISAID (Multimedia Appendix 2 lists GISAID contributors), NCBI, ENA, and CNGB. All databases provide the option of downloading data in a batch. We used Selenium [7] to automate the data download process.

### Data Preprocessing

We aggregated SARS-CoV-2 sequences from GISAID, NCBI, ENA, and CNGB. Many sequences represented incomplete genomes, sometimes containing only a single gene. We filtered these genomes using a lenient cutoff of 25,000 nucleotides because doing so removed distinctly incomplete genomes while retaining complete genomes (Figure 1 in Multimedia Appendix 1). Both NCBI and ENA are part of the International Nucleotide Sequence Database Collaboration (INSDC) and therefore contain duplicate submissions, which we removed by comparing the accession IDs. Further, dual submissions can appear in both GISAID and INSDC under different accession IDs. We considered two submissions as suspect duplications if they had identical genomic sequences. These suspect duplications were marked in the metadata but not removed because a strain can infect multiple patients.

### Pairwise Sequence Alignment

We performed pairwise alignment against the reference sequence (NCBI accession ID: NC\_045512.2) using Multiple Alignment using Fast Fourier Transform (MAFFT) [8] with default options.

### Variant Calling

We used a custom Python script for variant calling, in which we considered single nucleotide polymorphisms (SNPs), insertions, and deletions. We left-normalized each variant with bcftools [9] and removed samples with too many variants, indicative of sequencing error. We used a lenient cutoff of 350

variants because doing so removed samples with extremely large numbers of variants while keeping most samples (Figure 2 in Multimedia Appendix 1). During postprocessing, we removed multiallelic sites because these sites were more likely to occur in regions prone to sequencing error, such as the two ends of the genome (Figure 3 in Multimedia Appendix 1). Further, we removed variants within the poly-A tail. The filtered variant callset was annotated with snpEff [10].

### ORF Boundary Detection

To detect ORF boundaries, we employed a method similar to Viral Annotation Pipeline and iDentification (VAPiD) [11]. Since NCBI Genbank provides genetic annotations for the SARS-CoV-2 reference genomes, we translated the coordinates of ORF boundaries from the reference genome to the query genome using their pairwise alignment. For multisegment ORFs (ie, due to ribosomal slippage), we annotated each segment independently and combined them afterward.

### Interactive Visualization

The CoV-Seq web server is hosted on Amazon Web Services (AWS) Elastic Beanstalk with load balancer enabled, running with the Flask framework [12], Jinja template engine [13], and Werkzeug [14] Web Server Gateway Interface (WSGI) toolkit. After the user submits data through either a text box (for a single sequence) or file upload (for an arbitrary number of sequences), the back-end program will perform pairwise sequence alignment, variant calling, and ORF boundary detection to generate results in VCF and JSON formats. The front-end templates will then render genome sequences on a new page using JSON data, the ECharts [15] library, and dedicated designed JavaScript functions. The result page highlights mutations on submitted sequences against the reference sequence and shows details upon cursor hover. Users can also zoom in to check the details of the genomic sequence. Selecting a specific ORF will expand the display to show the mutation table, the ORF table, and the gene sequence for the selected ORF.

## Results

### Statistics on Collected Sequences

The number of SARS-CoV-2 sequences submitted to GISAID, NCBI, ENA, and CNGB has increased over time. Figure 1 shows the cumulative number of sequences by collection date. Sequences from Asia increased steadily since January, whereas sequences from other continents initially grew slowly but saw a dramatic increase in pace in March. The submission volume reflects the global spread of the virus, starting with the initial outbreak within China in January and followed by the subsequent global outbreak in March. Note that although the number of submissions correlates with the number of cases overall, the number of submissions does not reflect the actual case numbers (Figure 2). The ten countries with the highest number of submissions include five European countries (United Kingdom, Spain, Portugal, the Netherlands, and Switzerland), two Asian countries (India and China), two North American countries (United States and Canada), and one Oceanian country (Australia).

**Figure 1.** The cumulative number of sequences hosted by public databases has increased over time. Sequences from Asia increased steadily since January, whereas sequences from other continents saw a dramatic increase in March. Each data point represents a week. Note that the x-axis shows collection dates, which can precede submission dates by several weeks (eg, a sequence collected in July may be submitted in August). Therefore, lines that do not reach August indicate that sequences recently collected have not been submitted yet.

**Figure 2.** The number of submissions by country. The ten countries with the highest numbers of submissions are marked.

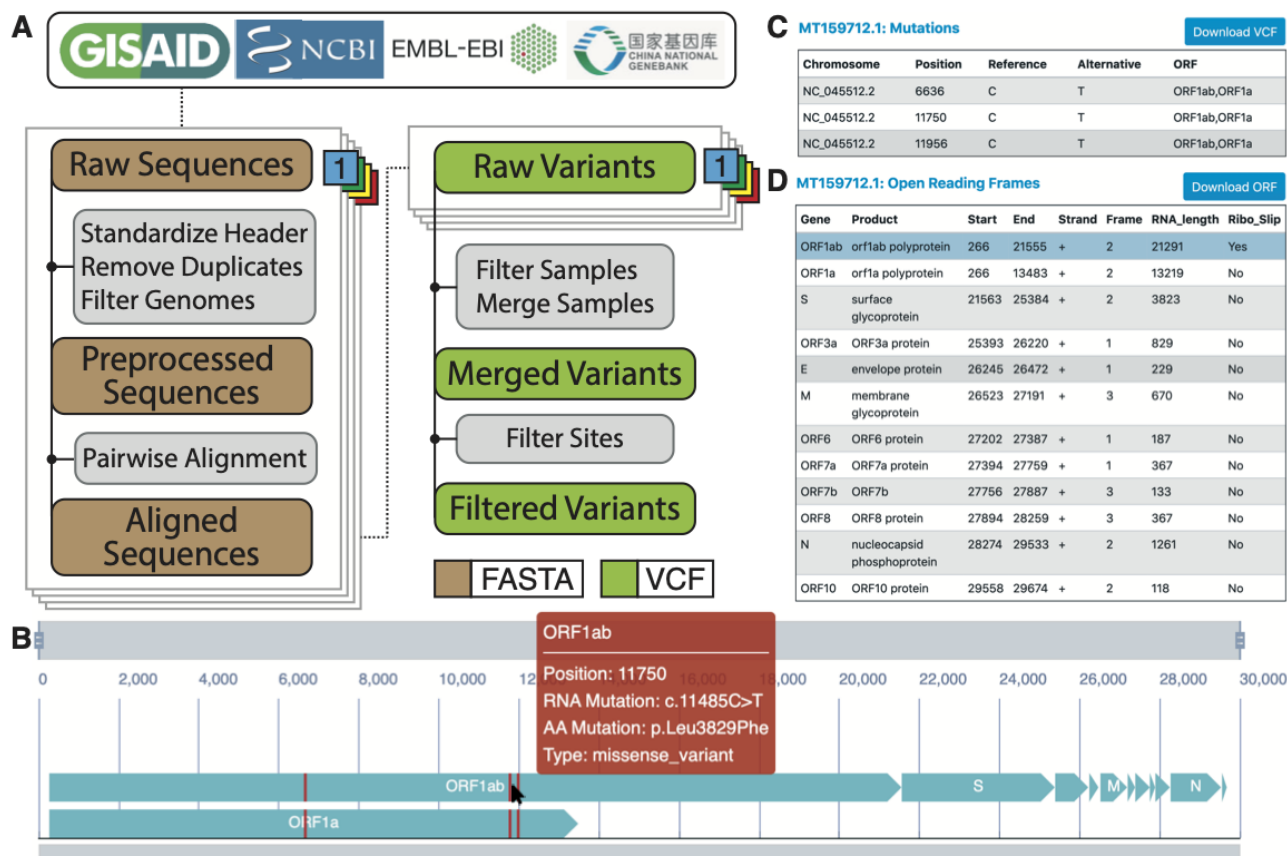

### Interactive Visualization With Custom Sequences

CoV-Seq provides an intuitive web interface (Figure 3A) for analyzing and visualizing SARS-CoV-2 variants and ORFs. Upon receiving custom sequences, CoV-Seq identifies ORF boundaries and genetic variants and displays them alongside a full-length genome (Figure 3B). Users interact with the genome by dragging the zoom bar to adjust the magnification and the position bar to pan along the genome. When the genome window contains less than 150 nucleotides, letters will appear to indicate both the nucleotide bases and amino acid residues. Hovering

over ORF bodies or variants will trigger pop-up windows for relevant information (Figure 3B, red box). Clicking on an ORF brings up three tables. The first table shows all variants and their positions, alleles, and ORFs in which they belong (Figure 3C). A second table shows ORF annotations obtained by aligning input sequences against the reference sequence and transferring annotations from Genbank (Figure 3D). A third table shows nucleotide and protein sequences for the selected ORF (not shown). All tables can be downloaded for further analysis.

**Figure 3.** The CoV-Seq pipeline and web interface. (A) Genomic sequences are collected from GISAID, NCBI, ENA, and CNGB. We remove incomplete genomes (length <25,000 nucleotides) and duplicate genomes before alignment with MAFFT against the reference genome NC\_045512.2. We use a custom Python script to generate raw variant calls and remove samples with too many mutations, indicative of sequencing error. After merging VCFs, we remove multiallelic sites and variants with the poly-A tail for a filtered set of variants. (B) The interactive genome visualizer shows ORFs (turquoise) and mutations (red). Users can zoom with the top bar and pan with the bottom bar. Hovering over ORF bodies and mutations will trigger pop-up windows for relevant information. (C) The mutation table shows positions, alleles, and intersecting ORFs. (D) The ORF table shows predicted ORF boundaries and supporting information. CNGB: China National GeneBank; ENA: European Nucleotide Archive; GISAID: Global Initiative on Sharing Avian Influenza Data; MAFFT: Multiple Alignment using Fast Fourier Transform; NCBI: National Center for Biotechnology Information; ORF: open reading frame; VCF: variant call format.

## CoV-Seq Command-Line Interface

Due to the rapid accumulation of SARS-CoV-2 genomic sequences, a point-and-click web interface is time-consuming for large collections. Therefore, we provide a command-line interface (CLI) for high-throughput processing of sequence batches [16]. The CLI allows the user to identify variants and ORF boundaries from multiple sequences with a single command. Further, the CLI allows the user to identify variants from multiple sequences from a FASTA file with one command.

## Downloading Analysis-Ready Data

To facilitate downstream analysis with publicly available data, we aggregated SARS-CoV-2 genomic sequences from GISAID, NCBI, ENA, and CNGB; we also identified and annotated genetic variants. In addition, we aggregated metadata with key information such as the location and collection date for each sequence (see Methods). All aggregated information can be downloaded from the CoV-Seq web server [17]. Based on this set of information, we provide statistics on the geographical and chronological distributions of sequence submissions and encourage further analysis by other scientists.

## Discussion

### Principal Results

In this paper, we have described CoV-Seq, a web server that enables the rapid analysis of SARS-CoV-2 genomic sequences. CoV-Seq consists of several components. The interactive visualization module accepts custom sequences as input and displays the genetic variants and ORF boundaries on an interactive genome browser. For batch processing needs, CoV-Seq provides a CLI interface that processes many sequences at once. To encourage downstream analysis with publicly available data, CoV-Seq provides downloadable analysis results (updated weekly) with sequence metadata and genetic mutations.

### Limitations

CoV-Seq is currently limited to SARS-CoV-2 sequences. The web server does not allow custom reference sequences other than SARS-CoV-2. We chose to focus on this virus because it has constituted the majority of processing requests during the COVID-19 pandemic. We plan to provide additional functionality to accept custom reference sequences in a future release.

## Comparison With Prior Work

The existing software packages VAPiD [11] and Viral Genome ORF Reader (VIGOR) [18] focus on gene annotations. To our knowledge, a software package that identifies, annotates, and visualizes genetic variants of SARS-CoV-2 has not previously been created.

## Conclusions

We developed the CoV-Seq web server for fast and easy analysis of SARS-CoV-2 sequences. We hope CoV-Seq will help improve our understanding of the genetics of COVID-19. In the future, we plan to expand the scope of CoV-Seq to include other viruses.

## Acknowledgments

We thank the Chinese Center for Disease Control and Prevention for codeveloping the idea behind this study and Xing Li for helpful discussions. We have no funding source to disclose.

## Authors' Contributions

BL and KL designed the web server. BL, KL, HZ, and LZ performed analyses. BL and LH wrote the paper.

## Conflicts of Interest

None declared.

## Abstract

**Background:** Patient-facing digital health tools have been promoted to help patients manage concerns related to COVID-19 and to enable remote care and self-care during the COVID-19 pandemic. It has also been suggested that these tools can help further our understanding of the clinical characteristics of this new disease. However, there is limited information on the characteristics and use patterns of these tools in practice.

**Objective:** The aims of this study are to describe the characteristics of people who use digital health tools to address COVID-19–related concerns; explore their self-reported symptoms and characterize the association of these symptoms with COVID-19; and characterize the recommendations provided by digital health tools.

**Methods:** This study used data from three digital health tools on the K Health app: a protocol-based COVID-19 self-assessment, an artificial intelligence (AI)–driven symptom checker, and communication with remote physicians. Deidentified data were extracted on the demographic and clinical characteristics of adults seeking COVID-19–related health information between April 8 and June 20, 2020. Analyses included exploring features associated with COVID-19 positivity and features associated with the choice to communicate with a remote physician.

**Results:** During the period assessed, 71,619 individuals completed the COVID-19 self-assessment, 41,425 also used the AI-driven symptom checker, and 2523 consulted with remote physicians. Individuals who used the COVID-19 self-assessment were predominantly female (51,845/71,619, 72.4%), with a mean age of 34.5 years (SD 13.9). Testing for COVID-19 was reported by 2901 users, of whom 433 (14.9%) reported testing positive. Users who tested positive for COVID-19 were more likely to have reported loss of smell or taste (relative rate [RR] 6.66, 95% CI 5.53–7.94) and other established COVID-19 symptoms as well as ocular symptoms. Users communicating with a remote physician were more likely to have been recommended by the self-assessment to undergo immediate medical evaluation due to the presence of severe symptoms (RR 1.19, 95% CI 1.02–1.32). Most consultations with remote physicians (1940/2523, 76.9%) were resolved without need for referral to an in-person visit or to the emergency department.

**Conclusions:** Our results suggest that digital health tools can help support remote care and self-management of COVID-19 and that self-reported symptoms from digital interactions can extend our understanding of the symptoms associated with COVID-19.

## Introduction

Contemporary health care systems have limited capacity for managing epidemics; they are structured on the model of in-person interactions between patients and clinicians, which results in the congregation of patients in emergency departments and waiting areas during crises [1]. During the COVID-19 pandemic, it has been suggested that digital technologies can be used to deliver rapid urgent assessments, aid management of nonurgent conditions, and reduce the risk of iatrogenic COVID-19 exposure [1-3]. Indeed, several medical associations have encouraged the use of these tools during the COVID-19 epidemic, including the American Medical Association and the American Academy of Family Physicians [4,5]. Moreover, it has been suggested that these technologies can provide novel insights regarding the epidemiology and clinical characteristics of this new disease [6], especially in early stages and in community settings, as most published studies focus on hospitalized patients [7].

Digital tools have been promoted and deployed during previous infectious disease outbreaks, such as severe acute respiratory syndrome (SARS) and Ebola virus [8,9]. These tools focused primarily on surveillance, contact tracing, case management, and management of laboratory results [10]. In recent years, a wide range of patient-facing digital health modalities have emerged. These include protocol-based triage tools, artificial intelligence (AI)-driven tools for diagnosis and self-assessment, use of at-home remote monitoring devices, and virtual consultations by remote physicians. These tools are rapidly being deployed to support the medical management of the current epidemic [2]. However, despite the rapid growth in patient-facing digital and AI-driven technologies, other than reports of user satisfaction [11-13], there are limited data on the usage patterns and characteristics of these technologies in the management of COVID-19 and on their utility for advancing clinical research of COVID-19. Examining the characteristics and symptoms of digital technology users can help identify novel features associated with positivity or severity of COVID-19 and advance our understanding of the disease. Analysis of use patterns of digital tools can provide insight regarding their utility in the management of COVID-19 and can also highlight opportunities for further development.

During the pandemic, K Health, a novel AI-driven digital health platform deployed in the United States [14], offered three tools: a protocol-based COVID-19 self-assessment tool, an AI-driven symptom checker, and text-based telemedicine visits. This study aims to further our understanding of the use of digital health technologies in COVID-19 management and research. Specifically, the study describes the demographic and clinical characteristics of people using digital health tools for COVID-19-related concerns, explores self-reported symptom patterns among digital health users with COVID-19 compared to users who do not have the disease, and characterizes the

information and management recommendations provided by different digital health tools.

## Methods

### Population and Settings

K Health is a novel AI-driven digital health app; at the time this paper was written, it was available for download in the United States, Mexico, Indonesia, and Israel [14]. The app was built using a data-driven approach in collaboration with Maccabi Health Services (MHS). MHS is the second largest health maintenance organization in Israel, with over 2 million members [15,16]. Data from the MHS health records were used to develop an AI-driven symptom-checker, whose methodology has been described elsewhere [14]. The K Health app was launched in the United States in 2018 and has been used by over 4 million adults [14]. The app is free to download, and the symptom checker is available for free to adults over 18 years of age; thus, the app provides the public with reliable and personalized information on diagnoses related to their symptoms and medical history.

In June 2019, K Health began offering a service that enables users to consult directly with a remote physician. The platform provides the users with the option to receive a diagnosis, prescriptions, lab referrals, a referral to remote management of mental health concerns, or a referral to primary or emergency care. Consulting with a remote physician involves a fee or enrollment in a relevant health plan.

Early in April 2020, a protocol-based COVID-19 self-assessment was added to the app to provide users with up-to-date guidance for managing suspected cases of COVID-19. The self-assessment was developed by a team of board-certified physicians and was based on guidance issued by the World Health Organization and the US Centers for Disease Control and Prevention [17,18]. The user was asked to report the presence and severity of COVID-19-related symptoms as well as the presence of concomitant conditions known to increase risk of severe disease. Following the self-assessment, users were provided with one of four recommended actions based on their risk profile: social distancing, quarantine, isolation, or seeking immediate medical evaluation. Users were also informed if they were at increased risk for COVID-19 complications, and users with risk factors and symptoms were encouraged to consult a physician. For further details, including the full questionnaire, see [Multimedia Appendix 1](#).

### Study Design

This study describes use of three digital tools, namely a protocol-based COVID-19 self-assessment tool, an AI-driven symptom checker, and communication with a remote physician, by adults (>18 years of age) seeking COVID-19-related health information and services during the 10-week period between the launch date of April 8 to the date of data extraction on June

20, 2020. Seeking COVID-19–related health information was defined as use of the COVID-19 self-assessment tool. This self-assessment tool can be activated by the user, and it is also activated automatically when users begin a symptom check with a complaint of cough, dyspnea, or fever. The study did not include repeated self-assessments.

After users perform the COVID-19 self-assessment, they are prompted to use the AI-driven symptom checker to receive additional information about other conditions that may be related to their symptoms. After receiving the results and information regarding these conditions, the users can choose to communicate with a remote physician for definitive medical management.

This study analyzed deidentified data. The protocol of the study was reviewed by the Western Institutional Review Board and qualified for exemption in accordance with 45 CFR § 46.104(d)(4). K Health is compliant with the Health Insurance Portability and Accountability Act (HIPAA) and the General Data Protection Regulation (GDPR). Encrypted transportation and storage were used at all stages of data management.

## Variables

Deidentified data on the characteristics of the digital interactions in the app were collected, including user-inputted demographic and clinical characteristics; COVID-19 exposure reporting; reports of COVID-19 testing, including results; and symptoms. We also collected the outputs provided by the three digital modalities: risk categories according to the protocol-based COVID-19 self-assessment; the most common conditions for similar people and symptoms (“potential diagnoses”) provided by the AI-driven symptom checker; and diagnoses, management, and disposition by remote physicians.

User characteristics included age, sex, risk factors, and comorbidities. Comorbidities included hypertension, smoking, obesity, diabetes (type 1 and type 2), cardiovascular disease, chronic lung disease (asthma, chronic obstructive pulmonary disorder, and interstitial lung disease), chronic renal and liver disease, cancer, and immune suppression.

Symptoms were obtained from two types of interactions on the platform: first, as part of the structured protocol-based COVID-19 risk assessment, and second, as part of the dynamic AI-driven health dialog.

The COVID-19 self-assessment included questions regarding symptoms known to be associated with COVID-19 (eg, cough, dyspnea, and fever) as well as symptoms hypothesized to be related to COVID-19 (eg, eye symptoms), which were inquired about for further research and development of the COVID-19 protocol. The symptom checker dialog allows the user to spontaneously discuss a wider array of 331 symptoms; it also queries the user regarding additional symptoms and symptom-specific attributes, such as the severity, timing, duration, and quality of a symptom (eg, dry or productive cough), as previously described [6].

## Analyses

The analyses assessed the user characteristics, reported symptoms, and output of the aforementioned digital services, namely the self-assessment protocol, AI- and data-driven

symptom checker, and remote physician consultation. This assessment was performed using descriptive statistics and bivariate analyses.

Descriptive univariate summary statistics were developed to assess the user characteristics, reported symptoms, diagnoses, and disposition. Symptoms were assessed for both the COVID-19 self-assessment and the symptom checker. Bivariate analyses were conducted for between-group comparisons of characteristics and symptoms. These included two primary analyses.

The first analysis explored the potential utility of self-reported data from digital health tools to identify symptoms associated with COVID-19. This analysis compared the self-reported symptoms by digital health users who reported testing positive for COVID-19 with those of users who reported testing negative. To ensure that the symptoms of cough, fever, and dyspnea were optimally captured, the presence of these symptoms was collected from both the self-assessment and the symptom checker dialog. More details are provided in [Multimedia Appendix 1](#).

The second analysis aimed to identify predictors related to the choice to consult with a remote physician. This analysis compared data provided by individuals who opted to consult with a remote physician with those provided by the entire cohort. Specifically, this comparison aimed to evaluate whether consultation with a physician was related to risk of COVID-19, symptom severity, or comorbidity.

Appropriate statistical tests were used to assess the significance of between-group differences: chi-square tests for differences in proportions and *t* tests for differences in continuous measures. Test assumptions were assessed analytically and graphically and were judged to be adequately met. We considered *P* values of .05 or less to be significant and did not correct for multiple comparisons. Analyses were conducted using Python version 3.6.9.

## Results

During the assessed timeframe, 71,619 individuals completed the COVID-19 self-assessment. The self-assessment included questions on COVID-19 exposure, testing, comorbid conditions, and the presence of COVID-19–related symptoms. The self-assessment output provided users with protocol-based information and recommendations on their COVID-19 risk. Of the 71,619 individuals who completed the self-assessment, 41,425 (57.8%) also completed a more detailed AI-driven symptom checker. The symptom checker provides the option to evaluate a wide range of 331 symptoms and to receive information about non-COVID-19 conditions that may be related to these symptoms. Following use of the symptom checker, a subset of 2523 users proceeded to consult with remote physicians, who provided guidance on the users’ disposition and health management ([Figure 1](#)).

Individuals using the COVID-19 self-assessment were predominantly female (51,845/71,619, 72.4%), with a mean age of 34.5 years (SD 13.9). The most commonly reported comorbidities were chronic lung disease, primarily asthma

(16,080/71,619, 22.5%), and hypertension (13,952/71,619, 19.5%) (Table 1).

The self-assessment results provided users with information and recommendations related to their risk of COVID-19, with

the most common recommendations involving social distancing (20,984/71,619, 29.3%) and isolation (23,706/71,619, 33.1%) (Table 2).

**Table 1.** Characteristics of the cohort of COVID-19 self-assessment users (N=71,619).

Characteristic	Value
<b>Demographics</b>	
Age, mean (SD)	34.5 (13.9)
Female, n (%)	51,845 (72.4)
<b>Chronic conditions, n (%)</b>	
Hypertension	13,952 (19.5)
Morbid obesity	7676 (10.7)
Smoking	13,505 (18.9)
Stroke	897 (1.3)
Cancer or immunosuppression	1868 (2.6)
Chronic kidney disease	1313 (1.8)
Chronic lung disease	16,080 (22.5)
Cardiovascular disease	3835 (5.4)
Diabetes	5958 (8.3)
<b>Tested for COVID-19 (n=2901), n (%)</b>	
Tested positive	433 (14.9)
Tested negative	2468 (85.0)

**Table 2.** Outputs provided by the digital health tools (N=71,619), n (%).

Output	Value
<b>COVID-19 assessment recommendation</b>	
Practice social distancing	20,984 (29.3)
Isolate yourself	23,706 (33.1)
Quarantine yourself	7735 (10.8)
Seek immediate evaluation	19,194 (26.8)
<b>Most common symptom checker potential diagnoses (n=41,425)</b>	
Upper respiratory infection	15,232 (36.7)
Anxiety disorder	2457 (5.9)
Gastroesophageal reflux disease	2075 (5.0)
Dehydration	1512 (3.6)
Tension-type headache	1152 (2.8)
Allergic rhinitis	957 (2.3)
Depressive mood disorder	833 (2.0)
Pulmonary embolism	783 (1.9)
Pneumonia	721 (1.7)
Acute food poisoning	708 (1.7)
<b>Remote physician management and disposition<sup>a</sup> (n=2523)</b>	
Medication or laboratory tests	1072 (42.5)
Information and reassurance	431 (17.1)
Other	363 (14.4)
Referral to primary care or a specialist	325 (12.9)
Referral to the emergency department	257 (10.2)
Referral to COVID-19 testing	169 (6.7)
Referral to a remote behavioral health service	73 (2.9)

<sup>a</sup>Dispositions are not mutually exclusive.

Testing for COVID-19 was reported by 2901 users, of whom 433 (14.9%) reported testing positive. Users who were tested for COVID-19 were predominantly female (2022/2901, 69.7%), with a mean age of 38.1 years (SD 13.8). Of users who were tested, those who reported testing positive were of similar age (mean 37.5 years, SD 13.8, vs mean 38.2 years, SD 13.8,  $P=.32$ ), less frequently female (62.4% vs 69.9%), and much more likely to have reported a close contact with a known case of COVID-19 (relative rate [RR] 7.13, 95% CI 6.00-8.49), compared to those who tested negative. The symptoms reported by users as part

of the COVID-19 self-assessment differed between those who reported positive and negative test results. Most notably, the relative prevalence of reporting loss of smell or taste was significantly higher among individuals who tested positive for COVID-19 (RR 6.65, 95% CI 5.53-7.94), as was the prevalence of fever (RR 2.58, 95% CI 2.04-3.26) and chest pain (RR 2.59, 95% CI 2.12-3.18). Cough, difficulty eating or drinking, dry eye, eye pain, feeling weak and lightheaded, and chest pain were also significantly associated with positive COVID-19 tests (Figure 2).

**Figure 2.** Forest plot presenting the RRs and 95% CIs of each item in the self-assessment questionnaire among users who reported testing positive for COVID-19 compared to those who reported testing negative. Muscle pain was not present in early versions of the self-assessment. Proportions were calculated for self-assessments where the symptom was reportable. RR: relative rate.

Individuals using the COVID-19 self-assessment were prompted to use the AI-driven symptom checker to receive additional information about other conditions potentially related to their symptoms. This tool enables users to input a wide range of symptoms that are not systematically collected as part of the COVID-19 self-assessment; thus, it recorded a wide range of additional symptoms that were not already included in the protocol-based self-assessment. Among these, the most common additional symptoms reported by individuals who tested positive for COVID-19 were headache, sore throat, fatigue, diarrhea, chest pain, nausea, nasal congestion, runny nose, and sweating (Supplementary Table 1, Multimedia Appendix 1). The AI-driven algorithm provided users with information about the most common conditions people with symptoms and personal characteristics similar to theirs were diagnosed with (“potential diagnoses”). The most common non-COVID-19 conditions classified as relevant for the 41,425 users were upper respiratory infection (15,232, 36.7%), anxiety disorder (2457, 5.9%),

gastroesophageal reflux disease (GERD) (2075, 5.0%), and dehydration (1512, 3.6%) (Table 2).

Among individuals initially evaluating their COVID-19 risk, a small subset (2523/41,425, 3.5%) chose to communicate with a remote physician. Users who chose to communicate with a remote physician were older (mean age 38.6 years, SD 13.2, vs mean age 34.3 years,  $P<.001$ ) and more likely to be male (37.9% vs 27.2%,  $P<.001$ ) than users who did not; however, they were less likely to have comorbidities (RR 0.88, 95% CI 0.82-0.95). These individuals were more likely to report severe symptoms such as severe chest pain (RR 1.13, 95% CI 1.03-1.25) and to be encouraged by the self-assessment to seek immediate evaluation (RR 1.19, 95% CI 1.02-1.32). Additionally, features and symptoms supporting higher suspicion of COVID-19 were more common among users who communicated with a remote physician, including exposure to a close contact with COVID-19 (RR 1.21, 95% CI 1.1-1.35), fever (RR 1.56, 95% CI 1.43-1.72), shortness of breath (RR 1.25, 95% CI 1.16-1.33), and loss of smell and taste (RR 1.22, 95% CI 1.09-1.37) (Table 3).

**Table 3.** User characteristics and self-assessment protocol disposition associated with consulting a remote physician (N=71,619).

Item or disposition	Did not consult a remote physician (n=69,096), n (%)	Consulted a remote physician (n=2523), n (%)	RR <sup>a</sup> (95% CI)
<b>Self-assessment items</b>			
Close contact	7431 (10.8)	331 (13.1)	1.21 (1.10-1.35)
Travel	1908 (2.8)	59 (2.3)	0.82 (0.66-1.09)
Eye pain	6257 (9.1)	218 (8.6)	0.95 (0.84-1.09)
Dry eye	7242 (10.5)	269 (10.6)	1.02 (0.93-1.17)
Joint pain	61,741 (89.4)	2271 (90.0)	1.01 (0.83-1.06)

Feeling weak/light-headed	11,101 (16.1)	462 (18.3)	1.14 (1.05-1.24)
Chest pain	8279 (12.0)	343 (13.6)	1.13 (1.03-1.26)
Muscle pain	7643 (11.1)	289 (11.5)	1.04 (0.93-1.16)
Cough <sup>b</sup>	21,832 (31.60)	859 (34.05)	1.07 (1.02-1.14)
Shortness of breath <sup>b</sup>	14,424 (20.8)	656 (26.0)	1.25 (1.16-1.33)
Fever <sup>b</sup>	7147 (10.34)	409 (16.21)	1.57 (1.43-1.72)
Testing for COVID-19	660 (1.0)	34 (1.3)	1.30 (1.00-2.00)
<b>Disposition of self-assessment</b>			
Practice social distancing	17,827 (25.8)	777 (30.8)	1.19 (1.15-1.13)
Isolate yourself	24,118 (34.9)	781 (30.9)	0.89 (0.67-0.96)
Quarantine yourself	9016 (13.1)	176 (6.9)	0.53 (0.34-0.65)
Seek immediate evaluation	18,135 (26.3)	789 (31.3)	1.19 (1.02-1.32)

<sup>a</sup>RR: relative rate.<sup>b</sup>Users could report these symptoms at the end of the self-assessment or as part of the symptom-checker dialog. See [Multimedia Appendix 1](#) for details.

The remote physicians provided a wide range of evaluation and counseling services, including assessing severe cases and referring them to the emergency department (257/2523, 10.2%) or to ambulatory care in the community (325/2523, 12.9%), advising on and prescribing medications (1072/2523, 42.5%), providing remote behavioral health services to individuals with mild to moderate anxiety or depression (73/2523, 2.9%), providing additional information and reassurance (431/2523, 17.1%), and referring users to COVID-19 testing (169/2523, 6.7%) ([Table 2](#)).

## Discussion

### Principal Findings and Interpretation

This study describes the characteristics and management of >71,000 individuals who used digital tools to seek health information and services related to COVID-19. These individuals were relatively young and predominantly female. Users received information regarding COVID-19 risk and management, received AI-driven information about other relevant diagnoses, and consulted with remote physicians. Users who chose to communicate with a remote physician were more likely to have been classified as requiring immediate medical evaluation by the COVID-19 self-assessment. Correspondingly, these users were also older, more likely to report severe

symptoms, and more likely to report characteristics cognate with risk of COVID-19 (such as known exposure to COVID-19 and loss of sense of smell or taste). The majority of consultations with a remote physician (1940/2523, 76.9%) were resolved without need for referral to an in-person health visit or to the emergency department.

Taken together, the differential communication with remote physicians according to symptom severity and the high resolution rates without need for referral to in-person visits suggest that the digital tools provided information and advice that assisted users in making health decisions. These tools may therefore reduce the burden on health care systems during times when resources are limited and may help minimize unnecessary physical interactions that could lead to iatrogenic COVID-19 exposure. However, research on health care use and health outcomes following digital health tool use is needed to conclusively demonstrate this potential.

In addition, individuals who chose to communicate with a remote physician tended to have lower rates of comorbidity. This suggests that these individuals were more likely to have an established relationship with a health care provider whom they consulted regularly and were more likely to require an in-person evaluation and more complex care when presenting with significant symptoms.

This study also highlighted differences in self-reported symptoms between users who reported testing positive for COVID-19 and those who reported testing negative. The symptom most strongly associated with positive testing for COVID-19 was loss of sense of taste or smell (RR 6.66, 95% CI 5.53-7.93). Surprisingly, travel to an area with COVID-19 appeared to be associated with a lower rate of positive testing (RR 0.47, 95% CI 0.23-0.90); however, this estimate is based on a relatively small number of subjects and should therefore be interpreted with caution. As the decision to test or be tested is driven by the presence of risk factors for COVID-19, travel to an area with COVID-19 may appear protective because individuals who were tested due to this risk factor may be less likely to have other stronger predictors of positivity, such as exposure to an individual with COVID-19 or the presence of COVID-19 symptoms. Additional features associated with COVID-19 included other widely recognized COVID-19 symptoms, such as fever and cough. These results emphasize the potential utility of taste and smell as strong signals of COVID-19 positivity in the community setting, and they are similar to results reported in recent studies of self-reported symptoms among individuals who tested positive for COVID-19 [19,20].

Finally, in our study, we found that dry eye (RR 1.87, 95% CI 1.57-2.22) and eye pain (RR 1.61, 95% CI 1.29-2.01) were more common among individuals who reported testing positive for COVID-19. These symptoms were added to the self-assessment to explore the possible link between COVID-19 and eye symptoms as well as the utility of these symptoms in evaluating suspicion of COVID-19. Although some early hospital-based studies reported low rates of ocular symptoms in patients with COVID-19 [20], several other studies have suggested that ocular symptoms are common among individuals with COVID-19 [21-23]. Ocular symptoms have been documented in some cases as the first [24] and even only [25] symptomatic manifestation of COVID-19, and studies have documented positive reverse transcriptase-polymerase chain reaction COVID-19 test results from ocular secretions [23,26]. This study adds to the body of evidence suggesting that the manifestations of COVID-19 include ocular symptoms and that they may be more common symptoms of COVID-19 than generally recognized.

Seen from a wider perspective, these results demonstrate that self-reported symptoms on a digital app can replicate symptoms known to be associated with COVID-19, that they can help distinguish between individuals who test positive and negative for COVID-19, and that they may add to our understanding of symptoms associated with COVID-19. This exemplifies the potential of data generated from digital tools to improve our understanding of the clinical manifestations of COVID-19 and of patient-reported experiences in general.

### Comparison With Prior Work

The potential benefits of digital tools during the COVID-19 epidemic have been noted in multiple health policy commentaries [1-3,19,27]. This stance has been adopted by several leading medical associations, including the American Medical Association and the American Academy of Family Physicians [4,5]. However, there has been limited research to

date on the actual usage patterns and impact of these tools during the COVID-19 epidemic. The body of literature on digital health for COVID-19 primarily features perspectives and opinion pieces, guidance papers, and a few studies. These studies tend to be small, focus on a single digital tool, and/or report primarily on survey results of user satisfaction. Two larger studies have provided some additional insight. The first study reported the results of a satisfaction survey of 6194 people following wide-scale deployment of digital tools for COVID-19 education, self-assessment, and symptom monitoring in the Netherlands; high satisfaction rates were reported [11]. The second study reported on the treatment and high satisfaction rates of 4589 patients in China using web-based physician consultation for COVID-19 concerns [13].

The demographic characteristics of digital health users described in this study match previous reports on digital health users. While the use of digital health technologies among seniors has been reported to be increasing [28], users of digital health applications are still predominantly younger adults [29]. The current low level of adoption of digital health by older adults is unfortunate, as digital health technologies have the potential to improve communication and collaboration and promote healthy and independent ageing. Indeed, recent research suggests that digital solutions tailored for older adults improve health management [30]. Barriers to the adoption of digital health by older adults include visual impairment, limitations in dexterity, and lack of self-confidence when using technology. Several solutions are being developed to circumvent these barriers, including the development of voice-based applications and unobtrusive sensors and trackers [31].

### Strengths and Limitations

This study has a number of strengths. First, it uses a large sample of over 71,000 individuals to provide timely information on the use of a number of different digital health tools for managing COVID-19-related concerns. Second, the study reported on the differential use of these tools by these individuals as well as on both self-reported variables and physician-reported disposition and management. Third, the study was able to provide insight into self-reported symptoms of individuals who were tested for COVID-19; the results highlighted the strong link between COVID-19 and loss of sense of smell and taste and added to the body of evidence that ocular symptoms may be a more common feature of COVID-19 than is widely recognized.

The study has a number of limitations as well. The population of this study is not representative of the entire population, and the study uses data from digital tools developed by a single provider. However, the characteristics of the study population and the COVID-19 symptoms reported correspond with those in previous reports on digital health tools [11,20-22]. In addition, data on COVID-19 test status were based on self-reporting and may not accurately capture test results. Furthermore, the data are limited to individuals who used a tool for initial COVID-19 assessment. Tools enabling longitudinal logging and monitoring of symptoms can both provide additional utility to users and improve our understanding of disease progression and the time course of symptoms. Enabling users to provide unsolicited data on their experience may provide important insight as well, as

the self-assessment tool described focused on a predefined list of questions. Lastly, while we had data on the disposition of users who chose to consult with a remote physician, the disposition of individuals who did not consult with a remote physician following use of the automated tools is unknown. Research on health care use and health outcomes of digital health users is needed to conclusively demonstrate the utility of these services in assisting individuals with health decision-making and reducing the burden on the health system.

## Conclusion

This study describes the integration of three digital health tools for the direct management of COVID-19–related concerns. The results suggest that automated, data-driven digital solutions as well as remote care provided by a human physician can help provide health information and guidance during an epidemic. In addition, interactions across digital services can provide insight regarding the characteristics of new diseases. The integration of these tools can be an important resource for health care providers and policy makers.

## Acknowledgments

This study was funded by K Health Inc.

## Authors' Contributions

AP and AVZ contributed equally to the study. AVZ had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. AP, AVZ, MD, YV, EF, YS, YN, and DS conceived and designed the study. AP, AVZ, PB, MD, MLV, YV, HEJ, EF, YS, YN, YG, and DS acquired, analyzed, or interpreted the data. AP and AVZ drafted the manuscript. PB, MD, MLR, YV, HEJ, EF, YS, YS, YG, and DS critically revised the manuscript for important intellectual content. AVZ, PB, and YN performed the statistical analysis. YN, TG, and DS supervised the work.

## Conflicts of Interest

All authors are salaried employees or consultants at K Health Inc.

## Abstract

**Background:** In December 2019, the COVID-19 outbreak started in China and rapidly spread around the world. Lack of a vaccine or optimized intervention raised the importance of characterizing risk factors and symptoms for the early identification and successful treatment of patients with COVID-19.

**Objective:** This study aims to investigate and analyze biomedical literature and public social media data to understand the association of risk factors and symptoms with the various outcomes observed in patients with COVID-19.

**Methods:** Through semantic analysis, we collected 45 retrospective cohort studies, which evaluated 303 clinical and demographic variables across 13 different outcomes of patients with COVID-19, and 84,140 Twitter posts from 1036 COVID-19-positive users. Machine learning tools to extract biomedical information were introduced to identify mentions of uncommon or novel symptoms in tweets. We then examined and compared two data sets to expand our landscape of risk factors and symptoms related to COVID-19.

**Results:** From the biomedical literature, approximately 90% of clinical and demographic variables showed inconsistent associations with COVID-19 outcomes. Consensus analysis identified 72 risk factors that were specifically associated with individual outcomes. From the social media data, 51 symptoms were characterized and analyzed. By comparing social media data with biomedical literature, we identified 25 novel symptoms that were specifically mentioned in tweets but have been not previously well characterized. Furthermore, there were certain combinations of symptoms that were frequently mentioned together in social media.

**Conclusions:** Identified outcome-specific risk factors, symptoms, and combinations of symptoms may serve as surrogate indicators to identify patients with COVID-19 and predict their clinical outcomes in order to provide appropriate treatments.

## KEYWORDS

SARS-CoV-2; COVID-19; risk factor; symptom; diagnosis; treatment; biomedical literature; social media; Twitter; tweets

## Introduction

COVID-19 is an emerging infectious disease that has quickly spread worldwide. Since its outbreak in China in December 2019, over 4 million cases have been confirmed across more than 200 countries [1] (as of May 20, 2020), with the number of cases continuing to increase. Several studies have characterized possible symptoms (physical or mental features indicating a disease condition) and risk factors (variables

associated with an increased risk of disease) for patients infected with COVID-19 [2,3]. However, the majority of retrospective studies have been based on a single outcome from a single center and counted the number of aggregate cases [4], providing a scattered and incomplete picture of the risk factors for disease severity. Furthermore, uncharacterized or uncommon symptoms have made COVID-19 difficult to diagnose, making it difficult to provide appropriate treatment to patients. Lack of a vaccine or optimized treatment raises the importance of early and definitive diagnosis for this disease. Additionally, there are

limited hospital resources to triage patients based on symptoms to determine who is more or less likely to require intensive treatment (eg, intensive care unit [ICU] admission or intubation).

All of these uncertainties suggest there are urgent needs for a low-cost and efficient method of gathering COVID-19 symptom- and risk factor-related data as quickly as possible to reduce the medical and economic burden in our society. Instead of conducting time-consuming and costly clinical trials to examine patients, an alternative research avenue involves scraping public social media data to investigate potential risk factors of COVID-19 development. Social media provides an efficient method of gathering large amounts of representative data on the general public, in a cost-effective, scalable, and convenient manner any time of day, especially in remote or unattended regions. Here, we systematically investigated published biomedical literature to identify risk factors associated with outcomes of patients with COVID-19. We then gathered public Twitter data from COVID-19-positive users to expand the scientific literature and also examine rare or uncommon symptoms that were not previously well characterized.

## Methods

### Compiling Biomedical Literature on COVID-19, and Identifying Clinical and Demographic Variables

COVID-19 (COVID-19 Open Research Dataset) [5] was used to find biomedical literature on COVID-19. We compiled retrospective studies that investigated clinical and demographic variables in various outcomes of COVID-19. To do this, we collected literature published between January 2020 and March 2020. We then generated two sets of keywords. The first set of keywords represented cohort-based and retrospective studies, and comprised the following keywords: “epidemiological characteristics,” “clinical characteristics,” “risk factors,” “clinical features,” “cohort,” “clinical course,” “clinical findings,” “risk of death,” “pathological characteristics,” “retrospective,” and “mortality risk.” The second set represented COVID-19 (“novel coronavirus,” “coronavirus,” “COVID-19,” “SARS-COV-2,” “severe acute respiratory syndrome coronavirus 2,” “2019 novel coronavirus,” “2019-ncov,” and “coronavirus disease 2019”).

From the semantic analysis, we found 116 articles that contained both keywords and were likely to be relevant to our study. We next extracted 535 tables in those articles using Camelot [6] based on the notion that tables listed clinical and demographical variables, and their associated statistics. Articles without tabulated information ( $n=12$ ) were removed. After careful manual curation of tables, reported data, and article themselves, 45 studies were chosen (Table S1 in Multimedia Appendix 1). In total, 304 clinical and demographic variables were evaluated in 45 studies. They were composed of 92 comorbidities/complications, 49 treatments, 124 lab findings, 34 symptoms, and 4 demographic variables (age, sex, alcohol drinking history, and smoking history). Literature collection was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) guidelines (Figure S1 in Multimedia Appendix 1) [7].

### Association Between Clinical and Demographic Variables and Clinical Outcomes

To explore the consistency between individual variables and clinical outcomes, we defined three types of associations. Positive associations indicated that a variable in the outcome group had a hazard or odd ratio  $>1$ , or a higher value with statistical significance ( $P$  value  $<.05$ ) compared to the control group. In case a statistical test was not performed, we decided that there was a positive association when the outcome group had a 1.5-fold higher value than the control group. Negative association indicated that a variable in the outcome group had a hazard or odd ratio  $<1$ , or a lower value with statistical significance ( $P$  value  $<.05$ ) compared to the control group. In case a statistical test was not performed, we decided that there was a negative association when the outcome group had a 1.5-fold lower value than the control group. When there was no significant change between the outcome group and the control group, the variable and clinical outcomes were assigned a “no association” designation. In terms of sex, when there were more males compared to females, we assumed there was a positive association with an outcome based on the case studies of sex and age of patients with COVID-19 in Italy [8] and New York City [9] (as of April 14, 2020). To identify outcome-specific risk factors in biomedical literature, we performed consensus analysis. Risk factors were the variables associated with an increased risk of disease or infection. Seven outcomes, which were studied at least twice, and 107 variables tested two or more times in studies were used for further analyses. Clinical and demographic variables with positive associations in  $>50\%$  of studies, which investigated the same output, were defined as outcome-specific risk factors.

### Compiling Social Media Data and Identifying Symptoms of COVID-19-Positive Users

Twitter was used as the social media source. To identify COVID-19-positive users, we first collected users who used one of these phrases: “my positive COVID test,” “my positive COVID diagnosis,” “I am positive for COVID,” “I tested positive for COVID,” and “I have COVID-19” in their original tweets between January 2020 and March 2020. In total, 1036 users were identified as self-identified patients with COVID-19. We then collected additional tweets generated 14 days before and 14 days after the original tweets mentioning users’ COVID-19 status ( $n=84,140$  tweets). To identify symptoms that were mentioned in tweets, we applied two symptom extraction methods. The Amazon Comprehend Medical tool [10] was applied to an entire set of tweets. Symptoms were physical or mental features indicating a disease condition. We considered two medical entities (symptoms and signs) as symptoms that users mentioned. We also implemented a symptom extraction model using Scispacy, version 0.2.4 (Python Software Foundation). Scispacy can handle scientific document and extracts medical and clinical terminology [11]. The model was trained on publicly available, domain-specific corpus of medical notes, which consists of 1500 PubMed articles with over 10,000 disease and related chemical terms. The model identifies medical name entities in tweet texts. We considered the medical entity “disease” as a symptom that users mentioned. In total, 51

symptoms from 574 COVID-19–positive users were identified from both symptom identification methods.

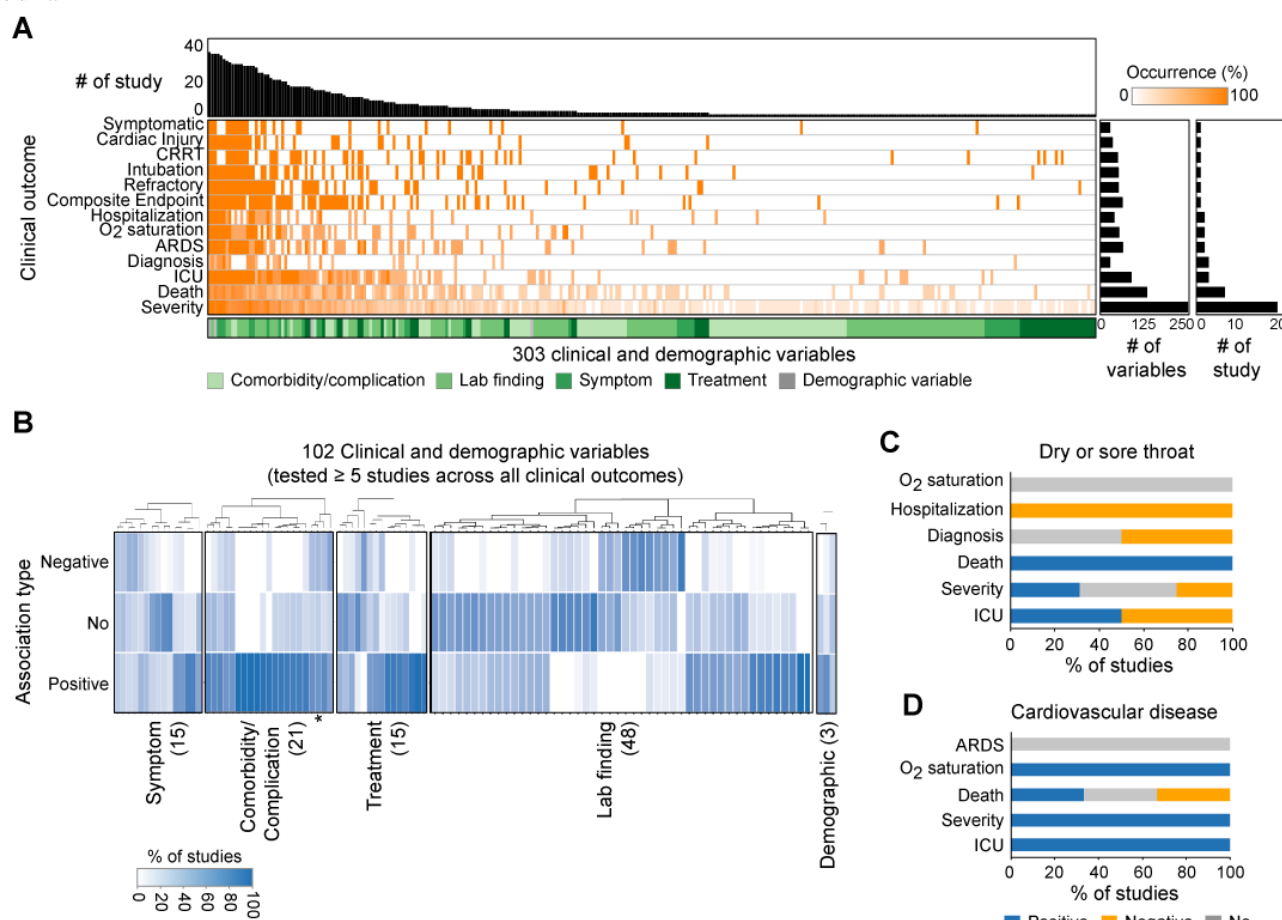

## Results

### Landscape of Clinical and Demographic Variables of COVID-19 in Biomedical Literature

To understand the clinical and demographic properties of COVID-19, we performed a meta-analysis of 45 recently published biomedical studies (Figure 1A, and Table S1 in Multimedia Appendix 1). The literature evaluated 299 clinical variables (92 comorbidities/complications, 124 laboratory findings, 49 treatment options, and 34 symptoms) and 4 demographic variables (age, sex, alcohol drinking history, and smoking history) in 13 clinical outcomes. Seven outcomes (disease severity, death, ICU admission, diagnosis, acute

respiratory distress syndrome [ARDS], O<sub>2</sub> saturation, and hospitalization) were studied at least twice (Figure 1). On average, each study examined 72 variables, and 102 variables were assessed in at least five studies. Age and sex were measured in more than 80% of the studies. Diabetes and hypertension were the most commonly measured comorbidities (>50% of studies). Fever, cough, myalgia/fatigue, chest tightness/dyspnea, diarrhea, and headache/dizziness were the most commonly measured symptoms (>50% of studies). Eleven laboratory test values that measured liver and kidney function (eg, alanine aminotransferase and aspartate aminotransferase) and hematologic index (eg, lymphocytes, platelets, and neutrophils) were examined in >50% of studies. Therapy involving antiviral agents, antibiotics, and oxygen inhalation were used in more than 30% of the studies (Table S2 in Multimedia Appendix 1).

**Figure 1.** Properties of clinical and demographic variables of COVID-19. (A) Landscape of clinical and demographic variables. (B) Association between variables and overall clinical outcomes. Number of variables tested in  $\geq 5$  studies appears in brackets. Asterisk indicated association types of cancer. (C) and (D) Association types of clinical outcomes of COVID-19; association types of (C) dry or sore throat and (D) cardiovascular disease depending on different clinical outcomes were shown. CRRT: continuous renal replacement therapy; ARDS: acute respiratory distress syndrome; ICU: intensive care unit.

We next investigated the association between identified variables and clinical outcomes of patients with COVID-19. We considered 102 frequently tested variables ( $\geq 5$  studies), and examined the proportion of studies that showed positive, negative, and no associations between clinical outcomes and a given variable (Table S3 in Multimedia Appendix 1). Positive associations indicated higher values (eg, disease severity increases as patients get older), while negative associations

indicated lower values (eg, disease severity increases as basophil count decreases) of variables associated with clinical outcomes (see Methods for details). A no-association designation indicated there was no relation between variables and outcomes.

We found that the majority of variables ( $n=95$ , 93%) had inconsistent associations across clinical outcomes showing mixed association types (Figure 1B). Of those, 46 (45%) variables had all three types of associations. For example, cancer

showed positive, negative, and no associations in 58% (n=11), 26% (n=3), and 16% (n=5) of studies, respectively (marked with an asterisk in [Figure 1B](#)). In total, 43% (9/21) of comorbidity/complication, 40% (6/15) of treatment, and 73% (11/15) of symptom variables showed all three types of associations. Laboratory findings showed relatively more consistent associations with clinical outcomes: 38% (18/48) of variables showed all association types. Furthermore, we found that variables had unique association types depending on different clinical outcomes. Dry or sore throat, one known symptom of COVID-19, showed positive, negative, and no associations in death, hospitalization, and O<sub>2</sub> saturation, respectively ([Figure 1C](#)). Meanwhile, it showed mixed associations with other clinical outcomes, such as disease severity, ICU admission, and diagnosis. Cardiovascular disease, one common comorbidity of COVID-19, showed mixed associations in death, positive association with ICU and disease severity, but no association with ARDS ([Figure 1D](#)).

### Consensus Identification of Outcome-Specific Clinical and Demographic Variables

According to biomedical literature at the time of publication, there were no effective treatment options, or well-identified symptoms, comorbidities, and lab findings to predict outcomes of COVID-19. Therefore, it seemed relevant to find a set of clinical and demographic variables that were specific for individual outcomes for better guidance on disease detection, treatment, and control. To generalize the importance of clinical and demographic variables, a consensus (level of agreement) analysis was performed. We collected 107 variables that were

tested at least twice in a given outcome and defined them as outcome-specific risk factors when they showed positive associations with a given outcome in more than half of studies ([Figure 2](#), and Table S4 in [Multimedia Appendix 1](#)). In total, we characterized 72 outcome-specific risk factors from the literature. As shown in [Figure 2A](#), different sets of variables were specifically associated with individual outcomes. Arrhythmia, thyroid disease (comorbidity/complication), confusion/fluster, tonsil swelling, enlargement of lymph nodes/sinus (symptom), and levels of interleukin (IL)-10 and N-terminal pro-brain natriuretic peptide (NT-proBNP; lab finding) were specifically associated with the severity of disease progression. Level of prothrombin time was a specific risk factor for ICU admission. For death, Sequential Organ Failure Assessment (SOFA) score (lab finding) and anemia (symptom) showed positive associations. Fever was specifically associated with O<sub>2</sub> saturation. We also observed 15 variables that were associated with several clinical outcomes ( $\geq 3$  outcomes; [Figure 2B](#)). Age was a risk factor for ARDS, disease severity, death, ICU admission, and O<sub>2</sub> saturation, but not for diagnosis and hospitalization. Sex (male) was a specific variable for ARDS, disease severity, death, and ICU admission. Three lab findings (D-dimer, C reactive protein, and lactate dehydrogenase) were specifically associated with four outcomes. Diabetes and hypertension (comorbidity/complication) were specific risk factors for disease severity and death. Identified outcome-specific variables could be surrogate risk factors to identify patients with COVID-19 and determine their treatment options.

**Figure 2.** Consensus identification of outcome-specific clinical and demographic variables. (A) Outcome-specific clinical and demographic variables in a given outcome of COVID-19. Variables that were only specific for one clinical outcome were shown in the red-dashed box. Clinical and demographic variables that were specific for at least three outcomes are presented in (B). Blue coloring indicates identified outcome-specific variables (risk factors). ICU: SOFA: Sequential Organ Failure Assessment; ARDS: acute respiratory distress syndrome; IL-10: interleukin 10; NT-proBNP: N-terminal pro-brain natriuretic peptide.

### Expanding the COVID-19 Symptom Landscape and Identifying Novel Symptoms Using Social Media

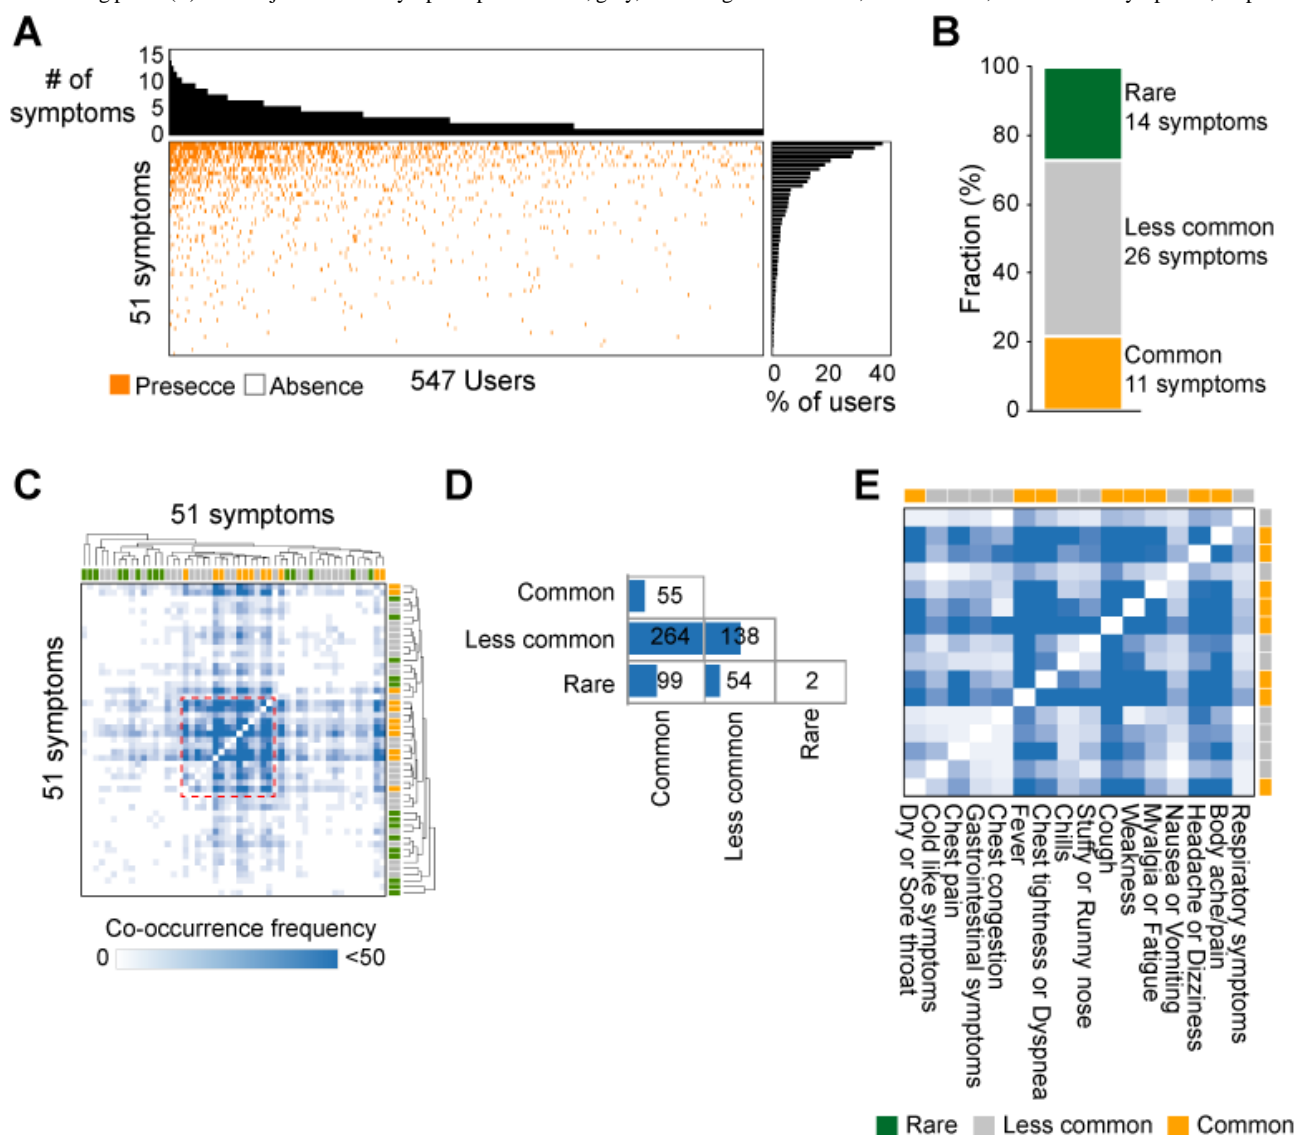

Early identification of symptoms is important for the successful treatment of disease [12]. Although COVID-19 showed heterogeneous and uncharacterized symptoms, a limited number of symptoms known to be associated with infectious diseases, such as fever, cough, and fatigue, were considered in the biomedical literature. Social media can provide rapid and efficient surveillance of disease risk and outbreaks [13,14]. Therefore, we decided to expand the symptom landscape by

integrating social media data with biomedical literature. We first identified 1036 twitter users who introduced themselves as COVID-19–positive patients, and selected 574 users (55%) who openly and voluntarily discussed their COVID-19 symptoms (see Methods for details). In total, 51 symptoms were identified in social media data (Figure 3A, and Table S5 in Multimedia Appendix 1). On average, individual users mentioned 3 different symptoms (range 1–15). We grouped 51 symptoms into three categories based on their frequency of mention (Figure 3B). Common symptoms (n=11) were mentioned by >10% of users. Many were nonspecific symptoms

of respiratory infections, such as fever, cough, and chest tightness/dyspnea (Table S5 in [Multimedia Appendix 1](#)). However, 14 symptoms were potentially COVID-19-specific and rarely reported in social media (ie, in <1% of users). Sputum, dehydration, anemia, urination problem, hair loss, enlargement of lymph nodes or sinus, and oral problems (eg, abrasions in mouth, mouth ulcers, sensitive teeth, toothache, and dry mouth) were defined as rare symptoms. In all, 26 symptoms were observed in 1% to 10% of users (less common). They included chills, chest pain, gastrointestinal symptoms, arthritis, anorexia, allergy-like symptoms, dyssomnias, ear- and eye-related problems, and skin problems such as blister, dry skin, chapped lips, rash, and itching. We next examined the symptoms that were mentioned together in social media ([Figure 3C](#)). We identified 612 co-occurring symptom pairs (Table S6 in [Multimedia Appendix 1](#)). In total, 264 (43%) symptoms ranged from common to less common ([Figure 3D](#)). One major

cluster of symptoms was frequently mentioned together ([Figure 3E](#)). They were composed of 8 common symptoms, such as dry or sore throat, fever, chest tightness/dyspnea, cough, weakness, myalgia/fatigue, headache/dizziness, and body ache/pain (eg, neck and back pain and general body ache), and 8 less common symptoms, such as cold-like symptoms, chest pain and congestion, gastrointestinal symptoms, chills, stuffy or runny nose, nausea/vomiting, and respiratory symptoms such as lung pain. In total, 99 (16%) pairs were between common symptoms and rare symptoms. Cough, fever, headache/dizziness and body ache/pain (common symptoms) co-occurred with sputum, dehydration, and anemia at least 10 times (Table S6 in [Multimedia Appendix 1](#)). There were also two pairs of rare symptoms ([Figure 3D](#)): anemia-weight gain and anemia-urination problems (eg, urinary retention and weakened bladder).

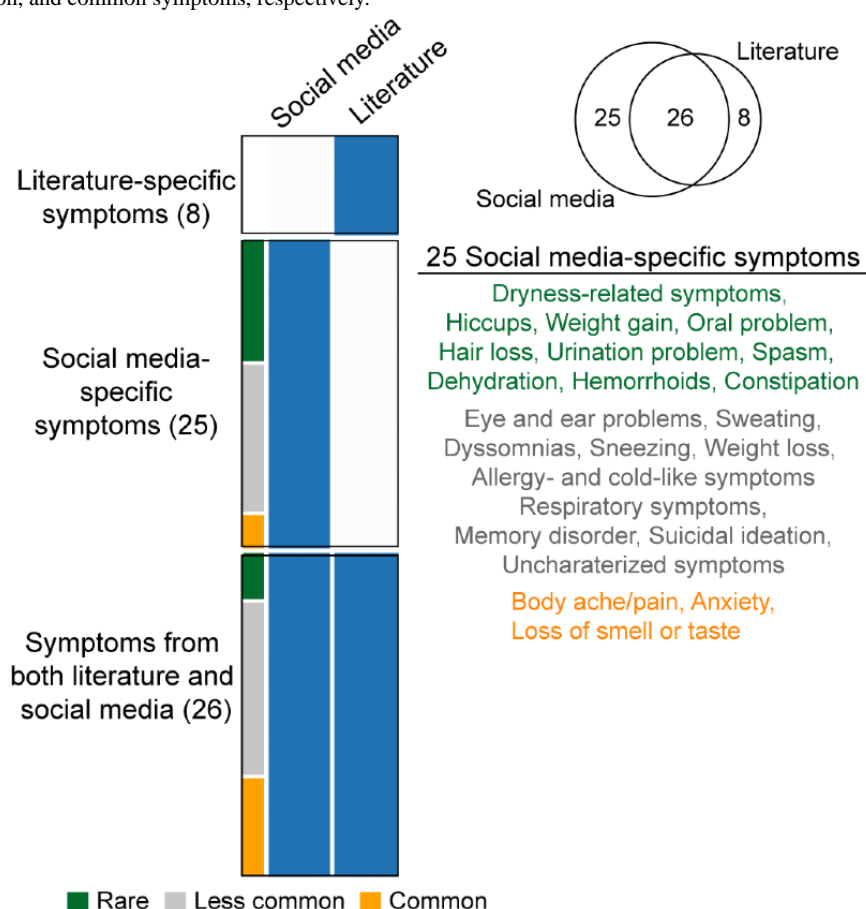

**Figure 3.** COVID-19-related symptoms extracted from social media data. (A) Landscape of symptoms identified from social media data. Orange and white indicate the presence and absence of symptoms in a given user, respectively. (B) Fraction of common, less common, and rare symptoms. Common symptoms were mentioned from >10% of users, and rare symptoms were mentioned from <1% of users. (C) Co-occurrence of symptoms. One major cluster was shown in the red-dashed box. (D) Number of symptoms pairs depending on mentioning frequency. Blue bars (bottom) indicate the number of co-occurring pairs. (E) One major cluster of symptom pairs. Green, gray, and orange indicate rare, less common, and common symptoms, respectively.

Finally, we identified novel symptoms potentially related to COVID-19. We first extended the repertoire of symptoms by integrating social media data with biomedical literature. In total, 59 symptoms were identified (Figure 4, and Table S7 in Multimedia Appendix 1). Indeed, social media identified more symptoms ( $n=51$ ) than the literature ( $n=34$ ), and most symptoms (26/34, 76%) in the literature were equally observed in social media. Interestingly, 25 (42%) were novel symptoms that were only mentioned in social media and were not considered in the literature. Loss of smell or taste, and body ache/pain were frequently mentioned common symptoms in social media. Problems involving eyes (eg, dry eye and eye pain) and ears

(eg, ear pain and earache), sweating, sneezing, and allergy-like symptoms were mentioned at a moderate frequency only in social media. Of 14 rare symptoms, 10 were only observed in social media: dehydration, dryness-related symptoms (eg, feeling dry), oral problem, hair loss, urination problem, spasm, hemorrhoids, constipation, hiccups, and weight gain. These social media-specific rare symptoms would be potential novel symptoms for COVID-19, when we considered that 4 rare symptoms (ie, abdominal pain, anemia, sputum, and enlargement of lymph nodes or sinus) were already evaluated in the literature (Figure 4).

**Figure 4.** Identification of novel symptoms of COVID-19, and comparison of symptoms between biomedical literature and social media data. Symptoms that were observed in the literature or social media are colored in blue; 25 social media-specific symptoms are presented. Green, gray, and orange indicated rare, less common, and common symptoms, respectively.

## Discussion

### Principal Findings

Our meta-analysis based on biomedical literature showed the inconsistency of clinical and demographic variables across clinical outcomes. From the consensus analysis, we identified outcome-specific risk factors that may be helpful to identify patients and predict their specific clinical outcomes. Social media data expanded the repertoire of COVID-19 symptoms from biomedical literature. In addition to more commonly reported symptoms, social media data revealed loss of smell or taste, body ache/pain, and back/neck pain, as well as other less common and rare symptoms such as urination problems, dehydration, allergy-like symptom, and ear- and eye-related

problems. Indeed, loss of smell or taste was recently proposed as one of the key features of a COVID-19 diagnosis model [15], and body ache/pain was suggested by the Centers for Disease Control and Prevention. COVID-19 is an ongoing health problem, and the symptoms that medical institutes and ordinary people should consider will be evolving as more studies are published and social media data are explored. This evolution may help improve the definitions of symptom types (common, less common, and rare symptoms) and social media-specific symptoms.

From social media data, we observed that certain combinations of symptoms were frequently observed among patients with COVID-19. Interestingly, we identified two pairs composed of rare symptoms (anemia-weight gain and anemia-urination

problems, such as urination retention and weakened bladder). It has been shown that COVID-19 attacks hemoglobin in red blood cells and restricts oxygen transportation [16]. A persistent reduction of oxygen transportation leads to the development of anemia [17]. Urinary bladder is enriched with ACE2 positive cells and proposed as a target organ for COVID-19 invasion [18]. Our results highlighted that symptom combinations could guide the reliable identification of patients with COVID-19 rather than a single common symptom that may result in false positives.

### Limitations and Future Work

One of the limitations of our study is the self-reported nature of social media data and the lack of more detailed information from the patients. We observed that 55% of social media users who were self-identified patients with COVID-19 mentioned symptoms, and an additional 8% mentioned potential comorbidities. Thus, only 63% of social media users communicated information on COVID-19 conditions, which means that at least 37% of users could be either false positives (they were not COVID-19-positive users) or asymptomatic patients. Alternatively, it is possible that we have not captured all COVID-19-positive patients in our social media collection due to the limited amount of keyword searches. Nevertheless, various studies have indicated that between 4% and 78% of all COVID-19-positive patients were asymptomatic [19], and this seems to vary widely based on age of patients, test location, and time of testing after infection [20-23]. Thus, our research is in line with other studies demonstrating the vast range of patients with COVID-19 who show or report no symptoms. It should also be noted that Twitter was the source of the social media data we examined, and perhaps more symptoms would be discovered if we analyzed other sources. Twitter does have a wide, representative user base around the world, and provides open source information that can be easily gathered, but future research could examine alternate social media sources.

Although social media may lack depth of patient information, it provides an effective method of collecting breadth of data. Social media data can be gathered noninvasively across the world, 24 hours a day, and is an extremely efficient method [24] for rapidly disseminating new knowledge related to COVID-19. In other words, clinicians and scientists can collect new patient information from various regional locations, as well as quickly circulate public service announcements for a wide range of audiences. Social media hubs provide a useful alternate source of patient data to explore clinical characteristics of various disease states and populations.

Another limitation of our research involves the limited number of available biomedical studies on individual outcomes. Of the 13 reported clinical outcomes for COVID-19, 7 were studied at least two times, limiting opportunities to perform more systematic and consensus analyses of the landscape of risk factors and symptoms. In fact, we observed there was no significant risk factors associated with diagnosis and hospitalization indicating the current lack of clinical understanding at the early stage of COVID-19. Use of additional literature that will be published in the future and electronic health record studies [25] may refine the assessment of risk factors and symptoms, and increase the accuracy of patient identification for different clinical outcomes.

### Conclusion

In this meta-data study, we demonstrated the extensive variability present in clinical and demographic variables across COVID-19 outcomes, and the usefulness of gathering social media data as an effective and alternative way to uncover less common or other types of symptoms that have not been previously reported. Our findings show the practicality and feasibility of employing social media data for investigating new disease states. These practices could be incorporated into routine procedures for early COVID-19 identification and determination of clinical outcomes, in order to provide appropriate interventions and treatments.

### Acknowledgments

We would like to thank all members of the Klick Applied Sciences team for their helpful advice and assistance. We especially thank Maheedhar Kolla, Jeremy J Jurksztowicz, JJ Mifsud, and Michael Lieberman for technical support and scientific advice for the study.

### Authors' Contributions

JJ and GB designed the study. JJ, GB, and SS collected the data. JJ and AP analyzed the data. JJ interpreted the data and wrote the manuscript with contributions from AP. All authors revised the manuscript and contributed to the final review and editing, and have approved the final manuscript. This research was internally funded and received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

### Conflicts of Interest

None declared.

## Abstract

**Background:** The COVID-19 outbreak has affected people's health worldwide. For college students, web-based physical education is a challenge, as these course are normally offered outdoors.

**Objective:** The aim of this study was to use data from a web-based survey to evaluate the relationship between the mental health status of college students and their sports-related lifestyles. Problems related to web-based physical education were also examined.

**Methods:** A web-based survey was conducted by snowball sampling from May 8 to 11, 2020. Demographic data, mental health status, and sports-related lifestyles of college students in Wuhan as well as issues related to web-based physical education were collected. Mental health status was assessed by the Depression, Anxiety, and Stress Scale (DASS-21).

**Results:** The study included 1607 respondents from 267 cities. The average scores of the DASS-21 subscales (2.46 for depression, 1.48 for anxiety, and 2.59 for stress) were significantly lower in our study than in a previous study ( $P<.05$ ). Lower DASS-21 scores were significantly correlated with regular exercise, maintaining exercise habits during the outbreak of COVID-19, exercising more than 1 to 2 times a week, exercise duration  $>1$  hour, and  $>2000$  pedometer steps (all  $P<.05$ ). None of the three forms of web-based physical education was preferred by more than 50% of respondents. Frequent technical problems were confronted by 1087/1607 students (67.6%). Shape-up exercises (846/1607, 52.6%), a designed combination of exercises (710/1607, 44.2%), and Chinese kung fu (559/1607, 34.8%) were suggested sports for web-based physical education.

**Conclusions:** Mental status was significantly correlated with regular exercise and sufficient exercise duration. Professional physical guidance is needed for college students in selected sports. Exercises not meeting students' preferences, frequent technical problems, and the distant interaction involved in web-based physical education were the main problems that should be solved in future.

## Introduction

In December 2019, a novel coronavirus, SARS-CoV-2, was first recognized in Wuhan and then quickly spread worldwide, infecting millions of people [1]. Furthermore, uninfected people were also greatly affected and were required to adopt a totally different lifestyle because of quarantine in Wuhan [2]. Many basic necessities of living, as well as education, were transferred to the internet [3,4]. Web-based education was not new in many fields [5]; however, it is novel in sports education, which requires essential interaction between teachers and students.

Previous studies have stated that mental illness symptoms are common among university students according to the Depression, Anxiety, and Stress Scale (DASS-21) [6,7]. Dogra's study [8] described that vigorous physical activity is associated with lower possibility of poor mental health and depressive symptoms. As physical education plays an important role in relieving pressure not only on the body but also on the mind [9], it is particularly essential during the pandemic [10]. According to a report by the United Nations Educational Scientific and Cultural Organization (UNESCO), more than 160 countries have shut down schools [11]; therefore, web-based physical education is an issue that most countries must face. It has been reported that SARS-CoV-2 will coexist with humans for a long time [12], which suggests that web-based physical education could last for a relatively long time in the future. A recent scientometric analysis reviewed research topics related to COVID-19; however, the impact of COVID-19 on physical education was not researched [13].

Since February, web-based physical education, which is the only choice in a quarantined city, has been adopted by many universities and colleges in Wuhan [14]. Whether the web-based physical education was efficient or a waste of time may be reflected by the mental and physical state of students. Several studies have reported the mental state of the general population, medical staff, or college students during the peak of the COVID-19 epidemic; these studies have proved the existence of anxiety, depression, and stress in different populations [15-18]. However, as far as we know, no report has evaluated the mental and physical state of students in universities and colleges in Wuhan after the implementation of web-based physical education.

As a newly developed mode of physical education, web-based physical education presents challenges and opportunities. Because of the characteristics of physical education, suitable sports should be chosen while considering the restrictions of sports fields and related equipment. Also, the performance of network platforms and teaching resources for web-based physical education remains a question. Furthermore, the extended effects of web-based physical education on family members when the activities are performed at home is a concern, which may be related to the similar atmosphere to class learning.

Therefore, the primary aim of our study is to describe the association between the mental health and physical activity of students in Wuhan universities and colleges after a 3-month web-based physical education program. The secondary aim of our study is to identify the problems that students encountered

during the web-based study, and we hope that these problems can be solved by educators in the near future.

## Methods

### Study Design and Study Population

This cross-sectional study was conducted from May 8 to 11, 2020. A snowball strategy was employed to recruit students in Wuhan universities and colleges after a 3-month web-based physical education program.

### Procedure

To minimize face-to-face interactions as recommended by the Chinese government, an anonymous questionnaire was completed through a web-based survey platform (SurveyStar, Changsha Ranxing Science and Technology). The web-based survey was first disseminated by teachers to students through the educational platform, and the students were encouraged to spread it to other students. This study was approved by the institutional review board of Wuhan Children's Hospital (WHCH 2020029). Informed consent was requested at the very beginning of this web-based survey, and informed consent was provided by all the respondents.

### Measurements and Outcomes

A structured questionnaire was employed to evaluate the mental health status and sports-related lifestyles of students in Wuhan universities and colleges as well as their issues related to web-based physical education. There were 45 items included in the questionnaire, and approximately 6 minutes were required to complete it.

Demographic data included gender, age, grade, residential location, and BMI, which was calculated as weight in kilograms divided by height in meters squared. The categorization of BMI was based on reference data for Chinese people ( $BMI < 18.5$ ,  $18.5 \leq BMI < 23$ ,  $23 \leq BMI < 26$ ,  $26 \leq BMI$ ) [19]. The mental health status of students was evaluated by the DASS-21, which consists of depression, anxiety, and stress subscales [20]. Sports-related lifestyle variables included exercise habits, changes in weight, frequency and duration of exercise, preferred sports, pedometer steps, and access to sports facilities. The minimal amount of weight to indicate weight loss or weight increase was 3 kg. The average number of pedometer steps was calculated as the average number of steps taken per day during the past month according to a mobile phone app, WeChat (Tencent). There was no control for other physical activities or exercises performed in addition to web-based physical education. Variables for characteristics of web-based physical education included different exercise classes offered, frequency of web-based physical education, influence on other family members which may be related to the similar atmosphere to class learning, problems confronted, and suggested sports for web-based physical education.

In addition to the total score of the DASS-21 scale, the scores of the three subscales were calculated as follows [15]: the depression subscale consisted of questions 3, 5, 10, 13, 16, 17, and 21, classified into normal (0-9), mild depression (10-12), moderate depression (13-20), severe depression (21-27), and

extremely severe depression (28-42); the anxiety subscale consisted of questions 2, 4, 7, 9, 15, 19, and 20, classified into normal (0-6), mild anxiety (7-9), moderate anxiety (10-14), severe anxiety (15-19), and extremely severe anxiety (20-42); the stress subscale consisted of questions 1, 6, 8, 11, 12, 14, and 18, classified into normal (0-10), mild stress (11-18), moderate stress (19-26), severe stress (27-34), and extremely severe stress (35-42).

### Statistical Analysis

Respondents who did not complete the questionnaire were not included in our study; we deleted the respondents with missing data. Descriptive statistics were employed for categorical variables, including demographic data, sports-related lifestyle, and issues related to web-based physical education. Each categorical variable was presented as the percentage of responses to the corresponding question, which was calculated by dividing the number of respondents per response by the number of total responses to the question. The scores of the DASS-21 scale and its subscales were expressed as mean (SD) as well as median (IQR). The Cronbach alpha values of the reliability of the DASS-21 and its subscales were calculated as a measure of internal consistency. We performed a descriptive comparison of the mean scores of the subscales of the DASS-21 between our study and Wang's first study [15], which described the mental health state of the general population during the peak of the COVID-19 epidemic. Linear regressions were used to

analyze the univariate associations between sports-related lifestyle variables and the DASS-21 scales. All the tests were two-tailed, with a significance level of  $P < .05$ . Statistical analysis was performed using SPSS 19.0 (IBM Corporation).

## Results

### Survey Respondents

A total of 1673 surveys were received; as 66 respondents did not complete the questionnaire, we included 1607 (96.1%) respondents from 267 cities in the study. Questionnaires were received on the first day (May 8) from 292 respondents, on the second day (May 9) from 1130 respondents, on the third day (May 10) from 130 respondents, and on the fourth day (May 11) from 55 respondents.

### Demographic Data

The demographic features of all the students in our study are shown in Table 1. Most respondents were male (1041/1607, 64.8%) and were aged 18 to 22 years (1573/1607, 97.9%). Most of the students were freshmen or sophomores (1524/1607, 94.8%), and urban areas (723, 45%) were the most common place of residence of the college students. The BMI values of most of the 1607 college students were in the normal range (969, 60.3%), while the BMI values of 638 respondents (39.7%) were out of the normal range.

**Table 1.** The demographic characteristics of the respondents (N=1607), n (%).

Demographic characteristic	Value
<b>Gender</b>	
Male	1041 (64.8)
Female	566 (35.2)
<b>Age (years)</b>	
<18	20 (1.2)
18-22	1573 (97.9)
>22	14 (0.9)
<b>Grade</b>	
Freshman	784 (48.8)
Sophomore	740 (46.0)
Junior	70 (4.4)
Senior	13 (0.8)
<b>Place of residence</b>	
Urban	723 (45.0)
Rural-urban	431 (26.8)
Rural	453 (28.2)
<b>BMI, kg/m<sup>2</sup></b>	
<18.5	275 (17.1)
18.5-22	969 (60.3)
23-25	231 (14.4)
≥26	132 (8.2)

## Mental Health Status

The respondents' mental health status was measured by the DASS-21 scale. The mean (SD) of the total DASS-21 score was 6.52 (7.86). The mean (SD) values of the depression, anxiety, and stress subscales were 2.46 (3.02), 1.48 (2.35), and 2.59 (3.09), respectively. The median (IQR) of the total score on the DASS-21 was 4 (1-10). The median (IQR) values of the depression, anxiety, and stress subscales were 1 (0-4), 0 (0-2), and 1 (0-4), respectively. The comparison between the mean

(SD) values in our study and Wang's study [15] is as follows: for the depression subscale, 2.46 (3.02) versus 6.25 (7.16); for the anxiety subscale, 1.48 (2.35) versus 6.16 (6.57); for the stress subscale, 2.59 (3.09) versus 7.76 (7.74). The classification of responses in the different groups for the depression, anxiety, and stress subscales are shown in Table 2. The Cronbach alpha value of the reliability of the DASS-21 was .94, and the Cronbach alpha values for the depression, anxiety, and stress subscales were .84, .85, and .86, separately.

**Table 2.** Classification of responses to the depression, anxiety, and stress subscales of the DASS-21 (N=1607), n (%).

DASS-21 <sup>a</sup> subscale	Normal	Mild	Moderate	Severe	Extremely severe
Depression	1551 (96.5)	36 (2.2)	19 (1.2)	1 (0.1)	0 (0.0)
Anxiety	1519 (94.5)	71 (4.4)	14 (0.9)	2 (0.1)	1 (0.1)
Stress	1574 (97.9)	30 (1.9)	3 (0.2)	0 (0.0)	0 (0.0)

<sup>a</sup>DASS-21: Depression, Anxiety, and Stress Scale.

## Sports-Related Lifestyle and Exercise Status

The sports-related lifestyle variables of the college students who responded to the survey are shown in Table 3. Although most of the 1607 students (1088, 67.7%) exercised regularly, 1279 (79.6%) of the students were disturbed by the outbreak of

COVID-19 and spent less time on sports (826, 51.4%) and/or gained weight (592, 36.8%). Exercising <3 times a week was observed in 1010/1607 students (62.9%), and <2000 average pedometer steps were observed in 1155/1607 students (71.9%). Restrictions on access to sports facilities were experienced by 1198/1607 students (74.5%).

**Table 3.** Sports-related lifestyle variables of the survey respondents after the outbreak of COVID-19 (N=1607), n (%).

Sports-related lifestyle variable	Value
<b>Regular exercise<sup>a</sup></b>	
Yes	1088 (67.7)
No	519 (32.3)
<b>Negative influence of COVID-19 on exercise habits</b>	
No, exercise habits were maintained	328 (20.4)
Yes, but only slightly	889 (55.3)
Yes, it has a great impact on my exercise habits	390 (24.3)
<b>Time spent on sports after the outbreak of COVID-19<sup>b</sup></b>	
Less	826 (51.4)
Same	460 (28.6)
More	321 (20.0)
<b>Weight change after the outbreak of COVID-19<sup>c</sup></b>	
Less	321 (20.0)
Same	694 (43.2)
More	592 (36.8)
<b>Frequency of exercise</b>	
Occasionally or never	549 (34.2)
1 to 2 times per week	461 (28.7)
≥3 times per week	377 (23.4)
Every day	220 (13.7)
<b>Average duration of exercise performed in a week (hours)</b>	
<1	1253 (78.0)
>1	354 (22.0)
<b>Favorite sport after the outbreak of COVID-19</b>	
High-intensity interval training	119 (7.4)
Shape-up exercises	200 (12.4)
Strength training	312 (19.4)

Walking	665 (41.4)
Body combat	23 (1.4)
<b>Average pedometer steps<sup>d</sup></b>	
0-500	413 (25.7)
501-2000	742 (46.2)
2001-4000	224 (13.9)
>4000	228 (14.2)
<b>Restricted access to sports facilities</b>	
Yes	1198 (74.5)
No	409 (25.5)

<sup>a</sup>Exercising regularly was defined as ≥3 times a week and ≥60 minutes each time.

<sup>b</sup>Time spent on sports was defined as time spent on all types of sports, including web-based physical education.

<sup>c</sup>The minimum amount of weight to indicate weight loss or weight increase was 3 kilograms.

<sup>d</sup>The average number of pedometer steps was calculated as the average number of steps taken per day during the past month according to the WeChat mobile phone app.

The differences in the association between sports-related lifestyle variables and the scores of the DASS-21 and its subscales are represented in Table 4. The respondents who exercised regularly had lower scores on the DASS-21 and all its subscales (for depression,  $B=-1.257$ ,  $t=-7.962$ ,  $P<.001$ ; for anxiety,  $B=-0.700$ ,  $t=-5.636$ ,  $P<.001$ ; for stress,  $B=-1.013$ ,  $t=-6.211$ ,  $P<.001$ ; for total score,  $B=-2.969$ ,  $t=-7.197$ ,  $P<.001$ ), as well as the respondents who maintained their exercise habits during the outbreak (for depression,  $B=-2.017$ ,  $t=-9.171$ ,  $P<.001$ ; for anxiety,  $B=-1.211$ ,  $t=-6.988$ ,  $P<.001$ ; for stress,  $B=-2.198$ ,  $t=-9.788$ ,  $P<.001$ ; for total score,  $B=-5.427$ ,  $t=-9.491$ ,  $P<.001$ ) or were influenced little by the outbreak (for depression,  $B=-1.301$ ,  $t=-7.299$ ,  $P<.001$ ; for anxiety,  $B=-0.783$ ,  $t=-5.572$ ,  $P<.001$ ; for stress,  $B=-1.446$ ,  $t=-7.941$ ,  $P<.001$ ; for total score,  $B=-3.530$ ,  $t=-7.616$ ,  $P<.001$ ). The respondents who exercised more than 1 to 2 times a week demonstrated significantly lower scores on the DASS-21 and all its subscales compared to respondents who exercised occasionally, with all  $P<.05$ . The respondents who exercised  $>1$  hour had lower total scores ( $B=-1.350$ ,  $t=-2.861$ ,  $P=.004$ ) and lower scores on the depression ( $B=-0.588$ ,  $t=-3.248$ ,  $P=.001$ ) and stress ( $B=-0.503$ ,  $t=-2.708$ ,  $P=.007$ ) subscales of the DASS-21 compared to respondents who exercised  $<1$  hour. Respondents with  $>2000$  average pedometer steps had significantly lower scores on the

DASS-21 and all its subscales compared to respondents with  $<599$  average steps, with all  $P<.05$ .

### Issues of Web-Based Physical Education

Three main modes of web-based physical education were adopted by universities and colleges in Wuhan. Interaction between teachers and students was the most common mode (1056/1607, 65.7%). Moreover, this was the only mode in which students could interact with the teacher; the other two modes involved unilateral teaching. Web-based physical education was accessed once per week or less by 1256/1607 students (78.2%). Surprisingly, the family members of 728/1607 students (45.3%) were motivated to exercise because of web-based physical education. Many problems arose during web-based physical education, which were confronted by 1087/1607 students (67.6%). Considering convenience and availability, the respondents suggested that shape-up exercises, designed combinations of exercise by teachers for a specific purpose, and Chinese kung fu were suitable sports for web-based physical education. Here, the designed combinations of exercise were combinations of various physical education exercises that were designed by teachers, such as a combination of shape-up exercises and Chinese kung fu. Detailed information is summarized in Table 5.

**Table 4.** Associations between sports-related lifestyle variables and scores on the DASS-21 and its subscales (N=1607).

Sports-related lifestyle variable	Depression subscale score			Anxiety subscale score			Stress subscale score			Total DASS-21 <sup>a</sup> score

## Discussion

### Principal Findings

The main purposes of our study were to determine the mental status of college students using the DASS-21 after 3 months of web-based physical education and to evaluate the relationship of the students' mental health status with their sports-related lifestyle. A web-based survey was employed to collect related information. The results showed that the average scores on the DASS-21 subscales were significantly lower than in a previous study. Lower DASS-21 scores were significantly correlated with positive sports-related lifestyle. Furthermore, web-based physical education was unsatisfactory due to several issues related to technology and content.

### Relationship Between Mental Health Status and Sports-Related Lifestyle

Previous studies have proven that the general population, including college students, suffered numerous negative effects induced by the outbreak of COVID-19 [21,22]. According to the DASS-21, depression, anxiety, and stress could be observed in various populations during the outbreak of COVID-19 in China, which lasted for at least 4 weeks [15]; these populations included the general population [21], general workforce [23], psychiatric patients [24], and health care professionals [25]. All groups in the general population were required to change and rebuild their lifestyles. For college students, in addition to the changes in their ordinary lifestyles, a brand new education style was rapidly established. Physical education, typically an outdoor course, was required to be conducted on the internet. Whether physical education is essential during the COVID-19 epidemic and how to suitably provide it are issues that most countries will be facing for a long period of time.

In Wang's study [15], which reported a higher psychological impact of COVID-19 in respondents aged 12-21.4 years, it was suggested that respondents in this age group might be affected by prolonged school closure and require web-based education support. Comparing our study with Wang's study, we observed lower scores on the DASS-21 subscales, which were obtained 3 months after web-based physical education was established. The difference between our study and the previous study may result from the restoration of web-based education support, of which physical education was an important part. To demonstrate the importance of exercise in our study, linear regression was employed to analyze the correlation between the DASS-21 scores and sports-related lifestyle variables. Unsurprisingly, lower scores on the DASS-21 and its subscales were observed in respondents who exercised regularly and maintained their exercise habits during the outbreak of COVID-19. The respondents who exercised more than 1 to 2 times a week, had an exercise duration >1 hour, and had >2000 average pedometer steps had significantly lower scores on the DASS-21 and all its subscales compared to other participants. These data suggest that exercise, especially regular exercise with sufficient duration, is related to a lower risk of mental disturbance, which is in accordance with a previous study [26]. It is surprising that although more than 70% respondents accumulated <2000 pedometer steps per day, the mean DASS-21 scores were low.

We believe that the low number of steps per day may be related to the exercises chosen for the physical classes during COVID-19 confinement. Some exercises may not involve many steps, such as tai chi and shape-up exercises. According to a large cross-section study, which verified that all exercise types are significantly associated with lower mental health burden [27], the exercise itself mattered rather than the type. Strong evidence from a meta-analysis supported that exercise can protect populations from depression regardless of age and geographical region [28], which may also apply to the COVID-19 pandemic. Therefore, we suggest that a positive sports-related lifestyle is significantly associated with mental health during the confines of the COVID-19 pandemic.

### Issues Related to Web-Based Physical Education

It is unfortunate that 1198/1607 respondents (74.5%) were restricted from using sports facilities, which may be an obstacle preventing them from exercising regularly. Moreover, the BMI of 638/1607 respondents (39.7%) was out of the normal range, which may be related to an unhealthy lifestyle [29]. These results suggest that the respondents were in need of professional guidance for physical education, considering the available facilities and equipment. Interestingly, 728/1607 respondents (45.3%) observed that other family members were motivated to exercise by web-based physical education. This may be related to the similar atmosphere to class learning, in which the other participating family members can be considered as classmates or companions. This also suggests that web-based physical education is not only a new learning style for college students but may also be a new lifestyle for the general population [30,31].

As stated above, effective web-based physical education is essential for lifestyle rebuilding not only for college students but also for the general population as part of behavior therapy [32], health education [33], and promotion by local health authorities [34]. However, as a totally new mode of physical education, web-based learning involved several issues that must be noted. As far as we know, only three types of web-based physical education were available to the college students, including watching recorded video, watching real-time video, and communicating with a teacher on an education platform. However, none of these types was preferred by more than 50% of respondents, and more than 50% of respondents did not want to experience physical education on the internet. However, in contrast, motivation of family members to exercise by web-based physical education was observed by nearly 50% of respondents. This suggests that web-based physical education is welcomed by the general population but cannot meet the requirements of college students. We believe that the dissatisfaction of college students may result from the comparison between web-based physical classes and face-to-face classes, whereas the general population would be more interested in trying this new style without having experienced face-to-face classes. Moreover, frequent technical problems were confronted by 1087/1607 respondents (67.6%), including network instability (752/1607, 46.8%) and unfamiliarity with software (384/1607, 23.9%), which further worsened the experience of the physical course. Furthermore, lack of interaction with the teacher (481/1607, 29.9%), lack of self-control (608/1607, 37.8%), and

inability to keep up with the lesson (73/1607, 4.5%) could be observed in the respondents, which was frustrating for the college students. However, Soffer's study [35] suggested that in many aspects of the examined effectiveness, web-based education was at least as effective as a face-to-face course [35]. We suppose that web-based physical education is promising if substantial improvements are made, such as technology support, optional exercises, and accommodation of students' preferences. According to Chekroud's study [27], all exercise types were significantly associated with lower mental health burden; numerous types of exercises could be chosen for web-based physical education. Considering the access to sports facilities and available sports equipment, only a few sports were suggested for web-based physical education, including shape-up exercises, a designed combination of exercises, Chinese kung fu, and rhythmic sport, and table tennis; meanwhile, ordinary physical courses could not be conducted properly, such as ball games and athletic events. Improving the physical fitness of college students with limited sports is the major issue of web-based physical education; to address this issue, we may learn from other courses and search for help from other fields, such as virtual reality [36].

### Limitations

There are several limitations of our study. First, due to anonymity and confidentiality requirements, a prospective study

could not be performed through the web-based snowball sampling survey, and the respondents to the survey may not be a representative sample of Chinese students. Second, mental health was evaluated by the DASS-21 scale instead of by mental health professionals; floor effects could not be excluded, although both methods of evaluation are based on the respondents' feelings and self-reporting. Third, due to the inherent nature of a cross-sectional study, we could only verify the association between sports-related lifestyle and mental health and could not verify the causal relationship. Finally, the assessment of sports-related lifestyle variables depends on non-standardized questions that have not been validated.

### Conclusions

The mental status of most of the college students in Wuhan who responded to our survey was normal. The mental status of the students was significantly correlated with regular exercise and sufficient exercise duration. Therefore, professional physical guidance is needed for college students as well as the general population. Considering the restrictions on sports facilities and equipment, selected sports were suggested for web-based physical education to improve physical fitness. However, web-based physical education is still far from satisfactory. Exercises not meeting students' preferences, frequent technical problems, and distant interactions are the main problems that should be solved in future.

### Acknowledgments

This research was supported by Hubei Province Health and Family Planning Scientific Research Project (WJ2018H0160) and the Wuhan Children's Hospital Foundation (2020FE002). The funding organizations had no role in the study design, data collection, data analysis, manuscript preparation, or publication decision. The work is the responsibility of the authors.

### Authors' Contributions

CD and WX conceived and designed the study. YG, XP, and JS contributed to the literature search. CD, JW, LZ, and HL collected the data. CD and WX analyzed the data. CD drafted the manuscript. WX revised the manuscript. WX had full access to all data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. All authors reviewed and approved the final version of the manuscript.

## Abstract

**Background:** The Great COVID-19 Shutdown aimed to eliminate or slow the spread of SARS-CoV-2, the virus that causes COVID-19. The United States has no national policy, leaving states to independently implement public health guidelines that are predicated on a sustained decline in COVID-19 cases. Operationalization of “sustained decline” varies by state and county. Existing models of COVID-19 transmission rely on parameters such as case estimates or  $R_0$  and are dependent on intensive data collection efforts. Static statistical models do not capture all of the relevant dynamics required to measure sustained declines. Moreover, existing COVID-19 models use data that are subject to significant measurement error and contamination.

**Objective:** This study will generate novel metrics of speed, acceleration, jerk, and 7-day lag in the speed of COVID-19 transmission using state government tallies of SARS-CoV-2 infections, including state-level dynamics of SARS-CoV-2 infections. This study provides the prototype for a global surveillance system to inform public health practice, including novel standardized metrics of COVID-19 transmission, for use in combination with traditional surveillance tools.

**Methods:** Dynamic panel data models were estimated with the Arellano-Bond estimator using the generalized method of moments. This statistical technique allows for the control of a variety of deficiencies in the existing data. Tests of the validity of the model and statistical techniques were applied.

**Results:** The statistical approach was validated based on the regression results, which determined recent changes in the pattern of infection. During the weeks of August 17-23 and August 24-30, 2020, there were substantial regional differences in the evolution of the US pandemic. Census regions 1 and 2 were relatively quiet with a small but significant persistence effect that remained relatively unchanged from the prior 2 weeks. Census region 3 was sensitive to the number of tests administered, with a high constant rate of cases. A weekly special analysis showed that these results were driven by states with a high number of positive test reports from universities. Census region 4 had a high constant number of cases and a significantly increased persistence effect during the week of August 24-30. This change represents an increase in the transmission model  $R$  value for that week and is consistent with a re-emergence of the pandemic.

**Conclusions:** Reopening the United States comes with three certainties: (1) the “social” end of the pandemic and reopening are going to occur before the “medical” end even while the pandemic is growing. We need improved standardized surveillance techniques to inform leaders when it is safe to open sections of the country; (2) varying public health policies and guidelines unnecessarily result in varying degrees of transmission and outbreaks; and (3) even those states most successful in containing the pandemic continue to see a small but constant stream of new cases daily.

## Introduction

Without question, SARS-CoV-2, the novel coronavirus that causes COVID-19 [1,2], has resulted in an unprecedented pandemic in modern history with significant morbidity and mortality [3-7]. Although some countries have had success in controlling COVID-19 [8-11], others have encountered much difficulty [12-17], resulting in significant adverse outcomes [18-21]. Beyond the overall implications related to infection and death [9,11,22-29], the COVID-19 pandemic has a deleterious impact on the global economy [27,30,31], violence [32-37], mental health [38-43], and food security [44-47], and disproportionately affects vulnerable populations such as the elderly [48-52], the poor [53,54], and racial and ethnic minorities [55-61]. We must establish COVID-19 control through good policy [10,12,62-68]; unfortunately, different states have implemented various and inconsistent COVID-19 policies [67,69-76] in the absence of a national plan [77,78]. Without a COVID-19 vaccine [79-81], we need *systematic public health surveillance* [7,82-89] to inform policies and guidelines for COVID-19 control and prevention such as quarantines, social distancing, face masks, crowd control, and hygiene to prevent viral spread [90-98]. Good surveillance can safely inform our leaders when, how, and where our country can reopen [76,99-103].

According to Teutsch and Churchill [85], public health surveillance is the “systematic, ongoing assessment of the health of a community, based on the collection, interpretation, and use of health data and information. Surveillance provides information necessary for public health decision making” (pg 1). Surveillance does not rely on a single indicator; it depends on a variety of metrics to identify high-priority COVID-19 health events such as incidence, prevalence, mortality, severity, cost, preventability, and communicability [104]. We need to meet these objectives of a surveillance system to prevent infectious diseases [104]. The United States must address several public health surveillance objectives, specifically to detect outbreaks (eg, the distribution and spread of COVID-19) and evaluate control strategies [104]. A surveillance system also includes “the functional capacity for data collection and analysis, as well as the timely dissemination of data” (pg 1) [87]. To this end, our study aims to create novel, validated metrics of speed, acceleration, and jerk in COVID-19 transmission in the United States.

The Great COVID-19 Shutdown refers to the variety of “lockdown” [105] public health policies adopted by countries around the globe to prevent the further spread of COVID-19, ranging from strict and complete quarantines [106-108] to disorganized and piecemeal closures [105]. It worked in places when it was implemented properly and in a timely manner, such as China, South Korea, Singapore, and Vietnam [10,11,62,109]. Some countries eliminated COVID-19, defined as achieving zero new cases over 14 days, while others flattened the curve

[64,110-113]. Governments that failed to effectively close down public movement and interactions resulted in increases in SARS-CoV-2 infections [50,114-120]. The United States had no national policy and was late in responding to the looming pandemic [105]. In fact, COVID-19 was technically classified as an epidemic by the Centers for Disease Control and Prevention when it accounted for >7.3% of all deaths in the United States. According to the National Center for Health Statistics, this was reached during the week of March 29-April 4 when COVID-19 accounted for 13.87% of all causes of death [121].

In response to the large death toll exacted by the epidemic, states independently implemented public health guidelines [14,19,70,71,122-125] regarding closures, social distancing, masks, and hand hygiene, which begs the question: when is it safe to reopen [126]? Reopening guidelines are predicated on a sustained decline in COVID-19 cases; however, operationalization of “sustained decline” varies by state [127]. Existing contagion models for COVID-19 rely on parameters such as case estimates or  $R_0$  and use intensive data collection efforts [128,129]. “Static” statistical models do not capture all of the relevant dynamics required to measure sustained declines [130-135]. Moreover, existing COVID-19 models use data that are subject to significant measurement error and other contaminants. Estimates of new SARS-CoV-2 infections suffer from undercounts due to asymptomatic carriers [136,137], access to testing [9,138-140], testing delays [141], testing sensitivity and specificity [142-145], and access to health care [60,146-150]. Surveillance systems and any enumeration of COVID-19 cases will err on the side of severity, meaning the most severe cases are more likely to be captured, the consequence of which is a significant undercount [71,104,130,151-156].

The conventional approach to modeling the spread of diseases such as COVID-19 is to posit an underlying contagion model and then to seek accurate direct measurement of the model parameters such as effective transmission rates or other parameters, often through labor-intensive methods relying on contact tracing to determine the spread of the virus in a sample population. For viral epidemics with an incubation period of up to 14 days, it takes weeks if not months to generate accurate parameter estimates even for simple contagion models [130]. For example, Li et al [157] provided early estimates of contagion parameters for COVID-19 using Wuhan data from contact tracing and methods developed by Lipsitch [158] but with weak statistical properties. It estimated the serial interval distribution and  $R_0$  from only six pairs of cases. These models also rely on underlying assumptions about immunity, common propensity for infection, well-mixed populations, etc [159]. Improvements in the models typically focus on relaxing these assumptions, for example, disaggregating the population by geography and modeling within-geography and cross-geographical personal interactions [160]. For example, Martcheva [161] provides an

excellent dynamic analysis of a wide variety of contagion models and their possible dynamics. Unfortunately, the study had limited options for the statistical inference of parameter values from actual data.

In contrast, we take an empirical approach that focuses on statistical modeling of widely available empirical data such as the number of confirmed cases or the number of tests conducted that can inform estimates of the current value of critical parameters like the infection rate or reproduction rate. We explicitly recognize that the data generating process for the reported data contain an underlying contagion component, a political-economic component such as availability of accurate test kits, a social component such as how strongly people adhere to social-distancing and shelter-in-place policies, and a sometimes inaccurate data reporting process that may obscure the underlying contagion process. We therefore seek a statistical approach that can provide meaningful information despite the complex and sometimes obfuscating data generation process. Our approach is consistent with the principles of evidence-based medicine, including controlling for complex pathways that may include socioeconomic factors such as mediating variables, and policy recommendations “based on the best available knowledge, derived from diverse sources and methods” (pg S58) [162].

There are two primary advantages to this empirical approach. First, we can apply the empirical model relatively quickly to a short data set. This advantage stems from the panel nature of the model. We used US states as the cross-sectional variable, so that a week’s data from all US states provides a reasonable sample size. In addition to enabling parameter estimation early in a pandemic, using this property we tested to see if there has been a shift in the transmission or reproductive rates of the transmission process in the past week, that is, whether there is statistical evidence that the US pandemic is peaking.

The second advantage is that the approach directly measures and informs policy-relevant variables. For example, the White House issued guidance on reopening the US economy that depends on a decrease in the documented number of cases and in the proportion of positive test results over a 14-day period, among other criteria and considerations [163]. As noted above, the number and proportion of positive test results are the outcome of a data generating process that includes not just the underlying transmission process but a multitude of mediating factors as well as idiosyncrasies of the data collection and reporting process. We specifically modeled the number of positive test results in our empirical model, which provides evidence of direct use in policy dialog.

This study has two objectives: (1) to create a proof-of-concept COVID-19 surveillance system using the United States as a prototype for a global system; and (2) to validate novel surveillance metrics/techniques including speed, acceleration, and jerk to better inform public health leaders how the pandemic is spreading or changing course.

## Methods

### Overview of Methodology

First, we will provide standard surveillance metrics including new counts of SARS-CoV-2 infections, moving 7-day averages of SARS-CoV-2 infections, rates of SARS-CoV-2 infections per 100,000 population, new numbers of COVID-19 deaths, moving 7-day averages of COVID-19 deaths, and rates of COVID-19 deaths per 100,000 population plus testing and positive testing ratios. Standard surveillance metrics are useful and allow us to compare data even though standard techniques are limited to more severe cases and suffer from data contamination.

Second, to address these data limitations we will validate novel surveillance metrics of (1) speed, (2) acceleration, and (3) jerk (change in acceleration). The basic question we are trying to inform is: how are we doing this week relative to previous weeks? From a public health perspective, in the midst of a pandemic, we would like (at least) three affirmative responses: (1) there are fewer new cases per day this week than last week, (2) the number of new cases is declining from day to day, and (3) the day-to-day decline in the number of cases is even bigger this week than last week. Additionally, we would like some indicative information about significant shifts in how the pandemic is progressing — positive shifts could be the first indicators of the emergence of a new or recurrent hotspot, and positive shifts could be first indicators of successful public health policy.

This study derives indicators to inform the three questions specified in the study objective above. Next, we provide a regression-based decomposition of the indicators. While it is beyond the scope of this study to determine the underlying causes of the pandemic and its trajectory over time, we provide a decomposition into proximate contributory factors such as whether an acceleration is due to a “natural” progression of the pandemic (eg, due to an increasing infectious population) or to a shift in an underlying model parameter (eg, a parameter shift that could be associated with reopening, other health policy changes, a viral mutation, the end of summer vacation for K-12 schools, or other underlying causes). Other factors can affect acceleration by “shifting” the underlying parameters (eg, the virus can mutate to become more or less infectious, states can impose lockdowns, social pressures can encourage or discourage people from wearing masks and social distancing, etc). Therefore, we use the regression analysis to provide a decomposition of speed, acceleration, and jerk into proximate contributory factors. Finally, this study is an innovation over traditional agnostic surveillancesystems in that we go beyond presenting metrics of the transmission of COVID-19 by providing probable scenarios regarding the context in which the disease is spreading.

The COVID Tracking Project [164] compiles data from multiple state sources on the web [165]; data for the most recent 36 days were accessed from the GitHub repository [166]. After accounting for lagged and differenced regressors, this resulted in a panel of 50 states plus the District of Columbia with 29 days in each panel (n=1352). Following Oehmke et al [167],

an empirical difference equation was specified in which the number of positive cases in each state at each day is a function of the prior number of cases, the level of testing, and weekly shift variables that measure whether the contagion was growing faster, at the same rate, or slower compared to the previous weeks. This resulted in a dynamic panel model that was estimated using the generalized method of moments approach by implementing the Arellano-Bond estimator in STATA/MP, version 16.1 (StataCorp LLC).

Arellano-Bond estimation of difference equations has several statistical advantages: (1) it allows for statistical examination of the model's predictive ability and the validity of the model specification; (2) it corrects for autocorrelation and heteroscedasticity; (3) it has good properties for data with a small number of time periods and large number of states; (4) it corrects for omitted variables issues and provides a statistical test of correction validity. With these advantages, the method is applicable to ascertaining and statistically validating changes in the evolution of the pandemic within a period of one week or less, such as changes in the reproduction rate [167-174].

### Speed: New Cases Per Day

The basic indicator of the pandemic's status on a given day is the number of new cases on that day. Since new cases per day is a rate (value per unit of time), we will adopt physics nomenclature and refer to this as the speed of the pandemic. This is consistent with heuristic descriptions of the pandemic as spreading rapidly (ie, a large number of new cases per day) or slowly (ie, a small number of new cases per day). The public health ideal is to bring the speed of the pandemic to zero.

We report the number of new cases for each state both as a number per day and as a number per 100,000 population per day (table and column references).

For mathematical formality, we write:

$$N_{it}$$

where we have suppressed the  $i$  subscript of the previous section. We will be reporting surveillance numbers for each state and for the District of Columbia.

### Acceleration

We are also interested in whether the number of cases per day is increasing, peaking, or decreasing, and why. Again, we will adopt physics nomenclature and refer to this datum as the acceleration. Since acceleration is difficult to ascertain on a daily basis, and there are weekend effects, etc, in the data, we report the weekly average for the acceleration as:

$$D.N_{it}$$

where  $D.$  is the difference operator. A positive acceleration indicates an increasing number of cases per day, and a negative acceleration (deceleration) indicates a decreasing number of cases per day. An acceleration of 0 is indicative of a peak, valley, or inflection point depending in part on whether the previous acceleration was positive or negative. For example, acceleration in Illinois changed from positive to zero in mid-May, indicating a peak, and from negative to zero toward the end of June, indicating a valley (Figure 1) [69,175].

**Figure 1.** The number of positives per day in Illinois, according to the COVID-19 Dashboard of the Center for Systems Science and Engineering [175].

We provide a regression-based decomposition of accelerations into proximate components. That is, this is the systematic component of changes in acceleration, where  $t$  denotes the end date for the most recent week. Subtracting Oehmke et al's [167] equation (3) at time  $t-1$  from the same equation at time  $t$  results in:

$$D.N_{it}$$

where we have suppressed the error terms and added a term for the "weekend effect." We refer to the term containing  $Pos_{t-1}$  as the 1-day persistence effect. This, in turn, comprises a natural progression effect measured by  $\beta_0 D.Pos_{t-1}$  that represents the effect of a change over time in the number of new positive

results where the magnitude of the effect is calibrated at the prior week's parameter  $\beta_0$ , and a shift effect  $\beta_2 D.Pos_{t-1}$  that measures the effect of the week's shift in the parameter from  $\beta_0$  to  $\beta_0 + \beta_2$ . The second term in this equation is the 7-day persistence effect and is analogous to the 1-day persistence effect, including its decomposition into a natural progression effect  $y_0 D.Pos_{t-7}$  and a shift effect  $y_2 D.Pos_{t-7}$ . The next part of equation 2 represents the portion of acceleration that is composed of changes in the contemporaneous component of the model.

The analogous expression for 1 week prior and 2 weeks prior are:

The expression for 2 weeks prior,  $D.Pos_{t-14}$ , represents the baseline and does not contain any shift parameters. The shift parameters  $\beta_1$ ,  $\beta_2$ ,  $y_1$ , and  $y_2$  represent shifts in the most recent 2 weeks relative to the week ending at time  $t-14$ .

The expressions for  $D.Pos_t$  from equations 3 or 4 are easily adapted from time  $t$  to time  $t-j$  for each week and averaged over the week to provide a decomposition of acceleration as defined by equation 2.

### Jerk: The Change in Acceleration

We now address the question of whether the day-to-day increase (or decrease) in new cases the current week is bigger or smaller than the day-to-day increase (or decrease) in new cases of the past week.

Formally, for the current week we are interested in is:

The first term to the right of the definitional equality is the average growth in the number of daily positive cases for the current week ending at time  $t$ , and the second term is the average increase in the number of daily positive cases for the prior week. Using physics nomenclature, the difference between these two acceleration rates is the "jerk." A positive jerk indicates that the acceleration in the number of daily cases this week is greater than the average growth last week. Such a finding would be

consistent with a scenario in which the pandemic was experiencing explosive growth; where a policy shift such as reopening had augmented the acceleration of the pandemic, possibly including a shift from deceleration to acceleration; or where a megaevent had "jerked" the acceleration upward, among other scenarios.

Using equation four, for the most recent week ending at time  $t$ , we can write:

The top row contains the 1-day persistence effect's contribution to the jerk. The first term on the right side of the equation represents the natural progression of the 1-day persistence effect on acceleration due to changes across weeks in the daily change in the number of new cases per day. The last term in the first row represents structural shifts in the 1-day persistence effect. The second row is analogous to the first row, except that it represents the 7-day persistence effect's contribution to the jerk. The third row represents the contribution of contemporaneous effects to the jerk.

The analogous equation for the prior week is:

Equations 6 and 7 are easily averaged over the week to provide a decomposition of jerk as defined by equation 5.

## Results

### Regional Regression

#### Findings

We group the states according to Census region and present regression results for each region below. The biweekly surveillance products will be based on these regressions.

For Region 1 (Northeast), the regression Wald statistic shows that the model was statistically significant ( $\chi^2_{10}=132$ ,  $P<.001$ ), and the Sargan test fails to reject the validity of the overidentifying restrictions. ( $\chi^2_{252}=258$ ,  $P=.38$ ) (Table 1).

**Table 1.** Arellano-Bond dynamic panel data modeling of the number of daily infections reported by state, August 2-30, 2020.

Variable	Region 1		Region 2		Region 3		Region 4	
	Coefficient	P value	Coefficient	P value	Coefficient	P value	Coefficient	P value
L1Pos	0.084	.22	−0.102	.02	−0.012	.77	0.273	<.001
L1shiftAug17	−0.129	.16	0.069	.24	0.221	.02	−0.213	.03

Constant	124.637	<.001	46.461	.89	429.167	<.001	397.678	<.001
Wald statistic for regression	$\chi^2_{10}=132$	<.001	$\chi^2_{10}=590$	<.001	$\chi^2_{10}=475$	<.001	$\chi^2_{10}=316$	<.001
Sargan statistic for validity	$\chi^2_{252}=258$	.38	$\chi^2_{338}=373$	.09	$\chi^2_{483}=446$	.89	$\chi^2_{368}=370$	.46

<sup>a</sup>Region 4 did not include the *Tests\_per\_100K* variable due to collinearity.

The coefficient on the first lag of the dependent variable is not statistically significant, nor are the shift parameters for the weeks of August 17 and August 24 for this coefficient. The coefficient on the 7th lag is positive and statistically significant (0.151,  $P=.02$ ). Neither of the shift parameters for the weeks of August 17 and August 24 are statistically significant. Of the variables representing the number of tests administered, the number per 100,000 population is significant (1.072,  $P=.04$ ). The weekend variable is not significant. The constant is positive and significant (124.637,  $P<.001$ ).

For Region 2 (Midwest), the regression Wald statistic shows that the model was statistically significant ( $\chi^2_{10}=590$ ,  $P<.001$ ), and the Sargan test fails to reject the validity of the overidentifying restrictions ( $\chi^2_{338}=373$ ,  $P=.09$ ).

The coefficient on the first lag of the dependent variable is not statistically significant. The shift for the week of August 17 for this coefficient is positive and statistically significant (0.221,  $P=.02$ ), but the shift for the week of August 24 is not significant. The coefficient on the 7th lag of the dependent variable is positive and significant (0.269,  $P<.001$ ). Neither of the weekly shift variables for this coefficient are significant. The tests, tests squared, and tests per 10,000 population are all statistically significant (0.047,  $P<.001$ ;  $-5.05E-07$ ,  $P<.001$ ; 8.023,  $P=.002$ ). Neither the weekend variable nor the constant are significant.

For Region 3 (South), the regression Wald statistic shows that the model was statistically significant ( $\chi^2_{10}=475$ ,  $P<.001$ ), and the Sargan test fails to reject the validity of the overidentifying restrictions ( $\chi^2_{483}=446$ ,  $P=.89$ ).

The coefficient on the first lag of the dependent variable is negative and statistically significant (−0.102,  $P=.02$ ). Neither

of the weekly shift variables for this coefficient are significant. The coefficient on the 7th lag of the dependent variable is positive and significant (0.288,  $P<.001$ ). The shifts for the weeks of August 17 and August 24 are negative and significant (−0.334,  $P<.001$ ; and −0.265,  $P=.003$ , respectively). The tests, tests squared, and tests per 10,000 population are all statistically significant (0.091,  $P<.001$ ;  $-4.89E-07$ ,  $P<.001$ ; and  $-15.986$ ,  $P<.001$ , respectively). The weekend variable is not significant. The constant is positive and significant (429.167,  $P<.001$ ).

For Region 4 (West), the regression Wald statistic shows that the model was statistically significant ( $\chi^2_{10}=316$ ,  $P<.001$ ), and the Sargan test fails to reject the validity of the overidentifying restrictions ( $\chi^2_{368}=370$ ,  $P=.46$ ).

The coefficient on the first lag of the dependent variable is negative and statistically significant (0.273,  $P<.001$ ). The shifts for the week of August 17 and August 24 for this coefficient are negative and statistically significant (−0.213,  $P=.03$ ; and −0.737,  $P<.001$ , respectively). The coefficient on the 7th lag of the dependent variable is not significant. The shift for the week of August 24 for this coefficient is positive and significant (0.397,  $P=.02$ ), but the shift for the week of August 17 is not significant. Of the test variables, only the coefficient on the number of tests administered is significant (0.017,  $P=.048$ ). The weekend variable is not significant. The constant is positive and significant (397.678,  $P<.001$ ).

### Interpretation

Region 1 appears to be fairly calm, with the only statistically significant persistence effect being a small 7-day lag effect. Region 2 is slightly less calm, but with a larger and statistically significant persistence effect and a noticeable positive effect of both the number of tests and the number of tests per 10,000.

Region 3 has the largest constant (average of state-specific effects) and the largest coefficient on tests, suggesting that the number of people newly tested for the virus is an important explanatory factor for the number of new cases. Region 4 has a high constant (average state-specific value) and significant shifts in both the 1-day and 7-day persistence values.

## University Reopenings

### Regression Results

A significant advantage of the panel data approach is that it can provide statistically valid quantifications of shifts in a fairly

short period such as 1 week. Perhaps the biggest pandemic issue during the week of August 24 was the high number of cases reported on university campuses as they reopened. We address this with an additional regression analysis. Six states in Region 3 reported 500 or more cases; at least one other university in these states reported 200 or more cases (Alabama, Florida, Georgia, North Carolina, South Carolina, and Texas). To inform this university effect, we split Region 3 into two groups of states—one with a high prevalence of university COVID-19 positives (denoted as group 3a) and another comprising the remaining Region 3 states (denoted as group 3b)—and then ran the regression analysis on the two groups (Table 2).

**Table 2.** Arellano-Bond dynamic panel data modeling of the number of daily infections reported by states in Region 3, grouped by the university effect, August 2-30, 2020.

Variable	Group 3a (with university effect)		Group 3b (without university effect)	
	Coefficient	P value	Coefficient	P value
L1Pos	−0.023	.76	0.037	.34
L1shiftAug17	0.249	.13	−0.029	.74
L1shiftAug24	−0.075	.69	0.005	.95
L7Pos	0.268	<.001	0.213	<.001
L7shiftAug17	−0.364	.007	−0.100	.22
L7shiftAug24	−0.252	.12	0.092	.26
Tests	0.121	<.001	0.029	<.001
Tests_squared	−6.59E-09	<.001	−5.61E-07	<.001
Tests_per_10K	−39.704	.005	−4.402	.06
Constant	910.482	.008	245.307	<.001
Wald statistic for regression	$\chi^2_9=169$	<.001	$\chi^2_9=491$	<.001
Sargan statistic for validity	$\chi^2_{165}=149$	.81	$\chi^2_{310}=301$	.63

For each group, the Wald statistic shows that the model was statistically significant ( $\chi^2_9=169$ ,  $P<.001$ ; and  $\chi^2_9=491$ ,  $P<.001$ , respectively), and the Sargan test fails to reject the validity of the overidentifying restrictions ( $\chi^2_{165}=149$ ,  $P=.81$ ;  $\chi^2_{310}=301$ ,  $P=.63$ ).

Without belaboring the individual coefficients, there are two important differences between the two groups. First is the coefficient on *Tests*, which numerically is the most important of the three test coefficients; group 3a (0.121,  $P<.001$ ) is more than four times the size of the coefficient for group 3b (0.029,  $P<.001$ ). The second important difference is that the constant for group a is more than three times the size of the constant for group b.

### Interpretation

The larger coefficient on *Tests* means that a higher percentage of tests are associated with positive results, possibly as large as 10% for group a (considering only the linear term). The larger value of the constant (which is an average of state-specific effects) means that there are larger state-specific risk factors, possibly related to the degree of “lockdown” and social compliance with recommendations such as social distancing or wearing masks. Coupling these two effects suggests that for the

week of August 24, the university effect is mostly due to increases in the number of asymptomatic students who got tested for the first time as they returned to university. This is consistent with the comparison of regional results across regions. It also suggests that the following week may be much worse if a significant fraction of the students are infectious and fail to practice social distancing, etc, thereby infecting others, who will likely show up in that week’s numbers.

These results may also help to explain spikes in other states, such as Iowa, Kansas, North Dakota, and South Dakota (which is also potentially affected by the Sturgis Motorcycle Rally), which all had significant numbers of COVID-19 cases at universities.

### Surveillance Results

Surveillance results are presented in Tables 3 and 4. The seven data elements in this proof-of-concept surveillance system are calculated as weekly averages and the speed, acceleration, and jerk are normalized per 100,000 population to compare the transmission of COVID-19 from week to week. These surveillance system data elements include (1) average weekly number of daily tests; (2) average weekly number of daily tests per 100,000 population; (3) average weekly number of daily positive tests; (4) average weekly number of daily positive tests

per 100,000 population referred to as *speed*; (5) weekly average of day-to-day change in the number of positives per day per 100,000 population, referred to as *acceleration*; (6) change in acceleration, referred to as *jerk*, which is the acceleration in the current week minus the acceleration in the prior week; a sustained positive jerk is typically associated with explosive growth; and finally, (7) the 7-day lag, which is the number of new cases of COVID-19 reported today per 100,000 population (ie, today's speed) that are associated with new cases reported 7 days ago (ie, last week's speed), and measures how much the increase in speed from last week persists into this week. Data are presented according to US Census regions. Data element 1 is reported as a number while 2-7 are reported as a rate, which better allows for comparison between US states.

The innovation of this study is the novel metrics we derived to measure how COVID-19 is spreading and changes in terms of transmission rates. These measures should be considered in combination with traditional static numbers including transmission rates and death rates. These novel metrics measure how fast the rates are changing, accounting for their data limitations.

As an example, we tracked the transmission of COVID-19 for the state of Illinois for the week from August 17 to 23, 2020. Illinois had a weekly average of 48,181 COVID-19 tests daily, also expressed as a weekly average of 380 tests per 100,000 population per day. Illinois had a weekly average of 2026 positive tests per day. The speed of the COVID-19 transmission is measured as an increase of 15.99 persons infected per 100,000 population per day. For the week of August 17 to 23 in Illinois, COVID-19 acceleration was 0.37, which means that every day there were .37 more new cases per 100,000 than the day before, or 2.6 more cases per day per 100,000 over the course of the

week. The jerk is 0.17, which means that acceleration was increasing: this increased acceleration accounted for 1.4 of the 2.6 additional cases per day per 100,000. Finally, the 7-day lag effect for speed is 3.58, which means that persistence or echo effects accounted for 3.58 or 22% of the 15.99 new daily positive cases per 100,000, which indicates an important but moderate persistence or echo effect for the week of August 17.

We see significant differences in COVID-19 transmission the following week (August 24-30, 2020). Illinois experienced a decrease in weekly average tests to 44,719 daily COVID-19 tests, also expressed as a weekly average of 353 tests per 100,000 population per day. This is 27 fewer tests per 100,000 population from last week. Illinois had a weekly average of 1923 positive tests per day, a decrease from the prior week, also expressed as a speed of 15.18 persons newly infected per day per 100,000 population. During the week of August 24-30, the acceleration decreased from the previous week to 0.11 and the jerk was negative (−0.26), indicating a leveling off of growth in new cases. Finally, the 7-day lag effect on speed is 5.35, which means that the persistence or echo effects accounted for 5.35 or over one-third of the 15.18 new daily positive cases per 100,000. The increased importance of echo effects rather than new cases from other (new) causes is consistent with a leveling off of COVID-19 growth in Illinois during the week of August 24-30.

In summary, the week of August 17-23 showed an increasing COVID-19 speed with positive acceleration and jerk. The week of August 24-30 exhibited a moderation in speed with lower acceleration and negative jerk. This is indicative of a leveling off or an inflection point: the pandemic in Illinois may be starting to decline, or this could be simply a pause before a continued increase in COVID-19 speed.

**Table 3.** Surveillance metrics for the week of August 17-23, 2020.

State	Tests per day, n (weekly average)	Daily tests per 100K people, n (daily average for the week)	Positives, n (reported number of new positive test results or confirmed cases per day per 100K people, weekly average)	Speed, n (daily positives per 100K people, weekly average)	Acceleration (day-to-day change in the number of positives per day, weekly average, per 100K people)	Jerk (week-over-week change in acceleration, per 100K people)	7-day persistence effect on speed (number of new cases per day per 100K people)

## Discussion

### Principal Findings

The dynamic panel data model is a statistically validated analysis of reported COVID-19 transmissions and an important addition to the epidemiological toolkit for understanding the progression of the pandemic. It is important to recognize that surveillance systems require a variety of metrics. Systematic surveillance with standardized measures of decreases and increases in COVID-19 transmission coupled with health policies and guidelines add a critical tool to the epidemiologic arsenal to combat COVID-19.

The specific findings of the modeling exercise confirm that SARS-CoV-2 infection rates are persistent but changeable, and for most states increasing during the period between June 13-19, 2020. We find that for every 100 new COVID-19 cases from June 13-19, the following day would result in 26 new cases, meaning there is a significant reduction each day. However, it is important to recognize that this is an average across states and that state and local experiences will vary, which we measured. From June 20-26, on average in the United States, every 100 new cases on Monday was associated with 65 new cases on Tuesday, indicating the contagion increased 2.5-fold the rate from the prior week. The American pandemic has been ramping up in the past 2 weeks.

Remarkably, the US states diverged into three distinct patterns: (1) decline, (2) constant, and (3) increases consistent with outbreaks. In the 30 states with increasing cases, over the course of 2 weeks, there was a 3.6-fold increase in new infections while the states that had sustained declines in cases decreased by 2.5-fold. Again, these are averages among the three classifications of decline, constant, and increases, but these data could be further refined to show how much each state contributed to increases and decreases. Further investigation could usefully model state and local differences in infection rates, as well as ascertain quickly whether the pandemic will continue to re-emerge in the United States, or whether infection rates will reverse track and decline again even though states reopen.

The strengths of this study are the derived new metrics of the transmission of COVID-19. The limitation of this proof-of-concept surveillance system is that it includes only dynamic cases of COVID-19 infections; a full surveillance system should also include static cases. For example, Table 2 refers only to dynamic, new infections.

Based on the empirical evidence that our metrics of the COVID-19 contagion is a good standardization of increases and decreases for public health surveillance purposes, our future work will focus on the surveillance of 195 countries in eight global regions as defined by the World Bank. When possible,

we will provide subcountry-level metrics of the COVID-19 contagion beginning with US states and Canadian provinces. Our surveillance system will include estimates of speed,

acceleration, and jerk in acceleration along with traditional surveillance metrics.

## Abstract

**Background:** A large number of web-based COVID-19 symptom checkers and chatbots have been developed; however, anecdotal evidence suggests that their conclusions are highly variable. To our knowledge, no study has evaluated the accuracy of COVID-19 symptom checkers in a statistically rigorous manner.

**Objective:** The aim of this study is to evaluate and compare the diagnostic accuracies of web-based COVID-19 symptom checkers.

**Methods:** We identified 10 web-based COVID-19 symptom checkers, all of which were included in the study. We evaluated the COVID-19 symptom checkers by assessing 50 COVID-19 case reports alongside 410 non-COVID-19 control cases. A bootstrapping method was used to counter the unbalanced sample sizes and obtain confidence intervals (CIs). Results are reported as sensitivity, specificity, F1 score, and Matthews correlation coefficient (MCC).

**Results:** The classification task between COVID-19–positive and COVID-19–negative for “high risk” cases among the 460 test cases yielded (sorted by F1 score): Symptoma (F1=0.92, MCC=0.85), Infermedica (F1=0.80, MCC=0.61), US Centers for Disease Control and Prevention (CDC) (F1=0.71, MCC=0.30), Babylon (F1=0.70, MCC=0.29), Cleveland Clinic (F1=0.40, MCC=0.07), Providence (F1=0.40, MCC=0.05), Apple (F1=0.29, MCC=–0.10), Docyet (F1=0.27, MCC=0.29), Ada (F1=0.24, MCC=0.27) and Your.MD (F1=0.24, MCC=0.27). For “high risk” and “medium risk” combined the performance was: Symptoma (F1=0.91, MCC=0.83) Infermedica (F1=0.80, MCC=0.61), Cleveland Clinic (F1=0.76, MCC=0.47), Providence (F1=0.75, MCC=0.45), Your.MD (F1=0.72, MCC=0.33), CDC (F1=0.71, MCC=0.30), Babylon (F1=0.70, MCC=0.29), Apple (F1=0.70, MCC=0.25), Ada (F1=0.42, MCC=0.03), and Docyet (F1=0.27, MCC=0.29).

**Conclusions:** We found that the number of correctly assessed COVID-19 and control cases varies considerably between symptom checkers, with different symptom checkers showing different strengths with respect to sensitivity and specificity. A good balance between sensitivity and specificity was only achieved by two symptom checkers.

COVID-19; symptom checkers; benchmark; digital health; symptom; chatbot; accuracy

## Introduction

In the modern world, large numbers of patients initially turn to various web-based sources for self-diagnoses of health concerns

before seeking diagnoses from a trained medical professional. However, web-based sources have inherent problems, such as misinformation, misunderstandings, misleading advertisements, and varying quality [1]. Interactive web sources developed to

provide web-based diagnoses are sometimes referred to as symptom checkers or chatbots [2,3]. Based on a list of entered symptoms and other factors, these symptom checkers return a list of potential diseases.

Web-based symptom checkers have become popular in the context of the novel COVID-19 pandemic, as access to physicians is reduced, concern in the population is high, and large amounts of misinformation are circulating the internet [1]. On COVID-19 symptom checker web pages, users are asked a series of COVID-19-specific questions; upon completion, an association between the answers and COVID-19 is given alongside behavioral recommendations, such as self-isolation.

In this context, COVID-19 symptom checkers are valuable tools for preassessment and screening during this pandemic; they can both ease pressure on clinicians and decrease footfall within hospitals. One example is practicing social distancing by not going to a physician's waiting room when feeling sick. The importance of social distancing has been highlighted in the COVID-19 pandemic [4,5], the 2009 H1N1 influenza pandemic [6], and the 1918-1919 influenza pandemic [7] and is reviewed in [8]. Symptom checkers can also ease pressure on medical telephone hotlines [9,10] by reducing the number of human phone operators needed.

A large number of symptom checkers specific to COVID-19 have been developed. Empirical evidence (eg, a newspaper article [11]) suggests that their conclusions differ, with possible implications for the quality of the symptom assessment. To our knowledge, there are no studies comparing and evaluating COVID-19 symptom checkers.

In this paper, we present a study evaluating 10 different web-based COVID-19 symptom checkers using 50 COVID-19 cases extracted from the literature and 410 non-COVID-19 control cases of patients with other diseases. We found that the classifications of many patient cases by the COVID-19 symptom checkers differ. Therefore the accuracies of symptom checkers also differ.

## Methods

### COVID-19 Symptom Checkers

In April 2020, we conducted a Google search for COVID-19 symptom checkers using the search terms *COVID-19 symptom checker* and *Corona symptom checker*. All ten COVID-19 symptom checkers that we found and that were freely available on the internet between April 3 and 9, 2020, were included in this study (Table 1). Nine checkers were implemented in the English language, while one was in German. These symptom checkers were used in the versions available in this date range, and updates after this date were not considered for analysis.

As a baseline for the performance evaluation of the 10 web-based COVID-19 symptom checkers, we developed two additional simplistic symptom checkers. These two checkers evaluate and weigh the presence of COVID-19 symptom frequencies provided by the World Health Organization (WHO) [12] (see Multimedia Appendix 1) based on vector distance (SF-DIST) and cosine similarity (SF-COS). These approaches can be implemented in a few lines of code (see Multimedia Appendix 2).

**Table 1.** List of web-based COVID-19 symptom checkers included in this study.

Name	Reference

Cleveland Clinic	[17]
Docyet	[18]
Infermedica	[19]
Providence	[20]
Symptoma	[21]
Your.MD	[22]

<sup>a</sup>CDC: US Centers for Disease Control and Prevention.

### Clinical Cases

We used a total of 460 clinical cases to evaluate the performance of the COVID-19 symptom checkers. Each case lists both

symptoms and the correct diagnosis alongside the age and sex of the patient when available. Details of the two case sets used are given below and in Table 2.

**Table 2.** Number of symptoms and age and sex distributions in each case set (N=460).

Characteristic	Case set	
	COVID-19, n=50	Control, n=410
<b>Number of symptoms</b>		
Mean (SD)	8.4 (4.1)	9.8 (4.4)
Median	7	9
<b>Age (years)</b>		
Mean (SD)	45.6 (16.9)	38.6 (22.4)
Median	45	38
<b>Sex, n (%)</b>		
Male	25 (50)	238 (58)
Female	21 (42)	160 (39)
Unknown	4 (8)	12 (2.9)

### COVID-19 Cases

A total of 50 COVID-19 cases were extracted by three trained physicians from the literature in March and April 2020 and are listed in [Multimedia Appendix 3](#). Each case describes one patient's medical situation (ie, symptoms experienced or COVID-19 contacts). The symptoms of each case were extracted separately from the COVID-19 engine construction and evaluation. The physicians entering the symptoms did not know how the engine would react to their symptom lists. To the best of our knowledge, we included all cases available at the time except for severe edge cases (eg, several severe comorbidities causing unrelated symptoms). Changes to the initial symptom lists were not allowed later.

### Control Cases

The COVID-19 case data enabled us to evaluate the sensitivity of the symptom checkers. To evaluate the specificity, 410 control cases from the *British Medical Journal* (BMJ) were also sourced [23,24]. To allow a fair assessment, we only used cases containing at least one of the COVID-19 symptoms reported by the WHO [12] (see [Multimedia Appendix 4](#)). Classifying nonrelevant cases (eg, a fracture) would overestimate the symptom checkers' specificity. Furthermore, these patients would not consult a web-based COVID-19 symptom checker. None of the 410 BMJ cases lists COVID-19 as the diagnosis, as the cases were collected before the COVID-19 outbreak.

### Mapping of Symptoms and Addressing Missing Inputs and Questions

Each of the symptom checkers has a different interface and different question sequences to reach the diagnosis. Therefore, we mapped the exhibited symptoms across our cases to the constrained input allowed by each checker via a synonym table and hierarchy created by a trained physician. For example, if a checker asked for "shortness of breath" but the case description listed "respiratory distress" or "(acute) dyspnea", the symptom was still correctly used for this case and symptom checker.

Not all cases contained answers to all the questions of a checker. In such cases, the answer "I don't know" was chosen; if the "I don't know" answer option did not exist in a checker, "No" was

used. In contrast, if a case contained information that did not fit any of the questions of the checker, this information was not used for this checker.

### Accuracy Evaluation

For statistical analysis, we used the following classification:

- True-positive : COVID-19 case classified as COVID-19
- False-positive: non-COVID-19 case classified as COVID-19
- True-negative: non-COVID-19 case classified as non-COVID-19
- False-negative: COVID-19 case classified as non-COVID-19

For each symptom checker, we calculated the following metrics:

Sensitivity (true-positive rate):

Specificity (true-negative rate):

F1 score (harmonic mean of the precision and recall):

Matthews correlation coefficient (MCC):

### Classification of the Outputs of the Symptom Checkers

Most COVID-19 symptom checkers return human-readable text that contains an association between the entered symptoms and COVID-19. We classified these associations into three different categories: high risk, medium risk, and low risk. Respective examples of a high, medium, and low risk classification are "There is a high risk that COVID-19 is causing your symptoms," "Your symptoms are worrisome and may be related to COVID-19," and "There's nothing at present to suggest that

you have coronavirus (COVID-19). Please practice physical/social distancing.” Our full mapping of text outputs to risk for all symptom checkers and all text outputs is given in [Multimedia Appendix 5](#).

Some symptom checkers only have two possible outputs: COVID-19 risk or no COVID-19 risk. To compare symptom checkers with three and two risk levels, we performed two different analyses: (1) medium risk and high risk were treated as COVID-19–positive (and low risk was treated as COVID-19 as negative), and (2) high risk was treated as COVID-19–positive (and low risk and medium risk were treated as COVID-19–negative).

### Bootstrapping

To evaluate the robustness of our statistical measures and account for the unbalanced dataset, we performed bootstrapping

across our cases. A total of 3000 random samples consisting of 50 COVID-19 cases and 50 control cases was created by sampling with replacement from the original set of 50 COVID-19 cases and the 410 control cases.

## Results

To analyze the performance of the 10 web-based symptom checkers, we calculated the sensitivity and the specificity of each symptom checker based on the cases described in the method section. Scatterplots of the sensitivity and specificity to COVID-19 of the different symptom checkers are given in [Figure 1](#), and detailed numerical values are provided in [Multimedia Appendix 6](#) and [Multimedia Appendix 7](#). These symptom checkers fall approximately into four groups: upper left corner, lower right corner, central region, and upper right corner.

**Figure 1.** Sensitivities and specificities of web-based COVID-19 symptom checkers to COVID-19 cases and controls. The means of the 3000 random samples and 90% bootstrap CIs are reported as dots and crosses, respectively. (A) High risk: A COVID-19–positive prediction is defined only by a high risk result returned by a symptom checker. (B) Medium-high risk: A COVID-19–positive prediction is defined by either a medium risk or high risk result returned by a symptom checker. CDC: US Centers for Disease Control and Prevention; SF-COS: symptom frequency based on cosine similarity; SF-DIST: symptom frequency based on vector distance.

Further analysis of the true and false case classifications of these groups shows that the group in the upper left corner is composed of symptom checkers that require the presence of one (or few) highly specific symptoms to classify a case as COVID-19–positive (eg, “intensive contact with a COVID-19–positive person”). In this way, these symptom checkers miss many patients who are positive for COVID-19 who did not exactly report this highly specific symptom. In contrast, these highly specific symptoms are rarely present in non–COVID-19 cases. This results in low sensitivity and high specificity.

The group in the lower right corner is composed of symptom checkers that predict a case as COVID-19–positive based on the presence of one or few COVID-19 associated symptoms (eg, the presence of fever or cough is sufficient to predict a patient to be COVID-19–positive). These checkers classify almost every patient that has a respiratory disorder or viral

infection as COVID-19–positive. As such, they do not miss many patients with COVID-19 but wrongly predict many patients who do not have COVID-19 to be COVID-19–positive. This results in low specificity and high sensitivity.

The group in the more central region is composed of symptom checkers that use a more balanced prediction but exhibit limited success in correctly classifying patients with and without COVID-19.

The group in the upper right corner is composed of symptom checkers that also use a more balanced model to associate symptoms to COVID-19; however, in this case, the classification of patients with and without COVID-19 is more successful.

## Discussion

### Principal Findings

We classified 50 COVID-19 case descriptions from the recent literature as well as 410 non-COVID-19 control cases using 10 different web-based COVID-19 symptom checkers. Only 2/10 symptom checkers showed a reasonably good balance between sensitivity and specificity (Figure 1). Most other checkers were either too sensitive, classifying almost all patients as COVID-19-positive, or too specific, classifying many patients with COVID-19 as COVID-19-negative (Figure 1). For example, our BMJ control cases included a patient suffering from a pulmonary disease who presented with various symptoms, including fever, cough, and shortness of breath, which are the three most frequent symptoms associated with COVID-19. Additional symptoms and risk factors were not considered by most checkers. Namely, loss of appetite, green sputum, and a history of smoking can be used to discern a correct diagnosis of COVID-19-negative.

Furthermore, in terms of F1 score, most of the symptom checkers were outperformed by a simplistic symptom frequency vector approach; the F1 scores were 0.57 and 0.79 for SF-DIST and SF-COS, respectively. Notably, the cosine version showed surprisingly good results, outperforming 8/10 symptom checkers based on the F1 score.

In contrast, it could also be argued that sensitivity is more important for a COVID-19 symptom checker than specificity (ie, numerous false-positive COVID-19 diagnoses are not of concern as long as no COVID-19 infections are missed). However, it is not difficult to create a symptom checker that is 100% sensitive by simply returning every test as COVID-19-positive. While no checker does this 100% of the time, some checkers tend to declare every person who reports any flu-like symptom to be COVID-19-positive. This assesses every patient with allergic asthma (“shortness of breath”), heatstroke (“fever”), or heavy smoker (“cough”) to be COVID-19-positive. Therefore, we believe that a healthy balance between sensitivity and specificity is necessary for a useful checker. However, from the figure in this paper, readers can decide for themselves which balance between sensitivity and specificity is most useful and select the corresponding checker.

An additional aspect is that the developers of the 10 checkers may have had different purposes in mind during development. For example, they may have envisioned the checker to be a self-triage and recommendation tool or a likelihood predictor (as classified in [2]). In our study, we found that most checkers provide a certain likelihood as well as recommendations; therefore, classification is difficult. Therefore, we did not further subgroup the checkers in our analysis.

To our knowledge, this is the first scientific evaluation of web-based COVID-19 symptom checkers; however, there are a number of related studies evaluating symptom checkers. These include a study that evaluated 23 general-purpose symptom checkers based on 45 clinical case descriptions across a wide range of medical conditions and found that the correct diagnosis

was listed among the top 20 results of the checkers in 58% of all cases on average [2]. The aforementioned study design was extended to five additional symptom checkers using ear, nose, and throat (ENT) cases, showing similar results [25]. Other evaluations include a study of symptom checkers used for knee pain cases; based on 527 patients and 26 knee problems, it was found that the physician’s diagnosis was present within the prediction list in 89% of the cases, while the specificity was only 27% [26]. In another study, an analysis of an automated self-assessment triage system for university students prior to an in-person consultation with a physician found that the system’s urgency rating agreed perfectly in only 39% of cases; meanwhile, for the remaining cases, the system tended to be more risk-averse than the physician [27]. Also, the applicability of web-based symptom checkers for 79 persons aged  $\geq 50$  years based on “think-aloud” protocols [28], deep learning algorithms for medical imaging [29], and services for urgent care [3] were evaluated.

The acceptability of the performance of a web-based symptom checker depends on the perspective and use of the results. In the case of COVID-19, a web-based assessment cannot fully replace a polymerase chain reaction (PCR) test, as some people are asymptomatic while others presenting with very specific COVID-19 symptoms may in fact have a very similar but different disease. Regardless, web-based COVID-19 symptom checkers can act as a first triage shield to avoid in-person physician visits or ease pressure on hospitals. Symptom checkers could even replace telephone triage lines in which non-medically trained personnel read a predefined sequence of questions. Although this was not part of this study, the authors believe that COVID-19 symptom checkers (if appropriately maintained and tested) may also be more reliable than the direct use of search engines such as Google or information via social media.

### Strengths and Limitations

The strength of this study lies in the fact that it is based on a large number of real patients’ case descriptions from the literature ( $n=460$ ) and a detailed evaluation of the best performing symptom checker in terms of F1 score (Multimedia Appendix 8). In contrast, a potential weakness of this study lies in its use of real literature-based cases, which may have biased the test set to rather severe cases of COVID-19 because mild and uninteresting cases are usually not found in the literature. We countered this bias by not including extreme edge cases from the literature in our 50 COVID-19 cases. A limitation of our study is that the benchmarking represents a specific point in time (April 2020; see Methods) and underlying algorithms may change. However, this temporal limitation is present in all benchmarking studies as knowledge increases and software is updated. Another bias may be that our control case descriptions do not report a COVID-19 contact, even though, for example, a person with a cold may have had a COVID-19 contact (and did not become infected). Another limitation of this study is the nonstraightforward mapping of the symptom checker outputs to risk levels (Multimedia Appendix 5). The interpretation of the textual output is debatable in some cases. We countered this by allowing three different risk levels and merging them in two different ways (see Figure 1A and Figure 1B). Also, every

symptom checker output was classified by multiple persons until consensus was reached.

## Conclusion

Symptom checkers are being widely used in response to the global COVID-19 pandemic. As such, quality assessment of

these tools is critical. We show that various web-based COVID-19 symptom checkers vary widely in their predictive capabilities, with some performing equivalently to random guessing while others show strength in sensitivity, specificity, or both.

## Abstract

**Background:** COVID-19 is a rapidly emerging respiratory disease caused by SARS-CoV-2. Due to the rapid human-to-human transmission of SARS-CoV-2, many health care systems are at risk of exceeding their health care capacities, in particular in terms of SARS-CoV-2 tests, hospital and intensive care unit (ICU) beds, and mechanical ventilators. Predictive algorithms could potentially ease the strain on health care systems by identifying those who are most likely to receive a positive SARS-CoV-2 test, be hospitalized, or admitted to the ICU.

**Objective:** The aim of this study is to develop, study, and evaluate clinical predictive models that estimate, using machine learning and based on routinely collected clinical data, which patients are likely to receive a positive SARS-CoV-2 test or require hospitalization or intensive care.

**Methods:** Using a systematic approach to model development and optimization, we trained and compared various types of machine learning models, including logistic regression, neural networks, support vector machines, random forests, and gradient boosting. To evaluate the developed models, we performed a retrospective evaluation on demographic, clinical, and blood analysis data from a cohort of 5644 patients. In addition, we determined which clinical features were predictive to what degree for each of the aforementioned clinical tasks using causal explanations.

**Results:** Our experimental results indicate that our predictive models identified patients that test positive for SARS-CoV-2 a priori at a sensitivity of 75% (95% CI 67%-81%) and a specificity of 49% (95% CI 46%-51%), patients who are SARS-CoV-2 positive that require hospitalization with 0.92 area under the receiver operator characteristic curve (AUC; 95% CI 0.81-0.98), and patients who are SARS-CoV-2 positive that require critical care with 0.98 AUC (95% CI 0.95-1.00).

**Conclusions:** Our results indicate that predictive models trained on routinely collected clinical data could be used to predict clinical pathways for COVID-19 and, therefore, help inform care and prioritize resources.

**KEYWORDS**

SARS-CoV-2; COVID-19; machine learning; clinical prediction; prediction; infectious disease; clinical data; testing; hospitalization; intensive care

## Introduction

COVID-19 was first discovered in December 2019 in China and has since rapidly spread to over 200 countries [1]. The COVID-19 pandemic has challenged health care systems worldwide, as a high peak capacity for testing and hospitalization is necessary to diagnose and treat affected patients, particularly if the spread of SARS-CoV-2 is not

mitigated. To avoid exceeding the available health care capacities, many countries have adopted social distancing policies, imposed travel restrictions, and postponed nonessential care and surgeries to reduce peak demand on their health care systems [2-4].

The adoption of clinical predictive models that accurately predict who is likely to require testing, hospitalization, and intensive care from routinely collected clinical data could potentially

further reduce peak demand by ensuring resources are prioritized to those individuals with the highest risk (Figure 1). For example, a clinical predictive model that accurately identifies patients that are likely to test positive for SARS-CoV-2 a priori could help prioritize limited SARS-CoV-2 testing capacity.

However, developing accurate clinical prediction models for SARS-CoV-2 is difficult as relationships between clinical data, hospitalization, and intensive care unit (ICU) admission have not yet been established conclusively due to the recent emergence of SARS-CoV-2.

**Figure 1.** We study the use of predictive models (light purple) to estimate whether patients are likely (i) to be SARS-CoV-2 positive and whether SARS-CoV-2 positive patients are likely (ii) to be admitted to the hospital and (iii) to require critical care based on clinical, demographic, and blood analysis data. Accurate clinical predictive models stratify patients according to individual risk and, in this manner, help prioritize health care resources such as testing, hospital, and critical care capacity.

In this systematic study, we develop and evaluate clinical predictive models that use routinely collected clinical data to identify patients that are likely to receive a positive SARS-CoV-2 test, patients who are SARS-CoV-2 positive that are likely to require hospitalization, and patients who are SARS-CoV-2 positive that are likely to require intensive care. Using the developed predictive models, we additionally determined which clinical features are most predictive for each of the aforementioned clinical tasks. Our results indicate that predictive models could be used to predict clinical pathways for patients with COVID-19. Such predictive models may be of significant utility for health care systems, as preserving health care capacity has been linked to successfully combating SARS-CoV-2 [5,6].

Concretely, this paper contains the following contributions:

- We developed and systematically studied predictive models for estimating the likelihoods of a positive SARS-CoV-2 test in patients presenting at hospitals, hospital admission in patients who are SARS-CoV-2 positive, and critical care admission in patients who are SARS-CoV-2 positive.
- We validated the performance of the developed clinical predictive models in a retrospective evaluation using real-world data from a cohort of 5644 patients.
- We determined and quantified the predictive power of routinely collected clinical, demographic, and blood analysis data for the aforementioned clinical prediction tasks.

## Methods

### Problem Setting

In the present setting, we are given 106 routine clinical, laboratory, and demographic measurements, or features,  $x_i \in x$

for presenting patients (see Multimedia Appendix 1 for full list). Features may be discrete or continuous, and some features may be missing as not all tests are necessarily performed on all patients. The clinical predictive tasks consist of using the routine clinical features  $x_i$  to predict, for a newly presenting patient, the likelihood  $\hat{y}_{SARS-CoV-2}$  of receiving a positive SARS-CoV-2 test result, the likelihood  $\hat{y}_{admission}$  of requiring hospital admission, and the likelihood  $\hat{y}_{ICU}$  of requiring intensive care. In addition, we are given a development data set consisting of  $N$  patients, their corresponding observed routine clinical features  $x_i$ , SARS-CoV-2 test results  $\hat{y}_{SARS-CoV-2} \in \{0,1\}$ , hospital admissions  $\hat{y}_{admission} \in \{0,1\}$ , and ICU admissions  $\hat{y}_{ICU} \in \{0,1\}$ , where 1 indicates the presence of an outcome. Using this development data set, our goal is to derive clinical predictive models  $\hat{y}_{SARS-CoV-2}$ ,  $\hat{y}_{admission}$ , and  $\hat{y}_{ICU}$  for the aforementioned tasks, respectively, to inform care and help prioritize scarce health care resources.

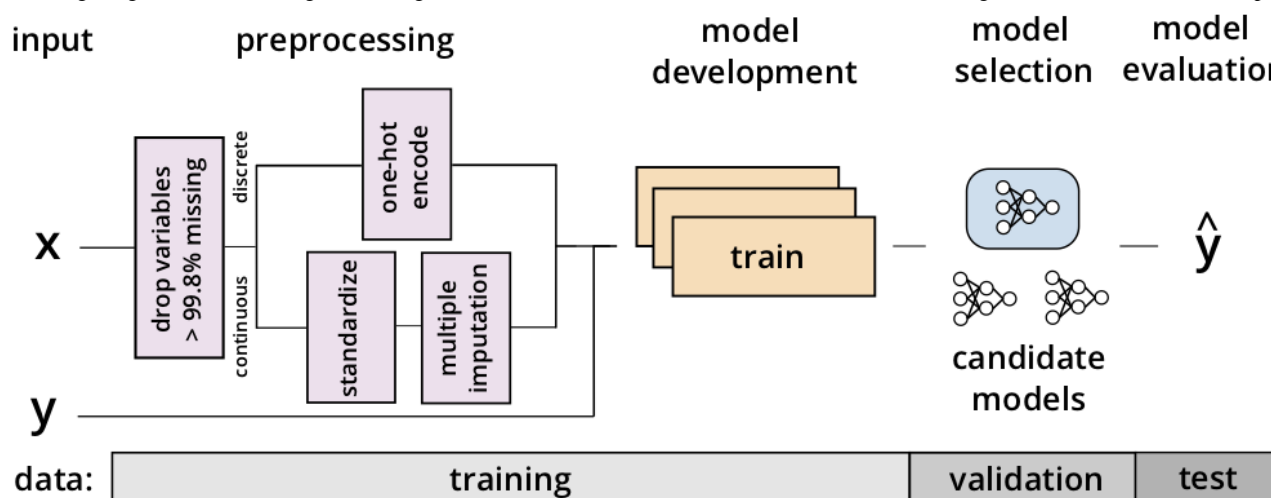

### Methodology

To derive the clinical predictive models  $\hat{y}_{SARS-CoV-2}$ ,  $\hat{y}_{admission}$ , and  $\hat{y}_{ICU}$  from the given development data set, we set up a systematic model development, validation, and evaluation pipeline (Figure 2). To evaluate the generalization ability of the developed clinical predictive models and to rule out overfitting to patients in the evaluation cohort, the development data is initially split into independent and stratified training, validation, and test folds without any patient overlap. Concretely, the multistage pipeline consists of preprocessing, model development, model selection, and model evaluation stages. For preprocessing and model

development, only the training fold was used, and only the validation and test folds of the development data were used for

model selection and model evaluation, respectively. We outline the pipeline stages in detail in the following paragraphs.

**Figure 2.** The presented multistage machine learning pipeline consists of preprocessing (light purple) the input data  $x$ , developing multiple candidate models using the given data set (orange), selecting the best candidate model for evaluation (blue), and evaluating the selected best model's outputs  $\hat{y}$ .

## Preprocessing

In the preprocessing stage, we first dropped all input features that were missing for more than 99.8% of all training set patients to ensure we had a minimal amount of data for each feature. This removed a total of 9 features from the original 106 routine clinical, laboratory, and demographic features. We then transformed all discrete features for each patient into their one-hot encoded representation with one out of  $p$  indicator variables set to 1 to indicate the discrete value for this patient, and all others set to 0 with  $p$  being the number of unique values for the discrete feature. We defined those features as discrete that have fewer than 6 unique values across all patients in the training fold. For discrete features, missing features were counted as a separate category in the one-hot representation. Next, we standardized all continuous features to have zero mean and unit standard deviation across the training fold data. Last, we performed multiple imputation by chained equations (MICE) to impute all missing values of every continuous feature from the respective other features in an iterative fashion [7]. We additionally added a missing indicator that indicates 1 if the feature was imputed by MICE and 0 if it was originally present to preserve missingness information in the data after imputation. After the preprocessing stage, continuous input features are standardized and fully imputed, and discrete input features are one-hot encoded. All preprocessing operations were derived only from the training fold and naïvely applied without adjustment to validation and test folds to avoid information leakage.

## Model Development

In the model development stage, we trained candidate clinical predictive models  $\square$ ,  $\square$ , and  $\square$  using supervised learning on the training fold of the preprocessed data. To derive the models from the preprocessed training fold data, we optimized various types of predictive models and performed a hyperparameter search with  $m$  runs for each of them. The model development process yielded  $m$  candidate models with different

hyperparameter choices and predictive performances for each model category.

## Model Selection

To select the best model among the set of candidate models, we evaluated their predictive performance against the held-out validation fold that had not been used for model development. We chose the top candidate model by ranking all models by their evaluated predictive performance in terms of the validation set area under the receiver operator characteristic curve (AUC). The model selection stage using the independent validation fold enabled us to optimize hyperparameters without using test fold data.

## Model Evaluation

In the model evaluation stage, we evaluated the selected best clinical predictive model against the held-out test fold that had not been used for training or model selection to estimate the expected generalization error of the models on previously unseen data. Using this approach, every selected best model from the model selection stage was evaluated exactly once against the test fold.

Using the presented standardized model development, selection, and evaluation pipeline, we compared various types of clinical predictive models in the same test setting with exactly the same amount of hyperparameter optimization and input features against the same test fold. This process enables us to systematically study the expected generalization ability, predictive performance, and influential features of clinical predictive models for predicting SARS-CoV-2 test results, hospital admission for patients who are SARS-CoV-2 positive, and ICU admission for patients who are SARS-CoV-2 positive.

## Experiments

We conducted retrospective experiments to evaluate the predictive performance of a number of clinical predictive models on each of the presented clinical prediction tasks using the standardized development, validation, and evaluation pipeline.

Concretely, our experiments aimed to answer the following questions:

- What is the expected predictive performance of the various clinical predictive models in predicting SARS-CoV-2 test results for presenting patients, hospital admission for patients who are SARS-CoV-2 positive, and ICU admission for patients who are SARS-CoV-2 positive?
- Which clinical, demographic, and blood analysis features were most important for the best encountered predictive models for each clinical prediction task?

### Data Set and Study Cohort

We used anonymized data from a cohort of 5644 patients seen at the Hospital Israelita Albert Einstein in São Paulo, Brazil in the early months of 2020. Exact data collection dates are unknown. The data set is available at [8]. Over the data collection time frame, the rate of patients who were SARS-CoV-2 positive at the hospital was around 10%, of which around 6.5% and 2.5% required hospitalization and critical care, respectively (Table 1). Notably, younger patients were

underrepresented in the SARS-CoV-2 positive group relative to the general patient population, which may have been caused by the reportedly more severe disease progression in older patients [9]. Information on patient sex was not included in our data set. Sex has been reported to be associated with COVID-19 outcomes with men reportedly being at higher risk for severe outcomes, and models including sex as a covariate may, therefore, achieve superior predictive performance [10]. We randomly split the entire available patient cohort into training ( $n=2822$ , 50%), validation ( $n=1129$ , 20%), and test folds ( $n=1693$ , 30%) within strata of patient age, SARS-CoV-2 test result, hospital admission status, and ICU admission status. We performed the stratification by randomly shuffling the entire set of available patients and then assigning a proportional number of patients within the same strata of patient age, SARS-CoV-2 test result, hospital admission status, and ICU admission status to each fold, resulting in three separate folds of the desired target fold sizes that had balanced proportions of the stratification covariates (Table 1). We used the implementation of the described stratification procedure provided in [11] (StratifiedShuffleSplit, package version 0.22.2).

**Table 1.** Training, validation, and test fold statistics for all patients and patients who are SARS-CoV-2 positive.

Property	Training	Validation	Test
<b>All patients</b>			
Patients ( $N=5644$ ), $n$ (%)	2822 (50)	1129 (20)	1693 (30)
SARS-CoV-2 (%)	9.85	9.92	9.92
Admission (%)	1.42	1.33	1.42
ICU <sup>a</sup> (%)	1.59	1.68	1.59
Age (20-quantiles) <sup>b</sup>	9.0 (1.0, 17.0)	9.0 (1.0, 18.0)	9.0 (2.0, 17.0)
<b>Patients who are SARS-CoV-2 positive</b>			
Patients ( $n=558$ ), $n$ (%)	279 (50)	112 (20)	167 (30)
SARS-CoV-2 (%)	100	100	100
Admission (%)	6.45	6.25	6.59
ICU (%)	2.87	2.68	2.99
Age (20-quantiles) <sup>b</sup>	10.0 (4.0, 17.0)	11.5 (4.5, 18.5)	10.0 (4.0, 17.5)

<sup>a</sup>ICU: intensive care unit.

<sup>b</sup>Patient ages are specified in 20-quantiles to maintain patient privacy (10% and 90% percentiles in parentheses).

### Models

Using the presented systematic evaluation methodology, we trained five different model types: logistic regression (LR), neural network (NN), random forest (RF), support vector machine (SVM), and gradient boosting (XGB) [12]. The NN was a multilayer perceptron consisting of  $L$  hidden layers with  $N$  hidden units each followed by a nonlinear activation function (rectified linear unit [13], scaled exponential linear unit [14], or exponential linear unit [15]) and batch normalization [16], and was trained using the Adam optimizer [17] for up to 300 epochs with an early stopping patience of 12 epochs on the validation set loss.

### Hyperparameters

We followed an unbiased, systematic approach to hyperparameter selection and optimization. For each type of clinical predictive model, we performed a maximum of 30 hyperparameter optimization runs with hyperparameters chosen from predefined ranges (Table 2). The performance of each hyperparameter optimization run was evaluated against the validation cohort. After computing the validation set performance, we selected the best candidate predictive model across the 30 hyperparameter optimization runs by AUC for further evaluation against the test set.

**Table 2.** Hyperparameter ranges used for hyperparameter optimization of logistic regression, neural network, random forest, support vector machine, and gradient boosting models for all tasks.

Model and hyperparameter	Range/choices <sup>a</sup>
<b>Logistic regression</b>	
Regularization strength $C$	0.01, 0.1, 1.0, 10.0
<b>Neural network</b>	
Number of hidden units $N$	16, 32, 64, 128
Number of hidden layers $L$	1, 2, 3
Activation $a$	ReLU <sup>b</sup> [13], SELU <sup>c</sup> [14], ELU <sup>d</sup> [15]
Batch size $B$	16, 32, 64, 128
L2 regularization $\lambda_2$	0.0, 0.00001, 0.0001
Learning rate $\alpha$	0.003, 0.03
Dropout percentage $p$	(0%-25%)
<b>Random forest</b>	
Tree depth $D$	3, 4, 5
Number of Trees $T$	32, 64, 128, 256
<b>Support vector machine</b>	
Regularization strength $C$	0.01, 0.1, 1.0, 10.0
Kernel $k$	polynomial, radial basis function, sigmoid
Polynomial degree $d$	3, 5, 7
<b>Gradient boosting</b>	
Subsample ratio $r$	0.25, 0.5, 0.75, 1.0
Max <sup>e</sup> tree depth $T$	2, 3, 4, 5, 6, 7, 8
Min <sup>f</sup> partition loss $\gamma$	0.0, 0.1, 1.0, 10.0
Learning rate $\alpha$	0.003, 0.03, 0.3, 0.5
L1 regularization $\lambda_1$	1.0, 0.1, 0.001, 0.0
L2 regularization $\lambda_2$	1.0, 0.1, 0.001, 0.0
Num <sup>g</sup> boosting rounds $B$	5, 10, 15, 20

<sup>a</sup>Parentheses indicate continuous ranges within the indicated limits sampled uniformly. Comma-delimited lists indicate discrete choices with equal selection probability.

<sup>b</sup>ReLU: rectified linear unit.

<sup>c</sup>SELU: scaled exponential linear unit.

<sup>d</sup>ELU: exponential linear unit.

<sup>e</sup>Max: maximum.

<sup>f</sup>Min: minimum.

<sup>g</sup>Num: number.

## Predictive Performance

To assess the predictive performance of each of the developed clinical predictive models, we evaluated their performance in terms AUC, area under the precision recall curve (AUPR), sensitivity, specificity, and specificity at greater than 95% sensitivity (Spec@95%Sens) on the held-out test set cohorts for each task (Table 1). After model development and hyperparameter optimization, we evaluated each model type exactly once against the test set to calculate the final performance metrics. Operating thresholds for each model were

the operating points on the receiver operator characteristic curve closest to the top left coordinate as calculated for the validation cohort. We chose a variety of complementary evaluation metrics to give a comprehensive picture of the expected performance of each clinical predictive model on the evaluated tasks. For each of the performance metrics, we additionally computed 95% CIs using bootstrap resampling with 100 bootstrap samples on the test set cohort to quantify the uncertainty of our analysis results. We also assessed whether differences between clinical predictive models were statistically significant at significance

level  $\alpha=.05$  using pairwise  $t$  tests with the respective best models for each task as measured by AUC.

### Importance of Test Types

To quantify the importance of specific clinical, demographic, and blood analysis features on each of the predicted outcomes, we used causal explanation (CXPlain) models [18]. CXPlain provides standardized relative feature importance attributions for any predictive model by computing the marginal contribution of each input feature toward the predictive performance of a model [19] and is, therefore, particularly well-suited for assessing feature importance in our diverse set of models. We used the test fold's ground truth labels to compute the exact marginal contribution of each input feature without any estimation uncertainty.

## Results

### Predictive Performance

In terms of predictive performance (Table 3), we found that the overall best identified models by AUC were XGB for predicting SARS-CoV-2 test results, RF for predicting hospital admissions for patients who are SARS-CoV-2 positive, and SVM for predicting ICU admission for patients who are SARS-CoV-2 positive with AUCs of 0.66 (95% CI 0.63-0.70), 0.92 (95% CI 0.81-0.98), and 0.98 (95% CI 0.95-1.00), respectively. Notably, we found that predicting positive SARS-CoV-2 results from routinely collected clinical measurements was a considerably more difficult task for clinical predictive models than predicting hospitalization and ICU admission. Nonetheless, the best encountered clinical predictive model for predicting SARS-CoV-2 test results (XGB) achieved a respectable sensitivity of 75% (95% CI 67%-81%) and specificity of 49% (95% CI 46%-51%). After fixing the operating threshold of the

model to meet a sensitivity level of at least 95% (Spec@95%Sens), the best XGB model for predicting SARS-CoV-2 test results would achieve a specificity of 23% (95% CI 7%-32%). We additionally found that the differences in predictive performance between the best XGB model for predicting SARS-CoV-2 test results and the other predictive models was significant at a prespecified significance level of  $\alpha=.05$  ( $t$  test) for all but the AUPR metric, where NN achieved a significantly better AUPR of 0.22, and the difference to SVM was not significant at the prespecified significance level. On the task of predicting hospital admissions for patients who are SARS-CoV-2 positive, the best encountered RF model achieved a sensitivity of 55% (95% CI 19%-85%), a high specificity of 96% (95% CI 92%-98%), and a Spec@95%Sens of 34% (95% CI 29%-97%). Owing to the lower sample size due to the smaller cohort of patients who are SARS-CoV-2 positive, the performance results for predicting hospital admission generally had wider uncertainty bounds but were nonetheless significantly better for RF than the other predictive models at the prespecified significance level of  $\alpha=.05$  ( $t$  test) for most performance metrics, with the exception of AUC, where XGB achieved an AUC of 0.91, and AUPR, where LR achieved an AUPR of 0.44. On the task of predicting ICU admission for patients who are SARS-CoV-2 positive, SVM had a sensitivity of 80% (95% CI 36%-100%), a specificity of 96% (95% CI 92%-98%), and a Spec@95% Sens of 95% (95% CI 91%-100%). Due to the small percentage of about 3% of patients who were SARS-CoV-2 positive that were admitted to the ICU (Table 1), uncertainty bounds were wider than for the models predicting hospital admissions, and the results of the best encountered SVM were found to be not significantly better than LR and RF in terms of AUC, LR, and NN in terms of sensitivity, and NN in terms of Spec@95%Sens at the prespecified significance level of  $\alpha=.05$  ( $t$  test).

**Table 3.** Comparison of LR, NN, RF, SVM, and XGB models in terms of AUC, AUPR, sensitivity, specificity, and Spec@95% Sens for predicting SARS-CoV-2 test results, hospital admission for patients who are SARS-CoV-2 positive, and intensive care unit admission for patients who are SARS-CoV-2 positive on the test set cohort.

## Feature Importance

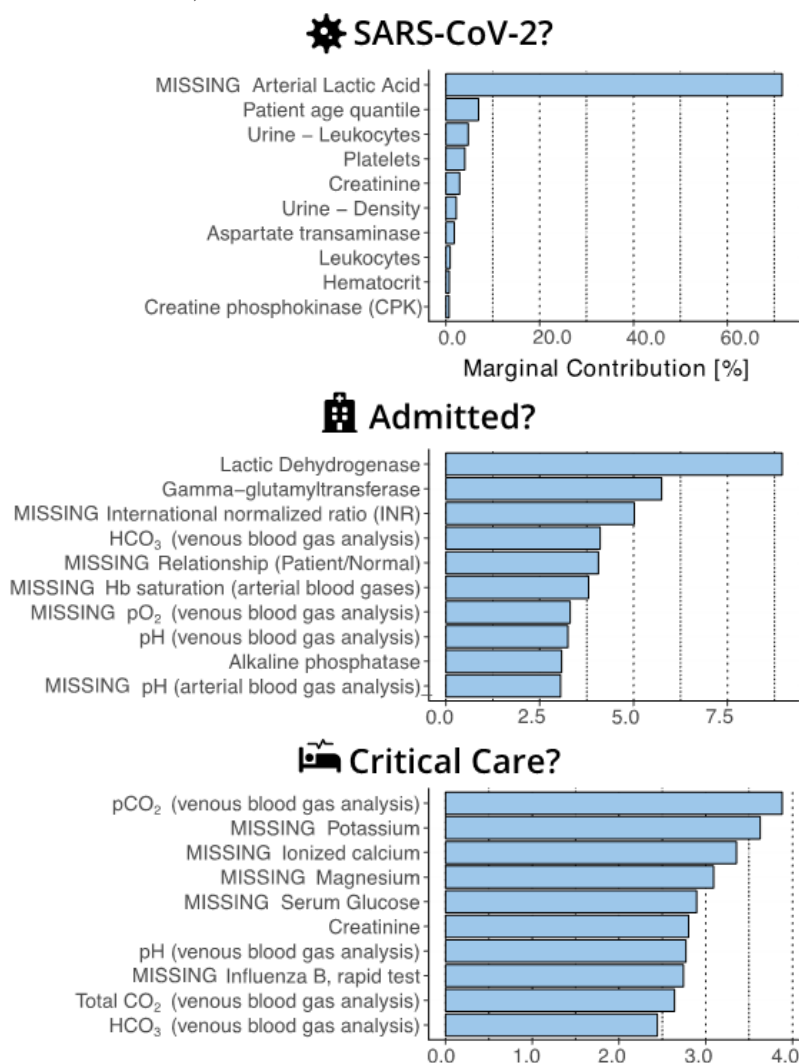

In terms of feature importance, we found that importance scores were distributed highly unequally, relatively uniform, and highly uniform for the best models encountered for predicting SARS-CoV-2 test results, for predicting hospital admissions for patients who are SARS-CoV-2 positive, and for predicting ICU admission, respectively (Figure 3). Most notably, we found that 71.7% of the importance for the best XGB model for predicting SARS-CoV-2 test results was assigned to the missing indicator corresponding to the arterial lactic acid measurement (ie, much of the marginal predictive performance gain of the XGB model was attributed to whether or not the arterial lactic acid test had been ordered). Beyond arterial lactic acid being missing, age, leukocyte count, platelet count [20], and creatinine

[21] were implied to be associated with a positive SARS-CoV-2 test result by the best encountered predictive model, which further substantiates recent independent reports of those factors being potentially associated with SARS-CoV-2 [20-24]. Similar to the best encountered XGB model for predicting SARS-CoV-2 test results, the top encountered predictive models for hospital admission and ICU admission for patients who are SARS-CoV-2 positive assigned a considerable degree of importance to missingness patterns associated with a number of measurements. A possible explanation for missingness appearing as a top predictor across the different tasks is that decisions on whether or not to order a certain test to be performed for a given patient were influenced by patient characteristics that were not captured in the set of clinical measurements that were available to the

predictive models. In the case of the missingness of the lactic acid test being predictive of SARS-CoV-2 test results, the importance could stem either from clinicians judging patients to be more likely to have COVID-19 due to their clinical presentation and, therefore, ordering a lactic acid test to account for potential lactic acidosis due to COVID-19–induced reduced oxygenation levels or from patients that clinicians see as at risk for lactic acidosis being likely to have their symptoms caused by an underlying SARS-CoV-2 infection. A controlled setting with standardized testing guidelines would be required to determine which confounding factors are behind the predictive power of the missingness patterns that have been implied to be associated with COVID-19 by the predictive models. Beyond

missingness patterns, top predictors for predicting hospital admission were lactate dehydrogenase [25]; gamma-glutamyl transferase, which through abnormal liver function has been reported to be implicated in COVID-19 severity [26]; and  $HCO_3$  [27]. For predicting ICU admission in patients who are SARS-CoV-2 positive,  $pCO_2$ , creatinine [21], and pH [23] were top predictors. Blood pH, and in particular respiratory alkalosis, has been reported to be associated with severe COVID-19 [28]. We note that several factors that were not included in our study have recently been reported to be implicated in COVID-19 outcomes, such as the number of ICU beds available at a hospital [29], patients' racial and ethnic backgrounds [30], and several pre-existing conditions [31].

**Figure 3.** A comparison of the top 10 features ranked by relative feature importance scores for the best-encountered model for predicting SARS-CoV-2 test results (gradient boosting, top), hospital admissions (random forest, middle), and critical care admission for patients who are SARS-CoV-2 positive (support vector machine, bottom), respectively. The bar length corresponds to the relative marginal importance (in %) of the displayed features toward the predictive performance of the respective model. Feature names that include “MISSING” indicate that the given marginal contribution refers to the importance of the presence of that feature's absence, not the feature itself.

## Discussion

### Principal Findings

We presented a systematic study of predictive models that predict SARS-CoV-2 test results, hospital admission for patients who are SARS-CoV-2 positive, and ICU admission for patients

who are SARS-CoV-2 positive using routinely collected clinical measurements. Models that predict SARS-CoV-2 test results could help prioritize scarce testing capacity by identifying those individuals that are more likely to receive a positive result. Similarly, predictive models that predict which patient who is SARS-CoV-2 positive would be most likely to require hospital and critical care beds could help better use existing hospital

capacity by prioritizing those patients that have the highest risk of deterioration. Facilitating the efficient use of scarce health care resources is particularly important in dealing with

SARS-CoV-2, as its rapid transmission significantly increases demand for health care services worldwide (Figure 4).

**Figure 4.** Receiver operator characteristic curves for the best-encountered model for predicting SARS-CoV-2 test results (gradient boosting, left), hospital admissions for patients who are SARS-CoV-2 positive (random forest, top right), and critical care admissions for patients who are SARS-CoV-2 positive (support vector machine, bottom right). Numbers in the bottom right of each subgraph show the respective model's AUC. Solid dots on the curves indicate operating thresholds selected on the validation fold. AUC: Area under the receiver operator characteristic curve.

## Limitations

The main limitation of this study is that its experimental evaluation was based on data collected from a single study site, and its results may, therefore, not generalize to settings with significantly different patient populations, admission criteria, patterns of missingness, and testing guidelines. Operationally, to ensure robustness, it is important to check for any significant deviations in terms of patterns observed in the training cohort when attempting to transfer predictive models trained in one context to another (ie, when transferring a model to another hospital). In case any significant deviations are detected, fine-tuning the predictive model for the new target context is strongly advised. In addition, we did not have access to mortality data for the analyzed cohort, and we were, therefore, not able to correlate our predicted individual risk scores with patient mortality, which is another related prediction task that may be of clinical importance. Future studies should include a broader set of clinical measurements and outcomes, cohorts from multiple distinct geographical sites, and under varying patterns of missingness to determine the robustness of the clinical predictive models to these confounding factors. Finally, we believe that the inclusion of data from other modalities such as genomic profiling and medical imaging, and data on comorbidities, symptoms, and treatment histories could potentially further improve predictive performance of clinical predictive models across the presented prediction tasks.

## Comparison With Prior Work

A substantial body of work is dedicated to the study, validation, and implementation of predictive models for clinical tasks. Clinical predictive models have, for example, been used to predict risk of septic shock [32,33], risk of heart failure [34],

readmission following heart failure [35-37], false alarms in critical care [38], risk scores [39], outcomes [40] and mortality in pneumonia [41,42], and mortality risk in critical care [43-45]. Predicting clinical outcomes for individual patients is difficult because many confounding factors may influence patient outcomes, and collecting and accounting for these factors in an unbiased way remains an open challenge in clinical practice [46]. Systematic studies such as this paper enable medical practitioners to better understand, assess, and potentially overcome these issues by systematically evaluating generalization ability, expected predictive performance, and influential predictors of various clinical predictive models. Beyond the need for systematic evaluation, missingness [47-50], noise [51,52], multivariate input data [38,53-55], and the need for interpretability [18,56-58] have been highlighted as particularly important considerations in health care settings. In this study, we build on recent methodological advances to develop and systematically study clinical predictive models that may aid in prioritizing health care resources [59] for COVID-19 and, thereby, help prevent a potential overextension of health care system capacity.

## Clinical Predictive Models for COVID-19

Several clinical predictive models have recently been proposed for COVID-19, for example, for predicting potential COVID-19 diagnoses using data from emergency care admission exams [60] and chest imaging data [61-66], for predicting COVID-19-related mortality from clinical risk factors [67,68], for predicting which patients will develop acute respiratory distress syndrome from patients' clinical characteristics [69], for predicting critical illness in patients with COVID-19 [70,71], and for predicting progression risk in patients with COVID-19 pneumonia [72]. Siordia [73] presented a review of

epidemiology and clinical features associated with COVID-19, and Wynants et al [74] performed a critical review that assessed limitations and risk of bias in diagnostic and prognostic models for COVID-19. In addition, Wang et al [23] performed a cohort study for clinical and laboratory predictors of COVID-19–related in-hospital mortality that identified baseline neutrophil count, age, and several other clinical features as top predictors of mortality. Beyond prediction, Ienca and Vayena [75] have argued for the responsible use of data in tackling the challenges posed by SARS-CoV-2.

Owing to the recent emergence of SARS-CoV-2, there currently exists, to the best of our knowledge, no prior systematic study on clinical predictive models that predict the likelihood of a positive SARS-CoV-2 test and hospital and ICU admission from clinical, demographic, and blood analysis data that accounts for the missingness that is characteristic for the clinical setting. We additionally assessed the influence of various clinical, demographic, and blood analysis measurements on the predictions of the developed clinical predictive models.

## Conclusions

We present a systematic study in which we developed and evaluated clinical predictive models for COVID-19 that estimate

the likelihood of a positive SARS-CoV-2 test in patients presenting at hospitals and the likelihood of hospital admission and ICU admission in patients who are SARS-CoV-2 positive. We evaluated our developed clinical predictive models in a retrospective evaluation using a cohort of 5644 hospital patients seen in São Paulo, Brazil. In addition, we determined the clinical, demographic, and blood analysis measurements that were most important for accurately predicting SARS-CoV-2 status, hospital admissions, and ICU admissions. Our experimental results indicate that clinical predictive models may in the future potentially be used to inform care and help prioritize scarce health care resources by assigning personalized risk scores for individual patients using routinely collected clinical, demographic, and blood analysis data. Furthermore, our findings on the importance of routine clinical measurements toward predicting clinical pathways for patients increases our understanding of the interrelations of individual risk profiles and outcomes in SARS-CoV-2. Based on our study's results, we conclude that health care systems should explore the use of predictive models that assess individual COVID-19 risk to improve health care resource prioritization and inform patient care.

## Acknowledgments

The anonymized data used in this paper were generously contributed by patients at Hospital Israelita Albert Einstein in São Paulo, Brazil and are freely available at [8].

## Conflicts of Interest

PS is an employee and shareholder of F Hoffmann-La Roche Ltd.

## Multimedia Appendix 1

Demographic, clinical, and blood analysis data used as features by our systematic model development and evaluation pipeline, and their respective value ranges in the data set.

## Abstract

**Background:** As the COVID-19 pandemic disrupted medical practice, telemedicine emerged as an alternative to outpatient visits. However, it is not known how patients and physicians responded to an accelerated implementation of this model of medical care.

**Objective:** The aim of this study is to report the system-wide accelerated implementation of telemedicine, compare patient satisfaction between telemedicine and in-person visits, and report provider perceptions.

**Methods:** This study was conducted at the UC Christus Health Network, a large private academic health network in Santiago, Chile. The satisfaction of patients receiving telemedicine care in March and April 2020 was compared to those receiving in-person care during the same period (concurrent control group) as well as in March and April 2019 (retrospective control group). Patient satisfaction with in-person care was measured using the Net Promoter Score (NPS) survey. Patient satisfaction with telemedicine was assessed with an online survey assessing similar domains. Providers rated their satisfaction and responded to open-ended questions assessing challenges, strategies used to address challenges, the diagnostic process, treatment, and the patient-provider relationship.

**Results:** A total of 3962 patients receiving telemedicine, 1187 patients from the concurrent control group, and 1848 patients from the retrospective control group completed the surveys. Satisfaction was very high with both telemedicine and in-person services. Overall, 263 physicians from over 41 specialties responded to the survey. During telemedicine visits, most providers felt their clinical skills were challenged (61.8%). Female providers felt more challenged than male providers (70.7% versus 50.9%,  $P=.002$ ). Surgeons, obstetricians, and gynecologists felt their clinical skills were challenged the least, compared to providers from nonsurgical specialties ( $P<.001$ ). Challenges related to the delivery modality, diagnostic process, and patient-provider relationship differed by provider specialty ( $P=.046$ ,  $P<.001$ , and  $P=.02$ , respectively).

**Conclusions:** Telemedicine implemented in response to the COVID-19 pandemic produced high patient and provider satisfaction. Specialty groups perceived the impact of this new mode of clinical practice differently.

**KEYWORDS**

telemedicine; telehealth; virtual medicine; health services evaluation; COVID-19

## Introduction

COVID-19 is the largest pandemic of the current century. It has generated transformative changes in health care, including the prioritization of emergency departments and intensive care units [1]. In addition, with physical distancing and isolation as major strategies to contain the spread of the disease, there are fewer patients receiving outpatient clinical care [2]. Although reducing in-person encounters is needed to contain the transmission of SARS-CoV-2, medical care is still needed for acute and chronic conditions.

In this context, telemedicine has emerged as a necessary clinical innovation to provide patient care [3]. This delivery modality has demonstrated clinical effectiveness, optimization in the delivery of health services, usability, and high patient and provider satisfaction [4,5]. Although appealing, several factors may hinder the sustainable use of telemedicine. First, providers prefer in-person encounters to virtual ones [6]. Potential concerns include uncertainty in the clinical encounter, difficulties performing a physical examination, and concerns with the patient-provider relationship [7]. These difficulties may reduce a clinician's motivation to deliver virtual services. In addition, health insurance agencies have not always recognized this type of clinical service to be reimbursable, limiting the scaling up of telemedicine. Even though telemedicine has existed for several years and has had several implementation barriers, the COVID-19 pandemic has quickly transformed the practice of ambulatory medicine [8,9] and the willingness of health care organizations to implement this mode of delivery. The effect of rapidly deploying new models of care is still incompletely understood.

In this context, the UC Christus Health Network in Santiago, Chile, implemented telemedicine services two weeks after the first patient with COVID-19 was diagnosed in the country. The purpose of this paper is to report the system-wide accelerated implementation of telemedicine, compare patient satisfaction with telemedicine and in-person visits, and report provider perceptions regarding the implementation of virtual visits.

## Methods

### Design

This study used a convergent parallel mixed methods evaluation. In this study design, quantitative and qualitative methods have similar relevance, the data are collected in the same phase of the research project, the analysis of the data is independent, and the findings are combined and interpreted together [10]. We chose this design to better understand participants' experiences. Quantitative data consisted of in-person and telemedicine visits, patient demographics, satisfaction, and challenges identified by clinicians. Data from patients receiving telemedicine care were compared to that of patients receiving in-person care between March 1 and April 30, 2019 (retrospective control group), and March 1 and April 30, 2020 (concurrent control group). Qualitative data included physicians' responses to open-ended questions asking about challenges related to using telemedicine and mechanisms to address those challenges when delivering virtual health services. This study was approved by the

Institutional Review Board of the Pontificia Universidad Católica de Chile.

### Setting

Chile's health system combines public and private health providers. Public health services are paid for by public health insurance. Private health providers are paid per service delivered, and health insurance pays some or all of the fees charged by the health care providers.

This study was conducted at the UC Christus Health Network, a large private academic health network in Santiago, Chile. This health network has two hospitals with nearly 500 beds in total and 6 primary and secondary care clinics, with more than 800,000 patient visits every year. UC Christus has been nationally recognized for its innovation and patient service with the "Best Place to Innovate," "Praxis Xperience Index," and "ProCalidad" Awards.

### Telemedicine and its Implementation

UC Christus Health started implementing telemedicine on March 17, 2020, about two weeks after the first patient with COVID-19 was diagnosed in Chile. Initially, it started with generalist specialties, including internal medicine and family medicine, which offered services and guidance for patients with respiratory symptoms. Telemedicine was subsequently implemented as a strategy to provide care across the entire health care system. Currently, more than 720 providers from 61 clinical specialties are providing patient care through telemedicine.

To access these encounters, patients schedule appointments online or over the phone. When scheduling the appointment, patients must accept the terms of telemedicine, including that providers cannot provide certain services virtually, such as ordering restricted prescriptions or providing official health certificates. Once the appointment is scheduled, patients receive a confirmation email and are invited to pay for their visit. The cost of this service is about US \$50, representing about two-thirds of the cost for in-person visits. Once the visit is paid for, patients and providers receive a Zoom link (Zoom Video Communications Inc) for their telemedicine visit, and they connect at the scheduled time. An administrative team supports patient-provider connections. Providers have access to the patient's electronic medical record and use a separate platform to order prescriptions, laboratory exams, images, and procedures, which are usually written manually during in-person visits. These electronic orders are emailed automatically to patients from the medication and laboratory platform.

### Outcomes and Data

#### Overview

Primary outcomes were patient and provider satisfaction along with providers' challenges in implementing telemedicine. This study used four databases, including the following: (1) demographics of outpatient and telemedicine visits, (2) patient satisfaction with in-person visits, (3) patient satisfaction with telemedicine visits, and (4) provider satisfaction with telemedicine visits. Demographic data were extracted from patients' electronic medical records for the complete months of March and April of 2019 and 2020, generating three different

groups: 2019 in-person care (retrospective control group), 2020 in-person care (concurrent control group), and 2020 virtual care (telemedicine group). Satisfaction data from patients and providers were stored in independent databases.

### **Patient Demographics**

The number of visits and physician's specialty, as well as patient's sex, date of birth, insurance type, and address for all visits were extracted from electronic medical records. In this study, physician specialty was classified as one of the following seven groups: generalist specialties (family medicine, general internal medicine, geriatrics, pediatrics), pediatric subspecialties (including genetics and infant neurology), internal medicine subspecialties (including neurology), surgical subspecialties (including anesthesia, orthopedics, urology), obstetrics and gynecology, psychiatry, and ophthalmology, dermatology, and otolaryngology.

### **Patient Satisfaction With In-Person Visits**

Patient satisfaction is usually evaluated using the Net Promoter Score (NPS) survey (Cronbach  $\alpha=.96$ ) (FBA Consulting, unpublished material, 2020) [11]. This measure assesses satisfaction across several dimensions including access, payment process, infrastructure, and provider's services, as well as general satisfaction, using a 5-point Likert scale (1=very bad, 5=very good). Data were collected through an online survey sent via SMS text messaging after the visit.

### **Patient Satisfaction With Telemedicine Visits**

An 8-item questionnaire was developed to assess patient satisfaction with telemedicine services using a 1-7 scoring system. Like the survey completed by patients receiving in-person services, survey domains included questions assessing satisfaction with access, payment process, web portal (infrastructure), and provider's services, as well as general satisfaction (Cronbach  $\alpha=.86$ ). This evaluation was sent via email after the encounter.

### **Physician Satisfaction With Telemedicine**

Using a 19-item anonymous survey, clinicians were asked about their demographics, telemedicine experience, and general satisfaction. Open-ended questions assessed challenges in care delivery, diagnostic process, treatment, and the patient-provider relationship, as well as strategies used to overcome these barriers.

### **Data Analyses**

Following the procedures of the selected mixed methods design, each type of data was analyzed independently.

### **Quantitative Data**

Patient and provider demographic information was summarized using descriptive statistics. Trends for in-person and

telemedicine visits were plotted and compared to the null hypothesis of no trend using the chi-square test for trend. Patient characteristics of those receiving telemedicine services were compared to the demographics of patients from the retrospective and concurrent control groups using the chi-square test. As satisfaction data did not have a normal distribution, the Wilcoxon-Mann-Whitney test was used, after converting in-person and telemedicine scoring systems to a 0-100 scale. Responses regarding considering telemedicine as challenging and counts of qualitative responses were modeled after conducting bivariate analysis with logistic regressions that included the physician's specialty category as an independent variable, and gender, age, years of clinical experience, and telemedicine experience as covariables. Adjusted odds ratios, predicted probabilities, and 95% confidence intervals for the selected outcomes were estimated for each specialty category. All analyses were conducted in STATA (Version 14; StataCorp) and resulting *P* values  $<.05$  were considered statistically significant.

### **Qualitative Data**

Responses to open-ended questions were coded by two independent researchers following the procedures of content analysis [12]. Using a combination of inductive and deductive approaches, physicians' perceptions were grouped into emerging categories and subcategories organized according to the domains of the guiding questions. To ensure coding reliability, a random sample of 20% of the clinician surveys ( $n=53$ ) were double-coded, resulting in 96.4% coding agreement. Responses in each category were counted and grouped by domain. Quotes were selected to represent the participant's opinions and these were translated to English.

Mixed methods integration was conducted at the finding interpretation and reporting phases. To interpret both sources of data jointly, researchers gathered to discuss quantitative and qualitative results together. Integration at the reporting level occurred through a continuous narrative approach, in which the mixed data are presented in a single report, but in different sections [13].

## **Results**

### **Change in Clinical Practice**

In 2019 and 2020 before COVID-19 arrived in Chile, there were an average of 3039 and 3163 daily outpatient visits in the UC Christus Health Network, respectively. In-person visits were reduced to an average of 384.7 daily visits 3 weeks after the first patient with COVID-19 was confirmed in Chile, representing an 87.9% reduction in outpatient visits (Figure 1,  $P<.001$ ). Since telemedicine services began, the number of daily visits has increased, with the UC Christus Health Network delivering up to 509 virtual visits each day ( $P<.001$ ).

**Figure 1.** Rates of in-person and telemedicine visits at UC Christus Health and cumulative COVID-19 cases from March 1 to April 30, 2020, as well as relevant dates of COVID-19 management in Chile and UC Christus Health.

#### Relevant dates:

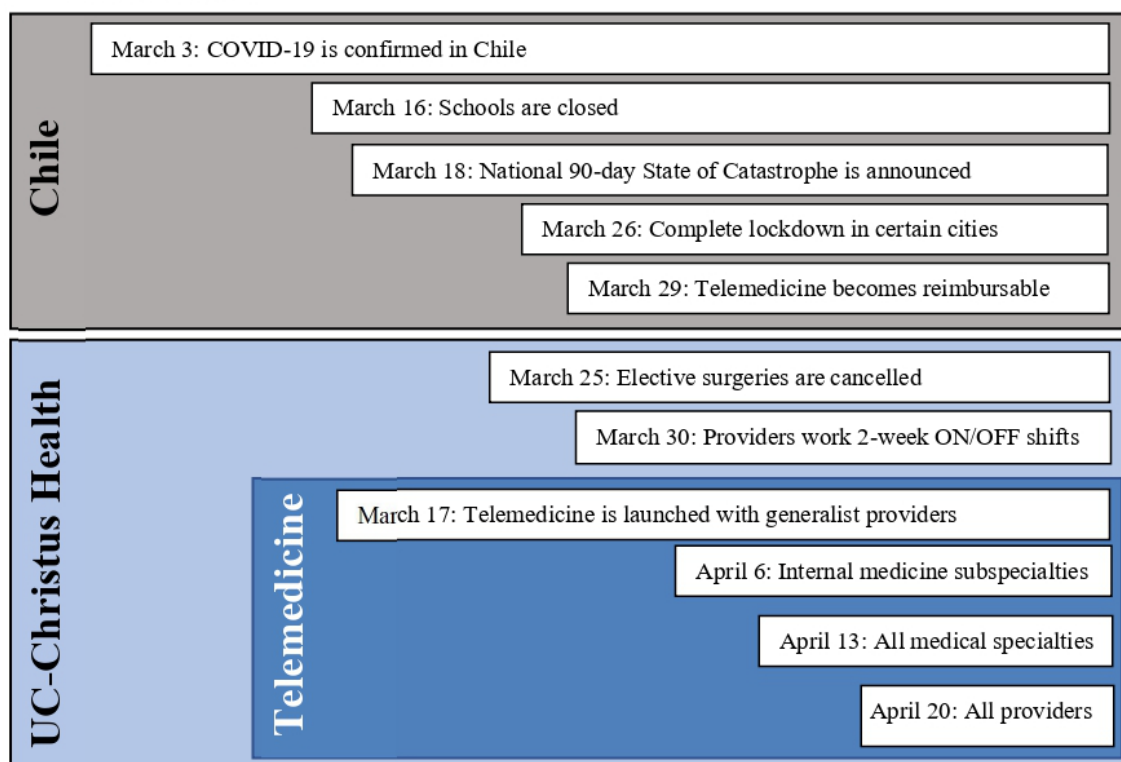

Figure 2 displays telemedicine and in-person activity across medical specialties during 2020 compared to 2019. All specialties except psychiatry decreased the number of in-person visits. Pediatrics subspecialties, along with ophthalmology,

otorhinolaryngology, and dermatology had the greatest reduction of in-person visits, experiencing between 61.6% to 70.0% of the demand of the previous year ( $P<.001$ ).

**Figure 2.** Rates of telemedicine and in-person visits by medical specialty.

Physicians from all specialty groups were able to implement virtual visits. Even though psychiatrists have been able to provide up to 24.7% of their 2019 volume of clinical encounters through virtual care, most medical groups have only delivered between 2.8% and 10.8% of visits compared to their 2019 baseline ( $P<.001$ ).

### Patient Demographics

Table 1 compares the demographic characteristics of the telemedicine, concurrent control, and retrospective control groups. Patients accessing telemedicine were more likely to be female and have private insurance, and less likely to be children or older adults, or residents of the Santiago Metropolitan Region compared to both in-person control groups ( $P<.01$  for all comparisons).

**Table 1.** Demographic characteristics of patients receiving care through telemedicine compared to patients from concurrent and retrospective control groups.

Characteristics	Telemedicine group (n=8592), n (%)	Concurrent control group (n=51,290), n (%)	P value	Retrospective control group (n=127,669), n (%)	P value
Gender (female), n (%)	5376 (62.6)	31,436 (61.4)	.024	77,845 (61.0)	.003
<b>Age category (years), n (%)</b>	N/A <sup>a</sup>	N/A	<.001	N/A	<.001
0-18	1749 (20.4)	11,855 (23.1)	N/A	34,357 (26.9)	N/A
19-64	5725 (66.6)	31,607 (61.6)	N/A	73,632 (57.7)	N/A
≥65	1118 (13.0)	7828 (15.3)	N/A	19,680 (15.4)	N/A
Private health insurance, n (%)	7542 (87.8)	21,319 (41.6)	<.001	56,495 (44.3)	<.001
Resident of the Santiago Metropolitan Region, n (%)	6529 (76.0)	42,833 (83.5)	<.001	111,822 (87.6)	<.001

<sup>a</sup>N/A: not applicable.

### Patient Satisfaction

During March and April of 2019 and 2020, 1848 and 1187 patients responded to the satisfaction questionnaire after the

in-person visits, respectively. In addition, 3962 patients responded to the telemedicine satisfaction assessment. Satisfaction was very high with both telemedicine and in-person services (Figure 3). Patients receiving telemedicine services

reported similar satisfaction with clinician's services compared to both control groups. Patients using telemedicine reported similar access to providers compared to in-person visits in 2020 ( $P=.08$ ), but greater access compared to in-person visits in 2019 (8.7% increase,  $P<.001$ ). Patients using telemedicine care reported less satisfaction with the payment process (5.3%

reduction,  $P<.001$ ) and infrastructure (web portal, 3.4% reduction,  $P<.001$ ) compared to patients receiving in-person visits concurrently. Ratings in these domains were not statistically different compared to patients receiving in-person visits in 2019.

**Figure 3.** Satisfaction of patients receiving care via telemedicine compared to concurrent and retrospective control groups.

### Physician Satisfaction

A total of 263 clinicians responded to the satisfaction assessment (36.5%). They were mostly female ( $n=155$ , 58.9%), with an average age of 44 years (SD 10.9), and an average of 16.8 years (SD 11.4) of clinical experience. Most providers reported limited experience with telemedicine, with 147 clinicians (61%) reporting 10 or fewer virtual patients encounters at the time they responded to the questionnaire. There were no differences in gender ( $P=.37$ ), age ( $P=.10$ ), or specialty category ( $P=.32$ ) among survey respondents and nonrespondents ( $n=721$  providers). Overall, 244 providers were satisfied or very satisfied with telemedicine (92.8%), and most would recommend this service to friends or family members (94.2%).

### Experiencing Challenges When Conducting Telemedicine Visits

When providing telemedicine care, most physicians felt their clinical skills challenged somewhat or a lot (61.8%). Female providers felt more challenged than male providers (70.7% versus 50.9%,  $P=.002$ ). Surgeons, obstetricians, and gynecologists felt that their clinical skills were challenged the least, compared to providers from other medical specialties ( $P=.02$ ). These associations persisted after adjusting for covariates in a logistic regression model (Figure 4). There were no statistically significant differences in feeling that clinical skills were challenged according to the provider's age, years of clinical experience, or the number of patients seen virtually.

**Figure 4.** Adjusted rate and 95% CIs of physicians perceiving their clinical skills being challenged when using telemedicine, by physician's specialty.

### Specific Challenges With Telemedicine and Mechanisms of Addressing Them

Table 1 in [Multimedia Appendix 1](#) summarizes the categories and subcategories of challenges experienced with telemedicine delivery, the diagnostic process, and the patient-provider relationship. Most challenges were related to the delivery mode, specifically accessing the platforms used, dealing with patient scheduling, and accessing the resources required for telemedicine. There were no challenges specifically related to patient treatment. Several strategies were implemented by physicians to address these barriers (Table 2 in [Multimedia Appendix 1](#)). Strategies most commonly used were directly contacting the patient, and requesting support from the help center, peers, or patients.

[Figure 5](#) represents the rates of physicians experiencing any challenge with the delivery modality, diagnostic process, and patient-provider relationship according to their specialty category. Providers from all specialties experienced challenges with the delivery system, especially providers from internal medicine subspecialties and psychiatry ([Figure 5A](#),  $P=.046$ ). There were differences by specialty when reporting challenges related to a patient's diagnostic process. Most physicians who experienced challenges were from primary care and pediatrics subspecialties ([Figure 5B](#),  $P<.001$ ). Challenges in the patient-provider relationship also differed by specialty group. About 60% of psychiatrists reported experiencing challenges in this domain compared to 16.4% of surgeons ([Figure 5C](#),  $P=.02$ ).

**Figure 5.** Adjusted rate and 95% CIs of providers reporting challenges with (A) the modality of service, (B) the patient's diagnostic process, and (C) the patient-provider relationship, by physician's specialty.

## Discussion

### Main Results

The COVID-19 pandemic has radically transformed clinical care and our organization was forced to quickly deploy telemedicine services without the standard change management and training strategies that are usually required for successful digital transformations in health care [14]. Despite this, we have

seen a quick uptake and the practice has been widely accepted in a short period of time [15]. According to Kotter's change management process, the first step toward successful change is the sense of urgency to change [16]; it is undeniable that the COVID-19 pandemic has generated an enormous sense of urgency to adapt to this reality. In a few weeks, we were able to include all clinical specialties in the telemedicine project. Moreover, the Chilean National Health Fund (FONASA), which

had delayed including clinical specialties in funding schemes for years, established insurance coverage for telemedical services three weeks after the first COVID-19 case in Chile [17]. The COVID-19 pandemic created the perfect environment for providers and health care organizations to bring down long-lasting barriers to the implementation of telemedicine and other digital innovations [18].

### Comparison With Prior Work

The fear of becoming infected with COVID-19 in health care settings drove many patients away from in-person care [19]. Specialties that focus on children or require medical equipment (eg, otorhinolaryngology or ophthalmology) experienced the highest reduction of in-person visits. This is consistent with recent studies that identified a lack of access to laryngoscopes as a downside of telemedicine visits [20]. Even though telemedicine has provided physicians with an option to deliver outpatient services, the recovery of outpatient clinical activity levels toward 2019 levels differed between specialty groups. Psychiatrists and internal medicine subspecialists have been able to implement the highest number of virtual visits. This different level of adoption could be attributed to patient or clinician characteristics and could be further explored in future studies. In addition, differences were observed in the demographics of patients accessing telemedicine services compared to in-person visits. To continue the growth of this modality of care among all medical groups, and reduce disparities in health care access, further innovations should be developed to provide access to the patient and provider groups that have unequally benefited from this clinical transformation. For example, physicians could use patient-controlled devices to supply equipment normally available in offices [21], and marketing can be focused on groups with less access to care. It is noteworthy that telemedicine increased access to specialty care that previously could have been limited by geographic barriers [22].

Overall, both clinicians and patients were highly satisfied with the implemented telemedicine services. This is partially comparable to the findings from a previous systematic review that synthesized 17 studies assessing patient and physician perceptions of telemedicine versus in-person consultations in different medical specialties [23]. The systematic review found that most studies reported no significant differences in patient-related outcomes such as convenience, format of the consultation, or rapport. In addition, the same systematic review found that overall, physicians showed reduced satisfaction with telemedicine visits regarding communication (patient-provider relationship), and physical examination or diagnostic assessment. These findings are compatible with the results of our study, as some of the concerns identified by providers related to the impact of telemedicine on diagnostic assessment and the patient-provider relationship, as well as complications associated with the implemented delivery modality. Even though the system was far from perfect (eg, using three different platforms during a virtual encounter), patients and providers valued telemedicine as an innovation that mitigated the risk of infection associated with in-person visits. Reducing the risk of contagion has been identified as a likely facilitator to adopting telemedicine [24].

In parallel with a high overall satisfaction with telemedicine, we observed that more than 60% of all clinicians felt that their clinical skills were challenged during virtual visits. This is similar to a previous study that reported an increase in overall workload, mental effort, and psychological stress during virtual visits [25]. We also observed differences across specialties in the perception of telemedicine consultations and how telemedicine can challenge their clinical skills; those in technical specialties found telemedicine less challenging than those in relationship-focused specialties [26,27]. This difference in the physicians' orientation toward patient care might also reflect differences in adjusting to a new service delivery process.

When analyzing the types of challenges faced by clinicians and the strategies used to address them, it is noticeable that most of the challenges faced were due to the delivery mode, the platform used, and patient scheduling. This finding was identified by embedding a qualitative assessment to the quantitative survey and is consistent with a Cochrane systematic review that found that technical difficulties experienced by clinicians during telemedicine services produced high dropout rates [28]. As telemedicine was quickly deployed as a system-wide innovation in response to COVID-19, there was no time to produce a user-friendly platform, but this will be fundamental to maintaining clinician engagement with virtual services as the pandemic evolves as well as once the pandemic is over. In addition, for telemedicine to overcome all identified challenges, further training is needed among providers. Although medical schools have embraced online training [29], medical students should also be trained in telemedicine [30]. The presented system-wide implementation required that all physicians, regardless of their specialty, were knowledgeable about virtual care. As providers become more experienced conducting telemedicine encounters, it is likely that these barriers will be reduced over time and their experience should be considered as valuable input for future curriculum design.

In the patient-clinician relationship domain there were striking differences between specialty groups. This is especially relevant since psychiatrists experienced the greatest relative increase in telemedicine consultations. We did not explicitly seek to study the causes of this difference, but it is probably a consequence of the differing types of clinician-patient relationships between specialties [26,27]. This is relevant since mental health is one of the areas that has seen the greatest increase in uptake in the past years [31] and it has been a major concern during the COVID-19 pandemic [32]. Mental health telemedicine services are, on average, equally effective when compared to face-to-face consultations [4,28].

### Limitations

Although the implementation of virtual care in response to COVID-19 has been reported in different settings [24,33-38], this is the first report of a system-wide accelerated implementation of telemedicine services using quantitative and qualitative methods. This large-scale implementation allowed us to identify and compare visits and challenges experienced by different specialty groups. However, as any other evaluation, this paper has limitations that are important to acknowledge. First, although there were no differences in the demographics

and medical characteristics of providers who did and did not respond to the satisfaction survey, selection bias is always present in voluntary surveys [39]. This limitation also affects patient satisfaction ratings. In this group, because the available data consisted of anonymous ratings, we could not assess potential responder bias. Second, because of the rapid deployment of telemedicine services, we developed a patient satisfaction questionnaire to assess patient satisfaction with telemedicine similar to the NPS but could have used validated measures [40] and integrated qualitative components, as we did in the developed questionnaire for providers. Finally, COVID-19 not only affected health care provider priorities but also changed patient priorities. For example, during the pandemic, patients may be less likely to seek care for chronic conditions, and this

could affect patient satisfaction. Future system-wide evaluations of telemedicine should be conducted once the current pandemic is controlled. Despite these limitations, this report highlights the challenges related to implementing telemedicine experienced by multiple groups of physicians and the mechanisms they used to address these challenges during the COVID-19 pandemic.

## Conclusions

Telemedicine produced high satisfaction among patients and providers. Although this modality of clinical care was rapidly deployed in response to the COVID-19 pandemic, there was high heterogeneity in its implementation across medical specialties. These differences need to be considered in future implementations of telemedicine when the current medical context is addressed.

## Abstract

**Background:** The COVID-19 pandemic has markedly affected renal transplant care. During this time of social distancing, limited in-person visits, and uncertainty, patients and donors are relying more than ever on telemedicine and web-based information. Several factors can influence patients' understanding of web-based information, such as delivery modes (instruction, interaction, and assessment) and social-epistemological dimensions (choices in interactive knowledge building).

**Objective:** The aim of this study was to systemically evaluate the content, delivery modes, and social-epistemological dimensions of web-based information on COVID-19 and renal transplantation at time of the pandemic.

**Methods:** Multiple keyword combinations were used to retrieve websites on COVID-19 and renal transplantation using the search engines Google.com and Google.nl. From 14 different websites, 30 webpages were examined to determine their organizational sources, topics, delivery modes, and social-epistemological dimensions.

**Results:** The variety of topics and delivery modes was limited. A total of 13 different delivery modes were encountered, of which 8 (62%) were instructional and 5 (38%) were interactional; no assessment delivery modes were observed. No website offered all available delivery modes. The majority of delivery modes (8/13, 62%) focused on individual and passive learning, whereas group learning and active construction of knowledge were rarely encountered.

**Conclusions:** By taking interactive knowledge transfer into account, the educational quality of eHealth for transplant care could increase, especially in times of crisis when rapid knowledge transfer is needed.

## Introduction

The COVID-19 pandemic is affecting transplant activity worldwide [1-3]. In addition to its impact on donation and transplantation numbers, the pandemic has markedly affected outpatient transplant care [1,2]. Additionally, patients experience uncertainty and fear; therefore, they rely more heavily on information provision [4]. For patients undergoing renal transplant, this uncertainty includes the fear of contracting COVID-19, the postponement of transplant procedures, screening strategies for COVID-19, mental health problems, and the risk of using immunosuppressive therapy during the pandemic [1,2]. With current measures limiting in-person visits between patients and health care providers, it has become vitally important to use alternative means of communication to inform patients undergoing renal transplant and living donors. Telephone and video communication have been generally adopted as means to continue outpatient care during the crisis [5,6]. Web-based information is used in the provision of eHealth to meet patients' information needs when they are facing uncertainty and fear [7].

Multiple eHealth interventions aimed at disease control and increasing knowledge were already available for renal patients before the outbreak [8]. The majority of patients with renal disease search the internet on a regular basis to obtain additional information on their disease and its treatment [9]. In general, patients' health-related internet use is associated with increasing health literacy [10]. Health literacy can be best described as an individual's well-considered health decisions and goal setting by accessing and understanding health-related information [11]. Patients' health literacy is positively associated with their self-management [12], motivation [13], risk perception [14], participation in health decision making [15,16], etc. However, despite the high number of patients with renal disease who use the internet as an additional information source, health literacy among renal patients and transplant recipients is still limited. A systematic review showed that in the United Kingdom, 25% of patients with renal disease not on dialysis, 27% of patients with renal disease on dialysis, and 14% of transplant recipients have limited health literacy [17].

Several factors could influence patients' health literacy, such as their understanding of web-based health information [18]. As knowledge transfer is an essential element in initiating behavioral change, the effective use of delivery modes could play a role in understanding information about COVID-19 and achieving this change [19]. Despite the increased provision of web-based information and eHealth interventions relating to COVID-19, it is not known how web-based information has been provided during the pandemic [20].

Information can be conveyed through instruction, interaction, and assessment [21]. Various delivery modes can be used for this, such as text messages, discussions, and quizzes. Some of these modes focus on the passive transfer of factual information to the receiver (called objectivistic modes), whereas others focus on knowledge construction, information processing, hands-on interaction with the content, and problem-solving (constructivist modes) [22,23]. Constructivist learning promotes more active

processing and personalization of information compared to receiving it passively. This results in deeper understanding and embedding of newly acquired knowledge [24-26]. In addition to this so-called epistemological dimension, delivery modes can also be categorized socially as individual or group learning [27]. From the literature, it can be assumed that people who learn both individually and collaboratively can construct knowledge better than learners who only learn individually [28].

Web-based information was rapidly developed by health services, academic centers, and patient associations to meet people's information needs related to COVID-19 and transplantation. However, if patients' understanding is to be optimized, the educational quality of this web-based information should be taken into account. The aim of this study is to provide a systematic overview of the source organizations, topics discussed, available delivery modes, and corresponding social-epistemological dimensions of websites for patients undergoing renal transplant and living donors on the topic of COVID-19. The practical implications derived from this study can be used to increase the quality of web-based information for transplant care, especially in times of crisis when rapid transfer of knowledge is needed.

## Methods

Websites on renal transplantation and COVID-19 were systemically identified using the most frequently consulted search engines for two countries [29]: Google.com [30] (for the United States, in North America), and Google.nl [31] (for the Netherlands, in Europe). The researcher's internet settings were deleted to obtain the cleanest and most objective search results possible. Additionally, the researcher's Google accounts, prerendering, and location sharing were turned off. The location setting was changed manually to the United States to minimize the influence of the researcher's location (the Netherlands) when using the search engine Google.com. Websites were searched from a laptop in the Netherlands in the month of March 2020.

To obtain a clearer picture of the available web-based source organizations, delivery modes, and social epistemological dimensions, general search engine queries related to renal transplantation and COVID-19 were used to obtain relevant websites. Because the English keywords *renal transplantation* and *COVID-19* have multiple synonyms, and patients might use any combination of those, a non-research-based selection of 14 keyword combinations was used to identify potentially relevant websites in English containing information on both renal transplantation and COVID-19 (Multimedia Appendix 1, columns A and C). In the Dutch search, a total of 7 keyword combinations were used (Multimedia Appendix 1, columns B and C).

Previous studies have demonstrated that searchers rarely read beyond the first 10 search results [32]. Therefore, in this study, websites were included if they were in the top 10 search results, including websites that used paid advertisements to top the search results. Front page news and suggested YouTube videos were not included. All possible English and Dutch keyword combinations were entered respectively in both Google search

engines. The first 10 recovered websites for each search were included for detailed examination.

In this study, we were interested in publicly accessible and available websites on the World Wide Web that patients and donors could access on an ad hoc basis. Therefore, for each search, websites were excluded if the website was no longer available, the website was under construction, or the website's content was behind a paywall. Websites were also excluded if the selected webpage was redundant (eg, press releases, news articles, blogs, academic journals, or webpages to sell products), or the webpage did not provide information on COVID-19 and renal transplantation. These websites were excluded because we were interested in websites which had as goal to objectively inform patients or living donors. Additional exclusion criteria were the website was a duplicate with a previous hit or the written language was other than English or Dutch, depending on the language of the keyword combination.

Potentially relevant webpages were obtained by using the same keyword combination in the website search function that was used for the website inclusion. The exclusion criteria for webpage selection per website were identical to those described for the website selection. Duplicated webpages obtained with different combinations of keywords were all noted. During data analysis, overlapping webpages were included only once. A total of 30 webpages, 15 in English and 15 in Dutch, were included for detailed examination.

Three randomly selected websites were individually examined by two authors. The results of both authors were discussed and calibrated until agreement on coding was reached. Then, the first author re-examined these three websites and examined the remaining websites. A calibration diary was maintained during examination, and another author was consulted when uncertainty arose.

Data analysis was performed in the month of April 2020. All websites were classified based on source organization, namely professional nonprofit organizations, such as hospitals; support groups, such as patient associations; governments, such as the Ministry of Health; individual practice, such as personal websites; or commercial organizations, such as independent dieticians. The website was labelled as "other" if the organizational source of a website did not match any of these categories. Additionally, English language websites were classified based on their generic top level domain (eg, .com, .org), which was not applicable to Dutch websites.

Each webpage was classified based on available topics and delivery modes. Immediately available content on COVID-19 and renal transplantation was categorized thematically. The available delivery modes on each webpage were classified into

instruction, interaction, or assessment based on the studies of Toven-Lindsey et al (2015) [21] and Hendriks et al (2019) [33]. Delivery modes that were not predetermined were categorized individually by two authors, followed by discussion and calibration until agreement was reached.

After data collection was completed, the Teaching Approach Framework described in 2006 by Arbaugh and Benbunan-Fich [27] was used to categorize the identified delivery modes into social-epistemological dimensions: objectivist-individual; objectivist-group; constructivist-individual; and constructivist-group. Previously implemented categorizations by Toven-Lindsey et al (2015) [21] and Hendriks et al (2019) [33] were taken into account. However, in contrast to these studies, links to external web-based resources were categorized as objectivist-individual instead of constructivist-individual because external links available on websites transmit knowledge and do not actively build knowledge as designed for massive open online courses (MOOCs), which was the context of the prior studies. Newly found delivery modes were categorized into a social-epistemological dimension individually by two authors and discussed and calibrated until concurrence was reached.

Descriptive statistics were used to analyze the variety of organizational sources, content topics, delivery modes, and social-epistemological dimensions within and between websites.

## Results

### Organizational Sources of Websites

In total, 14 websites (7 English and 7 Dutch) were analyzed. The source organization of 8 of the 14 websites (57%) was a support group, 4 websites (29%) had a professional nonprofit organizational source, 1 website (7%) was for an individual practice, and 1 website (7%), WikiKids [34], did not match any of the given categories and was therefore labelled as "other." All English websites had an organizational generic top level domain (.org).

### Topics Discussed on the Websites

The topics discussed on all 30 included webpages were analyzed and covered by 7 main themes: COVID-19 general information, recipient–pretransplant, recipient–posttransplant, donor–pretransplant and posttransplant, surgery and hospitalization, posttransplant regimens, and referral to.... Of these 7 main themes, 3 (43%) were discussed on all 14 websites: COVID-19 general information, recipient–posttransplant, and referral to... (Figure 1). The minimum number of different main themes available per website was 3, and the maximum number was 7. A total of 4/14 websites (29%) discussed all main themes.

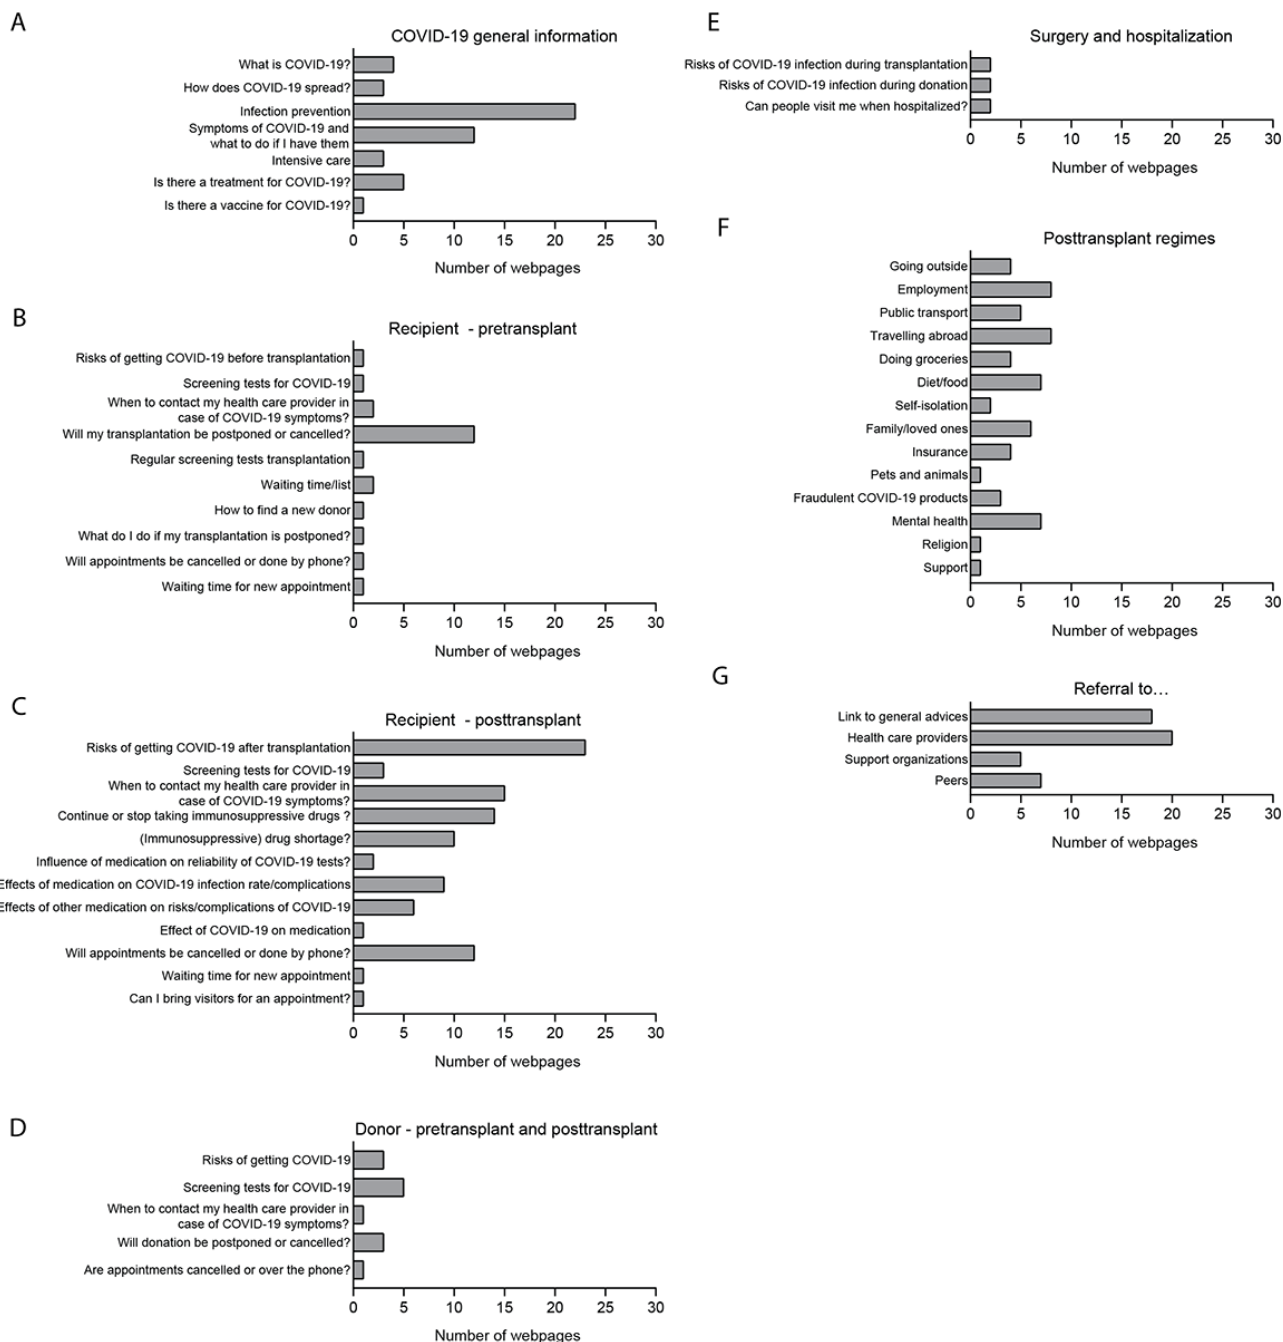

**Figure 1.** Distribution of different topics discussed on the included websites on COVID-19 for patients undergoing renal transplant and living donors, categorized in 7 main themes.

Within the 7 main themes, a total of 56 different topics were discussed (Figure 2). Most topics were related to issues on posttransplant care for recipients, such as risks of contracting COVID-19 after transplant (23/30 webpages, 77%); when to contact health care providers in case of COVID-19 symptoms after transplant (15/30 webpages, 50%); and whether renal transplant recipients should continue or cease taking immunosuppressive therapy (14/30 webpages, 47%). In total, 14 different topics related to regimens were found on the 30

webpages, such as employment (8 webpages, 27%), travelling abroad (8 webpages, 27%), mental health (7 webpages, 23%), and diet (7 webpages, 23%). General information on COVID-19 infection prevention was discussed on 22/30 webpages (73%). Referrals to health care providers were encountered on 20 of the 30 webpages (67%), and 18 webpages (60%) offered links to general advice. Topics related to surgery and hospitalization and living donor information were found on 6/30 webpages (20%) and 13/30 webpages (43%), respectively.

**Figure 2.** Numbers of webpages discussing content topics regarding COVID-19 for patients undergoing renal transplant and living donors. The webpages per included website that discussed the content topics were categorized in 7 main themes: (A) COVID-19 general information, (B) recipient–pretransplant, (C) recipient–posttransplant, (D) donor–pretransplant and posttransplant, (E) surgery and hospitalization, (F) posttransplant regimens, and (G) referral to....

### Delivery Modes on the Websites

A total of 13 different delivery modes were encountered (Table 1). Of 13 these modes, 8 (62%) were instructional, mainly links to external web-based resources and text. Of these 8 instruction modes, 3 (38%) were not predetermined by Toven-Lindsey et al [21] and Hendriks et al [33]: text-to-speech function, instruction video, and documentary. Of the 5 different

interaction modes found, 4 (80%) were not predetermined: question submission form, survey, webinar, and one-on-one chat. Webinars and discussion boards for dialogue were the most commonly offered modes (5 times each). All examined websites offered instructional modes, and 7/14 websites (50%) offered interaction modes (Figure 3). Assessment modes were not observed on any of the included websites.

**Table 1.** Numbers of available delivery modes on the 14 included websites with a total of 30 webpages (N=270), n (%). No assessment modes were encountered.

Delivery mode	Value
<b>Instruction modes</b>	
Text	30 (11.1)

Survey	1 (0.4)
Webinar	5 (1.9)

**Figure 3.** Distribution of delivery modes on each website.

The different delivery modes (n=13) were offered 270 times in total, consisting mainly of links to external resources (210, 77.8%) and text (30, 11.1%) (Table 1). Limited variation of available delivery modes was observed between all websites:

256/270 (94.8%) of all available modes were instructional. Text was the only delivery mode that was encountered on all websites (Table 2). Both instruction and interaction modes were offered by 7 of the 14 websites (50%). However, none of the websites

offered all available delivery modes. The minimum number of different modes available per website was 1 (text only), and the maximum number was 7.

**Table 2.** Presence of delivery modes per included website per search engine, classified as instruction or interaction mode.

## Social-Epistemological Dimensions

In addition to the previously categorized delivery modes, the 7 nonpredetermined modes were classified into social-epistemological dimensions (Table 3) [21,33]. Text-to-speech functions, instruction videos, and documentaries were classified as objectivist-individual, whereas question submission forms and surveys were categorized as constructivist-individual. Webinars and one-on-one chats were categorized as constructivist-group. Of the 13 different delivery modes available, 8 (62%) were objectivist-individual, 2 (15%)

were constructivist-individual, and 3 (23%) were constructivist-group. None of the offered delivery modes were within the objectivist-group dimension. The websites did not vary in the most commonly observed social-epistemological dimension (Figure 4). All of the 14 examined websites included objectivist-individual delivery modes, whereas constructivist-individual and constructivist-group modes were only offered by 2 (14%) and 6 (43%) websites, respectively. Individual-oriented delivery modes were observed the most frequently, with a minimum of 83% and a maximum of 100% per website.

**Table 3.** Social-epistemological dimensions of the delivery modes based on analysis of the social-epistemological dimensions according to the Teaching Approach Framework of Arbaugh and Benbunan-Fich [27] (N=270), n (%).

## Discussion

Since the COVID-19 outbreak, patients undergoing renal transplant and living donors have relied more than ever on telecommunication and web-based information because of fear and uncertainty about COVID-19 and limited in-person visits between the patient and health care provider. The aim of this study was to draw lessons from the topics conveyed and delivery modes used in web-based sources on COVID-19 and renal transplantation. The results show that the variety of content topics, delivery modes, and social-epistemological dimensions was limited. Additionally, the majority of the identified delivery modes focused on objectivistic and individual learning.

In our study, only 3 of the 7 main themes were discussed on all the websites. Additionally, 18 of the 30 webpages (60%) referred users to external sources, and 20 (67%) referred them to health care providers for the latest information and general advice. A logical explanation is that information on COVID-19 rapidly becomes outdated because of the dynamics of the pandemic, and time and financial investments are required to provide the latest information. Regarding the content, the most frequently discussed topics were related to posttransplant care, such as risks of contracting COVID-19 after transplant and whether recipients should continue taking immunosuppressive therapy. The variety of content topics and number of webpages for living donors were limited. Each of the content topics discussed for living donors was also found for transplant recipients. General information about infection prevention, symptoms of COVID-19, and suggestions of what to do if experiencing said symptoms were observed frequently. In addition, only a few webpages discussed issues relating to mental health, employment, insurance, and support. This is in concordance with a previous study that demonstrated that after transplant, the main focus of health care providers is often on dealing with the disease and treatment, whereas patients would also prefer information on managing life after transplantation, including social and emotional support [35].

Previous studies have already focused on the medical quality of web-based information about renal transplants [36,37]. They found that this information is often unvalidated, inaccurate, and unreliable. Here, we focused on information delivery modes because these may influence patients' health literacy (eg, understanding medical information and indirectly promoting behavioral changes and coping strategies) [8,9,27,28]. We found a limited variety of delivery modes; the majority of these modes were instructional, mainly consisting of text and links to external resources. Additionally, we did not find any assessment modes (eg, quizzes) on the websites of interest. Literature shows that there is a need for more interactive patient education. However, the desired education modalities of patients with renal disease are currently unknown [38]. We would suggest that web-based sources should offer more assessment modes because these are crucial to evaluating knowledge and can assist patients by providing insight into their personal goals [21,39]. Moreover, assessing patients' understanding is an important element of promoting prevention behavior [40].

The limited variety in delivery modes is in contrast to another web-based education platform, MOOCs, of which a greater variety can be found in the medical field. This is probably because there are fewer time constraints with MOOCs and a wide team of people are involved in their development, including education professionals [33,41]. MOOCs are not fully comparable to websites, as a MOOC is a course with a beginning and end and contains learning objectives to be achieved. However, taking the educational design of MOOCs into account when developing website content could help improve the knowledge or change the behavior of learners who access the websites. It is interesting to note that the London School of Hygiene & Tropical Medicine recently developed a MOOC for the general public, which focused on understanding and responding to COVID-19 by providing multiple modes: articles, videos, peer reviews, and quizzes [42].

Previous studies demonstrated that actively constructing information instead of passively transferring it results in better and deeper understanding and embedding of knowledge and behavioral changes [24-26]. The vast majority of the delivery modes in our study contained an objectivist-individual dimension and almost no applied constructivist learning. As renal patients must cope with new lifestyle regimens and in-person contact between patients and health care providers is often replaced by telemedicine, patients are expected to take a more active role. This includes monitoring their blood pressure and weight at home. To maintain these behavioral changes, a shift to more constructivist modes of information delivery is recommended.

Moreover, the integration of group learning, such as interaction with peers and participation in group activities, is favorable to learning [27]. Previous studies showed that group-based education for patients with type 2 diabetes promotes disease-specific knowledge, self-empowerment, and drug adherence, and it even improves clinical outcomes compared to individual education [43]. In addition to its effectiveness, patients favor group learning because it enables them to immediately receive answers to questions, discuss experiences and questions with peers, and experience a feeling of community [44]. To incorporate group learning during times of social distancing and limited in-person visits, a webinar may be a good option because this delivery mode offers the possibility of synchronous web-based interactive conversation between patients, living donors, and health care providers [45]. Additionally, contact with peers can increase patients' self-management, and group education settings can help patients to overcome feelings of isolation [46]. Moreover, implementing webinars in transplant care could help health care providers tailor information to patients' information needs because patients and living donors can submit questions beforehand.

A limitation of our study is that we mapped the available delivery modes on the included webpages at a single time point in April 2020. However, the variety of delivery modes may change over time. Therefore, future studies should analyze available delivery modes at multiple time points to investigate the dynamics and compare differences.

In conclusion, the variety of topics and delivery modes of web-based information on COVID-19 for patients who undergo renal transplants and living donors is limited. We therefore recommend providing information on COVID-19 in more diverse and interactive ways. Additionally, web-based sources

should focus more on knowledge construction than on passive information transfer, and they should take interactivity into account. This is particularly important in times of crisis, when rapid knowledge transfer is needed.

## Conflicts of Interest

None declared.

## Multimedia Appendix 1

Keyword combinations used to search for websites on renal transplantation and COVID-19 using the search engines Google.com and Google.nl.

## Abstract

**Background:** Risk and crisis communication plays an essential role in public health emergency responses. The COVID-19 pandemic has triggered spontaneous and intensive media attention, which has affected people's adoption of personal preventive measures and their mental health.

**Objective:** The aim of this study was to investigate the associations between exposure to COVID-19-specific information and mental health (depression and sleep quality) and self-reported compliance with personal preventive measures (face mask wearing and hand sanitizing). We also tested whether these associations were moderated by thoughtful consideration of the veracity of the information to which people were exposed.

**Methods:** A cross-sectional, closed web-based survey was conducted among a sample of 3035 factory workers at the beginning of work resumption following the COVID-19 outbreak in Shenzhen, China. A stratified two-stage cluster sampling design was used for recruitment. Multivariate linear and logistic regression models were used for the analyses.

**Results:** The prevalence of probable moderate-to-severe depression was 170/3035 (5.6%), while that of good or excellent sleep quality was 2110/3035 (69.5%). The prevalence of self-reported consistent face mask wearing in public places was 2903/3035 (95.7%), while that of sanitizing hands every time after returning from public spaces or touching public installations was 2151/3035 (70.9%). Of the 3035 respondents, 1013 to 1638 (33.3% to 54.0%) reported >1 hour of daily exposure to COVID-19-specific information through web-based media and television. After controlling for significant background variables, higher information exposure via television and via newspapers and magazines was associated with better sleep quality and higher compliance with hand sanitizing. Higher exposure via unofficial web-based media was associated with higher compliance with hand sanitizing

but was also associated with higher depressive symptoms. In contrast, higher exposure through face-to-face communication was associated with higher depressive symptoms, worse sleep quality, and lower compliance with hand sanitizing. Exposure to information about positive outcomes for patients with COVID-19, development of vaccines and effective treatments, and heroic stories about frontline health care workers were associated with both better mental health and higher compliance with preventive measures. Higher overall information exposure was associated with higher depressive symptoms among participants who were less likely to carefully consider the veracity of the information to which they were exposed; it was also associated with better sleep quality among people who reported more thoughtful consideration of information veracity.

**Conclusions:** This study provides empirical evidence of how the amount, sources, and contents of information to which people were exposed influenced their mental health and compliance with personal preventive measures at the initial phase of work resumption in China. Thoughtful consideration of information quality was found to play an important moderating role. Our findings may inform strategic risk communication by government and public health authorities during the COVID-19 pandemic.

COVID-19; information exposure; risk; communication; mental health; personal preventive measures; China; cross-sectional; public health; prevention

## Introduction

Risk and crisis communication plays an essential role in public health emergency responses [1]. During public health emergencies, the media is an essential tool used by government and public health authorities to manage crises [2], and the public relies on media to understand the situation [3]. Infectious disease pandemics, such as severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) trigger spontaneous and intensive media attention, which could have effects on various public responses [4,5]. One of the most desirable public responses is the adoption of personal preventive measures. Universal face mask wearing [6] and hand hygiene [7] are strongly advocated by the World Health Organization (WHO) and have been widely implemented during the COVID-19 pandemic [8,9]. Media exposure has been demonstrated to increase health knowledge among the public, which in turn encourages desirable preventive behaviors during infectious disease pandemics [4,10].

In addition, people facing a public health emergency often experience a range of negative emotions. During the COVID-19 outbreak, the unknown cause of the disease, fatal outcomes, and interruption of daily routines likely increased levels of negative emotions [11]. The COVID-19 pandemic also triggered mental health problems among the general public, such as stress, panic, depression, and anxiety [12-14]. The media tend to overemphasize risk and sensationalize crises, and repeated information exposure through the media may result in public panic and fear. According to Social Amplification Theory, this panic and fear can be further amplified through the exchange of information on diverse media platforms or through face-to-face communication [15]. Mental distress provoked by information exposure can fuel the proliferation of misinformation and amplify adverse health outcomes and maladaptive responses [16-18].

The importance of web-based media during public health emergencies has been increasing over time. Individuals have turned to web-based media during pandemics to find information related to safety precautions, news updates, and protective equipment. For example, during the SARS and MERS outbreaks,

Chinese and South Korean people turned to the internet to find information that was unavailable on traditional media channels [19,20]. During the early phase of the COVID-19 outbreak in 2020, 94% of Hong Kong residents considered social media to be their most important information source [21]. Compared to traditional media, web-based media platforms (such as social media) provide not only information but also emotional expression. It has been observed that negative emotions are more likely to be conveyed on social media than positive emotions during an infectious disease pandemic [22]. Another study suggested that social media has had a significant impact on the spread of fear and panic during the COVID-19 outbreak [23]. Studies conducted during the MERS outbreak of 2015 indicated that increased exposure to MERS-specific information through social media was simultaneously associated with higher adoption of personal preventive measures and higher levels of negative emotions [4,24]. However, traditional media consumption (eg, television and newspapers) did not influence personal preventive measures or mental health [4,24].

Previous studies have shown that people are likely to react emotionally rather than rationally during a disease outbreak [25]. For example, in one study [26], participants were less able to pay attention to external information and did not trust authorities. Moreover, they were more likely to absorb negative rather than positive information. Although web-based media is a powerful tool for disseminating information, there are concerns related to inaccurate data, unverified rumors, and even malicious misinformation on these platforms [4]. With the COVID-19 outbreak, a global epidemic of misinformation has also been spreading rapidly through social media, which poses a serious additional challenge for public health efforts [27,28]. In response, the WHO and many other public health authorities are verifying rumors and providing evidence-based information [29,30]. In this information environment, it is also important to understand how audiences process the obtained information (eg, the extent of thoughtful consideration of the veracity of health information) and whether these processes will affect their behaviors and mental health during the pandemic.

This study targeted workers who resumed work in China at the beginning of work resumption. Although the implementation

of strict nationwide control measures (eg, closure of all unessential businesses) effectively controlled the pandemic, it severely damaged China's economy [31]. Therefore, the Chinese government scaled up work resumption starting on February 20, 2020 [32]. However, there were concerns that the increase in public contact after work resumption would result in a second wave of COVID-19 in China [33]. Implementing effective risk communication can help workers comply with personal preventive measures without amplifying panic or negative emotions, which is crucial to achieve a balance of disease control with revitalization of the economy.

To the best of our knowledge, there have been no studies investigating behavioral or mental health outcomes of exposure to COVID-19-specific information at the initial phase of work resumption following the COVID-19 outbreak. The objective of this study was to investigate the associations between COVID-19-specific information exposure and four outcome variables, including depression, sleep quality, self-reported consistent face mask wearing, and hand hygiene. The study also tested whether the associations between information exposure and outcomes varied as a function of thoughtful consideration

of the veracity of information to which the participants were exposed.

## Methods

### Settings and Participants

A cross-sectional, closed web-based survey was conducted from March 1 to 14, 2020, in Shenzhen, China. Approximately 65.1% of the residents of this city are internal migrants, and 34.3% are factory workers [34]. During the COVID-19 pandemic, Shenzhen has been one of the most severely affected regions in China outside of Hubei Province, which is the epicenter of the pandemic. The daily increase in confirmed COVID-19 cases peaked at 60 on January 31. By March 1, 2020, 100 factories in Shenzhen had resumed work. A stratified two-stage cluster sampling approach was used for recruitment. First, 14 factories were randomly selected by the research team. Of these 14 factories, 10 (71%) manufactured electronic devices, 2 (14%) manufactured watches, 1 (7%) manufactured beverages, and 1 (7%) manufactured biotechnology products. All full-time employees aged  $\geq 18$  years who had resumed work in these factories were then invited to complete a web-based survey. Details of the study background are shown in Figure 1.

**Figure 1.** Background of the present survey, including the trend of cumulative confirmed COVID-19 cases in mainland China and critical responses to COVID-19 in Shenzhen, a city in Guangdong Province. PHE: public health emergency; WHO: World Health Organization.

### Procedure

We developed a web-based questionnaire using Questionnaire Star, a commonly used web-based survey platform in China. The link to access the web-based questionnaire was shared in WeChat, a popular messaging app. In addition to national guidelines, the Shenzhen government requested that each factory establish WeChat groups including all employees as part of the preparation for work resumption. A designated coordinator responsible for COVID-19 control in each factory facilitated the data collection. This coordinator posted the study information and the link to access the web-based questionnaire in the WeChat group and invited all eligible workers who had resumed work to participate. The coordinator also sent out

reminders in the WeChat groups twice per week during the study period. These designated coordinators did not participate in the survey. The coordinators and participants were asked not to disseminate the survey access link to people outside their factories. Before starting the web-based survey, the participants read a statement indicating that participation was voluntary, refusal to participate would have no effect on them, the survey would not collect personal contacts or identifying information, and the data would be kept strictly confidential and would only be used for research purposes. Web-based informed consent was sought. Each individual WeChat account was allowed to access the web-based survey once. The web-based survey platform performed completeness checks before each questionnaire was submitted. Participants were able to review

and change their responses using a Back button. Upon completion of the survey, an electronic coupon of ¥10 (US \$1.30) was sent to each participant. All data were stored in the server of the survey platform and were protected by a password. Only the corresponding authors had access to the database. Of 4158 workers who had resumed work in these factories on March 1, 2020, 3035 completed the web-based survey. The overall response rate was 73.0%. Ethics approval was obtained from the Seventh Affiliated Hospital, Sun Yat-sen University (reference: KY-2020-005-001).

## Measures

### Background Variables

Sociodemographic data such as age, gender, highest education level, marital status, monthly personal income, status as frontline workers or management staff, and type of factories the respondents were working in were collected.

### COVID-19-Specific Information Exposure

Five items assessed daily average time (hours) of COVID-19-specific information exposure through different sources from January 24 (the first day of the Chinese New Year holiday) through the survey date. Sources of health information included official web-based media (media accounts of government institutions), unofficial web-based media (media accounts of private organizations or self-published accounts), television, newspapers and magazines, and face-to-face communication. The Overall Information Exposure Scale was constructed by summing the individual item scores (1=almost none, 2=<1 hour, 3=1-2 hours, 4=3-4 hours, and 5=>4 hours). A higher score on the scale indicated exposure to a higher amount of COVID-19-specific information.

Participants were also asked to report their frequencies of exposure to information on the eight most popular topics related to COVID-19 during the outbreak (0=almost never to 3=always). These topics included statistics about the COVID-19 pandemic (number of confirmed or suspected cases, deaths, and recoveries), positive information about governmental responses to COVID-19 (eg, building mobile clinics, mobilizing national resources to epidemic areas), negative information about governmental responses to COVID-19 (eg, insufficient supply of protective equipment by some local governmental organizations), information about the development of vaccines and effective treatments, heroic stories about frontline health care workers, positive information about patients with COVID-19 (eg, recovery, discharge from hospital), negative information about patients with COVID-19 (eg, severe symptoms and deaths, other negative consequences for patients and their families), and information about negative impacts of the COVID-19 pandemic on the economy (eg, bankruptcy of businesses, layoffs, pay cuts).

A single item assessed the frequency of thoughtful consideration of the veracity of health information: “When you viewed information about COVID-19, how often did you carefully think about its veracity?” (0=almost never to 3=always). This variable was treated as a moderator.

### Mental Health

Depressive symptoms were measured using the validated Chinese version of the 9-item Patient Health Questionnaire (PHQ-9) [35]. Participants were asked to rate the frequency at which they experienced each of nine depressive symptoms over the past two weeks (0=never to 3=nearly every day). A mean score was calculated and used for analysis (alpha reliability=.91). A summative score  $\geq 10$  indicated the presence of probable moderate to severe depression [36].

Global sleep quality over a 7-day recall period was measured using a single-item Sleep Quality Scale with a rating range from 0 to 10. A higher score indicated better sleep quality. The original score was then recoded into four categories: 1=poor or terrible (0-3), 2=fair (4-6), 3=good (7-9), and 4=excellent (10) [37]. This instrument has been demonstrated to be a reliable and valid measure without significantly increasing respondents' survey burden.

### Self-Reported Compliance With Personal Preventive Measures

Participants were asked to report the frequency at which they wore face masks in the workplace and in other public settings (public places and transportation) in the past month (response categories: every time, often, sometimes, never). A composite variable of “consistent face mask wearing” was created to represent respondents who reported wearing a face mask every time both in the workplace and in other public settings (0=no, 1=yes). Participants also reported the frequency at which they sanitized their hands using soaps, liquid soaps, or alcohol-based hand sanitizers after returning from public spaces or touching public installations and equipment (eg, handrails, escalator control panels, or door knobs) (response categories: every time, often, sometimes, never). This item was also recoded into a binary variable of “sanitizing hands every time” (0=no, 1=yes).

### Statistical Analysis

The characteristics of all studied variables were described first. The associations between independent variables (including overall amount, sources, and content of COVID-19-specific information exposure) and mental health outcomes (depressive symptoms and sleep quality) were tested using multivariable linear regression analysis; the associations between the independent variables and behavioral outcomes (self-reported consistent face mask wearing and sanitizing hands every time) were tested using multivariate logistic regression analysis. Background characteristics that were significantly associated with the dependent variables were adjusted for in the regression models. Adjusted unstandardized coefficients (B) or adjusted odds ratios (AORs) and their 95% CIs were reported. An interaction term was further created by multiplying overall information exposure and thoughtful consideration of information veracity, and this term was included in the multivariable linear and logistic regression models to test its significance. SPSS version 24 (IBM Corporation) was used to conduct all analyses, with a two-sided *P* value <.05 indicating statistical significance.

## Results

### Background Characteristics

Over half of the 3035 participants were <30 years of age (1552, 51.1%), male (1612, 53.1%), married (1812, 59.7%), had attained an education level lower than college or university (2004, 66%), had a monthly income level lower than ¥5000 (US \$714) (1542, 50.8%), were frontline workers (1847, 60.9%), and were working in an electronic device manufacturing factory (2353, 77.5%) ([Table 1](#)).

### COVID-19–Specific Information Exposure

Of the 3035 participants, 1638 (54.0%), 1057 (34.8%), and 1013 (33.3%) had been exposed to COVID-19–specific information

via official web-based media, unofficial web-based media, and television for >1 hour per day, respectively. Smaller proportions reported a daily exposure of >1 hour via newspaper (499/3035, 16.5%) and face-to-face communication (506/3035, 16.7%). Regarding the contents of the information, over half of the 3035 participants were always exposed to statistics about the COVID-19 pandemic (1720, 56.7%), positive information about governmental responses to COVID-19 (1617, 53.3%), and heroic stories about frontline health care workers (1542, 50.8%). Only 1065 of the 3035 participants (35.1%) always thought carefully about the veracity of the COVID-19–specific information ([Table 2](#)).

### Mental Health and Self-Reported Compliance With Personal Preventive Measures

The prevalence of probable moderate to severe depression was 170/3035 (5.6%), and that of good or excellent sleep quality

was 2110/3035 (69.5%) (Table 3). Regarding behavioral responses, 2903/3035 (95.7%) and 2151/3035 (70.9%) participants reported consistent face mask wearing in any public places and sanitizing hands every time after returning from public spaces or touching installations, respectively.

### Associations Between Information Exposure and Mental Health Outcomes

In the univariate analysis, age, marital status, education level, monthly personal income, status as frontline worker or manager, and factory type were significantly associated with depressive symptoms and sleep quality ([Multimedia Appendix 1](#)).

After adjusting for these significant background characteristics, a higher overall amount of COVID-19-specific information exposure was associated with higher depressive symptoms (adjusted B=0.05,  $P=.006$ ). Specifically, higher exposure via unofficial web-based media (adjusted B=0.20,  $P=.001$ ) and face-to-face communication (adjusted B=0.45,  $P<.001$ ) was associated with higher depressive symptoms. Exposure to negative information about patients with COVID-19 (adjusted B=0.15,  $P=.049$ ) and about effects on the economy (adjusted B=0.31,  $P<.001$ ) was associated with higher depressive

symptoms, while exposure to information about development of vaccines and effective treatments was associated with lower depressive symptoms (adjusted B =-0.16,  $P=.045$ ) ([Table 4](#)).

A higher overall amount of COVID-19-specific information exposure was associated with better sleep quality (adjusted B=0.01,  $P=.01$ ). Specifically, exposure via face-to-face communication was associated with poorer sleep quality (adjusted B=-0.04,  $P=.01$ ), while exposure via television (adjusted B 0.05,  $P<.001$ ) and newspapers and magazines (adjusted B=0.07,  $P<.001$ ) was associated with better sleep quality. Exposure to negative information about patients with COVID-19 (adjusted B=-0.03,  $P=.04$ ) and negative impacts on the economy (adjusted B=-0.04,  $P=.02$ ) was associated with poorer sleep quality. In contrast, exposure to heroic stories about frontline health care workers (adjusted B=0.06,  $P=.002$ ) and positive information about patients with COVID-19 (adjusted B=0.04,  $P=.02$ ) was associated with better sleep quality.

**Table 4.** Linear regression on exposure to COVID-19–specific information and mental health outcomes (N=3035).

### Associations Between Information Exposure and Behavioral Outcomes

In the univariate analysis, age, gender, marital status, education level, and factory type were associated with face mask wearing and sanitizing hands every time ([Multimedia Appendix 1](#)).

After adjusting for these significant background characteristics, the overall or source-specific amount of COVID-19–specific information exposure was not significantly associated with consistent face mask wearing. Exposure to statistics about the COVID-19 pandemic (AOR 1.23, 95% CI 1.04-1.45;  $P=.02$ ), negative information about governmental responses (AOR 1.32, 95% CI 1.11-1.56;  $P=.001$ ), heroic stories about frontline health care workers (AOR 1.30, 95% CI 1.08-1.56;  $P=.007$ ), and

positive information about patients with COVID-19 (AOR 1.33, 95% CI 1.11-1.60;  $P=.002$ ) were positively associated with this outcome.

Overall amount of COVID-19–specific information exposure (AOR=1.03, 95% CI 1.01-1.05;  $P=.003$ ) and specific exposure through official web-based media, unofficial web-based media, television, and newspapers and magazines, with AORs ranging from 1.07 (95% CI 1.00-1.15) to 1.21 (95% CI 1.11-1.32), were positively associated with sanitizing hands every time, while a negative association was found for exposure through face-to-face communication (AOR=0.91, 95% CI 0.84-0.98;  $P=.02$ ). Exposure to all eight information topics was positively associated with this outcome, with AORs ranging from 1.09 (95% CI 1.01-1.18) to 1.36 (95% CI 1.24-1.49) ([Table 5](#)).

**Table 5.** Logistic regression of media exposure to COVID-19–specific information and behavioral outcomes (N=3035).

Media exposure	Consistent face mask wearing		Sanitizing hands every time	
	Adjusted odds ratio (95% CI)	P value	Adjusted odds ratio (95% CI)	P value
<b>Frequency of exposure to COVID-19–specific information through different channels</b>

### Moderation Effects of Thoughtful Consideration of Information Veracity

The interaction term was significantly associated with depressive symptoms (adjusted  $B=-0.04$ ,  $P=.047$ ) and sleep quality (adjusted  $B=0.01$ ,  $P<.001$ ). Overall amount of information exposure was associated with higher depressive symptoms among participants who were less likely to consider the veracity of the information to which they were exposed; this association was not significant among those who were more likely to

consider the veracity of this information. In contrast, overall amount of information exposure was associated with better sleep quality among participants who were more likely to consider the veracity of the information to which they were exposed; this association was not significant among those who were less likely to consider the veracity of this information (Figure 2 and Multimedia Appendix 2). Thoughtful consideration of information veracity did not moderate the association between overall amount of information exposure and behavioral responses.

**Figure 2.** The moderation effects of thoughtful consideration about the veracity of COVID-19–specific information on associations between overall information exposure and the mental health outcomes of (1) depressive symptoms and (2) sleep quality with adjustment for significant background factors.

(1) Outcome: depressive symptoms

(2) Outcome: sleep quality

## Discussion

### Principal Findings

The COVID-19 pandemic may have increased mental health problems among Chinese factory workers after work resumption, as their prevalence of moderate to severe depression was higher than that observed in the general population before the pandemic

(5.6% versus 2.4%) [38]. The prevalence of terrible or poor sleep quality was lower than that of Chinese workers who returned to work in Jiangsu Province (14.9%) [39]. Regarding self-reported compliance with personal preventive measures, the prevalence of consistent face mask wearing in all public spaces was very high, which is crucial for COVID-19 prevention in factories where physical distancing cannot be guaranteed.

Despite the WHO recommendation on hand hygiene [7], few participants always sanitized their hands. The importance of hand hygiene must be emphasized during work resumption.

Our findings suggest that the COVID-19 pandemic triggered intensive media responses, as our participants had been exposed to large amounts of COVID-19–specific information every day following the outbreak in China. Web-based media and television were the most common information sources, while newspapers and magazines and face-to-face communication were less common. These findings are consistent with previous reports, which showed a substantial increase in the use of web-based media and television following the COVID-19 outbreak [40].

Consistent with previous studies [4,24], we found that different sources of information exposure had differing effects on mental health and behavioral outcomes. First, television, newspapers, and magazines are traditional media outlets that are mainly operated by governmental organizations in China. Exposure to COVID-19–specific information through these channels not only increased compliance with personal preventive measures but also improved mental health and well-being. These media channels mainly report information verified by expert sources [4,24]. Previous studies suggested that the more people read newspapers and watched television reports about MERS, the more knowledge they acquired about the disease and its prevention strategies [4,24]. Being knowledgeable about COVID-19 was associated with better compliance with personal preventive measures [21] and lower levels of worry or panic [41]. In addition to knowledge dissemination, these traditional media outlets in China often disseminate information about the government's preparedness plans, actions, and progress in controlling COVID-19. This information is helpful to build trust in the government's capacity to counter the pandemic. Trust in government was positively associated with adoption of personal preventive measures and mental health during an infectious disease pandemic [42,43].

It was interesting to find that information exposure through official web-based media was associated with better hand hygiene but did not affect mental health status. In China, these media outlets are operated by governmental organizations and disseminate similar information to traditional media. However, instead of one-way communication, official web-based media platforms are interactive and allow readers to leave comments. We speculate that people viewed both positive and negative feedback for specific topics, which may have offset the positive influence on mental health. Information exposure through unofficial web-based media sources was likely to have both positive and negative aspects, as it motivated personal preventive measures but triggered mental health problems at the same time. These findings are similar to studies conducted during the 2015 MERS outbreak in South Korea [4,24]. Compared to official media sources (official web-based media and traditional media in China), unofficial web-based media sources contained not only factual information but also emotional content [22,44]. Negative emotions and unnecessary sensationalism are more likely to be present and amplified in these media outlets during an infectious disease outbreak than in official media channels.

Information exposure through face-to-face communication was limited, probably due to strict control measures implemented by the Chinese government to curb the COVID-19 pandemic (eg, intracity travel restrictions, community lockdown). However, the influence of face-to-face communication cannot be neglected. Higher levels of information exposure through this source were associated with decreased levels of hand hygiene and poorer mental health. It is likely that false and unverified information was disseminated by face-to-face communication during the pandemic. Studies have shown that “bottom-up” misinformation accounted for a significant proportion of information sharing between laypersons during the COVID-19 pandemic [45]. The consequences of misinformation can be long-lasting and should not be underestimated in health crisis management [29].

Our study covered eight types of COVID-19–related content that were active topics attracting public attention from the Chinese population during the pandemic [44,46]. Exposure to all these types of content was associated with increased compliance with face mask wearing and/or hand hygiene. A sufficient amount of information exposure about COVID-19, regardless of topic and valence (positive, negative, or neutral), could potentially cultivate a global sense of emergency and enhance compliance with these preventive measures. Exposure to content about positive outcomes for patients with COVID-19, development of effective treatments and vaccines, and heroic stories about frontline health care workers were associated with better mental health. This is understandable, as these types of information can increase people's confidence in the control of the pandemic and hence reduce their concern. Moreover, heroic stories may increase altruism, which has a protective effect on mental health during a pandemic. In contrast, negative information about patients with COVID-19 and about impacts on the economy were associated with decreased mental health. Observing the detrimental consequences of COVID-19 may induce fear, according to fear appeal theory [47]. Pay cuts or layoffs resulting from COVID-19 are potential stressors that may lead to worse mental health [48].

The measure of thoughtful consideration inherently assessed the participants' motivation to scrutinize information quality but also the ability to acquire, discern, and understand accurate health information [49–51]. During the global epidemic of misinformation that has accompanied the COVID-19 pandemic, some individuals were able to actively protect themselves against the crisis. Our results highlighted that thoughtful consideration of the veracity of information to which the participants were exposed significantly moderated the association between overall amount of information exposure and mental health. Participants who thought more about information veracity suffered less from the adverse effect of high information exposure on depression and even had better sleep quality compared to people with low information exposure. People with inadequate skills and resources to analyze and appraise the information to which they are exposed may be particularly vulnerable to mental distress due to high information anxiety, confusion about information quality, and unsatisfied information needs [12,52,53]. There is a significant need for

intervention, as only 35% of the participants always thought carefully about the veracity of COVID-19-specific information.

### Implications

Our findings may inform strategic risk communication by government and public health authorities during the COVID-19 outbreak and future public health emergencies to build public trust and facilitate prevention without amplifying panic. Future risk communication related to COVID-19 in China should make use of official web-based media and traditional media platforms; increase dissemination of information about patient rehabilitation, development of effective treatments and vaccines, and heroic deeds of frontline health care workers; and inform the public about effective strategies to reactivate the economy. Pilot testing of communication campaign messages among the target audience is also recommended. Furthermore, it is imperative to invest in building communication capacity to combat the crisis of misinformation. Government and public health authorities should proactively identify misinformation, provide clarifications, and empower the public with adequate skills to critically evaluate the veracity of information.

### Limitations

The present study has some limitations. First, causal relationships between information exposure and the studied outcomes cannot be determined due to the cross-sectional design. Reverse relationships are possible; for example, individuals with mental distress may spend more time searching for COVID-19-related information [16]. Second, the survey did not capture the temporal pattern of information exposure and its correlations with health outcomes [46]; instead, global

indicators were used to measure the average exposure levels over a critical period from the initial outbreak to the containment phase. Third, the measures did not differentiate active and passive information gathering; however, the majority of the Chinese population proactively sought related information during the COVID-19 pandemic [21,40]. Fourth, generalization of the evidence from a workforce sample should be made cautiously. The mental health impact of information exposure may be different for people who are unemployed or retired. This study was conducted in one city; however, the participants had resided in 29 of the 34 provincial regions in China prior to work resumption, and the observed findings are thus not only limited to the context of Shenzhen. Moreover, the data were self-reported and verification was not feasible. Participants may also overreport their compliance with personal preventive measures due to social desirability. The web-based survey was anonymous and did not collect participants' personal details. These measures may have reduced the degree of social desirability bias.

### Conclusion

This study provides empirical evidence of how different dimensions of COVID-19-specific information exposure influenced mental health status and compliance with personal preventive measures at the initial phase of work resumption in China. Thoughtful consideration of the veracity of information played an important role in moderating the associations between information exposure and mental health. These findings can help improve crisis communication during the response to the ongoing pandemic.

## Abstract

**Background:** Since its outbreak in January 2020, COVID-19 has quickly spread worldwide and has become a global pandemic. Social media platforms have been recognized as important tools for health-promoting practices in public health, and the use of social media is widespread among the public. However, little is known about the effects of social media use on health promotion during a pandemic such as COVID-19.

**Objective:** In this study, we aimed to explore the predictive role of social media use on public preventive behaviors in China during the COVID-19 pandemic and how disease knowledge and eHealth literacy moderated the relationship between social media use and preventive behaviors.

**Methods:** A national web-based cross-sectional survey was conducted by a proportionate probability sampling among 802 Chinese internet users ("netizens") in February 2020. Descriptive statistics, Pearson correlations, and hierarchical multiple regressions were employed to examine and explore the relationships among all the variables.

**Results:** Almost half the 802 study participants were male (416, 51.9%), and the average age of the participants was 32.65 years. Most of the 802 participants had high education levels (624, 77.7%), had high income >¥5000 (US \$736.29) (525, 65.3%), were married (496, 61.8%), and were in good health (486, 60.6%). The average time of social media use was approximately 2 to 3 hours per day (mean 2.34 hours, SD 1.11), and the most frequently used media types were public social media (mean score 4.49/5, SD 0.78) and aggregated social media (mean score 4.07/5, SD 1.07). Social media use frequency ( $\beta=.20$ ,  $P<.001$ ) rather than time significantly predicted preventive behaviors for COVID-19. Respondents were also equipped with high levels of disease knowledge (mean score 8.15/10, SD 1.43) and eHealth literacy (mean score 3.79/5, SD 0.59). Disease knowledge ( $\beta=.11$ ,  $P=.001$ ) and eHealth literacy ( $\beta=.27$ ,  $P<.001$ ) were also significant predictors of preventive behaviors. Furthermore, eHealth literacy ( $P=.038$ ) and disease knowledge ( $P=.03$ ) positively moderated the relationship between social media use frequency and preventive behaviors, while eHealth literacy ( $\beta=.07$ ) affected this relationship positively and disease knowledge ( $\beta=-.07$ ) affected it negatively. Different social media types differed in predicting an individual's preventive behaviors for COVID-19. Aggregated social media ( $\beta=.22$ ,  $P<.001$ ) was the best predictor, followed by public social media ( $\beta=.14$ ,  $P<.001$ ) and professional social media ( $\beta=.11$ ,  $P=.002$ ). However, official social media ( $\beta=.02$ ,  $P=.597$ ) was an insignificant predictor.

**Conclusions:** Social media is an effective tool to promote behaviors to prevent COVID-19 among the public. Health literacy is essential for promotion of individual health and influences the extent to which the public engages in preventive behaviors during a pandemic. Our results not only enrich the theoretical paradigm of public health management and health communication but also have practical implications in pandemic control for China and other countries.

## Introduction

### Background

COVID-19, an acute infectious disease, quickly spread worldwide after it emerged in December 2019 and has evolved from an epidemic to a pandemic. As of the end of May 2020, over 200 countries and territories had reported laboratory-confirmed cases of COVID-19, and the global number of confirmed cases of COVID-19 had exceeded 6,000,000 [1]. As a global pandemic, SARS-CoV-2, the novel coronavirus that causes COVID-19, has infected more people than either of its two predecessors, severe acute respiratory syndrome coronavirus (SARS-CoV) in 2003 and Middle East respiratory syndrome coronavirus (MERS-CoV) in 2012 [2]; thus, COVID-19 poses a serious threat to global development. There has been an obvious rise in the number of emerging and reemerging infectious diseases over the past two decades, such as severe acute respiratory syndrome (SARS, 2003), H1N1 (2009), Middle East respiratory syndrome (MERS, 2012), Ebola virus (2014), and Zika virus (2016). All these infections were difficult to control due to a lack of effective vaccines and medicines, which led to great concern and anxiety among the public and to challenges for public health systems [3,4].

Preventive behaviors are essential to control infectious diseases from both public and individual perspectives. Authorities and public health agencies should implement a variety of pharmaceutical and nonpharmaceutical interventions to prevent pandemic expansion, including vaccination and medical prophylaxis, hygienic precautions, patient isolation, and other social distancing measures [5]. Individuals should also take preventive measures to protect themselves, such as washing hands frequently with soap or hand sanitizer, avoiding crowded gatherings, and wearing face masks when going outside [6]. Because many infectious diseases erupt in a short time and have high morbidity and mortality rates, it is difficult for executive agencies to impose sufficient interventions to control these diseases in a timely fashion. Thus, effective disease-management activities benefit greatly from preventive measures by individuals [7]. Therefore, educating the public to enhance health awareness and increase disease knowledge is crucial in a pandemic.

Information communication and media use are well suited to achieve this goal by providing the public with professional information, decreasing public panic, disseminating health knowledge, and expressing appreciation to the public for their cooperation [8]. Regarding the COVID-19 pandemic, information communication is still crucial for disease prevention. China has potential advantages in the area of social media. Since the rapid development of the internet and emerging mobile media technologies, China has made remarkable achievements in mobile digital communication. Chinese internet users are also called “netizens,” defined as Chinese citizens who use the internet for at least 1 hour per week by the China Internet Network Information Center (CNNIC); these netizens have been

marked by the rise of a highly connected and digitally empowered general public [9]. As of June 2019, the number of Chinese netizens had reached 847 million according to the CNNIC [10]. Social media applications are becoming increasingly diversified; WeChat, Weibo, QQ, and TikTok are the most frequently used platforms by Chinese netizens.

Also, social media is widely used by Chinese authorities to inform the public about the latest news, disseminate public health knowledge, refute rumors, and facilitate effective coordination of medical, public, and pharmaceutical resources. Although social media has been broadly used in China, the effects of social media on disease prevention have still not been greatly investigated. In this study, we hope to explore the predictive role of social media use in public preventive behaviors and how health literacy moderates the causality between individuals' social media use and preventive behaviors during the COVID-19 pandemic in Chinese contexts.

### Literature Review and Hypotheses

The mechanisms underlying the effects of social media use on health behavioral changes is that coverage of a pandemic on social media can magnify the public's fear and urge the public to take preventive actions [11]. Prior studies indicated that mass media use can produce positive changes or prevent negative changes in health-related behaviors across large populations [12]; for example, frequency of listening to the radio and reading the newspaper were associated with increased odds of being vaccinated [13], while time spent watching television was positively correlated with water, sanitation, and hygiene behaviors [14]. Comparatively, social media (eg, Facebook, Twitter, WeChat, Weibo) has provided the public and health institutes with new avenues for disease prevention during an epidemic or pandemic, as it allows two-way communication between health authorities and the public. Social media has also been found to be useful in terms of health-promotion interventions, such as preventing increases in risky sexual behavior [15], contributing to improved knowledge and attitudes toward skin cancer [16], positively influencing maternal influenza vaccine uptake [17], and targeting lifestyle changes among users with chronic diseases [18]. Additionally, studies on the effects of social media have shed light on its utility in public health domains. For example, Facebook was used for strategic crisis communication by health authorities in Singapore during the Zika virus pandemic [19]; moreover, WeChat and Weibo use were found to significantly increase preventive behaviors for haze health [20]. Scholars are paying increasing attention to the role of social media during pandemics; however, the question of whether social media use can affect the public's affective responses or preventive behaviors still deserves exploration. Thus, we propose the first research question:

*RQ1: Does social media use predict preventive behaviors among Chinese netizens during the COVID-19 pandemic?*

Social cognitive theory is used to explain how people learn behaviors by observing others. It emphasizes the reciprocal

causation of individual behaviors between personal factors (eg, values, self-efficacy, outcome expectations), behavioral factors (eg, prior behavior) and social environmental factors (eg, others' behaviors, feedback). This theory provides a conceptual framework of how media use influences human beings' thoughts, affect, and actions. Media use leads to behavioral changes by communicating information through two pathways. On one hand, media use promotes changes by informing, enabling, motivating, and guiding users to take direct action to effect change [21]. On the other hand, people adopt, support, spread, and share innovative ideas or behaviors in the socially mediated pathways of social media [22]. As a socially mediated factor, social media frames and reinforces social norms and enriches the ability of the public to receive health information, such as news, knowledge, and health behavior patterns. This knowledge can be rapidly and widely diffused by exerting social influences on people's health behaviors through observational learning [23]. Therefore, the degree to which people's use of social media to access health information for disease management may influence an individual's health behavioral outcomes.

As media use is a composite concept that comprises a cluster of measurements, research questions about media use and health behaviors are usually presented as "how many hours did you spend on [social media platform, such as Facebook, Twitter, or YouTube] per day?" [13] or "how many times did you use a particular social media platform?" [24], which can be respectively summarized as "time of media use" (ie, how long) and "frequency of media use" (ie, how often). Time and frequency are also known to be the key variables of social media use. Thus, we proposed two hypotheses:

*H1: Social media use time is positively associated with preventive behaviors during the COVID-19 pandemic.*

*H2: Social media use frequency is positively associated with preventive behaviors during the COVID-19 pandemic.*

In addition to time and frequency, type is a crucial dimension of social media use. As the media landscape has changed dramatically, media types have rapidly become diversified in the new media environment [25]. In China, users usually obtain news or information via mobile news channels. The number of web-based news users has been reported to be 686 million, which accounts for 80.3% of Chinese netizens [10]. Web-based mobile news channels mostly consist of various applications that are characterized by social interactive functions such as reading, commenting, retweeting, and timely interaction. These platforms can be divided into different types by their functions. Official social media outlets, such as China Central Television (CCTV) and People's Daily, often serve as the voice of government or administrative institutions. Professional social media is an emerging form of social media that focuses on news in the professional domain. For example, Caixin News focuses on finance. Aggregated social media is a new type of media that collects and distributes news or information from different agencies. The scope of news on aggregated social media is widespread, including politics, the economy, culture, sports, and entertainment. Public social media (eg, WeChat, Weibo,

TikTok), also called interpersonal social media, is produced and disseminated by individuals. Netizens can use public social media to share news with their friends or strangers. All the above types of social media include almost all the social media platforms in China, and each media type is aimed at particular users. For instance, traditional official media represents the official voice of the government, while public or aggregated social media provides voices to grassroots organizations or individuals [26].

At the same time, various types of social media appear to have different effects. Web-based content has been reported to facilitate safer sex literacy and information-sharing intentions on social networking sites [27]. Traditional media (eg, television and radio) can be a more effective tool for managing crises than social media and websites; meanwhile, social media should also be considered to be effective during public health interventions, as younger people heavily rely on social media to seek information [28]. Additionally, when messages are transmitted through reliable web-based personal broadcasting channels, they can induce new attitudes or intentions to change in users [29]. In particular, previous studies have examined the associations of particular types of media access with information-seeking behaviors. For example, Alhuwail and Abdulsalam [30] indicated that people searched YouTube most for health information, but they did not place a high value on other social media platforms such as Twitter, Snapchat, and Facebook. Stawarz et al [31] found in their investigation that people used mobile technologies to support their mental health for specific purposes. Hence, inspired by previous results, it is essential to examine the relationship between different social media types and the public's preventive behaviors for COVID-19. Here, we propose another research question:

*RQ2: Do social media types (official social media, professional social media, public social media, aggregated social media) differ in terms of predicting users' preventive behaviors during the COVID-19 pandemic?*

## Health Literacy and Preventive Behaviors

### eHealth Literacy

The predictors of preventive measures are not merely based on the external impact of social media but also involve internal "assets," including the set of health knowledge, skills, and capabilities that is called *health literacy*. As a discrete form of literacy, health literacy is becoming increasingly important in predicting health promotion and prevention [32]. In 2004, the US Institute of Medicine [33] defined health literacy as "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions." This concept is also interpreted and has evolved as a wide range of skills that people develop to seek out, comprehend, evaluate, and use health information.

The internet is now widely used and has drastically changed how health information is disseminated [34]. eHealth literacy combines information and media literacies and applies them to eHealth promotion. It has been defined as "the ability to seek,

find, understand, and appraise health information from electronic sources and to apply the knowledge gained to addressing or solving health problems [35].” eHealth literacy is becoming increasingly important as individuals continue to seek medical advice from various web-based sources, especially social media. Empirical studies have also found that eHealth literacy positively influences health outcomes, such as health-promoting behaviors among people with diabetes [36] and people’s health-related quality of life [37]. College students with higher eHealth literacy were found to be less likely to consume unhealthy food [38].

### Disease Knowledge

In addition to eHealth literacy, disease knowledge is a vital component of health literacy; it enables people to recognize the symptoms, understand the causes, and perceive the risks of chronic diseases or infectious diseases [39]. Disease knowledge is also effective in improving health management, and it even acts as a predictor of change in an individual’s health behaviors. Authorities are generally implementing additional measures to improve the level of disease knowledge among the public, with the aim of changing the attitudes of citizens toward public health prevention [40]. For example, disease knowledge can change attitudes and practices toward rabies prevention [41], levels of oncological knowledge had an impact on individuals’ decisions to consent to particular medical procedures [42], and higher

public health knowledge was positively associated with more frequent handwashing [14].

Additionally, disease knowledge and eHealth literacy can combine as intermediate factors linking to health status [43]. eHealth literacy has been independently related to disease knowledge; it also further influences disease knowledge by an indirect pathway [44]. For example, diabetes knowledge was the most important factor associated with glycemic control, and health literacy through diabetes knowledge exerted an indirect influence on self-care and medication adherence [45].

Therefore, we propose four hypotheses here:

*H3: eHealth literacy is positively associated with preventive behaviors during the COVID-19 pandemic.*

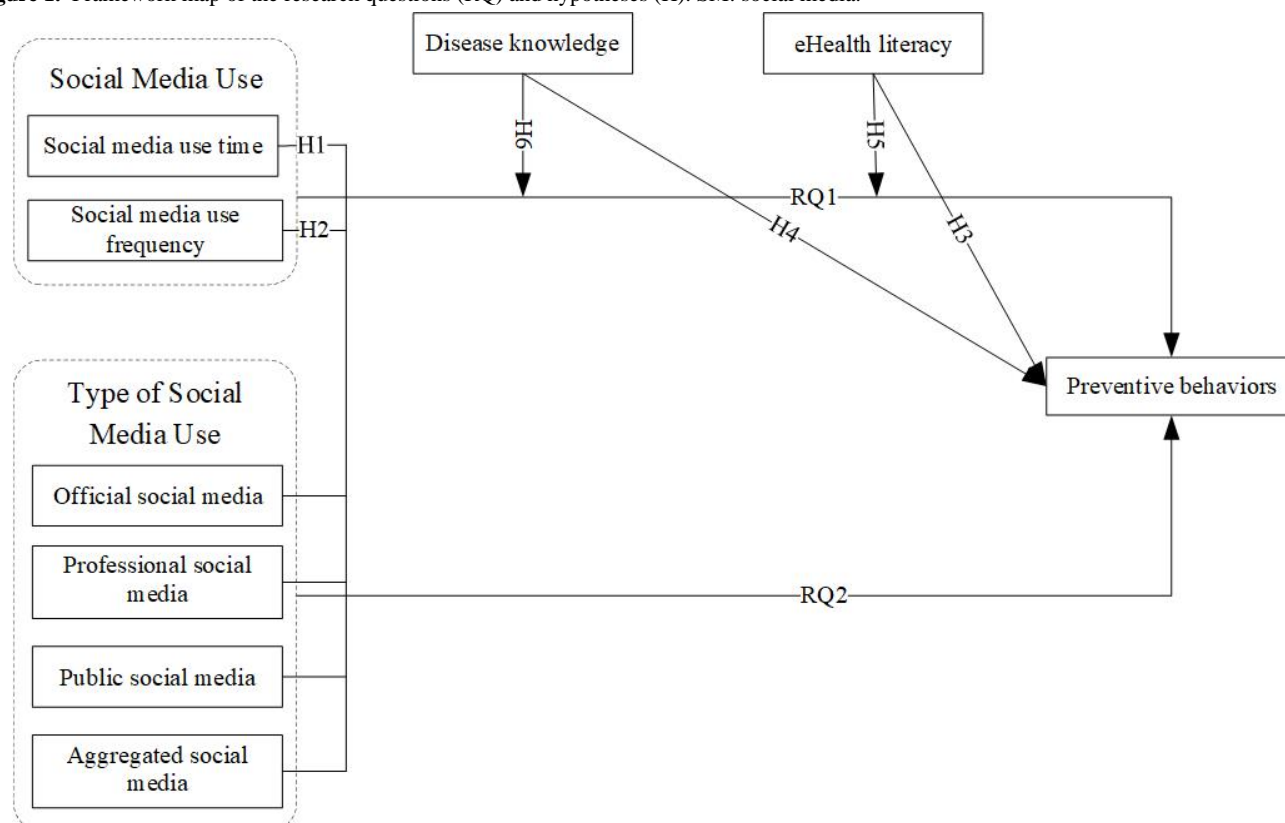

*H4: Disease knowledge is positively associated with preventive behaviors during the COVID-19 pandemic.*

*H5: eHealth literacy moderates the relationship between social media use and preventive behaviors during the COVID-19.*

*H6: Disease knowledge moderates the relationship between social media use and preventive behaviors during the COVID-19 pandemic.*

Figure 1 presents all the core variables and research hypotheses examined in this study.

**Figure 1.** Framework map of the research questions (RQ) and hypotheses (H). SM: social media.

## Methods

### Design and Recruitment

A national web-based cross-sectional survey was executed by proportionate probability sampling in this study to examine

whether social media use predicted Chinese netizens’ preventive behaviors during the COVID-19 pandemic and to explore the moderators of disease knowledge and eHealth literacy. The proportionate probability sampling method was employed according to the gender and age distributions of Chinese netizens reported in the 44th Statistical Report on Internet Development

of China (SRIDC) [10]. The SRIDC is an authoritative report that is released annually by the CNNIC and is based on a representative national survey with a sample size of 60,000. As the report showed, people 20 to 60 years of age were the main body of Chinese netizens; they represented 72.3% of the entire sample. In our survey, the web-based sample pool had an age limitation in that participants >60 years of age were rare. Thus, we selected 20 to 60 years of age as the target sample age range. We set the age intervals and proportions as 20 to 29 years of age (34.02%), 30 to 39 years of age (32.78%), 40 to 49 years of age (23.93%) and 50 to 59 years of age (9.27%); also, the proportions of men and women for each age range were 52.4% and 47.6%, respectively, according to the population distribution of Chinese netizens; these proportions were also in line with the SRIDC.

Participants were recruited using a web-based platform from the Questionnaire Star survey company [46], which contains over 2.6 million registered panelists in its sample pool. A structured questionnaire was developed and pretested for this study (Multimedia Appendix 1). Then, the web-based survey was partially adjusted and formally executed. The survey was conducted from February 13 to 21, 2020. After excluding ineligible samples (eg, incomplete or completed in a very short time), we finally collected 802 valid questionnaires from 952 respondents. The valid response rate was 84.24%.

## Ethics Statement

Authorization to conduct the research and recruit participants was obtained from the Institutional Review Board of the authors' university (ID: 20200203). In addition, the purpose of this study was elucidated by the "Notification of Sample Service" (Survey ID: 57071374). Consent was obtained from all the participants before the web-based survey was conducted by the survey agency [46]. Participation was completely voluntary, and the participants could choose to quit at any time for any reason during the process of answering the web-based questionnaire.

## Instruments

### Demographic Information

The six most frequently used sociodemographic variables were collected, including gender (0=female and 1=male), age (the respondents reported their birth year and we computed their actual age, eg, if the respondent entered "1980," we computed 2020 - 1980 to obtain an age of 40 years), education (from 1=middle school or less to 5=master's degree and above), monthly income (1, <¥1500; 2, ¥1500 to 3000; 3, ¥3001 to 5000; 4, ¥5001 to 8000; 5, ¥8001 to 12,000; 6, ¥12,001 to 20,000; 7, >¥20,000; 1 ¥=US \$0.14), marital status (1, single; 2, divorced or widowed; 3, separated; 4, cohabiting; 5, married), and health status (from 1=severe disease to 5=good).

### Social Media Use

Media use was measured by the following questions: social media use time ("In the past week, how much time did you spend using social media every day to learn about news of the COVID-19 pandemic?") with answers ranging from "less than one hour" to "5 hours and more"); type of social media use ("Which channel do you use often to obtain COVID-19

information every day?") with four types of social media channels, including "Official social media, such as People's Daily," "Professional social media, such as Ding Xiang Doctor," "Public social media, such as WeChat," and "Aggregated social media, such as Tencent News," with possible answers for each social media channel of 1, never used; 2, 1 to 2 times per week; 3, 3 to 4 times per week; 4, 5 to 6 times per week, and 5, one or more times per day). Additionally, the variable of social media use frequency was measured by the sum score of the frequencies of all four types of social media channels (maximum score: 20), and a higher score indicates more frequent use of social media.

### Preventive Behaviors

Preventive behaviors were measured by 10 items consisting of basic protective recommendations during the COVID-19 pandemic (eg, "Washing your hands after going home" and "Covering your mouth and nose with a tissue or sleeves when you cough or sneeze"). The 10 items were assessed by a self-reported measurement scale. Firstly, the measures of disease knowledge were drawn from the COVID-19 Protection Manual (Hong Kong version, February 2020) [47] and COVID-19 Protection Manual (China Mainland version, January 2020) [48]. 20 items were generated as alternative metrics. Second, we consulted with medical experts on all the metrics. According to their suggestions, we selected 10 items as the final measurement metrics. Before the formal survey was conducted, we invited 10 adults to conduct a pilot study and modified the survey correspondingly until the validity and reliability were acceptable. Finally, we adopted the adapted measures. Respondents were asked to indicate the extent to which they agreed with the statements on a 5-point Likert scale ranging from 1=never executed to 5=do it every time (Cronbach  $\alpha$ =.75).

### Disease Knowledge

Disease knowledge was assessed by a self-reported measurement scale consisting of 10 items (eg, "The incubation period of COVID-19 infections is generally 3-7 days, with a maximum of 14 days," "The coronavirus volume is about 3 microns"). Like the measurement process of preventive behaviors, the instrument of disease knowledge was drawn from the COVID-19 Protection Manual (Hong Kong Version, February 2020) [47] and COVID-19 Protection Manual (China Mainland version, January 2020) [48]. We generated 20 items, also in consultation with medical experts. Finally, 10 items were used as the final measurement metrics via a pilot study. The answer options were "yes" or "no" for each item. Participants were given 1 point for the correct answer and 0 points for an incorrect response for each item. The variable of disease knowledge had possible scores of 0 to 10 (Cronbach  $\alpha$ =.70).

### eHealth Literacy

eHealth Literacy was assessed by the 8-item eHealth Literacy Scale (eHEALS) [34]. The eHEALS is a reliable computer-based measure of patients' knowledge and self-efficacy for obtaining and evaluating web-based health resources. This brief scale assesses an individual's perceived ability to find, understand, and appraise health information from web-based sources and apply that knowledge to address health concerns (eg, "I know

what health resources are available on the internet” and “I know where to find helpful health resources on the internet”). The eHEALS was developed in English. It was translated into a Chinese version for our questionnaire, and we invited 5 adults to conduct a pilot study. The results indicated that the reliability of the Chinese version is high; therefore, we adopted it. Response options included a 5-point Likert scale ranging from 1=totally disagree to 5=totally agree (Cronbach  $\alpha=.82$ ).

### Statistical Analysis

Descriptive statistics were used to assess the sociodemographic characteristics of the respondents, including gender, age, education, monthly income, marital status, and health status. Category variables were described as *n* (%). Continuous variables were expressed as mean (SD). Category variables (including education, monthly income, marital status, and health status) were also dummy-coded, and one group was set as a reference group in each category. Pearson correlation analysis and hierarchical multiple regression were employed. Two-tailed Pearson correlations were used to examine the correlations between the control variables and the independent and dependent variables, respectively.

Two hierarchical regression models were used to test the research questions and hypotheses. The first hierarchical multiple regression was used to investigate RQ1, H1, H2, H3, H4, H5, and H6, in which the demographics were set as the control variables for Model 1. Then, the social media use time and social media use frequency were introduced in Model 2, and disease knowledge and eHealth literacy were introduced in Model 3. Finally, the two interaction items of social media use

frequency  $\times$  disease knowledge and social media use frequency  $\times$  eHealth literacy were entered in Model 4. Two additional interaction items, time  $\times$  eHealth literacy and time  $\times$  disease knowledge, were entered in Model 5. The second hierarchical regression was carried out to explore the predictors of the four social media types (RQ2). The demographics were set as the control variables for Model 1, and four types of social media channels (official social media, professional social media, public social media, aggregated social media) were introduced in Model 2. All statistical analyses were calculated with SPSS for Windows version 22.0 (IBM Corporation).

## Results

### Descriptive Statistics

#### *Sociodemographic Profiles*

Among the 802 participants, 416 (51.9%) were male and 386 (48.1%) were female. The ages of the respondents ranged from 20 to 60 years, which is representative of Chinese netizens according to 2019 CNNIC statistics [10]. The sample overrepresented high education (above bachelor's degree, 624/902, 77.7%) and high monthly income of  $>¥5000$  (US \$736.29, 525/802, 65.3%) compared with the respective values of 9.7% and 27.1% reported in the SRIDC. Most of the respondents had a bachelor's (undergraduate) degree or higher, and nearly half of the respondents' monthly income was  $>¥8000$  (US \$1178). Additionally, the majority of the respondents in our sample were married (496/802, 61.8%) and in good health (486/802, 60.6%). A detailed comparison of our sample profile and the CNNIC sample is presented in Table 1.

**Table 1.** Sociodemographic characteristics of our research sample and the CNNIC sample.

Characteristic	Research sample (N=802), n (%)	CNNIC <sup>a</sup> sample (N=60,000), %
<b>Gender</b>

### **Characteristics of Social Media Use, Health Literacy, and Preventive Behaviors**

**Table 2** presents the basic characteristics of social media users in terms of social media use, disease knowledge, eHealth literacy, and preventive behaviors. Respondents did not spend much more time on social media every day to learn about the COVID-19 pandemic, as the average social media use time was approximately 2 to 3 hours per day (mean 2.34, SD 1.12). By contrast, the respondents used social media more often (mean

score 13.59/20, SD 2.42) when compared with reference point 12. As the types of social media channels, respondents liked to use public social media and aggregated social media more than official social media and professional social media. Respondents had a high level of disease knowledge (mean score 8.15/10, SD 1.43) and eHealth literacy (mean score 3.79/5, SD 0.59). Moreover, respondents also took many preventive behaviors (mean score 4.30/5, SD 0.44) for health management during the COVID-19 pandemic.

**Table 2.** Characteristics of social media use, disease knowledge, eHealth literacy and preventive behaviors (N=802), mean (SD).

Characteristic	Value
Social media use time (hours)	2.34 (1.11)
Social media use frequency <sup>a</sup>	13.59 (2.42)
<b>Social media type<sup>b</sup></b>	
Official social media	2.54 (1.20)
Professional social media	2.48 (1.11)
Public social media	4.49 (0.78)
Aggregated social media	4.07 (1.07)
Disease knowledge <sup>c</sup>	8.15 (1.43)
eHealth literacy <sup>d</sup>	3.79 (0.59)
Preventive behaviors <sup>e</sup>	4.30 (0.44)

<sup>a</sup>Measured by the sum score of the frequencies of all four types of social media channels (maximum score: 20).

<sup>b</sup>Measured on a scale with scores of 1=never used to 5=one or more times per day.

<sup>c</sup>Measured by 10 yes/no questions with a possible score of 1 to 10 (Cronbach  $\alpha=.70$ ).

<sup>d</sup>Measured by the 8-item eHealth Literacy Scale with scores of 1=totally disagree to 5=totally agree (Cronbach  $\alpha=.82$ ).

<sup>e</sup>Measured by a 10-item scale with scores of 1=never executed to 5=do it every time (Cronbach  $\alpha=.75$ ).

## Predictors and Moderators of Preventive Behaviors

Before the two hierarchical multiple regressions were conducted, Pearson correlations were employed to assess the correlations between independent variables and dependent variables. As displayed in the correlation table in [Multimedia Appendix 2](#), significant correlations exist between demographics, social media use, disease knowledge, eHealth literacy, and preventive behaviors; however, social media use time ( $\beta=.07$ ,  $P>.05$ ) did not predict preventive behaviors. Thus, H1 was not supported.

To examine the predictors and moderators of the preventive behaviors, the first hierarchical multiple regression was carried out, and the full results are shown in [Table 3](#) (the change in  $R^2$  upon adding the interaction of the last step of Model 5 was insignificant; therefore, we selected Model 4 as our final model). Social media use frequency ( $\beta=.20$ ,  $P<.001$ ), disease knowledge ( $\beta=.11$ ,  $P=.001$ ), and eHealth literacy ( $\beta=.27$ ,  $P<.001$ ) significantly and positively predicted preventive behaviors, respectively, when controlling sociodemographic variables (gender, age, education, monthly income, marital status, and health status). eHealth literacy ( $\beta=.27$ ) also emerged as the main effect. These results supported H2, H3, and H4; they also partly answered RQ1, which states that social media use frequency rather than social media use time can predict preventive behaviors during the COVID-19 pandemic.

The results showed significant correlations of the social media use frequency  $\times$  disease knowledge and social media use frequency  $\times$  eHealth literacy interactions with preventive

behaviors ( $\beta=-.07$ ,  $P=.03$ , and  $\beta=.07$ ,  $P=.04$ , respectively). These results indicate that disease knowledge and eHealth literacy significantly moderate the relationship between social media use frequency and preventive behaviors. Moreover, eHealth literacy positively moderated the relationship between social media use frequency and preventive behaviors, while disease knowledge negatively moderated this relationship. We also checked the moderator effects of social media use time  $\times$  eHealth literacy ( $\beta=.02$ ,  $P=.51$ ) and social media use time  $\times$  disease knowledge ( $\beta=.05$ ,  $P=.15$ ); however, both these correlations were insignificant. Thus, H5 and H6 were partly supported.

The slope test is often applied to test the magnitude of a moderated effect on the conditional value of a moderator. Given that the interaction items were significant, we performed slope tests and plotted the predicted preventive behaviors separately for high and low eHealth literacy or disease knowledge (1 SD above the mean and 1 SD below the mean, respectively; see [Figure 2](#) and [Figure 3](#)). The simple slope analyses indicated that for social media users who had lower levels of eHealth literacy, a higher level of frequency of social media use (mean  $-1$ SD) was associated with higher levels of preventive behaviors ( $\beta$  simple $=.02$ ,  $P<.001$ ). For people with higher levels of eHealth literacy (mean  $+1$ SD), the positive association between the frequency of social media and preventive behaviors was also significant ( $\beta$  simple $=.044$ ,  $P<.001$ ), and the magnitude of this association was greater than that for lower levels of eHealth literacy.

**Figure 2.** Simple slope test of the moderating effect of eHealth literacy.

**Figure 3.** Simple slope test of the moderating effect of disease knowledge.

For disease knowledge, simple slope analyses indicate that for social media users who had lower levels of disease knowledge (mean  $-1SD$ ), a higher level of social media use frequency was associated with higher levels of preventive behaviors ( $\beta$  simple=.060,  $P<.001$ ). For people with higher levels of disease knowledge (mean  $+1SD$ ), the positive association between frequency of social media and preventive behaviors was also significant; however, the magnitude of the association was smaller ( $\beta=.035$ ,  $P<.001$ ).

Concerning demographics, gender, age, monthly income, and health status were all found to significantly predict preventive behaviors. Age, monthly income, and health status positively predicted preventive behaviors. However, gender negatively predicted preventive behaviors. In detail, participants with a monthly income of more than ¥5000 engaged in more preventive behaviors than the reference group of people with a monthly income of less than ¥1500. Compared with participants who reported their health status as “good,” those who reported unhealthy status took fewer preventive measures. This suggests that social media users who were older, had higher monthly

income, and had better health status were more likely to take preventive measures during the COVID-19 pandemic. Women generally engaged in more preventive behaviors than men. However, marital status and education had no significant effects on preventive behaviors.

### Types of Social Media Use and Preventive Behaviors

RQ2 focused on comparisons among the four media genres, namely official social media, professional social media, public social media, and aggregated social media. As shown in Table 4, the multiple regression results indicated that professional social media ( $\beta=.11$ ,  $P=.002$ ), public social media ( $\beta=.14$ ,  $P<.001$ ), and aggregated social media ( $\beta=.22$ ,  $P<.001$ ) positively predicted preventive behaviors, while official social media ( $\beta=.02$ ,  $P=.60$ ) did not. Furthermore, aggregated social media was found to be the highest predictor of preventive behaviors, closely followed by public social media and professional social media. However, use of official social media in China did not predict netizens’ preventive behaviors. Additionally, health literacy positively moderated the relationship between social media use and preventive behaviors.

## Discussion

This study had three goals. The first goal was to explore the predictors of preventive behaviors during the COVID-19

pandemic, the second goal was to examine the roles of disease knowledge and eHealth literacy in moderating public preventive behaviors, and the third goal was to explain the relationship between demographics and people's preventive behaviors. The

findings revealed that social media use frequency, disease knowledge, and eHealth literacy all positively predicted an individual's preventive behaviors during the COVID-19 pandemic. Aggregated social media, public social media, and professional social media were the significant predictors of preventive behaviors within the four social media channels. Moreover, eHealth literacy positively moderated the relationship between social media use frequency and preventive behaviors, while disease knowledge negatively affected this relationship. Concerning demographics, female sex, older age, high monthly income, and good health status were likely to take more preventive measures during the COVID-19 pandemic in China.

### Social Media Use and Preventive Behaviors

For a long time, mass media (eg, television, radio, and newspapers) was recognized as an important strategy for health-promoting practice [49]. For example, a mass media campaign increased physical activity, produced positive changes, and prevented negative changes in health-related behaviors [50]. Government and executive agencies have generally used mass media and social media as convenient tools for supervising and preventing epidemics. According to the main results of this study, social media use (frequency) played a positive role in public preventive behaviors during the COVID-19 pandemic in China. This may be an important indicator of health promotion, which encourages the public to take more health measures during emergencies. Compared to mass media, social media provides the public with convenient channels to obtain news or disease knowledge and delivers information effectively. Thus, social media should be an effective strategy for public health promotion, especially during an epidemic or a pandemic.

In contrast with social media use time (which was nonsignificant), social media use frequency was a significant predictor of preventive behaviors. In other words, "how often" rather than "how long" social media was used was a good predictor of an individual's preventive behaviors; this was an unexpected but interesting finding in this work. Time and frequency are often used to measure the regularity of social media use [51]. We attempted to draw an explanation from previous studies that investigated the relationship between social media use frequency and behavioral outcomes; we found that "frequency" may be a direct indicator of the motivations of social media use, such as self-expression, social learning, social comparison, or filtering [52,53]. Therefore, we cautiously concluded that frequency of social media use indicates the degree of engagement or investment in social media. "Frequency" may thus be a more significant predictor of social media effects.

### Types of Social Media Use and Preventive Behaviors

The positive correlation of social media use and preventive behaviors extended the study of the relationships between different types of social media use and preventive behaviors. Aggregated social media use was found to be the most significant predictor of preventive behaviors among four types of social media channels, followed by public social media and professional social media use. In contrast, official social media use was not significant. These results indicate that new media access (aggregated social media, public social media, and

professional social media) deserved more attention in affecting public preventive measures than traditional media (official social media), particularly in Chinese contexts.

Aggregated social media, a novel type of news aggregator, has ensured that readers can read news stories of high quality from many outlets; this simplifies the search process of news stories and allows users to save time and effort in finding news [54]. News aggregators such as Tencent News, Sina News, and Toutiao have emerged as important components of digital content ecosystems in China, along with overseas Google News, Reddit, Bing News, etc. These aggregated social media sites have drastically changed the ways in which users access information and interact with each other. They can also generate a substitution effect when users switch from news outlets (official media) to news aggregators [55]. Consequently, aggregated social media is competing with official social media for more users' attention and has led to an intensified propaganda crisis of official social media. This may partially explain our finding that aggregated social media was the most significant predictor for preventive behaviors among the four social media types, while official social media was not significant. Furthermore, official media outlets, such as CCTV, People's Daily and Xinhua Net, are state-driven media platforms in Chinese contexts. The content of official social media platforms mainly focuses on party ideology or party image [56]; meanwhile, the content spectrum of more extensive social imperatives is limited [57]. Therefore, the readability and humanity of public health content on official social media are lower than on aggregated social media, which may be another reason for the insignificant effect of official social media on public preventive behaviors.

Additionally, we found that public social media (eg, WeChat, Weibo, and TikTok) played a vital role in affecting users' adoption of preventive behaviors. Because public social media is the most popular media type in China, it accelerates news diffusion among people or across regions and enables users to learn from each other [31]. On the other hand, public social media mostly disseminates information via interpersonal communication, which intensifies the perceived credibility of this type of social media [58,59]. Thus, public social media can act as a significant predictor for preventive behaviors. Finally, as an emerging web-based platform, professional medical social media sites such as Ding Xiang Doctor provide professional health knowledge with enormous medical resources and are a promising information channel for future public health emergencies.

All these results suggest that information communication during a pandemic should be built on perceived credibility or trust. Aggregated social media usually provides various sources. Users can compare different sources for a news theme and select the most trustworthy news. In contrast, media with a single source delivers only one voice and has lower perceived credibility. This media will be abandoned in a competitive context. Additionally, public social media platforms are the most popular channels of interpersonal communication in China. These platforms are usually used among acquaintances with higher levels of trust. This shows that the credibility of the information source is important for news dissemination during a pandemic.

Governments should deliver more credible news and dispel rumors, which may be helpful in controlling the pandemic.

### **eHealth Literacy and Disease Knowledge as Predictors and Moderators of Preventive Behaviors**

Health literacy is being increasingly emphasized in public health-related studies. The relationship between health literacy and health behaviors or health status has also been highly recognized and understood based on empirical evidence. For example, it was found that poor health literacy created barriers to fully understanding individual health, illness, and treatment for people with HIV/AIDS [60]. Unimproved public mental health literacy predicted denial of self-help [61], and limited health literacy was correlated with worse health outcomes in terms of a patient's motivation, problem-solving ability, self-efficacy, and disease knowledge, among other factors [62].

However, prior studies mainly focused on chronic disease or unhealthy lifestyles. Less attention has been paid to public health emergencies such as pandemics. In this study, we investigated if and how health literacy influenced public preventive behaviors during the COVID-19 pandemic in China. Disease knowledge and eHealth literacy were selected as the core indicators of health literacy, as concluded from previous studies [63–66]. In line with most previous findings, we verified that both disease knowledge and eHealth literacy significantly predicted Chinese respondents' preventive behaviors during the COVID-19 pandemic. Additionally, eHealth literacy had more weight in predicting preventive behaviors than disease knowledge. Moreover, eHealth literacy positively moderated the relationship between social media use and preventive behaviors, while disease knowledge had a significant but negative effect. These findings highlight the importance of health literacy for pandemic prevention. Improving the public's level of health literacy is essential for health promotion, not only during a pandemic but in all contexts of public health in the future.

However, it should be mentioned that health literacy is not always positively correlated with preventive behaviors. Health literacy has shown inverse effects on individuals' healthy behaviors; for example, misinformation toward vaccination may lead to denial of the influenza vaccine [67], and a higher level of health literacy is not always associated with health-promotion behaviors [45]. This evidence underscored a compelling need to increase public awareness of health literacy in different disease conditions.

### **Demographics and Preventive Behaviors**

Many studies have indicated that sociodemographic indicators are vital in predicting health promotion behaviors. Our study showed similar outcomes to previous findings. We found that women engaged in more preventive behaviors than men during the COVID-19 pandemic in China. This finding may be explained by a study indicating that women are more sensitive to and interested in health information on social media than men [68]. Moreover, women usually have higher levels of disease knowledge and health literacy than men [69], and they search more frequently for health information on the internet related to changes in diet [70].

Furthermore, age, monthly income, and health status were positive predictors of preventive behaviors. These results indicate that people who are older and have higher income or good health status are more likely to take measures to prevent COVID-19, which is consistent with previous findings [67]. Additionally, education and marital status were significant predictors in the existing literature; for example, in one study [71], the odds of having accurate knowledge of malaria increased as individuals' educational levels increased, and unmarried people were found to be more likely to have positive attitudes toward rabies prevention than married people [41]. However, these variables were not significant in this study, perhaps due to the different social contexts.

### **Limitations**

The results of our study should be considered in light of several limitations, and the following improvements can be implemented in future studies:

Firstly, the sample consisted of netizens between 20 and 60 years of age. Younger people (age <20 years) and older people (age >60 years) had very low response rates in the survey database. Thus, we selected 20 to 60 years of age as the target age range of our sample. People younger than 20 years or older than 60 years could be included in future studies. Furthermore, the sample consisted of much more high-income and educated netizens because our sampling was proportioned according to gender and age without consideration of income and education. Future studies are suggested to comprise netizens with lower income and less education to facilitate the generalizability of our findings.

Secondly, a single measurement of disease knowledge was used in this study, which may have led to a ceiling effect on the respondents and impaired the validity of our test. Thus, a more suitable, reasonable, and valid instrument of disease knowledge should be constructed in future studies.

Finally, this article mainly focused on the frequency and types of social media use, while other variables of media use, such as motivations and content, were not included in this study. With the rapid development of various social media platforms, such as WeChat, Weibo, Facebook, Twitter, and WhatsApp, they will continue to play a vital role in public health promotion, as we found in this study. Future research is necessary to explore how social media access affects health behaviors, including the information sources and information content accessed. Also, the experience, needs, and motivations of one's social media use are suggested to be explored in health behavior studies in the future.

### **Conclusions**

Using a national web-based cross-sectional survey of a representative sample of Chinese netizens, we fully investigated our hypotheses and answered the proposed questions. We present our conclusions as follows: social media use frequency and disease knowledge and eHealth literacy were significant predictive factors of preventive behaviors; eHealth literacy and disease knowledge moderated the relationship between social media use and preventive behaviors. Aggregated social media use and public social media use were significant predictors of

preventive behaviors, while official social media use was not. These results not only enrich the theoretical paradigm of public health management and health communication but also have practical implications in pandemic control both for China and for other countries.

On one hand, the confirmed predictive ability of social media use suggests that social media is helpful to disseminate pandemic news and disease knowledge, which can help the public to collectively adopt necessary preventive measures for disease

control. On the other hand, the predictive ability of disease knowledge and eHealth literacy provided an endorsement that improving one's level of health literacy is essential during a pandemic in the long term. Additionally, sociodemographic factors such as gender, age, monthly income, and health status should be taken into account in public health interventions. More attention should perhaps be paid to the people who are male, are younger, have lower income, and have poor health status during a pandemic.

## Acknowledgments

The authors would like to thank WJX Company for their help with the data collection. The authors wish to thank Yuxin Han for her methodological and statistical help with the formal analysis. Also, we are grateful to the journal editors and the anonymous reviewers for their helpful comments and suggestions.

**Abstract**

**Background:** The estimates of several key epidemiological parameters of the COVID-19 pandemic are often based on small sample sizes or are inaccurate for various reasons.

**Objective:** The aim of this study is to obtain more robust estimates of the incubation period, serial interval, frequency of presymptomatic transmission, and basic reproduction number ( $R_0$ ) of COVID-19 based on a large case series.

**Methods:** We systematically retrieved and screened 20,658 reports of laboratory-confirmed COVID-19 cases released by the health authorities of China, Japan, and Singapore. In addition, 9942 publications were retrieved from PubMed and China National Knowledge Infrastructure (CNKI) through April 8, 2020. To be eligible, a report had to contain individual data that allowed for accurate estimation of at least one parameter. Widely used models such as gamma distributions were fitted to the data sets and the results with the best-fitting values were presented.

**Results:** In total, 1591 cases were included for the final analysis. The mean incubation period ( $n=687$ ) and mean serial interval ( $n=1015$  pairs) were estimated to be 7.04 (SD 4.27) days and 6.49 (SD 4.90) days, respectively. In 40 cases (5.82%), the incubation period was longer than 14 days. In 32 infector-infectee pairs (3.15%), infectees' symptom onsets occurred before those of infectors. Presymptomatic transmission occurred in 129 of 296 infector-infectee pairs (43.58%).  $R_0$  was estimated to be 1.85 (95% CI 1.37-2.60).

**Conclusions:** This study provides robust estimates of several epidemiological parameters of COVID-19. The findings support the current practice of 14-day quarantine of persons with potential exposure, but also suggest the need for additional measures. Presymptomatic transmission together with the asymptomatic transmission reported by previous studies highlight the importance of adequate testing, strict quarantine, and social distancing.

**KEYWORDS**

coronavirus disease 2019; COVID-19; incubation period; serial interval; basic reproduction number; presymptomatic transmission

**Introduction**

In December 2019, a novel enveloped ribonucleic acid (RNA) beta-coronavirus, which was later named SARS-CoV-2, was first reported in Wuhan, the capital city of Hubei province,

China [1]. COVID-19, the disease caused by SARS-CoV-2, spread across and outside China rapidly, and was declared a pandemic by the World Health Organization on March 11, 2020.

Despite the explosive growth of the number of studies on COVID-19 [2-4], several key epidemiological parameters of

the disease remain to be clarified, among which are incubation period and serial interval. The mean or median incubation period and serial interval estimated by previous studies were mostly 4-5 days [5-16]. However, many of the studies included a limited number of cases (around or less than 100) [5,7,9,12-16]. For example, in a study by Zhang et al [16], which included 8579 cases, only 49 cases and 39 pairs could be used for estimating incubation period and serial interval, respectively. On the other hand, some studies might have been limited by the inaccuracy of the original data. For example, if the interval of exposure was long or unclear, determining the exact exposure date would be difficult [6,8,17], which could give rise to error.

Another important parameter of transmission dynamics is the basic reproduction number ( $R_0$ ), which is defined as the average number of secondary cases caused by a single infectious individual in a totally susceptible population [18]. As  $R_0$  is often estimated based on the serial interval [19], the abovementioned issues affecting previous estimates of serial interval might have affected the estimates of  $R_0$  as well. On the other hand, some studies estimated  $R_0$  based on the latent period and infectious period [19,20], with latent period approximated by incubation period. This may not be appropriate for COVID-19 as presymptomatic transmission might occur [21,22]. However, few published studies [23] estimated how often and approximately when the disease could be transmitted prior to symptom onset.

This study made use of the large amount of data reported by the health authorities of and outside China, as well as data from studies published as of April 8, 2020, to address the above issues. Specifically, we aimed to obtain more robust estimates of the following epidemiological parameters of COVID-19: (1) incubation period, defined as the time interval between exposure and onset of disease symptoms; (2) serial interval, defined as the duration between symptom onset of an infector (eg, a primary case) and that of an infectee (eg, a secondary case) in a transmission chain, with a negative value meaning that the infectee's symptoms occurred before the infector's symptoms; (3) frequency of presymptomatic transmission; and (4)  $R_0$ .

## Methods

### Data Sources

The details of data sources can be found in [Multimedia Appendix 1](#). For China, all provinces, autonomous regions, and municipalities (including mainland China, Hong Kong, Macau, and Taiwan) that had reported cases of COVID-19 were identified according to the daily updates by the National Health Commission of China [24]. Subsequently, the official websites and WeChat accounts (if any) of local governments and health authorities (eg, Municipal Health Commission, Center for Disease Control and Prevention, Department of Health) were checked manually through April 8, 2020, to identify and download the reports on laboratory-confirmed cases of COVID-19. Google and Baidu were searched to identify public media reports written based on official press releases. Chinese words for the following terms were used to perform the search:

("family" OR "household") AND ("cluster" OR "dinner" OR "party") AND "infection."

Other countries reporting COVID-19 cases were identified according to the COVID-19 situation reports published by the World Health Organization [25] and the data were searched through April 8, 2020. For Japan and Singapore, information regarding confirmed cases was retrieved from their respective Ministry of Health. We also searched for individual cases from relevant departments and public media of the United States, the United Kingdom, Canada, and Australia, but failed to find any with details allowing for parameters estimation for this study. Typically, the dates of exposure and symptom onset were lacking (eg, see reference [26]). Owing to the language barrier, we did not do a comprehensive search for other countries.

PubMed was searched to identify relevant publications by using the following terms: "coronavirus," "2019-nCov," "SARS-CoV-2," and "COVID-19." The China National Knowledge Infrastructure (CNKI) was searched to identify publications in Chinese journals using "novel coronavirus" ("Xin Xing Guan Zhuang Bing Du" in Chinese pinyin), which is the official Chinese name for SARS-CoV-2. Both databases were searched from December 2019 through April 8, 2020. The reference lists of eligible publications were also checked to see if there were other eligible studies not found by previous searches. We also kept an eye on the COVID-19 studies disseminated by public media and the official WeChat accounts of various academic entities in China and those recommended by experts in this field to the authors of this study.

### Definitions and Inclusion Criteria

To be eligible, a report had to contain individual data that allowed for estimation of at least one of the following parameters of laboratory-confirmed cases of COVID-19: incubation period, serial interval, and symptoms-to-transmission time, which was defined as the day of an infectee's contact with the infector relative to the latter's symptom onset date, with a negative value meaning that the transmission occurred before the infector developed symptoms (ie, presymptomatic transmission).

To obtain an accurate estimate of incubation period, only the cases with an exposure period spanning 3 days or less were included in the analysis. For those exposed for three continuous days and those exposed on two dates with one day apart (ie, exposed on the first and third days), the second day was uniformly used as the exposure date in estimations. For those exposed for two continuous days, the first day was uniformly used as the exposure date in estimations. This approach ensured the upper limit of error in the estimated incubation period be smaller than 1 day for the cases with a 2- or 3-day exposure, regardless of when exactly (ie, first, second, or third day) the transmission occurred. The actual overall error was bound to be much smaller than 1 day, as most included cases were exposed for only 1 day, which would dilute the error caused by 2- or 3-day exposures.

Serial interval was estimated based on the symptom onset dates of infector-infectee pairs, which were typically from cluster infections. For two cases to qualify as an infector-infectee pair

and be included in this study, the following two criteria must both be fulfilled. First, there must be evidence that the presumed infector had been exposed outside the cluster (eg, close contact with a confirmed case, travel history to Hubei, exposure to a person who returned from Hubei) before he/she attended the group activities (eg, family gathering, business conference) that led to cluster infections. Second, in the 14 days prior to symptom onset, the presumed infectee was exposed to the presumed infector only, without other exposure histories.

The estimation of symptoms-to-transmission time also involved determination of exposure date and judgement about transmission chain, hence the above principles applied in estimating incubation period and serial interval were followed as well.

### Screening, Data Extraction, and Quality Control

In total, 6 researchers were involved in data collection. The reports retrieved through the above searches were scrutinized one by one according to the inclusion criteria specified above. The following data were extracted from eligible reports by using a standard extraction form which was pilot tested with the reports from Liaoning province of China: the geographical location concerned, age, sex, type of exposure, first date and period (if applicable) of exposure, date of symptom onset, initial symptoms, and whether the case was from a cluster. For a clustering case, the generation he/she belonged to, the exposure date, and symptom onset date were also recorded. The retrieved reports were split into six parts, with each researcher responsible for one part. For each part, the eligibility of and data extracted from reports were first determined by one researcher and then cross-checked by another three researchers. All uncertainty and disagreements were discussed among the researchers. If no consensus could be reached after discussion, the concerned cases would be excluded to ensure the correctness and accuracy of data. For example, if it could not be determined who was infected through attending a group activity (ie, infectee) and who had been infected before he/she attended the activity (ie, infector), then all clustering cases related to the activity had to be excluded.

### Data Analysis

The basic characteristics of included cases were summarized descriptively. Lognormal, Weibull, and gamma distributions were fitted to the data sets of incubation period and serial interval and the one with the smallest Akaike information criterion (AIC) score was used for the final analysis. For serial interval, which had negative values, shifted distributions were fitted, with the best-fitting values determined by maximum

likelihood. The key parameters were estimated by using the maximum likelihood approach. The data on symptoms-to-transmission time was roughly symmetrical according to visual inspection and thus fitted by normal distribution. For each parameter, the range, median, selected percentiles, mean, and standard deviation were estimated. The 95% confidence intervals of mean and standard deviation were estimated by using the bootstrap technique.  $R_0$  was estimated by the well-studied Euler-Lotka equation [19]:  $R_0 = 1/M[-r/h(\cdot)]$ , where  $r$  is the exponential growth rate,  $h(\cdot)$  is the estimated distribution of the generation time, and the function  $M[\cdot]$  is the Laplace transform (ie, moment generating function known for statisticians) for  $h$ . As generation time is hard to observe directly, it was approximated by serial interval in this study. Compared with generation time, serial interval is expected to have the same mean but a larger variance due to possibly differing incubation periods of infectors and infectees. The exponential growth rate was obtained directly from a previous study reporting incidence data of the early stage of the epidemic [1], while the other parameters came from this study.

Sensitivity analyses were conducted to examine the robustness of the two parameters involving exposure date. Specifically, the third day for those whose exposure period spanned three days and the second day for those exposed for two continuous days were used as their exposure dates in sensitivity analyses. The difference between the estimates from sensitivity analysis and those from primary analysis represents the largest possible error in the latter. All statistical analyses were conducted with SAS software (Version 9.4, SAS Institute).

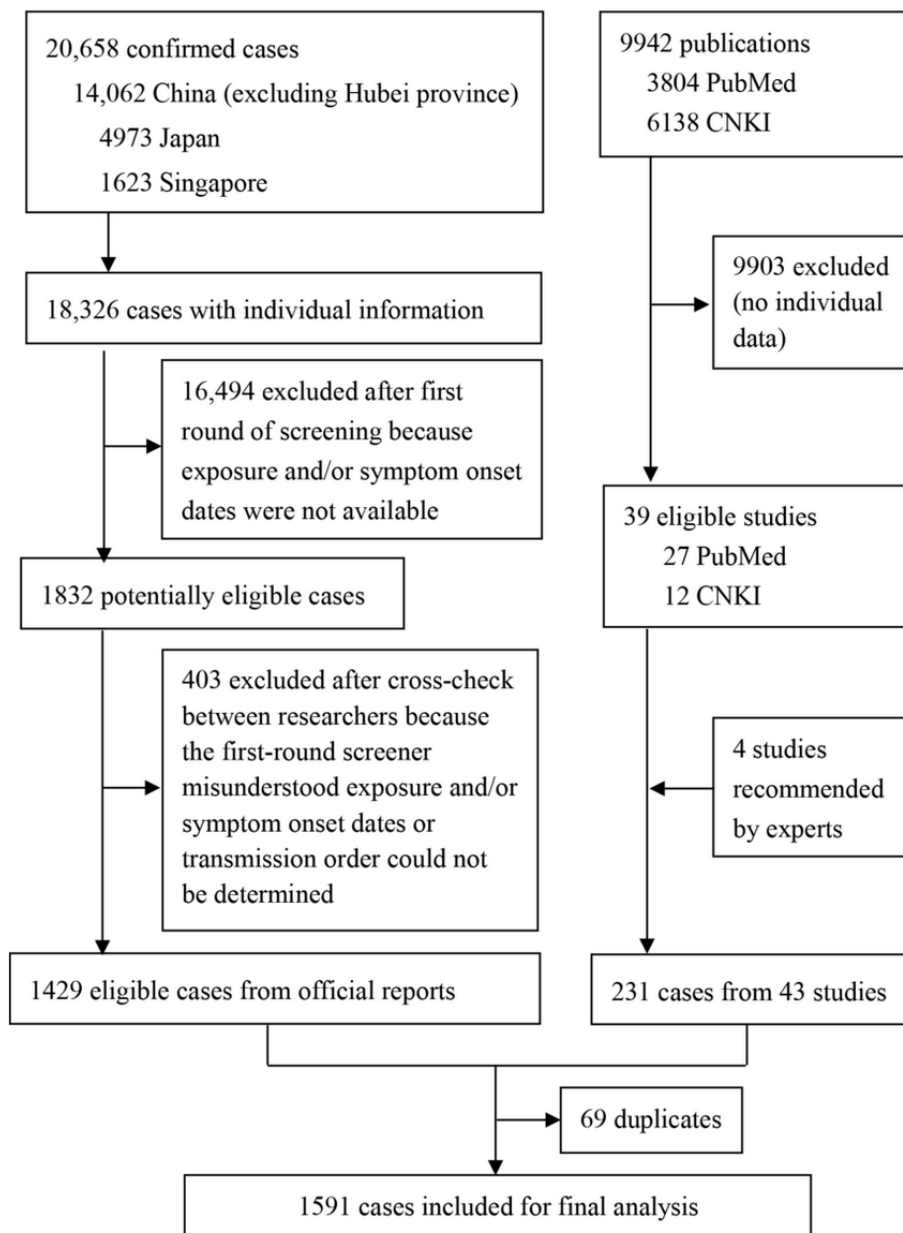

### Ethical Statement

No ethical approval was needed as the data used in this study was publicly available, either released by health authorities or retrieved from electronic databases.

## Results

### Overview

Figure 1 shows the process of data collection. We systematically retrieved and screened 20,658 case reports and 9942 publications. The 43 publications included in our analysis can be found in [Multimedia Appendix 2](#). In total, 1591 cases were included for the final analysis, including 1211 (76.12%) from China, 301 (18.92%) from Japan, 60 (3.77%) from Singapore, and 19 from five other countries. The cases from China covered 156 cities in 31 provinces of 34 in total.

**Figure 1.** The flowchart of cases selection from the official reports and published studies. CNKI: China National Knowledge Infrastructure.

### Characteristics of Included Cases

The age of included cases ranged from 5 days to 95 years (Table 1). There were 133 cases (10.74%) with a travel history to Hubei province, where Wuhan is the capital city. The source of exposure of 1302 cases (81.99%) was known confirmed cases. The exposure period was exactly 1 day in 508 cases (53.08%), spanned 2-3 days in 227 cases (23.72%), and spanned more

than 3 days in the other cases (which were not included in the estimation of parameters involving exposure date). The top 5 initial symptoms were fever (730/1009, 72.35%), cough (257/1009, 25.47%), fatigue (69/1009, 6.84%), sore throat (57/1009, 5.65%), and malaise (54/1009, 5.35%). Clustering cases accounted for 84.92% (1351/1591) of all, and most of them were second generation.

**Table 1.** Characteristics of included cases.

Characteristics	Value

Fourth or higher	32 (2.37)

## Epidemiological Parameters

Incubation period was estimated from 687 cases, of whom 482 (69.55%) were exposed for 1 day; the remainder were exposed for 2 or 3 days. The incubation periods of individual cases ranged from 0 to 23 days (Table 2), with a median of 6 days; in total, 5.82% (n=40) of incubation periods were longer than

14 days. The incubation period is best described by a gamma distribution (Multimedia Appendix 3, Figure 2A), with a mean of 7.04 days (95% CI 6.74-7.33) and standard deviation of 4.27 days (95% CI 3.92-4.43).

The serial interval was estimated for 1015 infector-infectee pairs and ranged from -5 to 29 days (Table 2), with a median of 6

days. For 32 pairs (3.15%), the serial interval was less than 0; for these 32 pairs, the mean was  $-2.50$  days, meaning that the infectee showed symptoms 2.50 days earlier than the infector. The serial interval is best described by a shifted gamma distribution (Multimedia Appendix 3, Figure 2B), with a mean of 6.49 days (95% CI 6.15-6.80) and standard deviation of 4.90 days (95% CI 4.68-5.25). Based on an exponential growth rate of 0.10 per day [1] and the mean and standard deviation of the serial interval,  $R_0$  was estimated at 1.85 (95% CI 1.37-2.60). The country-specific  $R_0$  for China, Japan, and Singapore was 1.83 (95% CI 1.37-2.54), 1.83 (95% CI 1.37-2.53), and 1.98 (95% CI 1.41-2.97), respectively.

The symptoms-to-transmission time was estimated from 296 infector-infectee pairs and ranged from  $-9$  to 14 days (Table 2), with a median of 0 day. Presymptomatic transmission

occurred in 129 infector-infectee pairs (43.58%, 95% CI 37.93%-49.23%); for these 129 pairs, the mean symptoms-to-transmission time was  $-2.88$  days, meaning that the transmission occurred 2.88 days before the infectors showed symptoms. Fitted by a normal distribution (Figure 2C), the mean of this parameter was  $-0.07$  days (95% CI  $-0.43$  to 0.31) and the standard deviation was 3.31 days (95% CI 2.96 to 3.66).

The symptoms-to-transmission time can also be inferred by mean serial interval minus mean incubation time ( $-0.55$  days), which is consistent with the direct estimate ( $-0.07$  days) as both suggest the mean symptoms-to-transmission time to be around the day before primary cases' symptom onset. Based on the above estimates, the timeline of infection for an "average" infector-infectee pair in a transmission chain is demonstrated in Multimedia Appendix 4.

**Table 2.** The estimates of incubation period, serial interval, and symptoms-to-transmission time (unit: day).

Metrics	Incubation period	Serial interval	Symptoms-to-transmission time
Range	0 to 23.00	$-5$ to 29.00	$-9$ to 14.00
$P_{2.5}, P_{97.5}$	1.00, 17.00	$-1.00$ , 18.00	$-7.00$ , 7.00
Median ( $P_{25}, P_{75}$ )	6.00 (4.00, 10.00)	6.00 (3.00, 9.00)	0.00 ( $-2.00$ , 2.00)
Mean (95% CI)	7.04 (6.74 to 7.33)	6.49 (6.15 to 6.80)	$-0.07$ ( $-0.43$ to 0.31)
SD (95% CI)	4.27 (3.92 to 4.43)	4.90 (4.68 to 5.25)	3.31 (2.96 to 3.66)
Mean (95% CI) <sup>a</sup>	6.74 (6.43 to 7.03)	N/A <sup>b</sup>	0.17 ( $-0.19$ to 0.55)
SD (95% CI) <sup>a</sup>	4.34 (3.98 to 4.50)	N/A	3.32 (2.96 to 3.68)

<sup>a</sup>Results of sensitivity analyses. For incubation period, the third day for those whose exposure period spanned three days and the second day for those exposed for two continuous days were used as their exposure dates in sensitivity analyses. For symptoms-to-transmission time, exposure dates were taken in a different way in sensitivity analyses (like those of the incubation period).

<sup>b</sup>N/A: not applicable.

**Figure 2.** The distribution of (A) incubation period ( $n=687$ ), (B) serial interval ( $n=1015$  pairs), and (C) symptoms-to-transmission time ( $n=296$  pairs).

## Sensitivity and Stratified Analyses

In sensitivity analyses, the estimates of incubation period and symptoms-to-transmission time remained stable, with a difference of 0.24-0.3 days from those in primary analysis (Table 2), which represents the largest possible error caused by

inclusion of cases with an exposure period spanning 2 or 3 days. The results of the stratified analysis are summarized in Multimedia Appendix 5. The difference between strata was statistically significant in four of the analyses (see footnote of Multimedia Appendix 5). Briefly, the incubation period was longer for those exposed for only 1 day (as compared with those

exposed for 2-3 days), while serial interval and symptoms-to-transmission time were longer for those at lower generations of clustered infection. The serial interval was also longer for those infected through nonhousehold contact.

## Discussion

By pooling the individual data of 1591 cases, we estimated the mean incubation period, serial interval, and symptoms-to-transmission time of COVID-19 to be 7.04, 6.49, and -0.07 days, respectively. The incubation period was longer than 14 days in 5.82% of the cases. Infectees' symptom onsets occurred before those of infectors in 3.15% of the infector-infectee pairs. Presymptomatic transmission occurred in 43.58% of the infector-infectee pairs.  $R_0$  was estimated to be 1.85 (95% CI 1.37-2.60).

To our knowledge, this study represents the largest case series with accurate data on incubation period, serial interval, and frequency of presymptomatic transmission. Our estimates of incubation period and serial interval are longer than most of the previous estimates [5-10]. There are several possible reasons for the difference. First, the sample size is generally small in previous studies [5,7,9,12-15], but much larger in this one. Second, most cases in previous studies had a long or unclear interval of exposure, making it difficult to determine the exact exposure date [6,8,17] and giving rise to error. By contrast, this study applied strict inclusion criteria regarding the exposure period and a simple method to determine exposure date to ensure the potential error in the estimates was small (<0.3 days, according to the sensitivity analysis). Third, the order of transmission (ie, who is the infector and who is the infectee) in clustering cases, which is crucial to estimation of both parameters, is easy to be mistaken given the possibility of presymptomatic and asymptomatic transmission [21,22,27,28]. According to our experience in screening the publicly available data, for many clusters, there was no clear evidence (eg, who got infected outside and brought the virus to the cluster?) to establish the transmission order. To ensure the accuracy of data, we excluded such clusters in this study, while previous studies rarely described how this issue was handled [11].

Our finding that the incubation period was within 14 days for 94% of the cases lends support to the current practice of 14-day quarantine of persons with potential exposure to SARS-CoV-2. In line with other studies [17], we also found some cases who developed symptoms more than 14 days after exposure, indicating that longer quarantine periods might be justified for some people. However, as it is hard to know beforehand who will develop symptoms beyond 14 days after exposure, the cost of extending mandatory quarantine of many people and the potential consequence of failure to identify a few symptomatic cases must be weighed carefully. Testing at the end of quarantine and social distancing afterwards may help reduce the risk associated with this phenomenon.

The negative values of the serial interval and symptoms-to-transmission time provide evidence of presymptomatic transmission. Specifically, 43.58% of the

transmission events in this study occurred before infectors' symptom onsets. Asymptomatic transmission was also reported by the publications included in this study (Multimedia Appendix 2). These phenomena constitute a challenge in the control of the epidemic and highlight the importance of adequate testing, strict quarantine, and social distancing to reduce the transmission caused by "hidden" cases.

The  $R_0$  we estimated is smaller than those from previous estimates, which were mostly between 2 and 4 [20,29,30]. The difference may be due to either the methodological issues in obtaining parameters as discussed above or due to the estimating method itself. In estimating  $R_0$ , the serial interval was used to approximate generation time in the Euler-Lotka equation, which may lead to underestimation because of the possibly differing incubation periods of the infector and infectee. Assuming the incubation periods of the infector and infectee follow the same distribution, we found that the  $R_0$  was 1.90, almost the same as the original one, suggesting a small error in our estimation. In any case, a smaller  $R_0$  should not be interpreted as a low risk of transmission. Slow response of government, presymptomatic and asymptomatic transmission, and insufficient protection measures taken by the public together could lead to an out-of-control epidemic, as is the current situation in many countries.

This study has some limitations. First, it was based on publicly reported cases. Previous studies suggested that such cases may overrepresent the severe ones. However, as the publicly available information on severity was incomplete and inaccurate, we were unable to assess the magnitude and potential impact of this issue. Another problem with publicly reported cases is that their epidemiology history might be reported in more detail at the early stage of epidemic than when the number of cases grew larger. We found that this was especially true for Japan and Singapore. Thus, in general, the results of this study reflected more the situation during the early stage of the pandemic. Second, to ensure accuracy in estimating the incubation period, the cases exposed for a long (>3 days) or unclear period were excluded (which was inevitable and justifiable). This might have contributed partly to the longer incubation period in this study than others, as there was a trend toward a longer incubation period in the cases exposed for 1 day only (a relatively shorter period) as compared with those exposed for 2-3 days (Multimedia Appendix 5). Third,  $R_0$  might have been underestimated as the Euler-Lotka equation was used; however, as explained in the last paragraph, the magnitude of underestimation, if any, was very small.

In conclusion, this study obtained robust estimates of several key epidemiological parameters of COVID-19. It provides additional evidence on the mean incubation period of COVID-19, which supports the current practice of 14-day quarantine of persons with potential exposure but also suggests the need for additional measures. Presymptomatic transmission together with the asymptomatic transmission reported by previous studies highlight the importance of adequate testing, strict quarantine, and social distancing.

## Acknowledgments

We thank all the people who worked hard, risked their health, and even sacrificed their lives to fight against COVID-19. They are real heroes. We also thank the numerous individuals who reduced their social activities to a minimum to help contain the spread of SARS-CoV-2.

## Authors' Contributions

YZ conceived the idea and designed the study, has full access to all data in the study, and takes responsibility for the integrity of data and the accuracy of data analysis. MS, ZJ, ZM, YQ, GW, ZY, and YZ contributed to data acquisition, statistical analysis, and the writing of the report. WMH and ZS contributed to statistical analysis. All authors contributed to data interpretation and critical revision and reviewed and approved the final version.

## Abstract

**Background:** As the COVID-19 epidemic increases in severity, the burden of quarantine stations outside emergency departments (EDs) at hospitals is increasing daily. To address the high screening workload at quarantine stations, all staff members with medical licenses are required to work shifts in these stations. Therefore, it is necessary to simplify the workflow and decision-making process for physicians and surgeons from all subspecialties.

**Objective:** The aim of this paper is to demonstrate how the National Cheng Kung University Hospital artificial intelligence (AI) trilogy of diversion to a smart quarantine station, AI-assisted image interpretation, and a built-in clinical decision-making algorithm improves medical care and reduces quarantine processing times.

**Methods:** This observational study on the emerging COVID-19 pandemic included 643 patients. An “AI trilogy” of diversion to a smart quarantine station, AI-assisted image interpretation, and a built-in clinical decision-making algorithm on a tablet computer was applied to shorten the quarantine survey process and reduce processing time during the COVID-19 pandemic.

**Results:** The use of the AI trilogy facilitated the processing of suspected cases of COVID-19 with or without symptoms; also, travel, occupation, contact, and clustering histories were obtained with the tablet computer device. A separate AI-mode function

that could quickly recognize pulmonary infiltrates on chest x-rays was merged into the smart clinical assisting system (SCAS), and this model was subsequently trained with COVID-19 pneumonia cases from the GitHub open source data set. The detection rates for posteroanterior and anteroposterior chest x-rays were 55/59 (93%) and 5/11 (45%), respectively. The SCAS algorithm was continuously adjusted based on updates to the Taiwan Centers for Disease Control public safety guidelines for faster clinical decision making. Our ex vivo study demonstrated the efficiency of disinfecting the tablet computer surface by wiping it twice with 75% alcohol sanitizer. To further analyze the impact of the AI application in the quarantine station, we subdivided the station group into groups with or without AI. Compared with the conventional ED ( $n=281$ ), the survey time at the quarantine station ( $n=1520$ ) was significantly shortened; the median survey time at the ED was 153 minutes (95% CI 108.5-205.0), vs 35 minutes at the quarantine station (95% CI 24-56;  $P<.001$ ). Furthermore, the use of the AI application in the quarantine station reduced the survey time in the quarantine station; the median survey time without AI was 101 minutes (95% CI 40-153), vs 34 minutes (95% CI 24-53) with AI in the quarantine station ( $P<.001$ ).

**Conclusions:** The AI trilogy improved our medical care workflow by shortening the quarantine survey process and reducing the processing time, which is especially important during an emerging infectious disease epidemic.

## KEYWORDS

SARS-CoV-2; COVID-19; artificial intelligence; smart device assisted decision making; quarantine station

## Introduction

In December 2019, a local outbreak of pneumonia was detected in Wuhan, Hubei Province, China. Initially of unknown cause, the pneumonia was quickly determined to be caused by a novel coronavirus [1,2]. The International Committee on the Taxonomy of Viruses termed this novel virus SARS-CoV-2; the disease it causes is called COVID-19 [3,4]. The COVID-19 outbreak subsequently spread to every province of mainland China and then globally, with 1,773,084 confirmed cases and 111,652 deaths as of April 14, 2020 [5].

COVID-19 is considered to be very contagious in human beings [6]. Person-to-person transmission has been documented for COVID-19 [7], and the prevention of in-hospital outbreaks has become an important issue for crowded departments with highly infectious areas, including emergency departments (EDs), outpatient clinics, and inpatient admission wards [8-10]. In response to this, Taiwan implemented a disaster preparation plan by moving to “heightened” military level status, the highest of the three security tiers during peacetime; this is similar to war preparation status, with increased alertness and enhanced caution regarding the possibility of cross-contamination among people, especially within hospitals. As the COVID-19 epidemic situation deteriorates, the burden on quarantine stations outside EDs at hospitals is increasing daily. To address the high screening workload at quarantine stations, all staff members with medical licenses are required to work shifts in these stations. Therefore, it has become necessary to simplify the workflow and decision-making process for physicians and surgeons from all subspecialties.

To address this pandemic, the government of Taiwan reacted with a swift, efficient, and precise response [11]. Taiwan prevented entry to travelers from high-risk regions outside Taiwan as the first step; also, Taiwanese citizens and alien residents were quarantined, screened, and isolated based on specific criteria and conditions announced by the Taiwan Centers for Disease Control (CDC). However, the situation was dynamic and fluid and changed daily, with new CDC announcements requiring immediate protocol changes. To

address these criteria in their screening strategy and to reduce the processing time in COVID-19 quarantine stations, National Cheng Kung University Hospital (NCKUH) designed an artificial intelligence (AI) system to address this unmet clinical need. The NCKUH AI team used previous experience from prior smart medicine research and applications to develop a specific computer-assisted technology device to accelerate medical decisions. The goal was to reduce potentially dangerous SARS-CoV-2 exposure by shortening the period of time spent by patients in the quarantine unit. In response to this increasing public health emergency, the NCKUH AI team developed a smart quarantine station for use outside the NCKUH ED to facilitate the screening and survey process. The aim of this study is to demonstrate how the NCKUH AI trilogy of diversion to the smart quarantine station, AI-assisted image interpretation, and a built-in clinical decision-making algorithm improved medical care and reduced quarantine processing times.

## Methods

### The Smart Quarantine Station AI Trilogy

To improve the workflow and efficacy of the COVID-19 infection survey at NCKUH, an AI trilogy policy was employed outside and adjacent to the ED. The three parts of the trilogy were diversion of suspected patients with COVID-19 to the quarantine station; a travel, occupation, contact, and cluster (TOCC) survey on a tablet computer; and an AI-assisted image interpretation feature with clinical strategy decision-making algorithms at the smart quarantine station. Together, these steps facilitated the screening and survey process for suspected cases with or without symptoms and the collection of TOCC histories at the NCKUH.

The NCKUH is a referral medical center and teaching hospital with the largest medical service capacity in Tainan, a traditional culture city. Tainan is the sixth largest city in Taiwan, with >1,880,000 citizens. NCKUH has three main care facilities: an outpatient building that houses short-term patient care and clinical laboratories; an inpatient building where long-term care, the intensive care unit, and surgery wards are located; and the

ED. With >5000 outpatient visits daily and 1300 inpatient beds in addition to >300 emergency critical care patients in the ED, NCKUH understood the need to prevent the emerging infectious disease epidemic from becoming a local disaster and overburdening the medical system. The lessons learned from Taiwan's previous experience with the severe acute respiratory syndrome coronavirus (SARS-CoV) outbreak in 2003 have paid substantial dividends during the current COVID-19 outbreak. To address the expected high influx of COVID-19-related hospital visits and prevent in-hospital outbreaks, a quarantine

station was established adjacent to the ED. NCKUH immediately set up eight temporary wartime quarantine tents according to the Wuhan Pneumonia Quarantine Action. Simultaneously, a more permanent structured housing facility for long-term quarantine was established near these wartime tents (Figure 1). This effective diversion of patients from the ED to the quarantine tents relieved pressure on the crowded ED. On average, each medical staff member was estimated to examine 35 to 50 quarantine patients per day.

**Figure 1.** The quarantine station at National Cheng Kung University Hospital. ED: emergency department.

### Workflow Survey and Definition of Survey Time

Because the COVID-19 outbreak was rapidly becoming an epidemic and posed a threat of high risk of exposure to our staff and patients, NCKUH urgently instituted a workflow survey. Patients who visited the quarantine station were asked to complete a questionnaire that included their TOCC history as well as any chronic illnesses, symptoms, or signs. Before they entered any private information, the patients gave signed consent allowing us to use their data and baseline characteristics for subsequent analysis of the workflow. The survey time was defined as the total of the time a patient took to complete the TOCC history with a nurse's written record and history taking; the time needed to undergo a chest x-ray examination with related inquiry and expert interpretation; and the time to revisit with the examining physician to discuss a medical decision based on the patient workflow recommended by the Taiwan CDC.

The physician would decide whether the patient should be hospitalized, be registered, or recover at home under self-care. Furthermore, the NCKUH staff could access electronic medical records using the tablet computer along with medical AI radiomics of chest x-rays to alert radiologists and pulmonary physicians to screen pneumonia patches earlier than usual. Finally, the embedded clinical decision-making algorithm assisted the staff in assessing potential cases; this could also be useful to physicians who were not familiar with the emerging virus. This process was updated daily using the most recent guidelines from the Taiwan Ministry of Health and Welfare in collaboration with the Taiwan CDC.

### Disinfection Protocol for the TOCC Tablet Computer

To assess if our disinfection process could effectively clean any possible SARS-CoV-2 contamination from a tablet computer surface, we performed an ex vivo study by spraying 20 microliters of a positive SARS-CoV-2 virus solution onto a computer in a P3 laboratory at NCKUH. After the computer

surface was air-dried for 30 minutes, it was swabbed by technicians to obtain the first sample (V0), which indicated the surface virus load after initial exposure to the virus. After V0 sample collection, the technicians used 75% alcohol to mimic the disinfection procedure that was recommended in the current Taiwan CDC guideline. Samples V1 and V2 were collected after disinfecting the surface once and twice using 75% alcohol, respectively. The crossing point (CP), which is the maximum second derivative of the amplification curve of the real time–polymerase chain reaction (RT-PCR), was measured to obtain the viral load on the tablet computer surface using the COVID-19 Genesig RT-PCR assay (Primerdesign Ltd) using a LightCycler 480 II PCR platform (Roche Holding AG). A positive viral load was defined by the CP of amplification curve <45 of the RT-PCR result. Two specific genes, RNA-dependent RNA polymerase (RdRp) and Envelope (E) genes, were simultaneously assayed to determine the results.

### AI-Assisted Reading of Chest X-Rays

COVID-19 pneumonia exhibits a milder radiological course than severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) pneumonia; only 33% of COVID-19 pneumonia cases in Korea and only 60% of cases in China were reported to have chest x-ray abnormalities [12]. Patients with COVID-19 pneumonia can have negative chest

radiographs or computed tomography (CT) images even if their RT-PCR test is positive. According to Pan et al [13], the time course of COVID-19 pneumonia adheres to a clinical progression. The subclinical group has a CT pattern of unilateral and multifocal ground-glass opacities (GGOs) that progress immediately to bilateral and diffuse GGOs. The image may be mixed with light consolidations by the peak of disease severity, which occurs approximately 2 weeks after symptom onset [14]. In current practice, it is difficult to interpret chest radiographs showing GGOs, and this can limit the early diagnosis of COVID-19 pneumonia within the first week of symptom onset. Radiographic deterioration observed in follow-up thoracic imaging implies poor prognosis of COVID-19 pneumonia. Therefore, NCKUH set up portable imaging equipment to accelerate the characterization of chest conditions and limit the transportation of suspected cases to lower the risk of transmission [15].

### Development of AI Models for Chest X-Ray Analysis

The development of AI models for chest x-ray analysis can ease the burden on medical staff and enable more rapid triaging of patients. To detect the precise location of pneumonia sites, we adopted a segmentation model with a class attention map [16]. The pneumonia segmentation model was based on U-Net [17], as shown in Figure 2.

**Figure 2.** The pneumonia segmentation model based on U-Net. ResNet-50 was used as the encoder backbone model. The squeeze-and-excitation block was added to each ResConv block to enhance feature extraction from feature maps. The skip connection was used to concatenate the encoder feature map with the decoder feature map after upsampling. Conv: convolutional; ResConv: residual convolutional.

The Conv block was constructed using a  $3 \times 3$  convolutional block and batch normalization [18] and was then activated using a rectified linear unit (ReLU) function. We also adopted a residual network, ResNet-50 [19], with the pretrained weight

on the ImageNet as the backbone of this model. Moreover, we leveraged the squeeze-and-excitation block [20], as shown in Figure 3, to capture more significant information in each residual convolutional block.

**Figure 3.** Model of the addition of the SE block to the residual convolutional block. Conv: convolutional; SE: squeeze-and-excitation.

After  $U$  was established, the global average pooling in  $F_{sq}$  was used to obtain global information from each feature map. Two fully connected layers were adopted with the ReLU and sigmoid functions to apply a nonlinear transformation to earn attention information in  $F_{ex}$ . The attention weight produced by  $F_{ex}$  was multiplied to feature map  $U$  to obtain more efficient features of  $X'$  in  $F_{scale}$ . The input  $X$  was added to  $X'$  to obtain the new feature map  $X''$  to implement the residual block.

The output masks of this model contained two different predictors: pneumonia and GGO. We used multiple bounding boxes to label all lesions or as many lesions as possible. Because it is possible to observe different illnesses at the same position, we used a sigmoid activation function to leverage two  $1 \times 1$  convolutional kernels, one for detecting pneumonia and one for detecting GGO. Next, we trained this model using pixel-wise binary cross entropy and then minimized the loss function as follows:

where  $N$  and  $M$  denote the height and width of the input image, respectively, and  and  represent the gold standard and predicted value of this pixel, respectively.

### Grouping of Survey Patients

Patients could follow three routes in the NCKUH ED or quarantine station from January 31 to March 17, 2020. Route 1 was the traditional ED route, which did not include AI or the smart device app; this route was followed by patients who visited the ED between 8 PM and 8 AM, when no quarantine station service was available. Route 2 was the quarantine station without AI or the smart device app; most patients followed this route between January 31 and February 5, 2020. Route 3 was the quarantine station with AI and the smart device app, which was mainly followed by patients from February 5 to March 17, 2020. To compare baseline characteristics, we merged Route 2 and Route 3 into a general quarantine station route. Route 1 was recognized as the traditional ED track for screening. Data regarding patients' preexisting conditions, including coronary artery disease, diabetes, hypertension, chronic obstructive pulmonary disease, underlying malignancy, and chronic kidney disease with or without end-stage renal disease, were all obtained from medical records or the SCAS database. Patients'

symptoms, including dyspnea, cough, stuffed nose, fever, and body temperature, were also recorded individually. Informed patient consent was built into the front page of the tablet computer app before the start of the questionnaire due to the urgent need to collect data while avoiding paper cross-contamination.

### Patient and Public Involvement and Ethical Issues

This study was designed by the investigators. Patients or the public were enrolled in the research study when they visited the quarantine station and agreed to participate before answering the SCAS questionnaire on the tablet computer. The NCKUH Institutional Review Board approved our use of information and images obtained from the quarantine station (A-ER-109-149). Furthermore, due to the pandemic, the dissemination of results to the study participants was not applicable.

### Statistical Analysis

Statistical analyses were performed using SPSS Version 22.0 (IBM Corporation). Continuous data are presented as mean (SD) or median (IQR) depending on the distribution. Dichotomous data are presented as  $n$  (%). Comparisons were conducted with nonparametric statistics using the Wilcoxon rank sum test or the Mann-Whitney U test for continuous variables.  $P$  values  $< .05$  were considered significant.

## Results

### Overview

To improve the efficiency of the survey to determine COVID-19 infection risk and safely reduce crowding in the ED, NCKUH in Taiwan established an AI trilogy comprising three parts. First, we built a quarantine station with a SCAS to accelerate the workflow (Figure 4). SCAS is a clinical decision tree algorithm that integrates the structured format of the TOCC history recording, AI-assisted interpretation of chest x-rays, and the clinically recommended workflow. Patients at the quarantine station who were suspected of having COVID-19 used a tablet computer to answer the SCAS questionnaire on their TOCC history, with adequate alcohol disinfection between users. To avoid cross-infection between front-line medical staff and patients, all physicians and nurses used independent computers.

**Figure 4.** Synergetic combination of quarantine station establishment, smart patient processing, and AI to improve the efficiency and safety of patient processing during the COVID-19 pandemic. ED: emergency department; TOCC: travel, occupation, contact, and cluster.

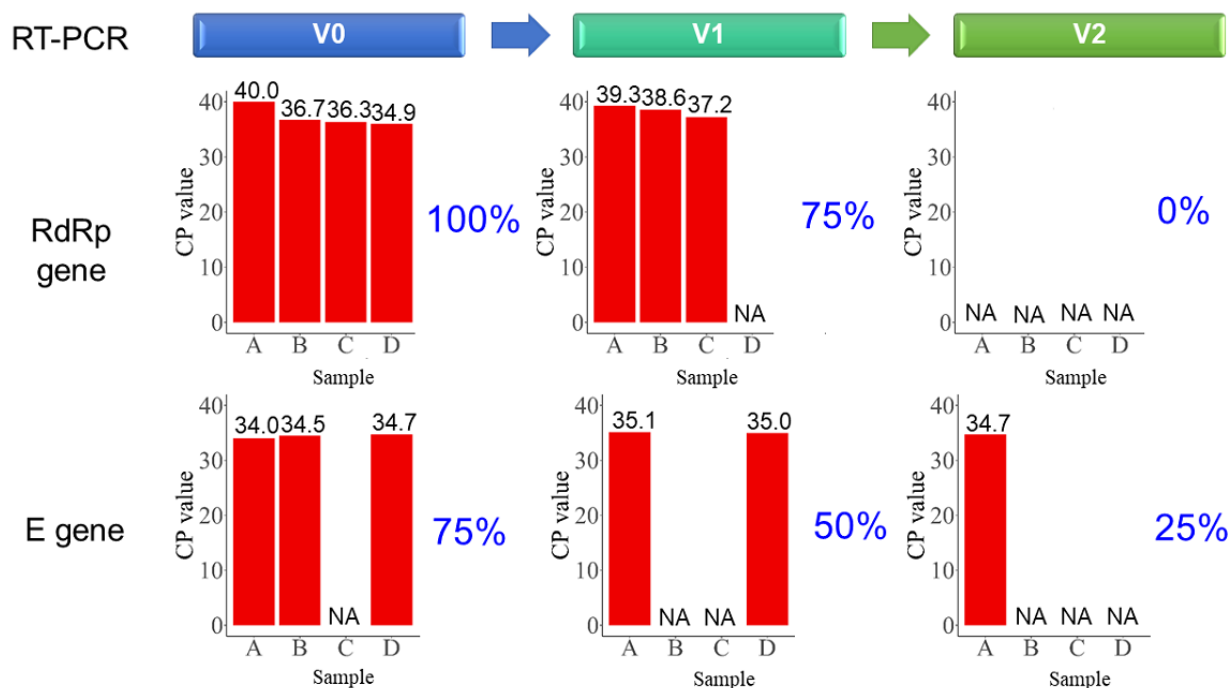

### Disinfection Process Assessment

To assess if our disinfection process of the tablet computer device using 75% alcohol sanitizer was effective and removed all residual viruses from the surface of the device, we performed an ex vivo study. First, 20 microliters of a positive SARS-CoV-2 virus solution was sprayed onto the computer surface. Subsequently, 75% alcohol was used to clean and disinfect the computer surface (Figure 5). We tested four samples without 75% alcohol treated and found that the initial results were 100%

positive tested by SARS-CoV-2 RT-PCR. Interestingly, the CP values for RdRp gene were 75% and 0% positive after the first and second disinfection procedures using 75% alcohol on the tablet computer surface, respectively. Similarly, the initial CP value for the COVID-19 E gene was 75% positive, and it decreased to 50% and 25% positive after the first and second alcohol disinfection procedures, respectively. These results supported our proposed tablet computer cleaning protocol of two careful disinfection processes using 75% alcohol between uses of the tablet.

**Figure 5.** Ex vivo study to determine the efficiency of disinfection of the tablet computer surface. Samples were collected from the tablet surface before disinfection (V0) and after the first and second disinfection processes using 75% alcohol (V1 and V2, respectively). The percentages indicate the positive rate (CP value <45 as positive) of the real time–polymerase chain reaction (RT-PCR, N=4 for each experiment). CP: crossing point. RdRp: RNA-dependent RNA polymerase gene. E: Envelope gene.

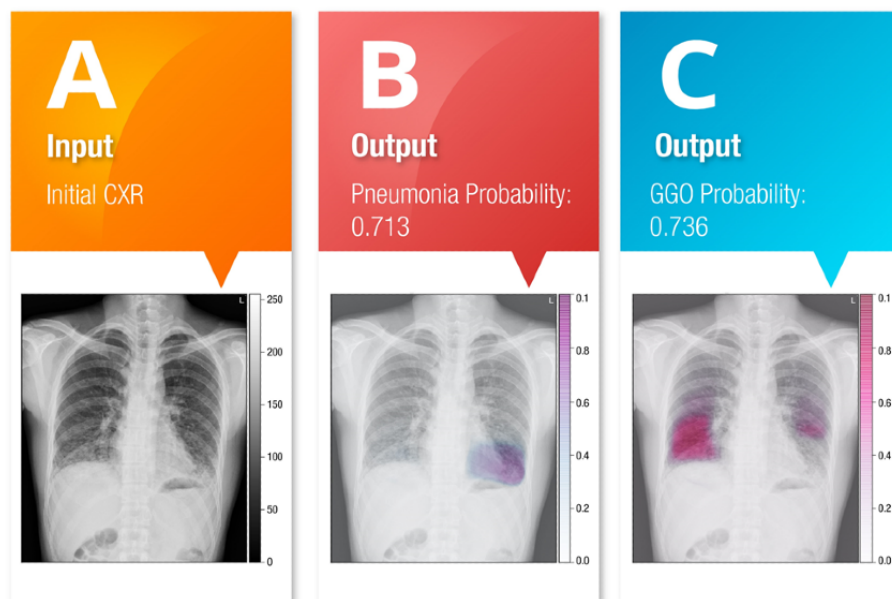

### AI Chest X-Ray Interpretation

To optimize AI chest x-ray interpretation, we retrospectively retrieved 4000 chest x-rays from our image archiving and communication system and identified 682 posteroanterior chest x-rays with pneumonia and 692 normal chest posteroanterior x-rays. All poor-quality anteroposterior chest radiographs and chest x-rays were excluded. To enhance the detection rate of light consolidations, we selected 46 cases with CT-evidenced GGOs and posteroanterior chest X-rays from the same day as the CT examination to serve as the GGO training data set (Figure 6). Our AI mode for quickly recognizing pulmonary infiltrates on chest x-rays was merged into the SCAS, with an area under

the receiver operating characteristic curve (AUC) of 0.99 (Figure 7), sensitivity of 94.1%, specificity of 95.1%, and accuracy of 94.6% using the training data set. Furthermore, we used cases of COVID-19 pneumonia from an open source data set in GitHub [21] including 59 posteroanterior and 11 anteroposterior chest x-rays to test the model. We achieved detection rates of 55/59 (93%) in posteroanterior and 5/11 (46%) in anteroposterior chest x-rays compared to interpretation by one cardiothoracic radiologist with 14 years of experience.

Our AI mode for quickly recognizing pulmonary infiltrates on chest x-rays was merged into the SCAS, with an AUC of 0.99, sensitivity of 94.1%, specificity of 95.1%, and accuracy of 94.6% using the training data set.

**Figure 6.** The artificial intelligence (AI) model for pneumonia detection incorporated into the smart clinical assisting system. (A) An original chest x-ray is automatically retrieved from the picture archiving and communication system and then interpreted by the AI model. (B) A consolidative lung is detected, and the diseased site is illustrated using a heat map. (C) A light consolidation GGO is identified by the AI model. CXR: chest x-ray; GGO: ground-glass opacity.

**Figure 7.** AUC of the AI chest x-ray interpretation system for recognizing pulmonary infiltrates on chest x-rays. AUC: area under the ROC curve; ROC: receiver operating characteristic.

## Clinical Data of Study Participants

The screening population of patients who visited the NCKUH ED and who agreed to provide their data for the study (N=643) was divided into two groups: the traditional ED group (n=281) and the smart quarantine station group (n=362). The baseline characteristics of these two groups are compared in Table 1.

The average age of the patients who visited the quarantine station was 35.6 years (SD 13.1), which was similar to the average age (34.7 years, SD 12.3) of patients visiting the traditional ED route. The most dominant trait in the TOCC was the traveling history for both groups, followed by the contact history. The screening population was a lower risk cohort, with

low prevalence rates of hypertension (9/281, 3.3%, and 19/362, 4.4%, in the ED and quarantine station groups, respectively) and chronic kidney disorder (8/281, 2.8%, and 5/362, 1.5%, in the ED and quarantine station groups, respectively); this suggests similar chronic illness histories in the two groups. Most patient symptoms manifested as a cough at the initial presentation (ED vs quarantine station: 140/281, 49.8% vs 226/362, 62.4%;  $P=.31$ ), followed by a stuffed nose (ED vs quarantine station: 88/281, 31.3%, vs 166/362, 45.8%;  $P=.31$ ) and fever (ED vs quarantine station: 78/281, 27.7%, vs 134/362, 37%;  $P=.37$ ). In general, the comparison between the two groups showed no difference in the distributions with respect to baseline age, gender, pre-existing conditions, or symptoms.

**Table 1.** Comparison of clinical data of patients seeking treatment in the traditional ED and at the smart quarantine station during the COVID-19 epidemic from January 31 to March 17, 2020 (N=643).

Characteristic	ED <sup>a</sup> (n=281)	Smart quarantine station (n=362)	P value
Age (years), mean (SD)	34.7 (12.3)	35.6 (13.1)	.41

<sup>e</sup>CKD: chronic kidney disease.

<sup>f</sup>ESRD: end-stage renal disease.

## Survey Times

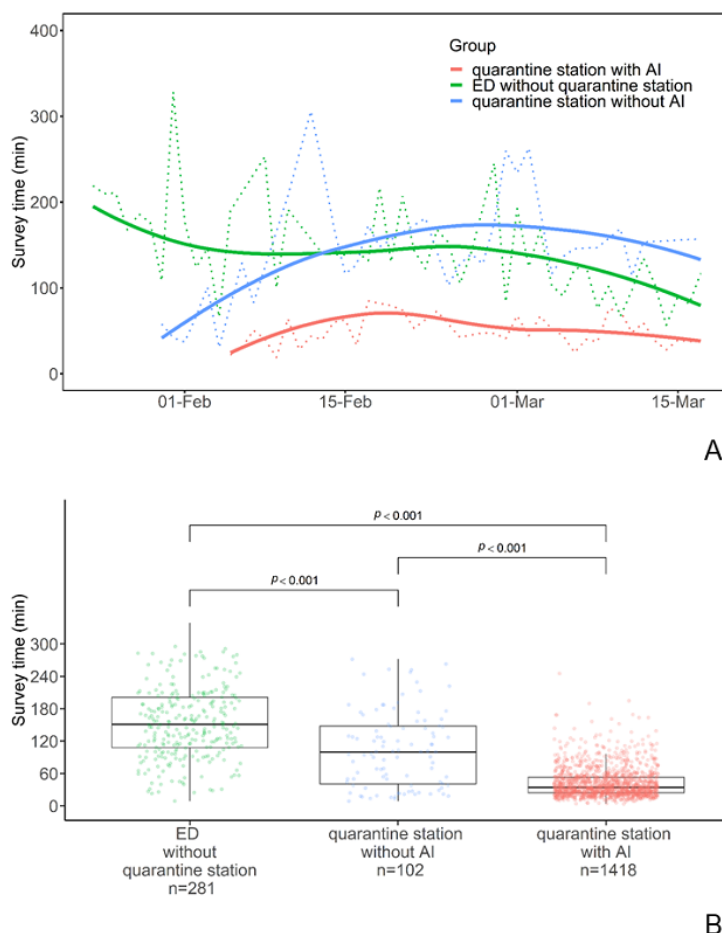

To further analyze the impact of the AI application on the quarantine station, we subdivided those in the quarantine station into groups with or without AI. As shown in Figure 8, compared with the conventional ED track (n=281), the survey time at the clinical quarantine station (n=1520) was significantly shortened,

with a median survey time at the ED of 153.0 minutes (95% CI 108.5-205.0) vs 35 minutes at the clinical quarantine station (95% CI 24-56;  $P<.001$ ). Furthermore, the use of the AI application in the quarantine station reduced the survey time in the station; the median survey time without AI in the quarantine

station was 100.5 minutes (95% CI 40.3-152.5), vs 34 minutes with AI in the quarantine station (95% CI 24-53;  $P<.001$ ).

**Figure 8.** (A) Comparison of survey processing times over the study period between the traditional ED and quarantine station groups with or without AI applications. (B) Box plots of the survey processing times for the traditional ED group, the quarantine station group without AI, and the quarantine station group with AI. AI: artificial intelligence; ED: emergency department; min: minutes.

## Discussion

### Principal Findings

In this study, we demonstrate how the NCKUH AI trilogy of diversion to a smart quarantine station incorporated with the SCAS, AI-assisted image interpretation, and a built-in clinical decision-making algorithm improved medical care and reduced the processing time at the quarantine station. In addition, our ex vivo study demonstrated the efficiency of 75% alcohol disinfection of the tablet computer after initial exposure to a positive viral load; by applying this procedure, the tablet computer is rendered safe for use by people in the quarantine station. This enhances patient quality of care and reduces risks to medical staff. Based on Taiwan's experience with SARS in 2003, the diversion of patients in the ED was crucial for early management and in-hospital infection control. Most Taiwanese hospitals needed to set up clinical quarantine stations near their EDs to survey patients who were suspected of being infected with COVID-19 due to the heavy caseloads experienced by hospitals daily. When a clinical quarantine station is set up, several factors can be detrimental to the conditions in the station. These factors include patient crowding in the restricted space within the quarantine station, high possibility of cross-contamination or coinfection, daily changes and

modifications to clinical guidelines by the Taiwan CDC, lack of familiarity of backup physicians with infectious disease control, and scarcity of radiology or pulmonary physicians in most hospitals to provide accurate and immediate pneumonia diagnoses.

To the best of our knowledge, this is the first time a smart quarantine station with a computer featuring a built-in clinical assistance system was used during an epidemic to accelerate complex workflows. Compared to the conventional ED track, the efficiency of the survey of the risk of COVID-19 infection was significantly improved by at least threefold for the NCKUH quarantine station. These results also highlight that the efficiency of the risk survey for COVID-19 infections at clinical quarantine stations is of general interest and helps address an unmet clinical need.

Triage in the ED for pandemic infectious disease screening is particularly challenging. Although telemedicine allows patients and physicians to communicate without direct contact, symptomatic or worried patients still directly visit the ED, and they can be efficiently screened by modern triage [22]. For in-person care, patients with positive signs of high-risk features should be immediately isolated to avert further contact with patients and health care workers. According to Hollander et al

[22], tablet computers can be cleaned between patients using well-defined infection control procedures. Furthermore, daily updates of the SCAS system help physicians or surgeons who may not be experts in radiologic interpretation of pneumonia patches or infectious disease to make proper decisions with little preparation before assuming their quarantine station duties.

The COVID-19 pandemic is affecting not only patients but also economies, politics, and daily life worldwide. Better management of future pandemics will reduce these human and economic burdens. All medical science personnel should use lessons learned from past and present pandemics to improve

upon past performance to prevent catastrophic effects of future disease outbreaks.

## Conclusions

We demonstrated a feasible, safe, and scientific application of a smart device with a built-in algorithm combined with an AI-based image system in a quarantine station to facilitate the survey process, avoid cross-infection, and reduce the burden on team members, including physicians, nurses, and technicians. This helpful process should be adapted into our strategies to address emerging endemic infectious diseases in the future.

## Acknowledgments

This study was supported by grants 109-2745-B-006-003, 109-2327-B-006-005, 109-2634-F-006-023, and 108-2314-B-006-098-MY3 from the Ministry of Science and Technology of Taiwan and grants D108-G2512 D109-G4803, D109-G4804, and D109-G2512 from Higher Education Sprout Project, Ministry of Education, to the Headquarters of University Advancement at National Cheng Kung University. We would like to thank all the NCKUH faculty members who participated in the quarantine station during this emerging infectious disease pandemic. We would also like to thank our technicians Chun-Sheng Yeh, I-Ting Lin, and Li-Rong Wang for their kind technical support and suggestions for the ex vivo study. Finally, we would like to thank Prof Michael W Hughes for his help with this English edition. We are grateful to Prof Pei-Fan Su for discussing and providing statistical consulting services from the Center for Quantitative Sciences, Clinical Medicine Research Center, NCKUH.

## Abstract

**Background:** COVID-19 is the most widely discussed topic worldwide in 2020, and at the beginning of the Italian epidemic, scientists tried to understand the virus diffusion and the epidemic curve of positive cases with controversial findings and numbers.

**Objective:** In this paper, a data analytics study on the diffusion of COVID-19 in Italy and the Lombardy Region is developed to define a predictive model tailored to forecast the evolution of the diffusion over time.

**Methods:** Starting with all available official data collected worldwide about the diffusion of COVID-19, we defined a predictive model at the beginning of March 2020 for the Italian country.

**Results:** This paper aims at showing how this predictive model was able to forecast the behavior of the COVID-19 diffusion and how it predicted the total number of positive cases in Italy over time. The predictive model forecasted, for the Italian country, the end of the COVID-19 first wave by the beginning of June.

**Conclusions:** This paper shows that big data and data analytics can help medical experts and epidemiologists in promptly designing accurate and generalized models to predict the different COVID-19 evolutionary phases in other countries and regions, and for second and third possible epidemic waves.

## KEYWORDS

COVID-19; SARS-CoV-2; big data; data analytics; predictive models; prediction; modeling; Italy; diffusion

## Introduction

The unexpected pandemic diffusion of COVID-19 [1] worldwide calls for the need to study all available data to promptly understand the epidemic curve of COVID-19 contagiousness [2-4] to help medical experts, epidemiologists, and political decision makers in designing prompt reaction plans.

In this paper, we aim to develop an accurate predictive model tailored to forecast the evolution of the diffusion over time, exploiting big data and data analytics. Generally, epidemics follow an exponential curve in the spread of positive cases. This is not the case of the curve observed in Wuhan, China [5], where the official curve of confirmed positive cases of COVID-19

follows a behavior that is different from typical epidemics. More precise studies are reported in [1,6-8]. Starting from this observation, we tried at the beginning of March to correlate the Wuhan official data set with the COVID-19 data set available in Italy by applying big data and data analytics techniques [9] to all official open data available worldwide [5] to design the logistic curve for early estimation of the number of COVID-19 positive cases day-to-day and in all the phases of the pandemic over time (eg, the peak in the number of daily cases, the logistic plateau, and at the end of the pandemic).

## Methods

To design the predictive model, we exploited all the official data sets available so far. We analyzed the Wuhan official data set, available at [5]. As for the Italian perspective, we adopted the official data set that is daily published and updated by the Department of the Italian Civil Protection [10]. All these data sets are freely available. Additional statistics (eg, percentage of people that have severe COVID-19, percentage of people that need intensive care, COVID-19 mortality index) have been imported from the World Health Organization (WHO) website [11].

Exploiting the similarity between the behavior of the COVID-19 contagion in Wuhan and the starting Italian scenario, we designed our predictive curve adapting well-known mathematical methods to this particular context: the Pearson correlation index to formally evaluate this similarity in the contagion, the logistic curve (sigmoid) to design the cumulative

number of COVID-19 positive cases, regression models to evaluate the best correlation fit for our predictions, and the power law to model the initial ascent of the pandemic.

## Results

In the first step of our method, we computed the Pearson correlation coefficient applied to a sample between the two data sets (Italy vs Wuhan) with reference to the daily new positive cases as:

Starting from the data set available from March 2, 2020, it was possible to observe a strong Pearson correlation between the data set related to Italy and the data set related to Wuhan with a *Correlation Index of 0.9944*, as depicted in Figure 1 where the Wuhan curve is compared with the Italian one.

**Figure 1.** Graphical comparison between the Italian curve and Wuhan curve (total cumulative positive cases).

Starting from this assumption, it was then possible to use the Wuhan data set (with a strong statistical significance) to try to predict the logistic curve of total positive cases to COVID-19 for Italy and the Lombardy Region. We started designing our model by the basic assumption that every pandemic phenomenon follows a logistic (sigmoid) curve. We then searched for a curve that best fit the initial growing part of the logistic, and we found that the best fit is a power law curve in the form of  $y = m \cdot x^b$ . To compute the coefficients  $m$  and  $b$  of the power curve, we started our elaborations with two other assumptions in mind:

1. We based our initial estimation on the number of swab tests analyzed in the initial days of the pandemic period, where an average of 8000 swab tests were performed daily (in May, the number of swab tests was increased significantly to an average of 50,000 tests/day).
2. We assumed that the Italian Government would act promptly with restrictions and lockdowns on the Italian population and that the Italian citizens would follow these restrictions with a sense of responsibility.

Moreover, we used the stabilized data set for Wuhan City, and we adopted additional official statistics (published by the WHO

[11]) about the COVID-19 spread in China (eg, percentage of severe disease cases, percentage of critical disease cases, crude fatality ratio, the number of days passed in each phase of the China pandemic) to adjust the multiplier coefficient of our predictive model. In this way, we were able to estimate the position of the first inflections of the curve (to estimate the date for the peak of new daily positive cases), the second curve inflection (to estimate the date of the curve plateau), and then to determine the day-to-day number of positive cases during the second part of the pandemic (ie, during the descent.)

Figure 2 shows the number of new daily cases in Italy starting from the first identification of a patient in the town of Codogno

(Lodi, Lombardy) on February 24, 2020. The dotted orange line is the classical exponential curve typical of epidemics, while the green line is the best fit for the data set available for Italy until March 2, that is a power curve in the form of  $y = 3.00 * x^{2.77}$ .

The goodness of fit for the detected model is high, with a high coefficient of determination ( $R^2=0.9917$ ).

Figure 3 compares the actual behavior of cumulative COVID-19 positive cases with the predictions of our model over time until the end of March (where our model predicted the logistic plateau).

**Figure 2.** The predicted curve of total positive cases in Italy (as of March 2, 2020).

**Figure 3.** Graphical comparison between the real vs predicted number of Italian cumulative cases. Tot.: total.

Our model forecasted (18 days in advance) the peak in the number of daily new cases on March 21, 2020, with a total of 42,000 positive cases against the official datum of 53,500 total positive cases, with a confidence level of 95%. The model significantly outperformed other predictions based on exponential models that forecasted more than 180,000 positive cases.

As highlighted in Figure 3, the model underestimated some of the real official values for several reasons:

- March 21, 2020, is registered as the date with the absolute peak in the number of daily new cases, hence the error (that is a cumulative error) is increasing over time.
- The Lombardy Region has the same consideration (where the peak has been forecasted and actually observed on March 17). The Lombardy Region accounts for 50% of the overall national value.

- The predictive model is strongly related to the curve of Wuhan. Although the increase of daily cases is similar between the Italian curve and the Wuhan curve, the decrease is a bit different. The Italian one is less steep than the Wuhan decrease since the restrictions implemented by the Italian government are less stringent than the Wuhan restrictions, and the Italian population reacted to the restrictions with less determination.

Moreover, it is important to highlight that (as depicted in Figure 4) the plateau for the Lombardy Region was predicted and confirmed to start at the end of March, a few days in advance of the plateau for the Italian curve, hence the absolute contribution of the Lombardy Region on the total national value was decreasing over time. It is important to observe that the Lombardy Region anticipated all the national restrictions by 1 week with the Decree to Manage the COVID-19 Emergency: DPCM-9 March 4, 2020.

**Figure 4.** Graphical comparison between the Lombardy Region curve and the Wuhan curve (total cumulative positive cases).

The model elaborated from the beginning of March 2020 (Figures 1-3) predicted the plateau (as confirmed by Prof S Brusaferrò from Istituto Superiore Sanità during a national live TV broadcast [12]) for the logistic Italian curve at the end of March with an estimate on the total positive cases to be 68,000 (while the actual value was 100,000 total cases). It is important to highlight that the model focused on the prediction of the pandemic timeline and not on the exact number of people officially testing positive for COVID-19, a number that is well known to be dependent on the number of analyzed swab tests. We based our initial estimation on the number of swab tests analyzed in the initial days of the pandemic period. The increasing amount of swab tests moved our curves toward higher values but did not modify the prediction regarding the starting day of the logistic curve plateau and the prediction about the different phases of the COVID-19 pandemic. As previously stated, another factor that contributes to the larger number of affected people is the different enforcement and timeliness applied to the restrictions and lockdowns by the Italian government and the Italian population compared to China, which we adopted in our initial assumptions. In any case, in the forecast of the total positive cases in a pandemic phenomena, the magnitude of the values is the real discriminant on the quality of the prediction. Exponential curves (adopted by several scientists at the beginning of the COVID-19 pandemic in Italy) predicted 1 million cases for the end of March, with a ten-fold overestimation, while our model underestimated for a value less than 40%. Ricolfi [13] estimated for March 8, 2020, 60,000 total cases, while the official value was 7400, thus an overestimation of 800%. In Italy, we have 60 million inhabitants; a difference of 32,000 cases between the estimated value and the actual value on this population introduces an error that is

less than 0.08%, and this does not impact the governmental policies and actions to preserve the national health system.

It is important to observe that reaching the plateau does not indicate that the COVID-19 epidemic has been solved, but it means that the cumulative number of COVID-19 positive cases is slowing down in its ascent. The WHO guidelines suggest waiting for the contagion to be +0 (ie, the new daily cases are reduced to a few dozen positive cases per day) and then taking restrictions for two additional cycles of COVID-19 incubation (mean incubation period 5-6 days, range 1-14 days.) Hence, considering the national plateau on March 31, 2020, we estimated the actual containment of the COVID-19 epidemic at the beginning of June for the following reasons:

- One additional month, after the beginning of the plateau, to reach a small and contained number of new daily cases (end of April)
- One additional month in waiting for the two COVID-19 incubation cycles (end of May)
- Gradual return to normal life starting from the beginning of June

In Figure 4, the two curves for total cases in Wuhan (orange line) and the Lombardy Region (gray line) are depicted. It is interesting to observe that in this case the two behaviors are similar and comparable. Figure 4 also shows that we are approaching the plateau for the Lombardy Region.

In Figures 5 and 6, we show the new COVID-19 cases per day in the Lombardy Region and Wuhan, respectively. As previously mentioned, the peak in the Lombardy Region was registered on March 17, 2020, with 2200 new daily cases; then, the number of daily cases decreased over time (with some exception as you can see in Figure 5).

**Figure 5.** Graphical plot of daily new cases in the Lombardy Region.**Figure 6.** Graphical plot of daily new cases in Wuhan.

This is a good indicator (the peak matches the inflection point in the logistic curve) that we had started the descent toward the plateau in the Lombardy Region (the last inflection point in the logistic curve).

Additionally, in that case, it is important to observe that the curve of fatalities and recoveries (as depicted in Figure 7) were misaligned temporally with the curve of new cases, since

fatalities occur on average after 8 days, while recoveries are an additional 14 days, and new cases are observed after 8 days of COVID-19 incubation (on average). This explains why the peak in the number of new cases had been reached, while the peak on daily fatalities was approaching, and we expected it at the end of March. The same is true for the peak of recoveries that we expected to appear in 2 more weeks (middle or end of April).

**Figure 7.** Graphical plot of COVID-19 fatalities and recovered in Italy.

## Discussion

This study was conducted in the early days of the pandemic in Italy to promptly define a model able to predict the curve of total positive cases in Italy and the Lombardy Region.

The model predicted the real data published daily by the Department of the Italian Civil Protection, estimating in a precise manner and several months in advance the plateau for both the logistic curves for the Lombardy Region and Italy, and the end of this first COVID-19 pandemic wave. This suggests

the possibility to generalize the model for other countries, which will follow the restrictions imposed by the Italian government, to have a clear picture on the evolution of the number of new cases and to act promptly with policies and restrictions that can maximize care and treatments offered to patients with COVID-19. Moreover, this paper shows that big data and data analytics can help medical experts and epidemiologists in promptly designing accurate models to predict the different COVID-19 evolutionary phases in other countries and regions, and for second and third possible epidemic waves.

## Abstract

**Background:** First detected in Wuhan, China in December 2019, the COVID-19 pandemic stretched the medical system in Wuhan and posed a challenge to the state's risk communication efforts. Timely access to quality health care information during outbreaks of infectious diseases can be effective to curtail the spread of disease and feelings of anxiety. Although existing studies have extended our knowledge about online health information-seeking behavior, processes, and motivations, rarely have the findings been applied to an outbreak. Moreover, there is relatively little recent research on how people in China are using the internet for seeking health information during a pandemic.

**Objective:** The aim of this study is to explore how people in China are using the internet for seeking health information during a pandemic. Drawing on previous research of online health information seeking, this study asks the following research questions: how was the “#COVID-19 Patient Seeking Help” hashtag being used by patients in Wuhan seeking health information on Weibo at the peak of the outbreak? and what kinds of health information were patients in Wuhan seeking on Weibo at the peak of the outbreak?

**Methods:** Using entity identification and textual analysis on 10,908 posts on Weibo, we identified 1496 patients with COVID-19 using “#COVID-19 Patient Seeking Help” and explored their online health information-seeking behavior.

**Results:** The curve of the hashtag posting provided a dynamic picture of public attention to the COVID-19 pandemic. Many patients faced difficulties accessing offline health care services. In general, our findings confirmed that the internet is used by the Chinese public as an important source of health information. The lockdown policy was found to cut off the patients' social support network, preventing them from seeking help from family members. The ability to seek information and help online, especially for those with young children or older adult members during the pandemic. A high proportion of female users were seeking health information and help for their parents or for older adults at home. The most searched information included accessing medical treatment, managing self-quarantine, and offline to online support.

**Conclusions:** Overall, the findings contribute to our understanding of health information-seeking behaviors during an outbreak and highlight the importance of paying attention to the information needs of vulnerable groups and the role social media may play.

## Introduction

### Background

On March 11, 2020, the World Health Organization (WHO) declared the COVID-19 outbreak a pandemic [1]. First detected in Wuhan, China in December 2019, the disease rapidly spread into more than 100 locations internationally, including Japan, Korea, and the United States [1]. In the Report of the WHO-China Joint Mission on COVID-19, the Joint Mission reminded the public that the virus is unique in its ability to cause societal and economic disruption [2]. In China, the disease has caused 3176 deaths out of the 80,813 total confirmed cases by March 12, 2020 [3]. The rapid increase in coronavirus patients stretched the medical system in Wuhan, which accounts for 60% of mainland China's total confirmed cases and about 77% of the deaths [4]. In an attempt to limit the spread of the virus, Chinese government has enforced an unprecedented lockdown on Wuhan by suspending transport both within the city and leaving the city [5]. During the quarantine, each household was allowed to have only one person go out for necessities every 2 days [6]. The traffic ban within the city has made it hard for patients to seek health care [7]. It was also difficult to organize medical care, frequently monitor disease progression, and refer hospital care for patients in home isolation in a timely manner [8]. The lockdowns caused public panic and resulted in many cross-infections at the crowded, overwhelmed hospitals [9], posing a challenge to the state's risk communication efforts. The dramatic increase in the number of infected individuals was causing a burden on the medical system [10].

Timely access to quality health care information during outbreaks of infectious diseases can be effective to curtail the spread of disease and feelings of anxiety [11,12]. Up-to-date information about specific threats and necessary precautionary measures was found to mitigate public anxiety, reduce morbidity and mortality, and contribute to minimizing negative mental impacts [13,14]. Furthermore, previous studies relate health anxiety, internet literacy, and chronic conditions to the willingness of individuals to engage in health information-seeking behaviors [15-17]. Health information-seeking behavior is purposeful activities such as searching for condition-specific information as well as disease prevention and treatment information to fulfill specific health information need [18,19]. An information need can arise when a patient experiences health-related uncertainty originating from an inaccurate, inconsistent, ambiguous, or excessive provision of information about the diagnosis, treatment, or aspects of medical decision making [16,20,21]. However, relatively little is known about what happens to the information-seeking behavior of patients during an outbreak, especially in the context of China. Therefore, this study explores the information-seeking behaviors during the coronavirus outbreak in China.

The internet, especially social media, has also been identified as a significant source for information searching and decision making [22]. Scholars suggest potential in the internet to supplement traditional sources of health information and to support patients' decision making [22,23]. In fact, health information seeking has been found to be a popular online

activity [24]. Thus, researchers have suggested that an analysis of web behaviors can provide insights into individuals' information seeking during an outbreak, as public reactions are visible more quickly online [12,25]. For instance, by monitoring web activities, previous studies identified large increases in activities on social networking websites, including posting and searching, that are closely associated with the outbreaks of pandemic diseases [26,27]. Text analysis programs that are developed for measuring emotional expression in natural language are also found to produce reliable results that are congruent with human ratings [28,29]. Using web-based text analysis to monitor public emotions is also suggested by researchers to avoid self-report biases from social desirability effects or memory distortions [12]. Therefore, using entity identification and text analysis on a total of 10,908 posts on Weibo, the largest social networking platform in China, we identified 1496 patients with COVID-19 living in or with family in Wuhan, China and explored their online health information-seeking behavior during a pandemic.

### Online Health Information Seeking

Health information seeking has been found to be a popular online activity. Studies in the United States and Europe have reported more than 70% of internet users have looked online for health information of one kind or another [24], or having used the internet for health purposes [30]. The motivations for seeking online health information are diverse, including self-diagnosing, coping with uncertainty, staying informed on preventing diseases, and looking for others with a similar health concern [24,31]. Through query construction and information source selection, information seekers can enjoy greater control over information acquisition processes and achieve desired levels of uncertainty [32]. In view of the features such as convenience, cost effectiveness, and private sharing, scholars suggest potential in the internet to supplement traditional sources of health information and support patients' decision making [22,23].

Previous studies have identified multiple factors that may influence patients' motivation to seek health information online, including biological sex, income, age, chronic illness, and travel time to offline sources of health care [16,17,33,34]. For instance, biological sex was found to significantly predict online health information seeking, with females more likely to seek out online health information than males—perhaps because females often take on primary caregiving roles in families and are more cautious in risk contexts [16,35]. Increased age is frequently associated with decreased levels of motivation for health-related information seeking online, as older adults are always found to have lower levels of internet literacy and experience more difficulties navigating websites [36,37]. Further, the digital divide, a gap between individuals from different socioeconomic backgrounds with regard to their access to and use of digital equipment and services, can increase challenges associated with online health information seeking, such as inequality of accessibility and difficulties to differentiate between high and low quality resources [17,21].

Additional factors, such as efficacious feelings about using the internet and health anxiety, may also influence one's motivation

of seeking out health information online [16,34,38]. User experience online was also found to influence one's feelings of efficacy and, thus, be linked to their likelihood to use online search strategies for health-related information [34]. Adding on to self-efficacy and health anxiety is chronic illness, as individuals with a chronic illness were more likely to use the internet to search for health information compared to those without a chronic illness [39]. A long travel time to offline sources of health care was also associated with a stronger likelihood of using the internet to find health information [17].

Although these existing studies have extended our knowledge about online health information-seeking behavior, processes, and motivations, rarely have the findings been applied to an outbreak. Therefore, in this study, we examine the ways in which patients with COVID-19 and families living in Wuhan, China used the internet to seek health information on the social media platform Weibo. The findings can help build an understanding of how the internet can be used to better serve the needs of the public, especially the patients at the peak of the outbreak, given the high level of uncertainty and risks.

### Online Health Information Seeking in China

In China, people are found to face challenges in accessing health care resources, among which are the difficulty in making medical appointments, short consultation times, and a significant socioeconomic disparity in health literacy [40,41]. Despite the governmental attempt to reform its health care system, patients still expressed unsatisfied needs for various kinds of health-related information, including the treatment of diseases and the effect, etiology, and risk factors, as well as use, of drugs and medication [42]. The barriers to accessing accurate information and subsequent health care also lead to people's lack of trust in doctors and their unwillingness to visit them [42]. In this context, the internet has been increasingly used to access health information, supplementing the traditional sources of health information [43,44].

According to statistics from the government-run China Internet Network Information Centre, the number of internet users in the country had skyrocketed to 854 million at the end of June 2019, with the internet penetration rate reaching 61.2% [45]. Although 18.2% of the total Chinese population are 60 years or older [46], users older than 60 years accounted for only 6.9% of all users on the internet [45]. A survey study found that 36.7% of the Chinese participants had sought online health information at least one or two times, citing saving money and easing the privacy concern as the two major reasons for seeking out health information online [43]. Despite the increase in health-related internet use in China, there is relatively little recent research on how people in China are using the internet for seeking health information. Almost all the studies were limited to individuals that were young and educated with certain levels of online health information-seeking experience, mostly in Hong Kong [42-44,47]. According to these studies, the overall health literacy level in China is lower than that in Western countries [48].

The majority of online health information was found to be of poor quality, and the functions of health websites were ineffective and hard to navigate [43]. However, information seekers in China have still been found to consider the internet

a highly reliable source of information [49]. Although some studies reported no correlations between education or gender on Chinese patients' online health information-seeking behaviors [42,50], some other studies have identified digital inequalities associated with education level, household income, and socioeconomic status, further leading to variations in personal health condition and family well-being [44,51]. These disagreements in the findings point to the need to conduct further research on how people in China, especially the general population in mainland China, are using the internet for health information, particularly during a pandemic. Therefore, drawing on previous research of online health information seeking, this study asks the following research questions: How was the "#COVID-19 Patient Seeking Help" hashtag being used by patients in Wuhan seeking health information on Weibo at the peak of the outbreak? What kinds of health information were patients in Wuhan seeking on Weibo at the peak of the outbreak?

## Methods

### Data Collection

During the COVID-19 outbreak, Weibo, the largest social networking platform in China, created a hashtag named #COVID-19 Patient Seeking Help ("Feiyan Huanzhe Qiuizhu Chaohua") for the patients and their families to leave their name, age, city, neighborhood, address, time of sickness, health condition, additional description, and contact information, making the posts structured. For the purpose of identity verification, patients were also asked to upload pictures of a medical examination, if any, which further improved the credibility of the data. We crawled and analyzed Weibo posts with this hashtag published from January 29, 2020, when the hashtag was first created, to February 17, 2020, to examine the online health information-seeking behaviors of patients with COVID-19. This period of 20 days was chosen because, by the end of this period, the number of patients posting with this hashtag fell to zero. In total, 10,908 Weibo post entries with the #COVID-19 Patient Seeking Help hashtag were collected.

For each post, in addition to the structured patient information previously noted, we further extracted the following items: *the date and time of posting, user ID, user gender, and URL of the thread* (for further referring back to the entry online). We excluded retweets and general comments about the outbreak. After this step, we obtained 4983 entries of patients with COVID-19 in Wuhan using the hashtag #COVID-19 Patient Seeking Help. Data consolidation was further carried out by patient name and detailed address, which resulted in 1496 unique patient cases.

We further standardized the patients' information that was crawled, as the language used on the social media platform was flexible. In particular, to standardize the patients' detailed address, we crawled a full list of housing estates in Wuhan, from the largest housing estates website in China, Lianjia [52], and mapped the original Weibo texts with patient's address to the housing estate names. We further obtained the longitudes and latitudes of the patients' locations through the Baidu map application programming interface (API) [53].

## Data Analysis

Previous studies identified multiple factors that may influence patients' motivation to seek out health information online, including biological sex, age, chronic illness, and travel time to offline sources of health care [16,17,33,34]. To answer the first research question, we examined the age of the patients. The original posts did not include patient gender, but we examined the gender of the posting users, as previous studies have found that about half of individuals' health information searches are on behalf of someone else's health situation [24,54]. We also examined the patients' underlying condition by extracting the health condition description in each entry. Specifically, we conducted word segmentation using the Chinese word segmentation module, Jieba [55]; computed document frequency for every single term that appeared in the content; and identified the terms indicating their underlying diseases.

We also examined the patients' shortest walking distance to offline sources of health care. Specifically, we extracted the list of 42 fever clinics and the 28 designated hospitals that was first published by the Health Commission of Hubei Province [56] and further updated by the Hubei Provincial People's Government [57]. Through Baidu map API, we further obtained the longitudes and latitudes of these clinics and hospitals, and calculated the shortest walking distance of each patient's location to the nearest fever clinic or designated hospital, as public transportation and private car driving in the city were prohibited during the period of our study, and patients may have faced difficulties seeking medical care due to the traffic ban [7].

To answer our second research question, we examined their information-seeking behavior, as indicated by the number of entries posted by each patient or user. We also examined the specific information they were seeking out by analyzing the content of health condition and additional description in each entry, where the patients had given more details about their needs. We carried out textual analysis on every post to identify the information needs of the patients. Specifically, thematic analysis was carried out. Open coding, the first step of the coding process entailed reading each entry and its messages, highlighting salient phrases and words [58,59]. At this stage, one of the authors conducted the open coding, reading the entries

in Chinese. More than 200 open codes were generated in this process. Some examples of open codes that emerged were queuing for test, called every hospital for bed, no foreseeable treatment, staying overnight for injection, the hospital is full of patients, waiting for confirmatory testing result, rushing between different hospitals, hundreds of people in the waiting list, reported to the neighborhood committee with no response, and have to find solutions by ourselves. Next, the open codes and phrases were conceptually clustered into more than 30 different axial code groupings through discussion among the authors [59]. Keeping the research question in mind, through additional discussion and data refinement, the authors agreed that the following themes best answered the research question: accessing medical treatment, managing self-quarantine, and accessing tangible support.

## Results

Figure 1 presents the numbers of Weibo posts with the #COVID-19 Patient Seeking Help hashtag and the daily number of confirmed cases in Wuhan reported by the Health Commission of Hubei Province. Figure 1 illustrates that the number of entries rapidly grew from February 3, 2020, and maintained a high level until February 12. On February 12, the daily confirmed cases peaked at 13,436, at which time the central government promised to admit all the patients with COVID-19 [60]. The number of the hashtag entries have steadily declined since then.

Table 1 is an age comparison between our sample and that of the WHO-China Joint Mission [2]. The WHO-China Joint Mission identified the median age of patients as 51 years based on a total of 55,924 confirmed cases. However, for our sample, the median age was 61 (IQR 50-70) years, with an average age of 59 years. According to the report published by the WHO-China Joint Mission, individuals 60 years or older are at highest risk for severe disease and death. Previous studies have also shown an age-related digital divide in China. Although 18.2% of the total Chinese population were 60 years or older by the end of 2019 [46], users older than 60 years accounted for only 6.9% of all users of the internet [45]. The age-related digital divide might prevent the patients from seeking information and help online.

**Figure 1.** Daily numbers of #COVID-19 Patient Seeking Help hashtag entries (the orange bar plot) and daily confirmed cases in Wuhan (the blue line plot).

**Table 1.** Age comparison between our sample and that of the WHO-China Joint Mission.<sup>a</sup>

Sample	Participants, n	Age range	Age IQR (years)	Age median (years)
WHO <sup>b</sup> -China Joint Mission	55,924	2 days-100 years	39-63	51
Our sample	1454	2-99 years	50-70	61

<sup>a</sup>Age was missing in 42 Weibo entries.

<sup>b</sup>WHO: World Health Organization.

Table 2 shows the document frequency of family members' names that appeared in the posts. Out of 883 entries, words such as "mum (mother)," "dad (father)," and "elder at home" appeared in 35% (n=308), 29% (n=255), and 24% (n=209) of the entries, respectively. Further examination of these entries showed that most of the entries were posted by the younger generation for their parents or an older adult at home. We examined the gender of the users seeking out health information.

Among the 2405 unique users, 69% (n=1660) were female and only 31% (n=745) were male. The median number of posting times by female users was 2 (IQR 1-2) times, which was higher than that of male users, 1 (IQR 1-2) time. It shows that there were more female users than male users trying to seek out health information online, and their internet use frequency might be higher than their male counterpart.

**Table 2.** Document frequency of names of family members.

Word	Frequency (n=883), n (%)	Quote
Mother (mum)	308 (35)	"My <i>mother</i> is highly suspected with COVID-19. She could not even get up right now...She has been running a fever for more than ten days..."
Father (dad)	255 (29)	"I am the son of the patient. My <i>father</i> has been infected with pneumonia. And the lung lesions are quite serious. I have reported to the neighborhood committee for many days, but they have not arranged hospital bed for us..."
Elder at home	209 (24)	"The <i>elder at home</i> have been diagnosed with the pneumonia...Please contact his daughter as the <i>elder at home</i> do not use the Internet."
Grandma	88 (10)	"Now my <i>grandma</i> is already in incontinence, but the neighborhood committee still asks us to wait."
Parents	80 (9)	"My <i>parents</i> are both confirmed and in dangerous condition. But we haven't received hospitalization notification. Please save my <i>parents</i> ."
Grandpa	62 (7)	"The patient is my <i>grandpa</i> , who is in dangerous condition. He has emphysema and threatening myocardial infarction."
Aunt	57 (6)	"The <i>aunt</i> is currently in recurring fever. We are all in desperation."
Uncle	52 (6)	"My <i>uncle</i> 's condition is worsening in self-quarantine, with eating and breath difficulties."

We further examined the patients' distance from their residential locations to offline health care. We first extracted the district of each patient's residential location to see the distribution of these patients across different districts of Wuhan. [Figure 2](#) shows

the number of patients in our sample by district. Districts of Hongshan, Jiangnan, and Qiaokou were found to have the most patients seeking information online.

**Figure 2.** Number of patients seeking health information and number of fever clinic and designated hospital by district (yellow point).

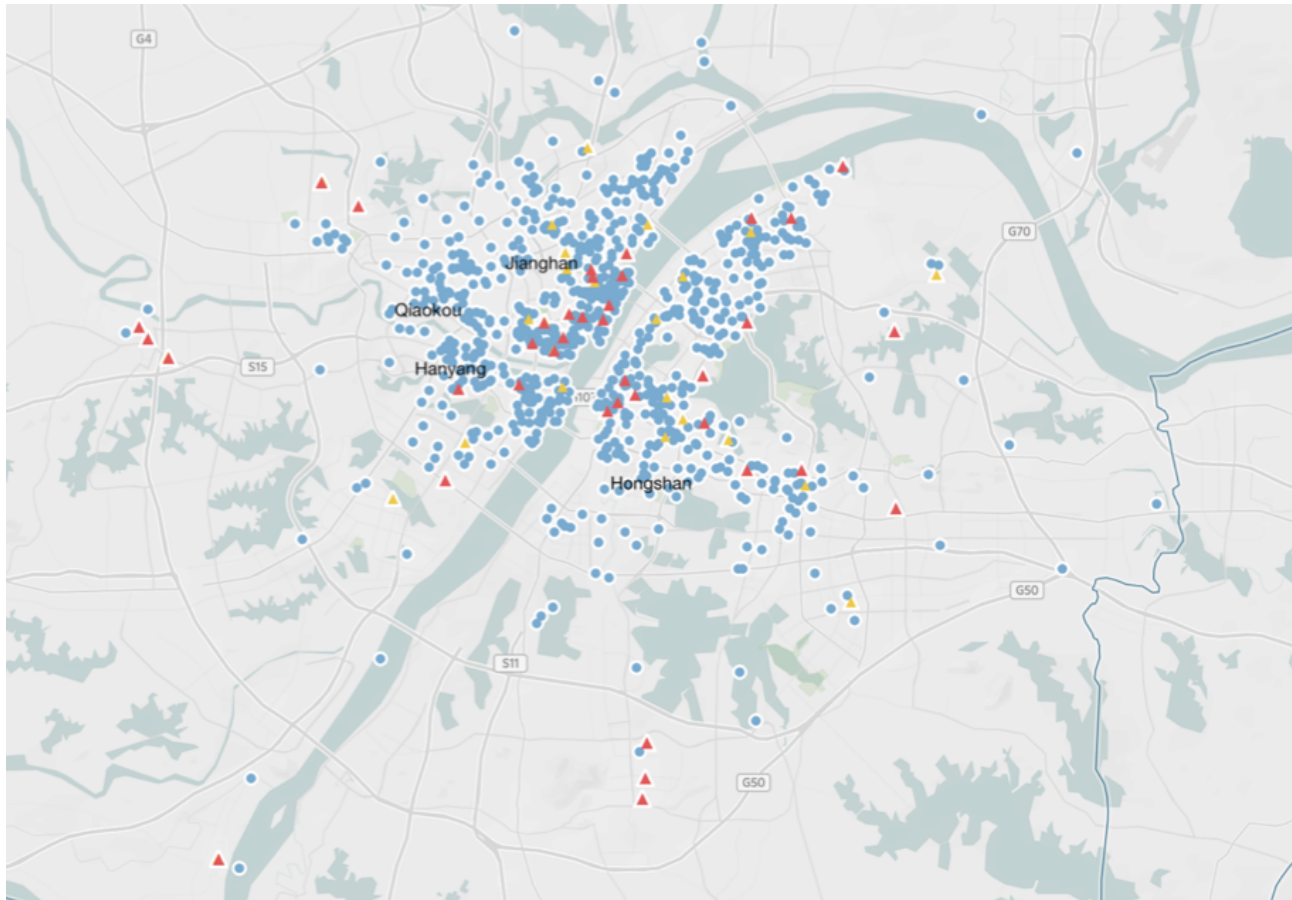

We also examined the geographic distribution of the fever clinics and designated hospitals in relation with the patients' residential locations. [Figure 3](#) is an overview of all the patients' locations, the fever clinics, and the designated hospitals on a map of Wuhan City. Seen from the map, in the districts of Hongshan, Jiangnan, and Qiaokou, some patients were far from the fever clinics and designated hospitals.

To further examine the exact distance of the patients to offline health care resources, we computed the distance between every residential location to its nearest fever clinic or designated hospital. [Table 3](#) maps the patients' distance by district to the

nearest fever clinic or designated hospital, and the average distance was 2.67 (SD 2.88) km. According to estimation by the Baidu map API, it takes 50 minutes to walk 3 km by an adult. Considering the average age of our sample was older, their actual walking time could be even longer. This means that 27.6% (n=413) of the sample had to walk for around 1 hour to access offline health care. In the context of our study, distance to offline health care is especially important. Due to the transport prohibition and quarantine enforced, patients could only walk to access health care offline. The difficulties to travel were also

cited by many users as a major reason for going online to seek health information as identified in textual analysis.

**Figure 3.** Overview of the locations of patient residential addresses (blue points), fever clinics (red triangle), and designated hospitals (yellow triangle).

**Table 3.** Patients' distance to the nearest fever clinic or designated hospital.

District	<1 km distance, n	1-2 km distance, n	2-3 km distance, n	>3 km distance, n
Qiaokou	68	17	4	124
Hongshan	28	66	67	116
Jiangnan	68	58	35	68
Hanyang	28	77	52	38
Dongxihu	3	0	7	27
Jiangnan	36	22	11	15
Wuchang	64	91	38	6
Huangpi	5	3	0	5
Zhuankou	0	6	1	4
Jiangxia	0	0	2	4
Caidian	0	2	0	3
Xinzhou	0	0	0	1
Qingshan	39	39	15	1
Hannan	0	0	0	1
All districts	339	381	232	413

Table 4 shows the patients' underlying conditions, which were extracted from the health condition description in each entry. Document frequency analysis shows that "hypertension,"

"diabetes," "heart disease," and "underlying disease" were mentioned in 12% (n=110), 9% (n=82), 9% (n=79), and 3% (n=30) of the 883 posts, respectively. According to the report

published by the WHO-China Joint Mission, individuals with highest risk for severe disease and death [2]. underlying conditions such as hypertension and diabetes are at

**Table 4.** Document frequency of terms indicating patients' underlying condition.<sup>a</sup>

Word	Frequency (n=883), n (%)	Quote
Hypertension	110 (12)	"The patient has <i>hypertension</i> , diabetes and other underlying conditions. He has had diarrhea for five days with continuous wheezing and breathing difficulties..."
Diabetes	82 (9)	"My father has multiple underlying diseases, including <i>diabetes</i> and hypertension. The CT <sup>b</sup> scan shows ground glass opacity. We have reported to the community hospital and they said that they could do nothing..."
Heart disease	79 (9)	"My grandpa has a history of <i>heart disease</i> for years and received emergency treatment for several times before."
Underlying disease	30 (3)	"The CT scan shows ground glass opacity in both lungs. My father has serious <i>underlying disease</i> of cardiomegaly. He needs to be hospitalized immediately..."

<sup>a</sup>Health condition was missing in 613 Weibo entries.

<sup>b</sup>CT: computed tomography.

Our second research question asks what kinds of health information patients in Wuhan were seeking on Weibo at the peak of the outbreak. We first examined the frequency of posting per patient. Seen from Figure 4, most of the patients have posted

at least 3 times, which accounted for 80.9% (n=1211) of the sample. Still, another 14.2% (n=213) of the sample posted 4-7 times. Although some patients did post more than 7 times, it was rare, which accounted for only 4.8% (n=72) of the sample.

**Figure 4.** Posting times per patient.

We also examined the specific information that these patients or their families were seeking. Textual analysis showed that information about accessing medical treatment, especially hospital beds and confirmatory testing, was most sought out by the patients. In those posts, the users shared their experience of "running around for medical treatment," "being denied service and/or a bed," and for "not knowing how to proceed." Turning to the hashtag, posters were desperately seeking information

on health care. Feelings of desperation and loss of desire for survival were prevalent, such as "my mother is very desperate, telling me no need for treatment any more. She has lost confidence to survive" and "my mom's desire for survival is waning."

The posters also sought information about managing self-quarantine. Due to the shortage of offline health care, the neighborhood committees and hospitals usually suggested the

patients to stay at home to conduct self-quarantine but did not help patients make strategic decisions about self-treatment. The posting highlighted that the patient's "illness deteriorated" due to "a lack of proper treatment and nutritious food." Many users recounted experience of "infection among family members" living under the same roof.

In addition to information and advice, the patients were also requesting for possible ways to provide tangible resources such as "childcare" and "transportation to seek offline health care." Particularly, many requested for social support to "check in on elderly parents" living in Wuhan, to "take them to the hospital," or to "help them with their medication," as they were isolated in a different province, different city, or different district. Although the lockdown policy cut off their offline social support network, the online platform provided a possibility to seek help.

Overall, the social media platform played a vital role connecting health information seekers with a reliable and timely source of information, tangible support, as well as a more empathetic crowd. This source provided not only informal advices but also important, timely discussion and caring interactions. Posts such as "I could do nothing other than following the updates on Weibo everyday," "thank all the kind-hearted people sending me clues and suggestions. Thank you for your empathy," and "my grandpa has been hospitalized. Hope every patient seeking help could be as lucky as me. Thank you all for your kind help" highlight the intangible benefits of using the online platform during the pandemic to seek health information.

## Discussion

### Principal Findings

In this study, we examined how patients with COVID-19 living in Wuhan, China used the "#COVID-19 Patient Seeking Help" hashtag to seek health information. Our findings provide important insights into health information-seeking behaviors during pandemic outbreaks. The curve of the hashtag posting provided a dynamic picture of public attention to the COVID-19 pandemic. Previous studies suggest that an analysis of web behaviors can provide insights into individuals' information seeking during an outbreak, as public reactions are visible more quickly online [12,25]. In our study, we identified a rapid increase in posting under the #COVID-19 Patient Seeking Help hashtag at the onset of the pandemic outbreak and a decrease following the government's effort to admit every patient. The steep curve of the hashtag indicates that online information-seeking behaviors such as posting, commenting, and reposting are useful markers of public reaction and draws attention to the need for public health practitioners to pay attention to online space in their responses. This finding is consistent with research identifying an increase in activities on social networking websites following the outbreaks of pandemic diseases [26,27].

In general, our findings confirmed that the internet is used by the Chinese public as an important source of health information. Previous studies have associated increased age with decreased levels of motivation for health-related information seeking online [36,37]. Similarly, our findings highlighted that younger

family members primarily sought information online for parents or for older adult patients at home [61]. Furthermore, our findings highlight the ability to seek information and help online, especially for those with young children or older adult members during the pandemic. This finding deserves consideration in the context of China, considering the age-related digital divide and the decline in health information-searching behaviors among older adults [50]. Although timely access to quality health care information during outbreaks is vital for reducing morbidity and mortality [13,14], it is equally important to pay attention to group-specific health information needs and their ability to act upon the information.

In our sample, we also identified a high proportion of female information seekers, which was consistent with previous studies that found females more likely to seek online health information [16,35]. However, posting frequency was comparable between female and male seekers in our sample. Another factor that may have contributed to the patients' use of the internet for health information is the long travel time to access offline health care resources. Previous studies indicated that the cost associated with time to visit health care providers in traditional settings has influence on patients' motivation for seeking out health information on the internet [17]. In our sample, around 30% of the patients with COVID-19 lived in a distance more than 3 km from their nearest clinic or designated hospital. The suspension of transportation in Wuhan meant that patients had to walk for at least an hour one way to access an offline health care source. The difficulties in travelling to clinics or hospitals were also cited by many as a major reason to seek health information and help from online platforms. The lockdown policy was also found to cut off the patients' social support network, preventing them from seeking help from family members. Social support was sought on social media to check in on older adults, to take them to the hospital, or to help them with medication, which highlights the vulnerability of this population despite the effectiveness of the policy in containing the disease.

Our findings give insight into the issues that patients and their families were most concerned about during the peak of the outbreak, including where and how to seek medical treatment and confirmatory testing, decision making on self-quarantine, and experience of infection among family members. Previous work indicated that an information need can arise when a patient experiences health-related uncertainty and, in turn, engages in health information-seeking behavior to get reassurance, to manage uncertainty, and to reconcile oneself with a new health situation [16,21]. Our findings highlight a need for information originating from the stretched condition in the health care system and the anxiety over the lack of access to proper treatment. To the patients and their families, the act of searching for information online is a help-seeking step so that they can manage their own health with the affordance of the internet. Scholars suggest this kind of behavior should be encouraged as an integral and positive part of the patients' journey because online health information seeking enables patients to accumulate more social support, which is associated with better health outcomes and health decision making [17,48].

Methodologically, our study also indicates the usefulness of using a computational method to explore individuals' responses

to public health crises in real time. For example, the increase and then decrease in public anxiety eased by the communication effort in response to the H1N1 epidemic was hard to capture by traditional survey methods [12]. Consistent with previous studies, our study shows that the number of entries with the #COVID-19 Patient Seeking Help hashtag rapidly grew and was kept at a high level within a period of more than 1 week and then steadily declined following the government's effort to admit every patient [60]. By monitoring and analyzing the patients' online data, our method enables a possible advantage over traditional approaches to offer a dynamic picture of changes in public response to the pandemic in real time.

Our study also helps build an understanding of how the internet can be used to better serve the needs of the public, especially the patients in the time of an outbreak. In general, our findings confirmed that the internet is used by the Chinese public as an important source of information and help. Although previous studies mainly focused on the online health information-seeking experience of the young and educated [43,44,47,51], our findings highlight the needs of older adults, who may have equal motivations but lack the ability for searching and comprehending online health-related information. Therefore, in addition to making relevant and high-quality information available online, it is vital to motivate social support to facilitate their information needs.

## Limitations and Conclusion

Using a nonprobability and convenience sample, this study focused on basic descriptive analyses of how people in China are using the internet for seeking health information during a pandemic. Nonprobability sampling means there lacks a sound theoretical basis for statistical inference [62]. Future studies using random sampling are needed to allow valid statistical analysis so that informed judgments can be made. Another limitation of our study is the lack of our ability to establish direct links with the patients' health outcomes. More in-depth discussion is needed to explore whether and how the information-seeking behaviors on social media aids in better health outcomes. Future studies should explore the link between information need and patients' health outcomes.

The COVID-19 pandemic has been found to stretch the local medical system and poses a challenge to the state's risk communication efforts. Social media is used by the patients to seek health information relevant to the outbreak. Some factors may contribute to their online information-seeking motivation including age, gender, underlying conditions, and travel time to offline health care service providers. Overall, the findings contribute to our understanding of health information-seeking behaviors during an outbreak and highlight the importance of paying attention to the information need of vulnerable groups and the role social media may play.

## Abstract

**Background:** The COVID-19 pandemic has threatened the health systems of many countries worldwide. Several studies have suggested that the pandemic affects not only physical health but also all aspects of society. A lot of information has been reported about the disease since the beginning of the outbreak. For that reason, it is essential to investigate the attitudes and level of knowledge and awareness that different populations had regarding COVID-19 during the critical period of the outbreak.

**Objective:** This study aimed to assess the knowledge and awareness of and attitudes toward the COVID-19 pandemic among different populations in Central China during the critical period of the outbreak.

**Methods:** A cross-sectional web-based survey was conducted in Central China from February to March 2020. The study participants included three different populations: medical workers, students, and those with other occupations. In this study, a questionnaire was designed to collect information on the following four aspects: sociodemographic information, knowledge related to COVID-19, awareness of COVID-19, and attitude toward COVID-19. The chi-square test and Fisher test were used for comparison among groups. The level of significance was set at  $P<.05$ .

**Results:** This study enrolled a total of 508 participants. Among them, there were 380 students (74.8%), 39 medical workers (7.7%), and 89 people with other occupations (17.5%). Most of the participants were female ( $n=272$ , 53.5%), lived in rural areas ( $n=258$ , 50.8%), and were single ( $n=423$ , 86.9%). The majority of the respondents had attended college ( $n=454$ , 89.4%). Most of the participants said they had heard about COVID-19 by January, and most of them looked for information on social media (Sina Weibo, 84.7%), and WeChat and QQ groups (74.2%). The participants showed an adequate level of knowledge about COVID-19 with no significant differences among the groups. However, medical workers demonstrated a slightly advanced knowledge in their responses to professional questions such as the potential susceptible population, possible host, treatment of COVID-19, and disease category. A higher proportion of medical workers (71.8%) and those in the other occupations group (52.8%) were highly concerned about the COVID-19 pandemic. More than 43% of the participants stated that the lockdown of their village/city had a significant impact on their lives. Nevertheless, the majority of respondents had an overall optimistic attitude toward the control of the disease (92.1% of students [ $n=350$ ], 94.9% of medical workers [ $n=37$ ], and 92.3% of those in other occupations [ $n=83$ ]).

**Conclusions:** All three groups reported an adequate background knowledge about COVID-19 but medical workers showed a slightly advanced knowledge in their responses to professional questions. Most of the participants were highly concerned about COVID-19 during the critical period of the outbreak. The majority of respondents declared that the village/city lockdown policy had a significant impact on their daily life but most of them held an optimistic attitude toward the control of COVID-19.

## KEYWORDS

COVID-19; knowledge; awareness; attitude

## Introduction

Coronavirus disease (COVID-19) rapidly spread around the globe and it has led to an economic crisis alongside a health care crisis in many countries and regions across the world [1]. It was declared a pandemic by the World Health Organization (WHO) on March 11, 2020, affecting 114 countries by that time [2]. Even today, COVID-19 is still a threat to the health systems of nearly 150 countries and regions, especially those dealing with an international health emergency for the first time. In China, authorities and citizens acted quickly and effectively to contain the spread of COVID-19. The measures taken included several lockdown policies and strict preventive measures across the country [3], offering a model of COVID-19 pandemic control to other countries and regions.

The increasing use of computers, tablets, and smartphones enables the rapid dissemination of information through the internet and social media, but such information lacks an effective guarantee of quality. As with previous epidemics such as Ebola or Zika virus disease, the internet has been used to spread misinformation regarding the COVID-19 pandemic [4]. It has been reported that social distancing promotes the spread of misinformation and has a profound impact on psychological well-being in vulnerable populations. Misinformation may lead to uncertainty, which is increased due to the novelty of the disease [5]. Therefore, it is essential to raise awareness and distribute accurate information about COVID-19 to avoid misinformation and decrease unnecessary stress in the population. Studies have described the effects that the pandemic can have on specific groups, such as medical workers [6], children and teenagers [7], older adults [8], and students [9]. In China, a study conducted by Yulan Lin and colleagues [10] determined the knowledge, attitudes, and anxiety levels of the general population in relation to the COVID-19 outbreak, as well as its impact on them. However, the knowledge- and attitude-related items in their study were limited to the symptoms and modes of transmission of COVID-19 and did not explore the differences between different population groups. To avoid the above limitations, this study was designed and conducted to evaluate the knowledge and awareness of as well as attitude toward COVID-19 of different populations groups in Central China during the critical period of the outbreak. This information might be necessary for policy makers to promote health education campaigns to better control the disease before the availability of a preventive vaccine. As there is no available vaccine or effective antiviral treatment against COVID-19, the active engagement of the population in preventive behaviors is necessary. For that reason, an adequate knowledge and high

level of awareness of COVID-19, as well as an optimistic attitude, are crucial for controlling the disease.

## Methods

### Study Design and Participants

This study presents data from the Central China part of a population-based multicenter cross-sectional online survey, conducted in seven geographical regions across China (Northeast China, East China, South China, North China, Northwest China, Southwest China, and Central China) in February and March 2020. The anonymous survey was conducted via Wenjuanxing, an online crowdsourcing platform in mainland China that provides professional online surveys, voting, testing, and comments. The survey was developed to investigate the knowledge and awareness of and attitude toward the COVID-19 pandemic in different populations (medical workers, students, and those in other occupations). The survey contained items related to participants' demographic background, knowledge, awareness, and attitudes.

The inclusion criterion was that the respondents were at least 18 years old when they filled out the survey. Thus, anyone that had the ability to complete this survey and met the age requirement was qualified to take part in the study. Respondents in this study were divided into three different population groups: students, medical workers, and those in other occupations.

Before starting the online questionnaire, a brief introduction was displayed to each participant, and electronic informed consent was obtained if they agreed to complete the questionnaire.

To confirm the quality of the online survey, two control items were included in the questionnaire. The first one was gender; although gender information was recorded initially, it appeared one more time in the questionnaire with confusing options. Another control item was a question about whether the influenza vaccine can prevent COVID-19. Two different descriptions were displayed, and the answers for the control items were supposed to match. Moreover, the members of the research team had been trained to ensure the quality of the questionnaire. Data cleaning and checking were done once the questionnaire was submitted.

### Sociodemographic Information

In the questionnaire, the following sociodemographic information was collected from all participants: gender, ethnicity, date of birth, marital status, household type, education background, monthly income, occupation, and smoking and drinking status.

In this study, respondents were identified as a current smoker or drinker if they reported being an active smoker or drinker.

### Knowledge and Awareness

The participants' knowledge was assessed using a series of questions related to COVID-19. The questions included the following items: "Did you hear about COVID-19?" "When did you hear about COVID-19?" "Do you agree that COVID-19 is the same as influenza virus?" "Do you agree that COVID-19 is the same as SARS?" "Do you agree that influenza vaccine can prevent COVID-19?" "Which level is the category and treatment of COVID-19 classified in China?" "What is the possible host for COVID-19?" "Which population group is susceptible to COVID-19?" "How long is the incubation period for COVID-19?" "Do you think that COVID-19 is contagious during the incubation period?" "Is there any effective treatment for COVID-19?" "When do you think that it is necessary to wear a mask during the COVID-19 pandemic?" and "Do you know that COVID-19 has been declared to be a Public Health Emergency of International Concern (PHEIC)?"

### Attitude Toward the COVID-19 Pandemic

In this section, the following items were designed to determine the participants' attitude toward COVID-19: "What is your level of concern about COVID-19?" "How often do you check updates about COVID-19?" "What impact does the village/city lockdown policy have on your daily life?" "What is your attitude toward COVID-19 pandemic control?" and "Do you think that COVID-19 could be a global outbreak?"

### Ethical Considerations

This study protocol was approved by the Ethics Committee of Jining Medical College (JNMC-2020-KY-001).

### Statistical Analysis

We calculated counts and proportions for countable data in the questionnaire. Bar plots were used if necessary. The chi-square test was used to compare the differences in the countable data of groups. The Fisher test was applied to data that was not qualified for the chi-square test due to the small size of the sample. The differences between groups were considered statistically significant if the *P* value was  $<.05$ . All statistics were completed with SAS (Version 9.5; SAS Institute Inc).

## Results

### Sociodemographic Characteristics

Table 1 summarizes the sociodemographic characteristics of respondents by group. In this study, a total of 822 questionnaires were collected, 508 were used in analysis, and 314 were excluded due to the age limitation or inconsistencies in control item responses.

Of the 508 respondents, there were 380 students (74.8%), 39 medical workers (7.7%), and 89 people in other occupations (17.5%). The mean age was 24.1 years. The mean age for each group was 21.5 years for students, 29.6 years for medical workers, and 32.8 years for those in other occupations. In total, 272 participants (53.5%) were female. A slightly higher percentage of participants lived in rural areas ( $n=258$ , 50.8%) than urban areas ( $n=250$ , 49.2%), and most of them were single ( $n=423$ , 86.9%). The education level of the majority of the respondents was college and above ( $n=454$ , 89.4%). For monthly income, 58.7% had no income; this answer was especially high among students (76.9%). Most of the participants said they were not currently smoking ( $n=452$ , 89%) or drinking ( $n=344$ , 67.7%).

**Table 1.** Sociodemographic characteristic distributions of participants by occupation group.

Characteristics	Students (n=380)	Medical workers (n=39)	Other occupations (n=89)	Total (N=508)

## Knowledge and Awareness About COVID-19

Almost all of the respondents said they had heard about COVID-19 (99% of students, 100% of medical workers, and 98.9% of those in other occupations). A higher proportion of medical workers (n=18, 46.2%) and students (n=155, 40.8%) heard about COVID-19 by December 2019. However, a sizeable percentage of the respondents said they found out about COVID-19 between January 1 and 20, especially those in other occupations (52.8%) and students (49.5%).

Regarding the host of COVID-19, all medical workers reported that it was possibly a wild animal (eg, bats), and 98.7% of students (n=375) and 95.6% of those in other occupations (n=85) made the same choice. When the participants were asked about the populations most susceptible to COVID-19, 44.5% of the students (n=169) and 41.6% of those in other occupations (n=37) thought that middle-aged and older adults were more vulnerable. In contrast, 66.7% of medical workers answered that people of all ages were susceptible. The majority of the participants agreed

that the incubation period of COVID-19 was between 1 and 14 days (86.5% to 92.3%), and over 98% of them agreed that the virus was contagious during the incubation period. Concerning treatment, most of the participants knew that there was no effective available treatment against COVID-19 (97.4% of medical workers [n=38] and 93.3% of those in other occupations [n=83]). In addition, 97.4% of medical workers (n=38) knew that COVID-19 was declared a PHEIC by the end of January, followed by students (n=319, 89%) and those in other occupations (n=78, 87.6%).

Regarding the use of masks, most of the participants agreed that it was necessary to wear a mask when going outside, with 90.5% (n=344), 87.2% (n=34), and 85.4% (n=76) of students, medical workers, and those in other occupations groups, respectively. This proportion was significantly higher than that of people that agreed to wear a mask in a crowded place.

As to the comparison between COVID-19 and other virus diseases, most of the students (n=321, 84.5%), those in the other

occupations group (n=77, 86%), and all medical workers (n=39, 100%), knew that COVID-19 and influenza virus were not the same. Correspondingly, a high proportion of students (n=319, 84%), medical workers (n=37, 94.9%), and those in other occupations (n=76, 85.4%) answered that COVID-19 was different from severe acute respiratory syndrome (SARS). When participants were asked if the influenza vaccine can prevent COVID-19, a low proportion of students (n=33, 8.7%), medical workers (n=1, 2.6%), and those in other occupations (n=7, 7.9%) responded “Yes.”

Although the majority of information about COVID-19 was well known by the participants, with no significant differences observed among the groups, medical workers showed a significantly advanced knowledge in their responses to professional questions (Table 2).

Regarding the sources used to search for information about COVID-19, most of the participants obtained information from social media (Sina Weibo, 84.7%), as well as WeChat and QQ groups (74.7%). The least used sources of information for all three groups were newspapers and magazines (3.4%; Figure 1).

**Table 2.** Participants' knowledge and awareness of COVID-19 by occupation group.

**Figure 1.** Ways by which participants obtained COVID-19 information, by occupation group.

### Attitude Toward the COVID-19 Pandemic

The three groups showed significant differences in their level of concern. A higher proportion of medical workers stated they were highly concerned ( $n=28$ , 71.8%), followed by those in other occupations ( $n=47$ , 52.8%) and students ( $n=149$ , 39.2%). The frequency of checking updates was also significantly different among the groups. Regarding the number of times per day participants reported checking for updates about COVID-19, 48.2% of students ( $n=183$ ) checked once per day, as did 46.1% of those in other occupations ( $n=41$ ). On the other hand, the proportion of medical workers that checked updates once per day ( $n=18$ , 46.2%) was slightly lower than the proportion that checked updates more than once per day ( $n=19$ , 48.7%). The

proportion of participants that thought that COVID-19 would not be a global outbreak was 71.3% ( $n=271$ ), 79.5% ( $n=31$ ), and 69.7% ( $n=62$ ) for students, medical workers, and those in other occupations, respectively.

Regarding the village/city lockdown policy, most of the participants from the three groups stated that the policy had a significant impact on their daily life (55.3% of students [ $n=210$ ], 43.6% of medical workers [ $n=17$ ], and 43.8% of those in other occupations [ $n=39$ ]). Nevertheless, most of them had an optimistic attitude toward COVID-19 control (92.1% of students [ $n=350$ ], 94.9% of medical workers [ $n=37$ ], and 92.3% of those in other occupations [ $n=83$ ]). Table 3 displays the attitude toward COVID-19 of participants by group.

**Table 3.** Participants' attitude toward COVID-19 by occupation group.

## Discussion

### Principal Findings

This study determined the knowledge and awareness of and attitude toward COVID-19 among students, medical workers, and those in other occupations during the critical period of the outbreak. It demonstrated that participants from different population groups had similar knowledge and awareness of COVID-19. However, medical workers performed significantly better on questions related to professional knowledge. It was confirmed that the lockdown policy had a substantial impact on the daily life of the analyzed groups. Nevertheless, most of the participants believed that COVID-19 would not be a global outbreak and they held an optimistic attitude regarding the control of the COVID-19 pandemic.

In this study, 314 respondents were excluded from the analysis as they did not answer the control items correctly. Of 314 unqualified participants, students accounted for 77.4% ( $n=226$ ), while 17.5% ( $n=51$ ) were in the other occupations group, and 5.1% ( $n=15$ ) were medical workers. No significant differences were found in the occupation distribution between the qualified and unqualified groups. However, the mean age of the unqualified group was significantly lower than that of the qualified group because of the high proportion of students. The difference in distribution of ethnicity and marriage status was not statistically significant between the two groups. Thus, it can be inferred that the participants in the qualified group are representative.

Our study revealed that most of the participants had heard about COVID-19, and a higher proportion of them had heard about it by January, which corresponded with other studies that found that the peak of information seeking about COVID-19 occurred by the end of January in various countries [11,12]. It is worth noting that a certain proportion of medical workers and students had heard about the virus by the end of December 2019.

Regarding general knowledge about COVID-19, our findings showed that almost all participants knew that the host of the virus was probably a wild animal. In addition, most of the participants knew that COVID-19 was different from influenza and SARS, and also had a good understanding of the incubation time of COVID-19, as well as the most susceptible populations. Medical workers showed a more advanced knowledge in their responses to professional questions than the other two groups. Compared with another similar study conducted in India, the level of knowledge and awareness among the participants in our study is higher; most of the respondents in India were passably aware of the basic elements of the disease [13]. Findings similar to ours were reported in another study performed in China that demonstrated that most of the participants were knowledgeable about COVID-19 [14].

Participants of this study used social media (eg, Sina Weibo) most often to obtain information about COVID-19, as well as other apps (WeChat and QQ). Traditional media such as newspapers and magazines were used less often to get updates. Similar findings were found in other studies that analyzed where people searched for information about COVID-19 [15-17]. A

possible explanation could be that social media apps have become popular and easily accessible compared with traditional media sources, thus speeding up the spread of information.

Regarding preventive measures, our study found that most of the participants would wear a mask when outside and in crowded places. However, there is controversial information about the effectiveness of wearing a mask among the general population [18]. In East Asia, especially in China, wearing a mask has been one of the main preventive measures recommended by the government since the beginning of the outbreak. This was possibly one of the main differences in response compared with other places in the world where the use of masks was not compulsory for the general population [19]. In fact, wearing a mask has contributed much to the effective control of COVID-19 in China. Furthermore, a wide range of countries and regions have recommended their citizens wear a mask if social distancing cannot be ensured.

Most of the study participants, especially medical workers, reported that they were highly concerned about COVID-19. Similarly, another web-based study conducted in China suggested that 97.1% of participants paid close attention to COVID-19 by checking updates more than once per day [20]. A possible reason for frequent update checking is the psychological stress associated with the pandemic that the public has experienced. Another study in China showed that more than 90% of the study population experienced concern and stress [21]. The high level of concern among medical workers could be due to their higher risk of exposure to COVID-19 and their fear of getting infected. A similar study performed in Henan, China, demonstrated that 85% of health care workers were afraid of being infected at work [22].

The lockdown policy has been an important preventive measure to deter the spread of COVID-19 in several countries [23,24], and it has been effective in China [25]. In our study, most of the respondents reported that the lockdown policy had a significant impact on their daily life. In this regard, other studies also confirmed that lockdown measures can have a substantial impact on the mental health of the population and affect people's daily lives due to social distancing and decreased physical activity [26]. Moreover, another study that reviewed the impact of COVID-19 on university students showed that most of them were concerned about the effects that the outbreak would have on their academic performance. Most universities closed and classes were online [27]; this may be why students considered the impact of lockdown significant. Nevertheless, as a positive outcome, the lockdown policy also provided the opportunity and time for families to stay close, especially if they learned to cope with tensions that occurred due to changes in the family routine. However, several countries, including China, reported an increase in domestic violence during lockdown [28]. There was also a general concern about parenting during the lockdown and how families could deal with the stress of the crisis [29].

Despite being highly concerned about COVID-19, more than 90% of the respondents declared to have an overall optimistic attitude toward COVID-19 control. Similar findings were reported in another cross-sectional web-based study among health care workers globally, especially in Asia, where 78% of

the participants held a positive perception of COVID-19 [30]. In contrast, a study performed in Uganda showed that only 21% of the participants had a good attitude toward the disease [31]. A possible cause of these differences in attitude toward the COVID-19 pandemic may be the social and economic gap among countries, which might influence the availability of medical services and sanitary conditions in houses and workplaces. The Human Development Index (HDI) might be an adequate measurement of this gap. In Asia, the HDI ranges from 0.647 to 0.866, while in Uganda it is 0.528. Similarly, more than half of the respondents said that COVID-19 could not become a global outbreak. This trend might be related to the low international incidence of cases when the survey was conducted.

This study evaluated the knowledge and awareness of and attitude toward COVID-19 among different populations in Central China, providing meaningful findings that might be useful for other countries and regions facing the COVID-19 pandemic. Nevertheless, limitations still exist. First, the sample size was small and unbalanced, especially for medical workers

and the other occupations group, which might limit the generalizability of findings. Therefore, the interpretation of the results should be cautious. Second, the findings related to mental health were not included in the current analysis. Finally, the sample representing the target population could be limited to some extent because all participants came from the same geographical region.

## Conclusions

In general, the findings show that the participants have an adequate background knowledge of COVID-19 and hold an optimistic attitude toward the control of the disease. However, most of the participants were highly concerned about the pandemic and said that the lockdown policy had a significant impact on their daily life, suggesting a need for effective preventive measures to relieve emotional and psychological stress. Finally, this research offers essential evidence for COVID-19 pandemic control prior to the availability of a prophylactic vaccine. Further studies are still needed to identify the specific impact that the COVID-19 pandemic has had on the lives and mental health of the population.

## Conflicts of Interest

None declared.

## Abstract

**Background:** With the continued spread of COVID-19 in the United States, identifying potential outbreaks before infected individuals cross the clinical threshold is key to allowing public health officials time to ensure local health care institutions are adequately prepared. In response to this need, researchers have developed participatory surveillance technologies that allow individuals to report emerging symptoms daily so that their data can be extrapolated and disseminated to local health care authorities.

**Objective:** This study uses a framework synthesis to evaluate existing self-reported symptom tracking programs in the United States for COVID-19 as an early-warning tool for probable clusters of infection. This in turn will inform decision makers and health care planners about these technologies and the usefulness of their information to aid in federal, state, and local efforts to mobilize effective current and future pandemic responses.

**Methods:** Programs were identified through keyword searches and snowball sampling, then screened for inclusion. A best fit framework was constructed for all programs that met the inclusion criteria by collating information collected from each into a table for easy comparison.

**Results:** We screened 8 programs; 6 were included in our final framework synthesis. We identified multiple common data elements, including demographic information like race, age, gender, and affiliation (all were associated with universities, medical schools, or schools of public health). Dissimilarities included collection of data regarding smoking status, mental well-being, and suspected exposure to COVID-19.

**Conclusions:** Several programs currently exist that track COVID-19 symptoms from participants on a semiregular basis. Coordination between symptom tracking program research teams and local and state authorities is currently lacking, presenting an opportunity for collaboration to avoid duplication of efforts and more comprehensive knowledge dissemination.

## Introduction

### Background

A 2019 outbreak of febrile respiratory illness in Wuhan, China, quickly evolved into the COVID-19 pandemic [1]. The disease has affected over 200 countries and territories worldwide. Globally, there are more than 18 million confirmed cases and over 700,000 deaths attributed to this flu-like illness, as of August 6, 2020 [2]. In the United States alone, there are more than 4.5 million confirmed cases and over 150,000 deaths [3]. The true number of those affected may be much higher due to the slow rollout and lack of availability of testing in the United States compared to other countries [4].

The United States, as well as other countries, has combatted this pandemic and sought to flatten the curve via social distancing, testing, isolation, and contact tracing [5]. Despite best efforts, the virus spread quickly with serious implications. In the first month of testing, the hospitalization rate was 4.6 per 100,000 people in the United States. Hospitalization rates were highest among adults over 65 years as well as those with underlying conditions [6]. At the present time, there is no specific antiviral treatment for COVID-19. Management of symptoms focuses on supportive care and oxygen therapy, both of which involve a plethora of hospital resources [5]. Modeling of COVID-19 shows that the pandemic has the potential to cause regional shortages of hospital beds, intensive care unit (ICU) beds, ventilators, and medical staff, which could lead to difficult ethical decisions [7]. A recent study suggests that COVID-19 will likely become endemic like cold and flu viruses [8]. There is a need to predict where resources should be distributed before potential patients with COVID-19 enter the hospital setting to alleviate strain on medical staff and facilities.

Epidemiological surveillance is fundamental in coordinating both immediate and long-term strategies for the detection and prevention of infectious disease outbreaks [9,10]. However, since collecting and disseminating these data take several weeks, during highly transmissible outbreaks, it may not be entirely reflective of the current prevalence of the disease. As these data are used to inform health authorities and prompt a public response, the resulting time delay can lead to inappropriate or inadequate response to actual need. Additionally, the collected data may be incomplete or insufficient to discern regional demographics that may impact effective intervention and treatment [11,12].

To overcome the limitations of epidemiological surveillance, internet-based technologies have been developed to estimate and monitor real-time changes in population, soliciting participation from the public at large [12,13]. One approach that has been introduced is self-reported symptom tracking. Symptom tracking is a form of crowd-sourced participatory surveillance that solicits individuals to report their health status on a daily or weekly basis, often with emails or notifications to prompt timely response, allowing researchers to see potential changes in the population before seeing changes in clinical presentation at hospitals and medical centers. Symptom tracking is used primarily to track and forecast influenza activity throughout the country; however, researchers have been looking

to apply this technology to other diseases, such as COVID-19 [12,13]. Participatory surveillance such as this may prove vital to complement epidemiological surveillance during highly transmissible epidemics, as it allows for the detection of outbreaks before they reach the clinical threshold, affording more time for logistical support and appropriate allocation of resources [11]. Research by Baltrusaitis et al [13] indicates that collected participatory surveillance of influenza later correlated with confirmed epidemiological surveillance data. With the current highly transmissible and deadly COVID-19 pandemic putting a strain on portions of the United States health care system, participatory surveillance is more important than ever to bolster local prevention efforts [14].

### Research Purpose

This study uses a framework synthesis to inform decision making about the utility of existing self-reported symptom tracking programs for COVID-19, with a focus on the US population, as an early-warning tool for probable clusters of infection. Due to the rapidly changing nature of both the pandemic and work in this area, this research will be updated at 6- and 12-month intervals.

### Objective

The purpose of this framework analysis is to assess the number and scope of self-reported symptom tracker programs focused on the United States and COVID-19. An innovative best fit framework analysis was chosen because of its strength, utility, and appropriateness in drawing conclusions for an evolving subject [15,16]. According to Booth and Carroll [17], the best fit framework approach is considered a highly structured and pragmatic methodology for research synthesis suited for qualitative research with specific questions, a limited time frame, and issues that have been previously identified; this served the purpose of our research well [18]. The outcomes of this synthesis and its updates should inform decision makers and health care planners about these technologies and the information they can ascertain from them in order to aid in federal, state, and local efforts to combat the pandemic both now and in the future.

## Methods

A framework analysis was conducted to assess symptom tracking programs. A best fit framework was constructed by collating information collected from each program into a table for easy comparison between programs.

### Target Population

This framework synthesis sought to identify programs that track COVID-19 symptoms in the US population for all ages, genders, and ethnicities. Inclusion and exclusion criteria are shown below:

- Inclusion criteria: programs were included if they aimed to capture and geographically collate self-reported potential symptoms of COVID-19 and if they were available for use in the United States. For our purpose, a symptom tracking tool is defined as a program that allows individuals to report symptoms of COVID-19 to identify geographic areas with emerging or changes in progression of disease.

- Exclusion criteria: programs were excluded if they did not track specific symptoms for COVID-19, were symptom checkers for individual use only, or were not targeting the US population.

### Program Identification

Programs were identified using Google search for keywords (“symptom trackers covid,” “symptom trackers coronavirus,” “symptom tracking covid,” “symptom tracking coronavirus,” “daily symptom tracking covid,” “daily symptom tracking coronavirus,” “self-reporting covid,” “self-reporting coronavirus”). The time frame for the search for programs ranges from April 7, 2020, to May 9, 2020. Further, we used snowball sampling to identify other symptom tracker programs for COVID-19.

### Screening Method

Reviewers (JK, MJ, TK) screened programs to determine if inclusion criteria were met. Reviewers (MJ, JK, TK) then extracted data from program websites using a standardized form. To complete the collection of information not available via the program webpages, we contacted the managers of the programs via email.

### Synthesis Method

Data relating to program characteristics were extracted from all included programs and organized into a table format, which was used to guide data collection and build the framework for analysis. Data were then synthesized in order to form meaningful statements about the programs.

## Results

We identified 6 programs that met the inclusion criteria. Information was gathered from the public webpages of all

eligible symptom trackers (BeatCOVID19Now, COVIDcast, COVIDNearYou, COVID Symptom Tracker, HelpBeatCOVID19, and HowWeFeel) (Table 1). Two programs, C19Check and the Department of Defense’s MySymptoms.mil, were excluded from our synthesis since they are symptom checkers that do not identify probable clusters of emerging infection.

All of the included programs were affiliated with a university, school of medicine, or school of public health. Half of the programs (n=3) included were based in Boston, Massachusetts, and affiliated with Harvard University (COVIDNearYou, COVID Symptom Tracker, and HowWeFeel), with COVIDNearYou also collecting data from participants in Canada and Mexico. Two other programs are based elsewhere within the United States (COVIDcast and HelpBeatCOVID19), and one is based in Australia, designed for international use (BeatCOVID19Now).

The number of responses, defined as unique symptom entries by an individual, to each program varied widely, with the lowest being ~27,000 (BeatCOVID19Now) and the highest being 2,573,240 (COVIDcast). COVID Symptom Tracker collected data from patients currently enrolled in large cohort studies and clinical trials not related to COVID-19 and had obtained much of their initial influx of responses through that mechanism. Two-thirds of the programs had fewer than 100,000 responses. Three programs utilized a website to collect data, while two exclusively used an app available for both Apple and Android devices (COVID Symptom Tracker and HowWeFeel), and only one utilized a survey on a social media platform (Facebook). While most of the programs had no form of follow-up with participants, COVIDNearYou and HelpBeatCOVID19 sent text message reminders, and COVID Symptom Tracker sent phone notifications every third day.

**Table 1.** Overview of self-reported symptom tracker programs.

Publicly available data privacy statement	Yes	Yes	Yes	Yes	Yes	Yes

<sup>a</sup>This data was collected at the time that the synthesis was performed and is subject to change.

The programs collected a variety of data elements, but several were common among them (Table 2). All of the symptom trackers collected demographic data on the participant's age, gender, and zip code. They also all collected information on symptoms experienced by the participant, although the time frame considered varied from the present to 7 days prior. Additionally, every program asked if the participant had been tested for COVID-19 at the time of the survey. Five of the six trackers also asked for information on any chronic conditions that the participant is experiencing, and if they are or are not a smoker.

Some of the programs had special interest in certain topics that were not explored by others. Only four of the programs asked the participant if they had been exposed to anyone who had COVID-19, while two asked if the participant came into direct contact with the public. Two programs asked if participants had received an annual flu shot this past year. Two programs asked questions related to the impact of the pandemic on participant's mental health. Two programs asked the participant to answer questions about others in their household in addition to themselves.

**Table 2.** Data elements across programs.

Data elements	Beat- COVID19Now	COVIDcast	COVIDNearYou	COVID Symptom Tracker	HelpBeatCOVID19	HowWeFeel
Is the survey being completed on behalf of another person?					✓	
Age	✓	✓	✓	✓	✓	✓
Gender/sex	✓	✓	✓	✓	✓	✓
Race/ethnicity	✓				✓	
Zip code	✓	✓	✓	✓	✓	✓
Number of people in the household	✓	✓			✓	
Employment status	✓					
Languages spoken in the household	✓					
Is the participant an essential worker?	✓					
Is the participant a health care worker?	✓			✓		
International travel within the past 2 months?	✓					
Has the participant traveled out of state within the past 5 days?		✓				
Travel within the past 2 weeks?			✓			
Does the participant come in direct contact with the public?				✓	✓	
How many people has the participant had direct contact with outside of their household?		✓				
Has the participant gone outside for work within the past 5 days?		✓				
What activities has the participant engaged in outside of their household?	✓					
Has the participant been in contact with health care professionals?			✓			
Has the participant visited a long-term care facility or nursing home within 5 days?		✓				
To what extent is the participant complying with social distancing guidelines?		✓				
How many days has the participant spent in quarantine or social isolation?			✓			
Has the participant been quarantined over the past 2 weeks?				✓		
Has the participant been quarantined over the past 24 hours?						✓
How is the participant feeling today? (good/not good)			✓	✓	✓	✓
Has the participant been exposed to anyone with COVID-19?		✓	✓	✓	✓	✓
Has the participant been tested for COVID-19?	✓	✓	✓	✓	✓	✓
Does the participant suspect they have COVID-19 despite not being tested?				✓		✓
Symptoms of the participant over the last 24 hours	✓					

Data elements	Beat-COVID19Now	COVIDcast	COVIDNearYou	COVID Symptom Tracker	HelpBeatCOVID19	HowWeFeel
Symptoms among the participant or household member(s) within 24 hours		✓				
Symptoms currently being experienced by the participant			✓	✓		✓
Symptoms over the last 7 days					✓	
How many days has the participant been experiencing symptoms?		✓				
What date did the participant begin experiencing symptoms?			✓			
Has the participant had difficulty completing normal activities over the past 24 hours?	✓					
Is anyone within the participant's household experiencing symptoms?					✓	✓
Number of people in the household who are sick		✓				
Number of people the participant knows in the community who are sick		✓				
Has the participant been to the hospital within the past 24 hours?		✓				
Is the participant at home or hospitalized?				✓		
Is the participant able to move freely?				✓		
Does the participant require outside help on a regular basis?				✓		
If the participant needs help, can they get it from someone close to them?				✓		
Highest temperature		✓				
Does the participant have a non-COVID-19 respiratory illness?	✓					
Impact on immediate mental health or changes in mood or behavior	✓	✓				
Is the participant worried about their ability to engage in daily activities or about the security of their future?	✓	✓				
Does the participant have health problems that require staying indoors regularly?				✓		
Chronic conditions	✓	✓		✓	✓	✓
Smoking status				✓	✓	✓
Height				✓		
Weight				✓	✓	
Pregnancy status					✓	✓
Has the participant had the flu vaccination?	✓	✓	✓			
Is the participant currently taking aspirin?				✓		
Is the participant currently taking nonsteroidal anti-inflammatory drugs (NSAIDs)?				✓

Is the participant currently taking blood pressure medication?				✓		
Is the participant currently taking immunosuppressants?				✓		
Does the participant have access to transportation?					✓	
Does the participant have health insurance?					✓	
Type of domicile					✓	
Can the participant afford a medical co-pay if needed?					✓	
Has the participant completed the survey before?					✓	

## Discussion

### Principal Results

Self-reported symptom trackers have been shown to be beneficial in tracking and monitoring the spread and progression of influenza each year and may prove to be vital as the United States continues to loosen shelter-in-place guidelines across the country. Due to the nature of the rapidly changing pandemic, this resource will be updated at both 6- and 12-month intervals to better reflect the evolving pandemic response.

Two of the programs were created by groups who already have existing infrastructure for tracking influenza outbreaks each year, BeatCOVID19Now, which is a derivative of Flu-iiQ, and COVIDNearYou, the sister tracker to FluNearYou. Flu-iiQ, in particular, was developed to solicit patient-reported outcome measures during large-scale clinical trials to measure the presence or absence of disease within a small subset of a population, allowing for extremely sensitive measurements without requiring thousands of responses [19]. The flexibility of these programs to track symptoms associated with diverse flu-like illness is imperative in identifying outbreaks of disease both for the purposes of this current pandemic as well as future flu and other respiratory disease outbreaks [20].

The data elements collected varied between programs, but all asked for zip code data, which means that even groups that do not currently have their data geolocated on maps have the potential to do so in the future in order to make data accessible to state and local health officials. They also all collect data regarding testing status, which enables local, state, or national program managers or planners to see the impact of current testing expansion efforts. Almost all of the programs asked about race and/or ethnicity, which may highlight racial disparities in testing, symptoms, unemployment status, and other chronic health conditions. The similarities in the data elements being collected by the different programs indicates that collaboration to build a larger, single picture is a possibility; standardization could be beneficial to the programs and to the local leaders and planners, health care providers, and researchers who would receive the outputs. The differences in collected

data highlight areas of focus between the programs that other programs may want to consider incorporating as well.

Notable differences between the programs include unique data elements as well as the manner of recruitment. Two of the programs, BeatCOVID19Now and COVIDcast, are collecting information related to the mental health impact of the pandemic. This topic is currently being discussed in the scientific community since individuals with current mental health conditions can be at higher risk for infections [21,22]. Additionally, mental health conditions can be made worse by the anxiety and fear brought on by the pandemic [21]. Individuals without existing mental health conditions may develop emotional responses to the pandemic similar to disaster scenarios, particularly those who are working in response to the pandemic or those who are more susceptible to infection. Quarantine in general can spur a number of emotional responses that can remain after stay-at-home orders are lifted [22]. These programs could help to track the effect of mental health during the COVID-19 pandemic and help to inform prevention efforts for future pandemics requiring social isolation and quarantine. Another key difference was the reach of each program. Programs that partnered with or heavily relied on social media platforms (COVIDcast and HowWeFeel) had significantly more responses than those that did not utilize social media, suggesting that social media is a powerful recruitment tool for these efforts, even more so now since people depend on these platforms to stay connected due to social distancing measures. Therefore, its use should be considered by other groups going forward.

One of the notable results of this synthesis is the demonstrated overlap or duplication of effort between the programs. Each program is competing for the same group of potential respondents, who are more than likely going to be completing only one group's survey. Without ongoing coordination between groups, the beneficiaries of their work—the public, lawmakers, state and local health care officials, etc—will not obtain information reflective of the full potential of symptom tracking. Although many of the groups recognize this, active collaboration between the groups has been a difficult process, even among

the groups located in the same city (eg, Boston, Massachusetts) and based in the same institution.

A key challenge facing these programs is a lack of recognition at the national level. Only one of the trackers, COVIDNearYou, had a partnership with the Centers for Disease Control and Prevention, an extension of their ongoing partnership for FluNearYou. Despite this long-term collaboration, there is no outward support from the agency urging people to engage with this new program. The lack of local, state, or national promotion or outward partnership further exacerbates the potential for gaps between programs. Additionally, there is the potential that endorsement by local authorities or agencies could increase the number of responses, reaching people who were previously unaware of these programs and influencing them to contribute their data, which would in turn would allow for more complete data. This has been found to be the case in the United Kingdom, where the National Health System has endorsed the sister application to COVID Symptom Tracker, based at King's College in London. Because of this, at the time of interview, they had received ten times as many responses as their US counterparts [23].

### Limitations

Several limitations must be acknowledged for this study. First, our analysis was limited to English language programs, and therefore may have missed nuances of data collection which are more important to non-English speaking residents. Second, although the speed of framework analysis enables rapid evaluation of commonalities, it does not provide the in-depth rigor of a full systematic review. Third, our collected data did

evaluate differences in the number of responses to each program but not analyze the effectiveness, market penetration, or user demographics of evaluated programs. Fourth, we recognize that program participation is limited to only those who have access to the internet or cellular phone service, creating an unintended disparity among respondents based on their access to and utilization of technology. Therefore, the underlying reasons for the difference in response rate remain beyond the scope of this study. Last, this synthesis does not provide critical appraisal of programs or evaluate programs for effectiveness.

### Conclusion

Self-reported symptom tracking programs offer potential benefits as states and counties continue to reopen after the large-scale stay-at-home orders. Frequently reported data with high participation in geographic areas would allow officials to better monitor potential emerging hotspots and institute public health policy and reallocate resources more quickly to combat the spread of disease. However, there are unique challenges to address with self-reported symptom tracking programs to ensure successful implementation. Recognition or endorsement at the national, state, or local levels; increased funding to expand social media advertisements and partnerships; and collaboration between existing programs to generate a more comprehensive data picture would be essential steps in bolstering the utility of symptom tracking programs to achieve optimal effectiveness. If these challenges are addressed and symptom tracking programs become more widely used, the reopening process could be safer in the short term with the potential to monitor communities more closely for long-term management of the COVID-19 pandemic or future outbreaks.

## Abstract

**Background:** With restrictions on movement and stay-at-home orders in place due to the COVID-19 pandemic, social media platforms such as Twitter have become an outlet for users to express their concerns, opinions, and feelings about the pandemic. Individuals, health agencies, and governments are using Twitter to communicate about COVID-19.

**Objective:** The aims of this study were to examine key themes and topics of English-language COVID-19–related tweets posted by individuals and to explore the trends and variations in how the COVID-19–related tweets, key topics, and associated sentiments changed over a period of time from before to after the disease was declared a pandemic.

**Methods:** Building on the emergent stream of studies examining COVID-19–related tweets in English, we performed a temporal assessment covering the time period from January 1 to May 9, 2020, and examined variations in tweet topics and sentiment scores to uncover key trends. Combining data from two publicly available COVID-19 tweet data sets with those obtained in our own search, we compiled a data set of 13.9 million English-language COVID-19–related tweets posted by individuals. We use guided latent Dirichlet allocation (LDA) to infer themes and topics underlying the tweets, and we used VADER (Valence Aware Dictionary and sEntiment Reasoner) sentiment analysis to compute sentiment scores and examine weekly trends for 17 weeks.

**Results:** Topic modeling yielded 26 topics, which were grouped into 10 broader themes underlying the COVID-19–related tweets. Of the 13,937,906 examined tweets, 2,858,316 (20.51%) were about the impact of COVID-19 on the economy and markets, followed by spread and growth in cases (2,154,065, 15.45%), treatment and recovery (1,831,339, 13.14%), impact on the health care sector (1,588,499, 11.40%), and governments response (1,559,591, 11.19%). Average compound sentiment scores were found to be negative throughout the examined time period for the topics of spread and growth of cases, symptoms, racism, source of the outbreak, and political impact of COVID-19. In contrast, we saw a reversal of sentiments from negative to positive for prevention, impact on the economy and markets, government response, impact on the health care industry, and treatment and recovery.

**Conclusions:** Identification of dominant themes, topics, sentiments, and changing trends in tweets about the COVID-19 pandemic can help governments, health care agencies, and policy makers frame appropriate responses to prevent and control the spread of the pandemic.

## Introduction

As the effects of the COVID-19 pandemic are felt worldwide, social media platforms are becoming inundated with content associated with the disease. Since its initial identification and reporting in Wuhan, China, the novel disease COVID-19 has spread to multiple countries across all continents and has become a global pandemic. The World Health Organization (WHO) declared the outbreak to be a pandemic on March 11, 2020, and the US government declared it to be a national emergency on March 13, 2020. As of June 30, 2020, the virus has infected over 10 million individuals and has caused approximately 503,000 deaths worldwide [1]. To contain the spread of the virus, several countries have implemented lockdown and quarantine measures and imposed travel bans, restricting people's movement. Schools have been closed, many workers have become unemployed, and numerous individuals are locked down in their homes. With millions of lives affected by the COVID-19 pandemic, social media platforms such as Twitter have become an outlet for users to express their concerns, opinions, and feelings about the pandemic.

Social media has emerged as a significant conduit for health-related information; the majority of people across multiple countries use some form of social media [1,2]. Pew Research surveys examining multiple countries have identified social media as an important source of health information [3]. In recent years, sharing and consuming health information via social media has become prevalent. It is unsurprising that social media has become a prominent platform for people to share information and feelings about COVID-19.

The science of understanding health-related information that is distributed via a digital medium such as the internet or social media with the aim to inform public health and public policy is known as infodemiology. A related term, infoveillance, refers to syndromic surveillance of public health-related concerns that is expressed and diffused on the internet through digital channels. Infoveillance has been particularly useful to identify

outbreak patterns and to study public perceptions of several diseases, including H1N1 influenza ("swine flu") [4], Ebola virus [5,6], and Zika virus [7-9]. Analysis of health event data posted on social media platforms not only provides firsthand evidence of health event occurrences but also enables faster access to real-time information that can help health professionals and policy makers frame appropriate responses to health-related events.

The COVID-19 outbreak has propelled an emergent set of studies that have examined public perceptions, thoughts, and concerns about this pandemic using social media data (Table 1). Most of these studies relied on data from the Twitter or Weibo platforms and analyzed data from early periods of the pandemic. The amount of data used in these studies varies from a few hundred tweets to a few million. These studies have collectively provided a rich body of knowledge on how Twitter users have reacted to the pandemic and their concerns in the early stages of the outbreak. Many of these studies did not differentiate between sources of tweets, such as whether the tweet originated from an individual or an organization such as a news channel or health agency. From an infoveillance perspective, it is important to understand the social media discourses pertaining to COVID-19 among the common public rather than by news agencies or other organizations. Further, there is limited understanding of the changes in public sentiments and discourse about COVID-19 over time. To address these gaps, we examined COVID-19-related tweets using a much larger data set covering a time period from January 1 to May 9, 2020. We performed a temporal assessment and examined variations in the topics and sentiment scores over a period of time from before to after the disease was declared a pandemic to uncover key trends.

Our research goals were to examine key themes and topics in COVID-19-related English-language tweets posted by individuals and to explore the trends and variations in how COVID-19-related tweets, key topics, and associated sentiments changed over a period of time from before to after the disease was declared a pandemic.

**Table 1.** Summary of key studies on the COVID-19 pandemic using social media data.

Source	Social media platform	Data set	Time period	Key findings
Abd-Alrazaq et al, 2020 [10]	Twitter	167,073 tweets	Tweets from February 2 to March 15, 2020	Identified 12 topics that were grouped into four themes, viz the origin of the virus; its sources; its impact on people, countries, and the economy; and ways of mitigating infection.
Li et al, 2020 [11]	Weibo	115,299 posts	Posts from December 23, 2019, to January 30, 2020	Positive correlation between the number of Weibo posts and number of reported cases in Wuhan. Qualitative analysis of 11,893 posts revealed main themes of disease causes, changing epidemiological characteristics, and public reaction to outbreak control and response measures.
Shen et al, 2020 [12]	Weibo	15 million posts	Posts from November 1, 2019, to March 31, 2020	Developed a classifier to identify “sick posts” pertaining to COVID-19. The number of sick posts positively predicted the officially reported COVID-19 cases up to 14 days ahead of official statistics.
Sarker et al, 2020 [13]	Twitter	499,601 tweets from 305 users who self-disclosed their COVID-19 test results	N/A <sup>a</sup>	203 users who tested positive for COVID-19 reported their symptoms: fever/pyrexia, cough, body ache/pain, fatigue, headache, dyspnea, anosmia and ageusia.
Tao et al, 2020 [14]	Weibo	15,900 posts	December 31, 2019, to March 16, 2020	Analysis of oral health–related information posted on Weibo revealed home oral care and dental services to be the most common tweet topics.
Wahbeh et al, 2020 [15]	Twitter	10,096 tweets from 119 medical professionals	December 1, 2019, to April 1, 2020	Identified eight themes: actions and recommendations, fighting misinformation, information and knowledge, the health care system, symptoms and illness, immunity, testing, and infection and transmission.
Budhwani et al, 2020 [16]	Twitter	193,862 tweets by US-based users	March 9 to March 25, 2020	Identified a large increase in the number of tweets referencing “Chinese virus” or “China virus.”
Rufai and Bunce, 2020 [17]	Twitter	203 viral tweets by 8 G7 <sup>b</sup> world leaders	November 17, 2019, to March 17, 2020	Identified three categories of themes: informative, morale-boosting, and political.
Park et al, 2020 [18]	Twitter	43,832 users and 78,233 relationships	Few weeks before February 29, 2020	Assessed speed of information transmission in networks and found that news containing the word “coronavirus” spread faster.
Lwin et al, 2020 [19]	Twitter	20,325,929 tweets from 7,033,158 users	January 28 to April 9, 2020	An examination of four emotions (fear, anger, sadness, and joy) revealed that emotions shifted from fear to anger, while sadness and joy also surfaced.
Pobiruchin et al, 2020 [20]	Twitter	21,755,802 tweets from 4,809,842 users	February 9 to April 11, 2020	Examined temporal and geographical variations of COVID-19–related tweets, focusing on Europe, and the categories and origins of shared external resources.

<sup>a</sup>N/A: not applicable.<sup>b</sup>G7: Group of Seven.

## Methods

### Data Collection

We collected all COVID-19–related tweets from January 1 to May 9, 2020. The Python programming language was used for our data collection and analyses, and Tableau was used as a supplementary tool for visualization purposes. We used three

sources to assemble the tweets required for our analysis. First, we relied on the COVID-19 Twitter data set at IEEE Dataport [21], which contained COVID-19–related tweets from March 20, 2020. Second, we used a Twitter data set posted in GitHub [22] that contained COVID-19–related tweets posted since January 21, 2020. Both these data sets are publicly available and provide a list of tweet IDs for all tweets related to COVID-19. Third, we collected COVID-19–related tweets for

the remaining period, including texts and metadata, from Twitter using GetOldTweets3, a Python 3 library that enables scraping of historical Twitter data [23]. Because we were combining tweets from multiple sources, we used a common set of keywords and phrases that other sources had used: *corona*, *coronavirus*, *covid-19*, *covid19*, and their variants, including their hashtag equivalents. The language-tag setting “EN” and the retweet tag “RT” were used to filter English-language tweets and retweets. We also used the retweets feature in GetOldTweets3 to filter out retweets. Due to restrictions of the Twitter platform, the public data sets contained only the tweet IDs. The process of extracting complete details of a tweet, including metadata, from Twitter using the tweet ID is referred to as hydration, and a number of tools have been developed for this purpose [11]. We used the Hydrator software [24] listed in IEEE Dataport to gather the complete text and metadata of the tweets.

### Data Preprocessing

Our next step was to classify all the tweets posted by individuals versus those that originated from organizations. We first gathered the unique Twitter user IDs of all the Twitter users in our data set. Following the approach outlined in [25], we used a naïve Bayes machine learning model to classify the tweeters into individuals versus organizations. We used a published data set that contained 8945 Twitter users and their profile descriptions, which human coders used to annotate users as individual or institutional [26]. To these data, we added 2000 Twitter user IDs pulled from our data set along with their associated profiles, and we manually annotated them (interrater reliability  $\kappa=0.84$ ). Using the combined data set of 10,945 users, we divided our data set into training versus validation sets using an 80:20 split, and we used these sets to train and test our classifier model, respectively. The naïve Bayes classifier yielded an accuracy of 83.2% with a precision of 0.82, a recall of 0.83, and an F1 score of 0.81; these values were considered satisfactory and are comparable to those in other studies [27–29]. [Multimedia Appendix 1](#) presents the confusion matrix. Our classifier performance was also robust across multiple split strategies for dividing the data set for training and validation. This classifier was then used to identify all the individual users in our full data set, and only tweets posted by individuals were retained for further assessment. We also eliminated duplicate tweets and retweets (filtered using the “RT” tag), resulting in a data set that contained only original tweets posted by individual users. We preprocessed and cleaned the tweets using the Natural Language Toolkit (NLTK), regular expression (RegEx), and the gensim Python library [30]. We removed stop words, user mentions, and links, and we also lemmatized the text of the tweets.

### Topic Modeling and Sentiment Analysis

Topic modeling is an unsupervised machine learning approach that is useful for discovering abstract topics that occur in a collection of textual documents. It helps uncover hidden semantic structures in a body of documents. Most topic modeling algorithms are based on probabilistic generative models that specify mechanisms for how documents are written in order to infer abstract topics. One popular topic modeling

algorithm, latent Dirichlet allocation (LDA), is an unsupervised generative probabilistic method for modeling a corpus of words [31]. A key advantage of LDA is that no prior knowledge of topics is needed. By tuning the LDA parameters, one can explore the formation of different topics and the resultant document clusters. Despite the usefulness of LDA, its outcomes can be difficult to interpret and can drastically vary based on the choice of parameters. With a large corpus of texts, the unsupervised nature of LDA can result in the generation of topics that are neither meaningful nor effective, requiring human intervention and multiple iterations [10]. An improvised variant to traditional LDA, the guided LDA algorithm [32], enables the provision of a set of seed words that are representative of the underlying topics so that the topic models are guided to learn topics that are of specific interest.

We used two broad approaches to prepare the initial set of topics and the seed words for guided LDA. First, we used the extant literature on COVID-19 infoveillance using Twitter to identify a broad set of topics and potential keywords. Second, we performed traditional LDA with multiple numbers of topics as inputs ( $n=10, 20, 30$ , and  $40$ ) iteratively and examined the word lists that were generated. We used both steps to generate a list of topics and anchor words for the guided LDA (see [Multimedia Appendix 2](#)). The GuidedLDA package in Python was used for the topic modeling. Through discussions, the authors then grouped the topics and identified dominant themes. Further, we computed a sentiment score for each tweet using the VADER (Valence Aware Dictionary and sEntiment Reasoner) tool in Python. VADER is a lexicon and rule-based sentiment analysis tool that is specifically attuned to sentiments in social media texts such as tweets [33].

To assess the sentiments of tweets, VADER provides a compound score metric that calculates the sum of all Lexicon ratings that have been normalized between  $-1$  (most extreme negative) and  $+1$  (most extreme positive); this method takes into account both the polarity (positive/negative) and the intensity of the emotion expressed. For each tweet, we classified the sentiment as positive, negative, or neutral based on the compound score. A tweet with a compound score greater than  $0.05$  was classified as positive, a tweet with a score between  $-0.05$  and  $0.05$  was classified as neutral, and a tweet with a score less than  $-0.05$  was classified as negative. To further understand the changes in the sentiment scores over time, we qualitatively analyzed the content of tweets to explore the rationale behind the changes in the compound sentiment scores. The authors manually examined the tweets pertaining to specific topics in weeks in which variations were observed to infer possible reasons for the variations in sentiment.

## Results

We obtained a total of 13,937,906 tweets from 10,868,921 unique users after eliminating 4,085,264 tweets posted by organizations and institutions. Our primary goal was to understand public perceptions and sentiments pertaining to COVID-19; hence, only tweets posted by individuals were retained for analysis.

## Themes and Topics From Text Mining

Our analysis of tweets yielded 26 subtopics, which we framed into 10 broad themes (Table 2). Of the 13,937,906 tweets we examined, 2,858,316 (20.51%) pertained to the theme of the impact of COVID-19 on the economy and markets, followed by spread and growth in cases (2,154,065, 15.45%), treatment and recovery (1,831,339, 13.14%), impact on the health care

sector (1,588,499, 11.40%), and government response to the pandemic (1,559,591, 11.19%). Although tweets related to the theme of racism formed only 4.14% (577,066/13,937,906) of the data, over 500,000 tweets were found to contain racist content. It should be noted that all the tweets we assessed were public discourses pertaining to broader themes, as our data set consisted of tweets posted by individuals about various issues pertaining to the COVID-19 pandemic.

**Table 2.** Themes and topics of COVID-19–related tweets (N=13,937,906), n (%).

Theme and topics	Value
<b>1. Source (origin)</b>	<b>966,372 (6.93)</b>
1.1 Outbreak	489,768 (3.51)
1.2 Alternative causes	476,606 (3.42)
<b>2. Prevention</b>	<b>1,076,840 (7.73)</b>
2.1 Social distancing	575,786 (4.13)
2.2 Disinfecting and cleanliness	501,054 (3.59)
3. Symptoms	558,332 (4.01)
<b>4. Spread and growth</b>	<b>2,154,065 (15.45)</b>
4.1 Modes of transmission	472,749 (3.39)
4.2 Spread of cases	617,946 (4.43)
4.3 Hotspots and locations	459,039 (3.29)
4.4 Death reports	604,331 (4.34)
<b>5. Treatment and recovery</b>	<b>1,831,339 (13.14)</b>
5.1 Drugs and vaccines	442,413 (3.17)
5.2 Therapies	483,109 (3.47)
5.3 Alternative methods	416,530 (2.99)
5.4 Testing	489,287 (3.51)
<b>6. Impact on the economy and markets</b>	<b>2,858,316 (20.51)</b>
6.1 Shortage of products	513,703 (3.69)
6.2 Panic buying	667,320 (4.79)
6.3 Stock markets	535,262 (3.84)
6.4 Employment	505,510 (3.63)
6.5 Impact on business	636,521 (4.57)
<b>7. Impact on health care sector</b>	<b>1,588,499 (11.4)</b>
7.1 Impact on hospitals and clinics	441,895 (3.17)
7.2 Policy changes	615,027 (4.41)
7.3 Frontline workers	531,577 (3.81)
<b>8. Government response</b>	<b>1,559,591 (11.19)</b>
8.1 Travel restrictions	519,406 (3.73)
8.2 Financial measures	485,277 (3.48)
8.3 Lockdown regulations	554,908 (3.98)
9. Political impact	767,486 (5.51)
10. Racism	577,066 (4.14)

## Trends in the Proportions of Positive, Negative, and Neutral COVID-19 Tweets

For each theme pertaining to COVID-19, we examined the trends in the proportions of positive, negative, and neutral tweets over time (Figure S1 in [Multimedia Appendix 3](#)). Of the total tweets concerning the source of the COVID-19 outbreak, the proportions of neutral and negative tweets remained fairly high (approximately 35% to 45%) in the weeks before the WHO announced that COVID-19 was a pandemic. The proportion of positive tweets exceeded those of negative and neutral tweets in the week of the WHO declaration. In the subsequent weeks, the proportion of positive tweets dropped to approximately 25%, whereas the proportions of neutral and negative tweets were approximately 30% to 45%. When we examined tweets pertaining to the prevention of COVID-19, the proportion of positive tweets exceeded those of neutral and negative tweets in almost all the weeks from February 2020, reaching approximately 40% in the beginning of May 2020.

The proportion of negative tweets was considerably higher than those of the positive and neutral tweets for the themes of symptoms (approximately 60%) and of spread and growth in cases (approximately 45%). This pattern was observed for almost all the weeks we examined. In February 2020, over 90% of tweets on the theme of symptoms were negative. Although this trend gradually declined over the next few weeks, it still formed over 50% in the last week of our examination. Similarly, negative tweets about the spread and increase in COVID-19 cases constituted between 40% and 50% from February 2020 until the beginning of May 2020. For the theme of treatment and recovery, the proportion of positive tweets (20%) gradually increased to over 40% over the 17-week period. The negative tweets in the initial weeks (30% to 35%) declined to 25% in April and early May 2020.

We noted a gradual increase in the proportion of positive tweets pertaining to the impact of COVID-19 on the economy and markets over time. Proportions of negative tweets were higher in the months of February and March 2020 but gradually declined to approximately 30% toward the beginning of May 2020.

An increase in the proportion of positive tweets over time was seen for the themes of government response and impact on the health care industry. The theme pertaining to government response captured the Twitter discourse by users concerning various measures taken by different governments to address COVID-19. The proportion of negative tweets about government response was approximately 45% up to mid-March 2020 and then declined to approximately 30% by the first week of May. The proportion of negative tweets on the theme of the political impacts of COVID-19 was considerably higher (>50%) from March 2020. We also noted a substantial proportion of negative tweets on the theme of racism.

## Trends in Sentiments of Themes of COVID-19 Tweets

We examined the trends pertaining to the changes in the sentiment scores of each of our themes and topics over the time period of examination. To plot the trends, we used the average

compound scores by topic and week. Our results are presented in Figure S2 ([Multimedia Appendix 3](#)).

Average compound sentiment scores were found to be negative throughout the time period of our examination for the themes of spread and growth of cases, symptoms, racism, source of the outbreak, and political impacts of COVID-19. In contrast, we saw a reversal of sentiments from negative to positive for the themes of prevention, impact on the economy and markets, government response, impact on the health care industry, and treatment and recovery; the negative sentiment scores in the initial weeks of the COVID-19 outbreak for the aforementioned themes changed to positive scores in the final few weeks of our examination. This reversal of sentiments is noteworthy, as it reflects a collective opinion of a fairly larger set of Twitter users on how the pandemic is being managed by key stakeholders.

## Trends in Sentiments of Topics of COVID-19 Tweets

We further examined the trends in the sentiment scores for topics underlying the broader themes. Compound scores from VADER were averaged over each topic for every week (Figure S3, [Multimedia Appendix 3](#)). This assessment helped us to understand the progression of sentiments for specific topics over the period we examined. To understand the variations in the sentiments, we also qualitatively examined the tweets for weeks in which changes were observed. Sample tweets for each of the themes and topics are shown in [Multimedia Appendix 4](#).

Our analysis revealed a consistently negative average compound score for the topic of the outbreak in Wuhan, China, for all the weeks that we examined. We found that Twitter users frequently referred to the geographical origin of the disease even in the later weeks of our examination. When we examined the topic of alternative causes of the outbreak, we found several tweets about hypothetical causes and conspiracy theories pertaining to COVID-19 (eg, use of SARS-CoV-2 as a bioweapon and origin of the virus in a lab in Wuhan). The average sentiment scores remained negative for weeks until the week of March 22 to 28, then showed a spike to positive values and continued to remain positive until the beginning of May 2020. This positive trend in later weeks is due to tweets dismissing the conspiracy theories that were circulated during the early weeks. Further, the spike in the positive score in the week of March 22 to 28 is partly due to a large number of tweets that contained references to “coronavirus as an act of God” and prayers to end the pandemic, as well as tweets that viewed COVID-19 as “nature’s way to heal the planet.” These types of tweets provide qualitative evidence for the positive sentiment scores we observed in the analysis, such as:

*This virus is certainly God’s call to humanity to wake up and recognise him before it is too late.*

*Wow. Earth is recovering, Air pollution is slowing down, Water pollution is clearing up, Natural wildlife is returning home, Coronavirus is earth’s vaccine. We’re the virus.*

*This planet will surely heal, in the most magical ways. I can feel the vibrations coming on.*

The average compound score for social distancing remained negative until the first week of March. During this time period,

COVID-19 had not yet spread worldwide. However, from the second week of March 2020, the average sentiment score was positive for all the weeks we examined, reflecting that the general public supported and had a favorable disposition toward social distancing as a mechanism to combat the spread of the virus. We observed that several Twitter appealed to others and advocated social distancing measures, such as:

*Kindly stay at home. Wash your hands. Practice social distancing.*

*Ran two miles even when I didn't want to! Made excuses all day! Get out there and do it! But practice social distancing, let's flatten this curve!*

The topic of disinfecting and cleanliness showed average positive sentiment scores for all weeks from the third week of January 2020. We found that Twitter users used gaming strategies such as challenges (eg, #SafeHandsChallenge) involving a chain of users to advocate cleanliness and create broader awareness about the importance of disinfecting and cleanliness. We found that many Twitter users shared tips about disinfecting groceries and products after shopping. We also found that some Twitter users condemned people who did not wear face masks or follow recommended safety protocols in public.

Three of the four topics under the theme of spread and growth exhibited negative average compound sentiment scores. The average compound scores for the topic of death reports were negative for all the weeks, with values ranging between  $-0.2$  and  $-0.5$ . The topic pertaining to spread of cases exhibited negative trends throughout, with average compound scores ranging between  $-0.1$  and  $-0.3$ . The topic of modes of transmission of COVID-19 also showed negative scores across all the weeks, with values between  $0$  and  $-0.2$ . The topic of hotspots and locations for COVID-19 transmission exhibited negative scores until February 2020 but showed positive scores thereafter. Tweets mentioning hotspots of COVID-19 transmission often included mentions of places such as churches, places of religious worship, beaches, events, and festive occasions with mass gatherings; these mentions primarily contributed to the positive values.

All four topics under the theme of treatment and recovery showed negative scores in the initial weeks, which changed to positive average compound scores from April 2020. For the topic of testing, Twitter users reacted negatively to the lack of availability of test kits and testing methods in the initial weeks of the pandemic (eg, tweets containing phrases such as “not all in the hospitals can be tested as they are often short with test kits” or “Many places are not testing people for coronavirus due to test shortage. Its annoying”); however, with the improvement in availability of COVID-19 test kits and test centers worldwide, the sentiment became positive:

*We got tested today. Easy as could be, no waiting, felt really safe, cheek swabs.*

*In lots of states, it's very easy to get tested now, even if you're asymptomatic.*

As more information on the efficacies of drugs such as remdesivir became available, Twitter users' sentiments regarding

drugs and medicines for COVID-19 became positive by the end of March 2020. Twitter users reacted to news about drugs, as can be seen in these example tweets:

*HCQ and Remdesivir, are effective at limiting duration of illness, hospitalization and viral spread if given early.*

*Remdesivir is effective in mitigating COVID-19 symptoms if taken early, ideally pre-hospitalization.*

We also noted a small increase in the average positive compound score for the topic of drugs and medicines in the last week of April; this can be attributed to the US Food and Drug Administration's authorization of emergency use of the antimalarial drug chloroquine to treat COVID-19 on April 27, 2020. Tweets such as these contributed to this positive compound score:

*Hydroxychloroquine protocol: effective, cheap and can be produced in many laboratories. HCQ functions as both a cure and a vaccine.*

However, it should be noted that this authorization was later revoked on June 15, 2020, a date outside the time period covered by our study. The negative sentiments about various therapies in the initial weeks of the pandemic also started to become positive in the third week of March. Twitter users positively reacted and shared information on plasma therapy and associated trials that were being conducted on patients with COVID-19. For instance, some tweets provided examples of positive sentiments from Twitter users:

*We desperately need a treatment for those severely suffering with Coronavirus. Blood plasma could be the answer.*

*The effects of coronavirus are scary for many families, but this treatment of using antibodies from recovered patients could save lives.*

The topic of alternative methods of treatment for COVID-19 (traditional Chinese medicine, Indian Ayurveda, etc.) had mildly positive sentiment scores for most of the time period in our examination.

Among the topics that comprise the theme of impact on the economy and markets, Twitter users' average compound scores for sentiments about the topic of employment remained negative for all the weeks we examined. Many Twitter users posted information about their job loss and unemployment:

*Lost my job a couple weeks ago due to Coronavirus and now it's impossible to find a new job.*

*Well....I just got the call. Lost my job due to Covid.*

Moreover, other users organized crowdfunding campaigns to help people who lost their jobs. Similar negative scores were seen across all the weeks for the topic pertaining to stock markets. Tweets pertaining to the topic of panic buying by consumers showed negative sentiment scores for all the weeks until mid-April, after which the scores began to be positive. Many users shared tweets about long queues and panic buying, as can be seen in these tweets:

*2020 and panic buying has reduced us to this. Waiting in line for at least 2 hours to get pull ups and baby wipes because no one else has them.*

*No panic buying y'all hear that? So leave some damn bread and milk for me please.*

Tweets about the topic of shortages (of food and essential items) swung between positive and negative scores in the first few weeks of the pandemic but became positive from mid-March until early May. Twitter users reacted positively to measures adopted by supermarkets and grocery stores to practice safety measures, as can be seen in this illustrative tweet:

*Yes! Longos Markets requires all customers to wear masks. Went there today, it was a good, safe shopping experience, better than any other store. Will definitely be shopping there again.*

Twitter users' sentiments about the topic of businesses exhibited negative scores in the initial weeks of the pandemic, primarily fueled by news about closures and losses. However, this sentiment score changed to positive in the first week of March 2020. The positive score seen here reflects the adaptation of businesses to the new pandemic and their reopening and revival across different countries. Tweets such as the following provide indicators of positive sentiments of users about reopening of businesses:

*Most of HK open for business now. Emphasis on testing and tracing.*

*Open for business. Trusting the people to take care of themselves. Freedom smells sweet.*

Sentiment scores pertaining to the topic of hospitals and clinics largely remained negative throughout the time period of our examination. Tweets about lack of beds, facilities, NS ventilators, overcrowding of patients, and the struggles of health care institutions to cater to the influx of COVID-19 patients contributed to the negative sentiment scores. Illustrative tweets about these negative sentiments include:

*Madrid hospitals now have double the number of intensive care patients than beds. Means you can no longer get intensive care in a Madrid hospital.*

*Lack of safety gear for healthcare workers, shortage of beds and doctors, inadequate labs to conduct tests - our healthcare system is very fragile!!*

However, we noted a reversal in the trends of sentiment scores for the topic of frontline health care workers. Twitter users' negative sentiments until the end of March 2020, reflecting the lack of personal protective equipment and gear for health care professionals, health worker burnout, and increased workload for health care workers, became positive in April and early May 2020 as the situation improved. We saw tweets in the initial period of the pandemic with negative sentiments, such as "the knighted geniuses at the top of the NHS can't even organise protective equipment for our doctors and nurses". In the later weeks of our examination, hashtags such as #coronawarriors and tweets hailing the services of frontline workers (eg, "Deepest gratitude to the #CoronaWarriors who are working tirelessly in these difficult times") contributed to positive sentiment scores. The topic of health policy, which reflects the

newer safety guidelines, protocols, and policies pertaining to patients with COVID-19 implemented by health care organizations, exhibited a negative trend in the early period, with tweets such as:

*The ventilator situation is even more dire than we know. Not every hospital had an allocation policy in place.*

*Spain has begun a no ventilator policy for anyone over 65.*

However, this topic showed a positive trend after the end of March 2020 as many agencies, governments, and health care institutions began to establish clear policies for treating patients with COVID-19. In the later weeks of our examination, many hospitals had framed clearer guidelines for use of masks, visitations, and restrictions pertaining to COVID-19. These illustrative tweets point to a possible rationale behind the positive sentiments pertaining to the topic of health policy in the later weeks of our examination:

*The hospital has an understandable policy during this crisis of limiting visitation for the safety of all & to reduce use of critical PPEs.*

*Spouse can't visit under hospital's no visitation policy. Psychologically excruciating but family all recognize it's the right thing, and hard to limit exceptions once you start"*

Twitter users' sentiments about the topic of travel restrictions imposed by governments worldwide were largely negative for most of the weeks we examined, except for the week of March 22 to 28, 2020. In this week, governments in populous countries such as India and Canada announced travel restrictions such as flight suspensions and isolation and quarantine measures for individuals entering these countries. Tweets indicated positive sentiments about travel restrictions:

*I believe it was a good move from India to have a complete travel restriction to all countries. When we don't have the health systems to treat huge populations, the best thing to do is to shut doors.*

*The fine for breaking self-quarantine / self-isolation in BC, Canada is \$25,000 AND jail time. Canada is taking travel and quarantine very seriously. Great job.*

Many Twitter users welcomed travel bans and restrictions and expressed positive sentiments about them.

Except for the first two weeks of April, the average compound sentiment scores about the topic of lockdown regulations remained negative in most of the weeks we examined. Twitter users' sentiments about stay-at-home orders, shutdowns, and lockdowns of complete cities were negative. This can be seen from these sample tweets:

*This lockdown really does do bad things to good peoples mental health, trying to stay positive is a task in itself when this shite feels never ending.*

*Lockdown extended for another 3 weeks I hate it here.*

However, the sentiment scores were positive in the weeks in which different governments announced financial measures

such as stimulus payments to people affected by closures and lockdowns. In some tweets, users expressed positive sentiments about the financial relief measures to help individuals suffering due to the impact of COVID-19:

*I got my stimulus check today! Woohoo!*

*Zoe and I finally received our stimulus/relief check from the federal government.*

*India is preparing a stimulus package that would put money directly into the accounts of more than 100 million poor people and support businesses hit the hardest by the 21-day lockdown.*

## Discussion

### Principal Findings

This study joins the growing body of inveillance studies on COVID-19 that examine social media data to uncover public opinions about the pandemic. We used a corpus of over 13 million tweets from January until the first week of May 2020 to uncover the trends in sentiments regarding various themes and topics. Our study is comprehensive, covering 26 different topics underlying COVID-19–related tweets under 10 broader themes. In response to a call made by Liu et al [34], we combined the topic modeling approach with sentiment analysis to observe the trends in sentiments for various themes and topics over time. By assimilating the collective opinions of several million users, we found interesting patterns in the trends pertaining to sentiments of themes and topics of COVID-19–related tweets.

We combined two publicly available sources with our own search to assemble a unique data set that contained English-language tweets about various topics associated with COVID-19. We further used a naïve Bayes classifier to segregate tweets made by individuals. We employed guided LDA to identify the underlying topics and associated themes, and we also examined the sentiments associated with the tweets and their changes over time.

Our key finding is that the impact of COVID-19 on the economy and markets was the most discussed issue by Twitter users. The number and proportions of tweets on this theme were remarkably higher than those of tweets on the other themes we uncovered. Further, users' sentiment was negative until the third week of March but gradually became positive in the final weeks we studied. Users' initial negative sentiments about shortages, panic buying, and businesses gradually turned positive from April 2020. Users started feeling positive about government responses to contain the pandemic, including financial measures to support and assist them in dealing with the disease outbreak.

Twitter users felt negative about continued spread and growth of the number of cases and the symptoms of COVID-19. However, we also found that Twitter users were more positive about treatment of and recovery from COVID-19 in later weeks than they were during the earlier stages of the pandemic. They expressed positive feelings by sharing information on testing, drugs, and newer therapies that show promise to contain the outbreak. Another notable finding is the Twitter users' gradual change in sentiment from negative to positive regarding

COVID-19 prevention measures such as social distancing and cleanliness. Twitter users who initially expressed negative sentiments regarding COVID-19's impacts on the health care sector, comprising hospitals, clinics, and frontline workers, gradually became positive in the later weeks.

Another key finding of our study is the continued negative sentiments about political fallouts due to COVID-19. Although leaders worldwide are struggling to contain the pandemic, we noted that Twitter users felt negative about how COVID-19 was used for political purposes. Similarly, we noted strong negative sentiments about racist content in users' tweets.

Our study offers several insights for health policy makers, administrators, and officials who are managing the impact of the COVID-19 pandemic. Identification of topics and associated sentiment changes provide pointers to how the general public are reacting to specific measures taken to tackle the pandemic. Variations in sentiment scores serve as a feedback mechanism for assessing public perceptions of various measures taken with respect to social distancing, cleanliness and disinfecting, lockdowns, travel restrictions, and efforts to revive the economy. Public sentiments have also started to become positive about COVID-19 testing, treatment, and vaccines as well as health policies. Our study shows that observing aggregate sentiments and changes in trends via social media posts can offer a cost-effective, timely, and valuable mechanism to gauge public perceptions regarding policy decisions being made to address the pandemic.

### Limitations

This study has a few limitations that should be kept in mind while interpreting the results. We relied on a large data set that was partly compiled by us and included two other publicly available data sets. These data sources contained tweets from varying dates and used different search terms and search strategies to gather the tweets. Our analysis may have inadvertently omitted certain COVID-19–related tweets that were not captured by the data sources. In addition, COVID-19–related tweets from users who chose to make their accounts private were not included in our study. Further, we did not consider any geographical boundaries when examining the tweets. Studies focusing on tweets from specific countries can find different topics and sentiments that reflect country-specific opinions and concerns. We also restricted our study to tweets in the English language and to those posted by individuals. It should be noted that our naïve Bayes classifier with over 80% accuracy helped us identify tweets posted by individuals. It is possible that some individual users posted tweets on behalf of organizations, and these tweets may have been included in our data set. A more refined approach with deep learning techniques to identify individual tweets can aid in classifying and assembling a tweet data set with increased accuracy. As a future research extension, tweets posted by organizations could be another frame of reference to understand their concerns and sentiments. Another important limitation is that our findings are reflective of Twitter users, who are fairly familiar with social media and use of technology. The results may not generalize to the larger worldwide population of people who do not use Twitter.

## Conclusion

As COVID-19 continues to affect millions of people worldwide, our study throws light on dominant themes, topics, sentiments and changing trends regarding this pandemic among Twitter users. By examining the changing sentiments and trends surrounding various themes and topics, government agencies,

health care organizations, businesses, and leaders who are working to address the COVID-19 pandemic can be informed about the larger public opinion regarding the disease and the measures they have taken so that adaptations and corrective courses of action can be applied to prevent and control the spread of COVID-19.

## Abstract

**Background:** Physical distancing measures taken to contain COVID-19 transmission may substantially reduce physical activity levels and cause individuals to adopt a more sedentary lifestyle.

**Objective:** The objective of this study is to determine if there was any change in daily steps, an important component of daily physical activity, and examine risk factors for frequent low daily steps during the COVID-19 epidemic.

**Methods:** We used data collected from the Step Study, a population-based longitudinal study of walking activity among residents aged  $\geq 40$  years in Changsha, China. Daily steps were collected via a smartphone linked to WeChat, a social networking platform. We plotted mean daily steps and the prevalence of low daily steps ( $\leq 1500$  steps/day) 30 days before (reference period) and 30 days after (epidemic period) January 21, 2020 (date of the first COVID-19 case diagnosed in Changsha), and compared it with the same corresponding period from 2019. We examined the association of risk factors with the prevalence of frequent low daily steps ( $\leq 1500$  steps/day for  $\geq 14$  days) using logistic regression.

**Results:** Among 3544 participants (mean age 51.6 years;  $n=1226$  females, 34.6%), mean daily steps dropped from 8097 to 5440 and the prevalence of low daily steps increased from 3% (2287/76,136 person-day) to 18.5% (12,951/70,183 person-day) during the reference and epidemic periods, respectively. No such phenomenon was observed during the corresponding period in 2019. Older age ( $P$  for interaction=.001) and female sex ( $P$  for interaction<.001) were both associated with a higher prevalence of frequent low daily steps and were more pronounced during the epidemic period. More education was associated with a lower prevalence of frequent low daily steps during the reference period but not the epidemic period ( $P$  for interaction=.34). Body mass index or comorbidity were not associated with frequent low daily steps during either period.

**Conclusions:** Daily steps of Changsha residents aged  $\geq 40$  years dropped significantly during the COVID-19 period, especially among older adults and females. Although successful physical distancing, measured by the rapid downward trend in daily step counts of residents, played a critical role in the containment of the COVID-19 epidemic, our findings of an increase in the prevalence of frequent low daily steps raise concerns about unintended effects on physical activity.

## KEYWORDS

COVID-19; pandemic; physical distancing; steps; walking activity

## Introduction

COVID-19 has caused morbidity and mortality worldwide [1]. To control this highly contagious infectious disease, many countries have implemented “physical distancing” and “shelter-in-place” measures to contain COVID-19 transmission [2,3]. However, such measures may substantially reduce physical activity levels and cause individuals to adopt a more sedentary lifestyle [4].

There is ample evidence that regular physical activity is crucial for health, with physical inactivity characterized as the fourth leading cause of global mortality [5]. Results from the National Health and Nutrition Examination Survey (NHANES) and the Women’s Health Study both showed that a lower number of daily steps, which is an important component of daily physical activity, was significantly associated with higher all-cause mortality [6,7]. Studies also demonstrated that individuals who walked less than 1500 daily steps for 14 days were at a higher risk of muscle mass loss and low insulin sensitivity [8,9]. To date, several studies have reported changes in daily steps of residents in areas affected by COVID-19 [10–14]; however, none of these studies specifically described the prevalence of frequent low daily steps ( $\leq 1500$  steps/day for  $\geq 14$  days over one month) [8,9], a strong predictor of poor health outcomes, and examined its risk factors.

Using data collected from the Step Study, a longitudinal study conducted among the urban residents of Changsha, China, we therefore described the trends of daily steps around the COVID-19 epidemic period in 2020 and compared them with that of a similar period one year earlier. We examined the relationships between several sociodemographic factors, anthropometric factors, and comorbidity and the prevalence of frequent low daily steps.

## Methods

### Study Population

The Step Study (registration number: ChiCTR1800017977) is a population-based longitudinal study initiated in September 2018 in Changsha, China. The aims of the Step Study were to describe patterns of walking activity, factors related to walking activity, and its sequelae among the community-living population. Participants in the Step Study comprised individuals who had their annual physical checkup at Xiangya Hospital of Central South University in Changsha, China [15,16]. To be eligible for the Step Study, participants had to meet the following criteria: (1) be a resident of Changsha; (2) be aged  $\geq 40$  years; (3) own a personal smartphone and have a WeChat

account; and (4) be willing and able to give consent. Individuals with severe mental illness were ineligible. During each annual physical checkup, participants were queried about their sociodemographic and lifestyle factors, comorbidities, health-related symptoms and signs (eg, joint pain), and ability to perform daily activities. They also received clinical examinations and laboratory tests, including physical function tests (eg, lower limb muscle strength measurements).

For each participant, walking activity measured as daily step counts was collected through a smartphone linked to WeChat. WeChat is a multipurpose social network platform (Tencent Inc) with approximately 1.1 billion monthly active users in China [17]. One of its apps can extract daily step count information from the accelerometer sensor in a smartphone. Thus, if a participant is a WeChat user and wears a smartphone, his/her step counts can be captured by WeChat’s app.

### Study Outcome

The outcome variable was daily step counts recorded by the accelerometer sensor in the smartphone and extracted by WeChat. To be eligible for the current analysis of daily step counts, we required participants to wear their smartphone for  $\geq 10$  hours on a given day, a standard convention for measuring daily walking [18,19]. The smartphone wear time was calculated as the difference between the times of the first recorded step count and the last recorded step count each day. This algorithm was used in the Activity Inequality Project to calculate daily step counts for more than 700,000 individuals across 111 countries [19]. Participants with no valid daily step count were excluded in the current analysis. We defined a low daily step count as  $\leq 1500$  steps/day [8,9]. If a participant had  $\geq 14$  days of low daily step counts over a 30-day period, we considered that person as having experienced frequent low daily steps [8,9].

We conducted two validation studies to assess the accuracy of daily step counts collected from WeChat. To determine the accuracy of steps measured at various walking speeds by iOS and Android devices, we visually counted steps from 14 subjects walking on a treadmill at 4.8, 6.4, 8.0, and 9.6 km/h while subjects held/wore smartphones in different positions (ie, pants pocket, hand, and arm). These methods are consistent with previous studies [20–22]. We found step count accuracy to be high, with intraclass correlation coefficients (ICCs) ranging from 0.64 to 0.99. Second, we assessed the accuracy of step counts extracted from WeChat in free-living conditions. Specifically, 36 participants from the Step Study were instructed to wear both a Fitbit Charge 3 (Fitbit Inc), as the criterion measure [23], and their personal smartphone for 7 consecutive days [24]. The results also demonstrated a moderate to high

agreement on step counts, with ICCs ranging from 0.67 to 0.81. Detailed information from these validation studies is shown in [Multimedia Appendix 1](#).

### Study Exposures

Information on age, sex, educational level, height, weight, and comorbidity were obtained from the annual physical checkup visit. Body mass index was calculated. The modified Charlson Comorbidity Index (CCI) was computed based on self-reported comorbidities [25].

### Statistical Analyses

On January 22, 2020, one day after the first case of COVID-19 was diagnosed in Changsha (January 21, 2020, ie, the index day) the municipal government issued an emergency notice to implement physical distancing measures (ie, staying at home, closing schools, working from home if possible, travelling only when necessary, and cancelling mass gatherings) [26,27]. In this analysis, we defined the time interval from January 22 to February 20, 2020 (30 days after the index date), as the COVID-19 epidemic period, and the time interval from December 22, 2019, to January 20, 2020 (30 days before the index date), as the reference period. Since the COVID-19 epidemic occurred around the holiday season of Chinese New Year, for the purpose of comparison we also used data collected between January 2 and March 3, 2019, which corresponded to the same Chinese lunar calendar period. Details of the selection of study periods are shown in [Multimedia Appendix 2](#).

First, we plotted the mean daily steps from December 22, 2019, to February 20, 2020 (around COVID-19 epidemic period), and mean daily steps from January 2 to March 3, 2019 (historic comparison period), respectively, using a 3-day moving average smooth method [28]. Second, we used the same approach to plot the prevalence of low daily steps ( $\leq 1500$  steps/day) for the corresponding periods. We calculated the mean difference (MD) and its 95% confidence interval for daily steps using Generalized Estimating Equations (GEE) between the epidemic period and reference period in 2020, and the corresponding periods in 2019, respectively. Specifically, we included each qualified daily step count into the GEE model using the PROC GENMOD procedure

in SAS (Version 9.4; SAS Institute) with identity links to calculate the MD and its 95% CI between the epidemic and reference periods. We added the REPEATED statement to account for correlation of the repeated measurements of individuals' daily step counts [29].

Similarly, prevalence ratios (PR) were calculated for the prevalence of low daily steps ( $\leq 1500$  steps/day) between the two comparative time periods in 2019 and 2020, respectively [30]. Finally, we estimated the prevalence of frequent low daily steps ( $\leq 1500$  steps/day for  $\geq 14$  days over 30 days) during epidemic and reference periods and examined whether age, sex, BMI, educational level, and comorbidity were associated with the prevalence of frequent low daily steps using logistic regression. We tested the additive effect measure of modification of physical distancing with each of the risk factors mentioned above by adding an interaction term in the regression model [31].

All  $P$  values for interaction were two-sided and  $P$  for interaction  $< .05$  was considered statistically significant for all tests. All statistical analyses were conducted using SAS (Version 9.4).

### Ethical Considerations

This study was approved by the Ethics Committee of Xiangya Hospital, Central South University (#201806910), and written informed consent was obtained from study participants.

## Results

A total of 7262 Changsha residents aged  $\geq 40$  years had a physical checkup at the study center between September 2018 and January 2020, and 4145 of them (57.1%) had a WeChat account and agreed to participate in the Step Study. Of these, 3544 with at least one valid daily step count during the study period were included in the analysis ([Table 1](#)). The mean age of participants was 51.6 (SD 8.9) years, 1226 (34.6%) participants were females, and the mean BMI of participants was 24.0 (SD 4.3)  $\text{kg/m}^2$ . Overall, 2616 (73.8%) participants were Android users, 765 (21.6%) were iOS users, and 163 (4.6%) participants' phone types were unknown.

**Table 1.** Baseline characteristics of included participants.

Characteristics	Total sample (N=3544)	Males (n=2318)	Females (n=1226)

<sup>a</sup>N=3202.<sup>b</sup>N=2554.

As shown in [Figure 1](#) and [Table 2](#), daily steps (mean 8097 steps/day, range 6942-9153 steps/day) during the reference period (30 days prior to the COVID-19 epidemic in 2020) were similar to that during the corresponding period in 2019 (mean 7872 steps/day, range 6649-8912 steps/day). However, the daily steps decreased substantially after implementing physical

distancing measures, from 8624 steps/day on the day before the index day to 4121 steps/day on Day 4 after the index day; this trend continued during the rest of the epidemic period. Compared with the reference period, the mean daily steps dropped by 2678 steps (95% CI 2582-2763). However, this trend was not observed during the corresponding period in 2019.

**Figure 1.** Average daily step count around the Chinese Lunar New Year period among participants in 2019 and 2020. Day 0 represents the index date; in 2020, this represents the date of the first COVID-19 case diagnosed in Changsha.

**Table 2.** Associations of time period with daily step count.

Time period	2019 daily step count		2020 daily step count	
	Mean (SD)	Mean difference (95% CI) <sup>a</sup>	Mean (SD)	Mean difference (95% CI) <sup>a</sup>
Reference	7872 (4842)	0 (reference)	8097 (4793)	0 (reference)
Epidemic	7472 (4979)	-413 (-501 to -325)	5440 (4571)	-2672 (-2763 to -2582)

<sup>a</sup>Mean differences were adjusted for age and sex.

Figure 2 and Table 3 present the prevalence of low daily steps ( $\leq 1500$  steps/day) in 2019 and 2020. The prevalence of low daily steps was similar during the reference period in 2020 (3.0%, 2287/76,136 person-day) and the corresponding period in 2019 (3.3%, 1006/30,647 person-day). In contrast, the prevalence of low daily steps increased substantially after implementing physical distancing measures, from 2.0%

(53/2693) on the day prior to the index date to 25.5% (639/2505) on Day 4 after the index date; this trend continued during the rest of the follow-up period. Compared with the reference period, the PR of low daily steps was 6.2 (95% CI 5.8-6.7). However, no such trend was observed during the entire historic comparison period in 2019.

**Figure 2.** Prevalence of low daily step count ( $\leq 1500$  steps/day) around the Chinese Lunar New Year period among participants in 2019 and 2020. Day 0 represents the index date; in 2020, this represents the date of the first COVID-19 case diagnosed in Changsha.

**Table 3.** Associations of time period with prevalence of low daily steps ( $\leq 1500$  steps/day).

Time period	2019 low daily steps		2020 low daily steps	
	Person-day, n (%)	Prevalence ratio (95% CI) <sup>a</sup>	Person-day, n (%)	Prevalence ratio (95% CI) <sup>a</sup>
Reference	1006 (3.3)	1.0 (reference)	2287 (3.0)	1.0 (reference)
Epidemic	1488 (5.1)	1.6 (1.4-1.7)	12,951 (18.5)	6.2 (5.8-6.7)

<sup>a</sup>Prevalence ratios were adjusted for age and sex.

As shown in Table 4, only 12 (0.4%) of 2879 participants had walked less than  $\leq 1500$  steps/day for 14 days or more (frequent low daily steps) during the 2020 reference period; however, the prevalence of frequent low daily steps increased to 7.4% (196/2655) during the COVID-19 epidemic period, after physical distancing measures were implemented. Older age ( $P$  for interaction=.001) and female sex ( $P$  for interaction<.001) were both associated with a higher prevalence of frequent low daily steps than their counterparts during the reference and COVID-19 epidemic periods, and such associations were more

pronounced during the epidemic period. Participants with a university education or more had a lower prevalence of frequent low daily steps than those with only high school or less education during the reference period but this was not observed during the COVID-19 epidemic period. During the physical distancing period, no significant interaction between education and prevalence of frequent low daily steps was observed ( $P$  for interaction=.34). There was no apparent association of either BMI or CCI with the prevalence of frequent low daily steps during either period.

**Table 4.** Association of prevalence of frequent low daily steps cases ( $\leq 1500$  steps/day for  $\geq 14$  days) and basic characteristics.

## Discussion

### Principal Findings

Using objective data collected from the longitudinal Step Study, we found that daily steps among middle-aged and older residents in Changsha dropped rapidly and substantially (2672 fewer daily steps on average) after implementing physical distancing measures during the COVID-19 epidemic period. In addition, more than 7% (196/2655) of residents had walked  $\leq 1500$  steps/day for  $\geq 14$  days over the one-month epidemic period compared with 0.4% (12/2879) of residents in the month prior to the epidemic. The reduction of steps/day during the COVID-19 epidemic was more pronounced among older adults and females.

### Comparison With Previous Studies

To date, several studies have reported changes in daily steps during the COVID-19 epidemic [10-14]. One worldwide study based on a smartphone app (Argus) showed that mean daily steps in different regions decreased by 5.5% and 27.3% (287 and 1432 steps/day, respectively) within 10 and 30 days after the COVID-19 pandemic was declared [10]. Another study that

used a wristwatch with an embedded accelerometer (Withings) demonstrated a marked decrease in daily steps (from 25% to 54%) following the official dates of home confinement in countries adopting a total lockdown [11]. Similar findings were also reported in other countries [12-14]. Our results demonstrated that such a change also occurred in the Chinese population. Furthermore, we examined daily steps within the same period in the previous year and observed no such change during this period, which enabled us to minimize the potential impact of the holiday season of Chinese New Year on daily steps.

In addition, we found that the effect of implementation of physical distancing measures on frequent low daily steps was more pronounced among older adults and females. Previous studies have examined associations between walking activities and sociodemographic factors, anthropometric factors, and comorbidity. The results from the NHANES report indicated that those of advancing age (OR 1.95, per 16.7-year increments) and female sex (OR 1.86) both had higher odds of walking less than 5000 steps/day [32]. Another study found that education was associated with increased walking activity, with one additional year of education associated with a 560 daily steps

increase [33]. Our results corroborate these findings. However, after the implementation of physical distancing measures, the prevalence of frequent low daily steps among residents with university or above education was similar to those with high school or below education, suggesting both groups followed physical distancing measures and reduced their outdoor walking activities. Nevertheless, the magnitude of relative increase in the prevalence of frequent low daily steps during the COVID-19 epidemic appeared to be greater among residents with university or above education than among those with high school or below education, indicating the former are more likely to follow instructions and communicate effectively with health providers [33,34]. Previous studies also showed that both BMI and comorbidities (eg, hypertension and diabetes) were associated with fewer daily steps [6,7,35,36], but this was not the case in the present study, nor was any association modified by the implementation of physical distancing measures.

### Public Health Implications

Physical distancing measures play a critical role in containing COVID-19 transmission and monitoring population mobility data can provide evidence as to whether people are complying with these measures [37]; however, the impact of physical distancing on other aspects of daily life should not be overlooked. Recently, Hall and colleagues [4] commented that “The world is experiencing an extraordinary, life-altering challenge due to the COVID-19 pandemic. Many countries have become accustomed to a new normal – ‘social distancing’ and ‘shelter-in-place’ are now a part of everyday vernacular and life.” The authors warned that this health crisis has the potential to further impact and accelerate the pandemic of physical inactivity and sedentary behavior.

Our data showed that average daily steps among residents of Changsha dropped by more than 30% (from 8097 to 5440) during the COVID-19 epidemic period after implementation of physical distancing measures. These data raise concerns about the potential adverse effects of such measures on health and well-being. Previous studies have showed that higher daily steps are associated with better cardiometabolic profiles and lower all-cause mortality [6,7,38]. Other studies have also found that a decrease in daily steps of 2000 steps, irrespective of previous habitual step counts, increases the risk of insulin sensitivity and higher cardiovascular events [39,40]. Thus, our findings have important implications for public health recommendations and the prevention of other health crises during the COVID-19 pandemic. Furthermore, our data showed that the reduction in daily steps is much more common among older adults and females. In general, older adults and females are more likely to develop sedentary behaviors, placing them at greater risk of various diseases related to inactivity [32,41]; thus, the worsening trend of physical inactivity during the COVID-19 epidemic period compounds the risk of sequelae related to a sedentary lifestyle.

It is uncertain as to how long it will take to completely control the COVID-19 pandemic worldwide. If similar trends toward a sedentary lifestyle are seen in other countries, the avoidance of further sedentary lifestyle behaviors and promotion of regular physical activity during this time are an urgent global public

health issue. It is also unknown whether the observed decline in daily walking is a temporary phenomenon that may revert back to baseline levels after the disease is under control; thus, further longitudinal studies are needed so that evidence-based strategies can be developed and implemented to encourage greater participation in regular physical activity.

### Strengths and Limitations

Several strengths of our study are noteworthy. First, we used data from a large population-based longitudinal study (Step Study), which allowed not only investigation of COVID-19–related changes in daily step counts from over 3500 residents, but also inclusion of a historic comparison period from the prior year to account for a secular trend in daily step counts. Second, the study took advantage of a social network platform (WeChat) to capture daily step count data via smartphone in real time among the community-living population. As a smartphone has become a daily necessity for most adults, this approach allowed long-term monitoring of daily step count trends. This contrasts to previous studies using wearable devices (accelerometers) that generally only collect step count data for a relatively short time (eg, a week or less) [42]. It can be challenging to extrapolate such short-term data to describe step count patterns over a long period owing to various potential confounders [42].

Potential limitations of our study also deserve comment. First, the WeChat app may underestimate daily step counts because some individuals may not always carry their smartphone with them [43], especially when participants were housebound. Thus, some light walking activities at home may not be captured. However, one previous study reported that the average wear time of smartphones among Chinese citizens was more than 13 hours during the day time, indicating that most walking activities should be captured by a smartphone [19]. Second, although our validation study demonstrated that daily step counts collected from iOS and Android devices both showed close agreement with actual step counts under controlled laboratory settings, previous studies found that iOS and Android devices have different accuracies in capturing the daily step count under free-living conditions [44]. This could have led to misclassification of daily step counts in this study. Third, participants in our study were slightly younger (51.6 versus 54.8 years) and more likely to be male (65.4% versus 51.2%) than those who are aged  $\geq 40$  years and live in Changsha, according to the latest census data in 2010. However, our results showed that the prevalence of frequent low daily steps increased more among women and older people, suggesting that the overall prevalence of frequent low steps among all residents in Changsha aged  $\geq 40$  years may be even higher than what was reported in our study. Fourth, participants in our study were urban residents in Changsha who came to Xiangya Hospital for their annual health checkup. The percentage of WeChat users among these individuals (57.1%) was higher than that of the population with the same age range in China (41.5%) [45]. Thus, our findings may not be generalizable to residents living in other parts of China, especially those living in rural areas. Finally, we were unable to capture the intensity of steps (eg, slow versus fast steps); however, total steps/day has recently been shown

to be an important predictor of mortality independent of step intensity [6].

## Conclusions

Using data collected from a large population-based longitudinal study, we demonstrated that walking activity, indicated by daily step count, decreased rapidly and substantially during the COVID-19 epidemic period among middle-aged and older adult

Chinese residents living in urban areas. These results suggest that appropriate strategies need to be taken to encourage residents to actively engage in regular physical activity while maintaining personal hygiene and physical distancing. They also call for further studies to evaluate whether the low levels of walking activity observed following the implementation physical distancing measures will be maintained and whether they will have significant adverse impacts on health outcomes.

## Acknowledgments

This work was supported by the National Natural Science Foundation of China (81772413, 81702207, 81702206, 81930071), the National Health and Medical Research Council Principal Research Fellowship, the National Key Research and Development Project (2018YFB1105705), and the Key Research and Development Program of Hunan Province (2018SK2070, 2018SK2071). No funding bodies had any role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

The authors thank Xiaoxiao Li, Wei Li, Huizhong Long, Jiatian Li, Haochen Wang, Yuqing Wang, Ning Wang, Bei Xu, Zidan Yang, Jing Wu, Zhenglei Zhu, and Xin Huang (Xiangya Hospital) for their contribution to this study.

## Authors' Contributions

GL and CZ had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. CZ and GL are joint corresponding authors. All authors have read the manuscript, provided critical feedback on intellectual content, and approved the final manuscript. CZ, GL, YW, and YZ contributed to the concept and design. All authors contributed to the acquisition, analysis, or interpretation of data. YW, CZ, GL, and YZ drafted the manuscript. All authors critically revised the manuscript for important intellectual content. YZ and JW contributed to statistical analysis. CZ, GL, and JW obtained funding. YW, CZ, and GL provided administrative, technical, or material support. GL, YZ, and CZ provided supervision.

## Conflicts of Interest

None declared.

## Abstract

**Background:** The ongoing pandemic has placed an unprecedented strain on global society, health care, governments, and mass media. Public dissemination of government policies, medical interventions, and misinformation has been remarkably rapid and largely unregulated during the COVID-19 pandemic, resulting in increased misinterpretations, miscommunication, and public panic. Being the first full-scale global pandemic of the digital age, COVID-19 has presented novel challenges pertinent to government advice, the spread of news and misinformation, and the trade-off between the accessibility of science and the premature public use of unproven medical interventions.

**Objective:** This study aims to assess the use of internet search terms relating to COVID-19 information and misinformation during the global pandemic, identify which were most used in six affected countries, investigate any temporal trends and the likely propagators of key search terms, and determine any correlation between the *per capita* cases and deaths with the adoption of these search terms in each of the six countries.

**Methods:** This study uses relative search volume data extracted from Google Trends for search terms linked to the COVID-19 pandemic alongside *per capita* case and mortality data extracted from the European Open Data Portal to identify the temporal dynamics of the spread of news and misinformation during the global pandemic in six affected countries (Australia, Germany, Italy, Spain, the United Kingdom, and the United States). A correlation analysis was carried out to ascertain any correlation between the temporal trends of search term use and the rise of *per capita* mortality and disease cases.

**Results:** Of the selected search terms, most were searched immediately following promotion by governments, public figures, or viral circulation of information, but also in relation to the publication of scientific resources, which were sometimes misinterpreted before further dissemination. Strong correlations were identified between the volume of these COVID-19-related search terms (overall mean Spearman rho 0.753, SD 0.158), and *per capita* mortality (mean *per capita* deaths Spearman rho 0.690, SD 0.168) and cases (mean *per capita* cases Spearman rho 0.800, SD 0.112).

**Conclusions:** These findings illustrate the increased rate and volume of the public consumption of novel information during a global health care crisis. The positive correlation between mortality and online searching, particularly in countries with lower COVID-19 testing rates, may demonstrate the imperative to safeguard official communications and dispel misinformation in these countries. Online news, government briefings, and social media provide a powerful tool for the dissemination of important information to the public during pandemics, but their misuse and the presentation of misrepresented medical information should be monitored, minimized, and addressed to safeguard public safety. Ultimately, governments, public health authorities, and scientists have a moral imperative to safeguard the truth and maintain an accessible discourse with the public to limit fear.

chloroquine; coronavirus; COVID-19; fake news; Google Trends; ibuprofen; infodemiology; misinformation

**Introduction**

The COVID-19 pandemic has encouraged an unprecedented international panic. Since its emergence in late 2019 in the Hubei Province of China, COVID-19 has spread worldwide, and its associated infectivity and death rate have challenged world leaders, health care systems, and the public [1,2]. Unlike comparable previous pandemics, such as the Spanish flu in 1918, the internet has provided to the public a source of connectivity and a means to rapidly acquire emerging information about the virus [1]. The information available is, however, not always verifiable or scientifically supported.

The dissemination of government policy and cutting-edge medical research is unquestionably important in the remit of a global pandemic, but misinterpretation is commonplace. The desperation of the public encourages the opportunistic adoption of unverified medical interventions. The misuse and misrepresentation of such information presents a critical challenge to governments and to the public. Equally, the public may seek out and enable misinformation (eg, the virus being spread by 5G towers [3]), which is rapidly distributed via social media [4]. The increased dependence of the public on social media and other inherently biased sources of information may inflate the rate at which misinformation spreads, possibly fostering disenfranchisement with government and health care organizations [5-7]. This could ultimately provoke disregard toward restrictions enforced for public safety, lead to reduced supplies of medicines and personal protective equipment (PPE), or potentially even to reduced medical engagement and worsening of chronic conditions, increasing pressure on already strained health care providers.

Given the rapid flow of digital information during the COVID-19 pandemic, real-time data collection and analysis provides an unparalleled opportunity to assess the public response to information as it emerges. Through internet-derived information from social media, news, and search engine use, public reactions and perceptions can be assessed in real time [4,8-11]. Google Trends (GT) has been used for not only the analysis of epidemiologically relevant data regarding influenza [9] and disease outbreaks [10] but also, more recently, COVID-19 [11]. By assessing the temporal dynamics of search terms related to the pandemic, particularly those relating to misinformation, it is possible to infer likely sources, propagators, and impacts. This study employs GT for the analysis of search terms used during the COVID-19 pandemic relating to

government policy, potential treatments, and misinformation, specifically in three English and three non-English speaking countries: Australia, the United Kingdom, the United States, Germany, Italy, and Spain. The aims of this study are to identify any correlation between the relative search volumes (RSVs) for information relating to the first wave of the pandemic, and to discuss these search volumes in the context of emerging news, alongside the prevalence of cases and deaths in each of the six focal countries.

**Methods****Mortality, Case, and Testing Data Extraction**

Worldwide mortality and case data, and country population sizes were extracted from the European Union Open Data Portal [12] on April 17, 2020 (Figure 1). Data were retained only for the six focal countries. Dates for which no data were available from November 1, 2019, to the first recorded numbers for that country were marked as zero. *Per capita* cases and deaths were also calculated using the included population sizes and retained for later analyses and figures. *Per capita* values, although not widely reported by the media at this time, were used in this study to correct for the large variation in population sizes of the focal countries, and to better represent the proportional pressure upon each country.

The objective reliability of these data is questionable given the internationally variable extent of testing and the resultant predicted inaccuracy of the case numbers in each country. International variations in the definition of COVID-19-related deaths and failures to report the full extent of case numbers also warrant skepticism. In the remit of this study, however, these data represent the immediate perceived threat and pressure elicited upon the societies of each focal country, thus providing a suitable comparison against the temporal dynamics of the search terms used. The numbers of COVID-19 tests per thousand citizens were downloaded from Our World in Data [13]; given the irregularity of testing and resultant unavailability of data for some countries, these data were not used for correlation analysis. The number of tests completed by April 17, 2020, was recorded, except for Germany and Spain for which values represented the tests per thousand completed by April 19 and 13, respectively, due to a lack of data for April 17. Testing data represent the number of tests performed, rather than the number of individuals tested, given the wider availability of these data; the nature of Australia's testing units is, however, unclear.

**Figure 1.** Data extraction and workflow.

### Search Volume Data Extraction

Data were extracted from GT on April 17, 2020, for the period of November 1, 2019, to April 17, 2020, which includes a brief period before the first confirmed case of COVID-19 for comparison. These data provide a proxy for public interest in government policy, emerging health care interventions, and misinformation, later contextualized as a response to the release of such information. The data extracted from GT are RSVs for predetermined search terms, allowing comparison of search rates for different terms via Google, the most widely used internet search engine, especially in the countries selected [14,15]. These RSVs are presented for each date of a given time period within a given country. Data are normalized relative to the highest RSV peak in that time period (this peak represented as 100).

Data were extracted for searches generated from Australia, Germany, Italy, Spain, the United Kingdom, and the United States. These countries were selected due to their widespread use of Google (precluding China and many other Asiatic countries), variation in the extent to which they were impacted by the pandemic, nuances in their responses to the pandemic, and the accessibility of their news and media in one predominant language. All search terms were preceded by “coronavirus” to ensure relevance to the pandemic; “coronavirus” was selected over “COVID19” and similar terms due to its greater prevalence of searches (eg, in the United States, “coronavirus vaccine” yielded four-fold the search volume of “corona vaccine” and “covid vaccine”, and twenty-fold that of “covid19 vaccine” and “covid-19 vaccine”).

All search terms were selected based on their widespread media coverage and their high Google search volumes. Their placement in the broad categories of *government policy*, *medical interventions*, and *misinformation* were based on the context of their wide reporting by media, government, research, and health

care organizations of those particular countries. The designation of search terms as *medical interventions* did not equate to their effectiveness in treating COVID-19 but scientific discussion around, or political endorsement of, their experimental or genuine use in treating the virus. Chloroquine, for example, was not empirically shown to benefit patients at the time of this study, and its early endorsement during the pandemic largely emanated from the United States, but international research nonetheless endeavored to ascertain any benefit it conferred to patients with COVID-19, this being the primary focus of its initial widespread news coverage. Misinformation search terms were labeled as such when there was no empirical evidence nor active published peer-reviewed research regarding their relevance to COVID-19, and their media coverage indicative of their potential for controversy; such search terms could often be traced back to an initial misinterpretation or false statement, some of which are highlighted in the discussion. All terms were identified as COVID-19 misinformation by Dhillon et al [16]. Other search terms relevant to COVID-19 were considered but for a contained and meaningful statistically significant comparison only those with relatively high and comparable RSVs within the three aforementioned categories were included. Search terms for which variations were possible (eg, chloroquine vs hydroxychloroquine) were included as the variation with the greatest GT search volume with the simpler terminology routinely having the greatest search volume.

Searches were carried out in the language native to each country unless the English terms provided a greater number of results (ie, where English phraseology was adopted). Searches were carried out in batches to identify relative differences in search volumes, with three batches coarsely defined as “government policies,” “medical interventions,” and “misinformation.” All search batches contained “coronavirus chloroquine” as a standard to facilitate some comparison between categories given its relatively central positioning in most batches. Chloroquine was selected for its relatively average search volume across

countries and categories, acting as an anchor to facilitate visual comparison between higher and lower RSVs. The search term RSVs were all also individually downloaded (independently normalized with the highest peak being 100) for subsequent correlation analysis to evenly represent the extent of searching and focus on the temporal dynamics. Given the representation of numbers less than one as “<1” by GT, all RSVs of “<1” were converted to 0.5 to facilitate quantitative comparison.

The government policy search terms comprised chloroquine (control standardization term), social distancing, sanitizer, mask, isolation, gloves, and testing (Textbox 1). Social distancing was implemented by many countries as an early and maintained means to prevent viral spread, as was isolation, although the latter may also have been searched in association with the well-being and mental health consequences of reduced social contact during lockdown. The use of sanitizer for cleansing of

hands was also encouraged by governments throughout the pandemic, although depleting public availability in most countries led many to attempt to create homemade sanitizer [17]. Masks and gloves were employed as a protective means to prevent spread, although predominantly by frontline health care workers; public purchase of this PPE was problematic in many countries, resulting in reduced availability for medical practitioners [18,19]. Testing and tracing was carried out for coronavirus, but the extent of testing and the national focus on its importance varied internationally [13]. The US spelling of “sanitizer” was maintained for the UK searches given a higher prevalence than the UK spelling “sanitiser.” Due to the GT search limit, the government policy search was split into two batches (batch 1: chloroquine, social distancing, sanitizer, mask, and isolation, and batch 2: chloroquine, gloves, and testing, with linguistic variations for Germany, Italy, and Spain).

**Textbox 1.** Google Trends search terms used in each of the three categories.

#### Government policy

- Australia, the United Kingdom, and the United States: social distancing, sanitizer, mask, isolation, gloves, testing
- Germany: social distancing, desinfektion-smittel, maske, isolation, handschuhe, testen
- Italy: distanziamento sociale, disinfettante, maschera, isolamento, guanti, analisi
- Spain: distanciamiento social, desinfectante, mascara, aislamiento, guantes, pruebas

#### Medical interventions

- Australia, the United Kingdom, and the United States: chloroquine, remdesivir, paracetamol, vaccine, ibuprofen
- Germany: chloroquin, remdesivir, paracetamol, impstoff, ibuprofen
- Italy: chlorochina, remdesivir, paracetamolo, vaccino, ibuprofene
- Spain: cloroquina, remdesivir, paracetamol, vacuna, ibuprofeno

#### Misinformation

- Australia, the United Kingdom, and the United States: 5G, man made, lab
- Germany: 5G, hergestellt, labor
- Italy: 5G, creato, laboratorio
- Spain: 5G, creado, laboratorio

The medical intervention search terms comprised chloroquine (control standardization term), remdesivir, paracetamol, vaccine, and ibuprofen (Textbox 1). All of these search terms pertain to treatments that were suggested to have potential effects against COVID-19 symptoms. The public focus on vaccines reflected the ongoing development of vaccines and the desire for relief from the pandemic [20]. Paracetamol and ibuprofen were used to subdue pain associated with COVID-19 symptoms, but public perception became antagonistic toward using ibuprofen for COVID-19 symptoms, which shifted focus toward paracetamol [21].

The misinformation search terms comprised chloroquine (control term), 5G, man made, and lab (Textbox 1). These search terms pertain to internationally prevalent misinformation related to COVID-19, often specifically suggesting a disingenuous cause or source of the viral spread. Specifically, these entail theories that the virus was being spread by the new 5G phone masts, that the virus was manufactured, and that the virus was released

from a laboratory [3,16,22-24], all of which have subsequently been debunked [25-27].

#### Statistical Analysis

Statistical analyses and plotting of data were carried out using R version v4.0.0 (R Foundation for Statistical Computing) [28]. Line graphs were created for *per capita* cases and deaths, and a bar chart for tests per thousand citizens using *ggplot* in the *ggplot2* package version 3.3.0 in R [29], with colors assigned via the *RColorBrewer* package v1.1-2 [30]. The data were identified as nonnormally distributed via Shapiro–Wilk tests, so nonparametric statistical analyses were selected. Correlations between RSVs and *per capita* deaths and cases were tested using Spearman rho rank correlation via the *rcor* function of the *Hmisc* package version 4.4-0 [31]. The output was then presented in a correlogram via the *corrplot* function of the *corrplot* package version 0.84 [32], with colors assigned via the *viridis* package v0.5.1 [33]. Line graphs were created for each of the three

categories of search terms for each country to aid comparison of both the extent and temporality of RSV trends in GraphPad Prism version 8 (GraphPad Software) [34]. All statistical data is included in [Multimedia Appendix 1](#).

### Information Sources and Reliability

The sources for the non-search term data (The European Union Open Data Portal and Our World in Data) are reputable sources that derive their data from official national reports, scientific publications, and other reliable sources. The data extracted from these sources align with those published internationally in response to the pandemic situation as it develops. The GT data are collected and presented by Google based on the input of users of their service, thus should be fully reliable. Although most sources cited in this report are from reputable scientific, government, or public health authority sources, others discussed throughout the manuscript are taken from mass media, social media, and other heavily biased sources or from scientific articles that discuss such sources; these sources are being referred to on the basis of these biases or simply to refer to the temporal development and emergence of global news, for which bias is an important factor. The paper discusses the reporting of this information in an objective manner, with no subscription to the reported ideals or beliefs represented in the text.

## Results

### Mortality, Case, and Test Results

All countries show similar *per capita* case (Figure 2) and death (Figure 3) trends temporally, with both beginning to

exponentially increase in most countries between late February and early March. Of the six countries, Italy was the first to present a substantial number of cases and deaths (mid-February 2020). Australia, the United Kingdom, and the United States were the last to experience rapidly increasing *per capita* case numbers (~March 10). The *per capita* case number trends are relatively similar in their extents for most countries, except for Spain, which exhibits approximately 50% more peak *per capita* cases than the second highest peak, the United Kingdom (Spain: 0.01937, UK: 0.013113), and Australia, which exhibits approximately a quarter of the peak *per capita* cases for the majority of the countries (Australia: 0.002445, average for other countries, excluding Spain: 0.010603, SD 0.0023). The *per capita* deaths similarly increase last for Australia, the United Kingdom, the United States, and Germany. Germany and the United States display a shallower trajectory of *per capita* death increases, and Australia shows a minor peak of *per capita* deaths. Spain again exhibits the greatest peak of *per capita* deaths, but only with an approximate 30% increase over the peaks of Italy, the United Kingdom, and the United States (Spain: 0.002033, Italy: 0.001607, the United Kingdom: 0.001474, the United States: 0.001506), compared to the ~50% increase over the second highest peak for *per capita* cases. Testing for COVID-19 varied massively between countries, with Germany showing the highest tests per thousand, with around 25 tests per thousand, and the United Kingdom showing the lowest with around 6.5 tests per thousand (Figure 4).

**Figure 2.** Per capita cases of COVID-19 during the study period.

**Figure 3.** Per capita COVID-19–related deaths during the study period.**Figure 4.** Total COVID-19 tests per thousand citizens in the six focal countries, as of April 17, 2020, except for Germany and Spain, which are represented by April 19 and 13, respectively, due to a lack of data for April 17.

## Search Volume Results

Of the government policy search terms (Figure 5), “testing” was prevalent in all countries, and “isolation” relatively high in all but the United States and Germany. “Sanitizer” was highly searched in Germany, Italy, and Spain. “Masks” was highly searched in Australia, Germany, Italy, and the United States, and to a lesser extent the United Kingdom. “Gloves” was

searched less in all but Italy and Spain. “Social distancing” was searched less except in Australia and the United Kingdom, where this term was the third most searched. Most search terms peaked at a similar time (mid-March) in most countries, although “mask” also peaked in late January to early February in Australia, the United Kingdom, and the United States, and to a lesser extent in Germany and Italy. In Germany and Italy, “sanitizer” and “mask” peaked in early March, 2-3 weeks earlier

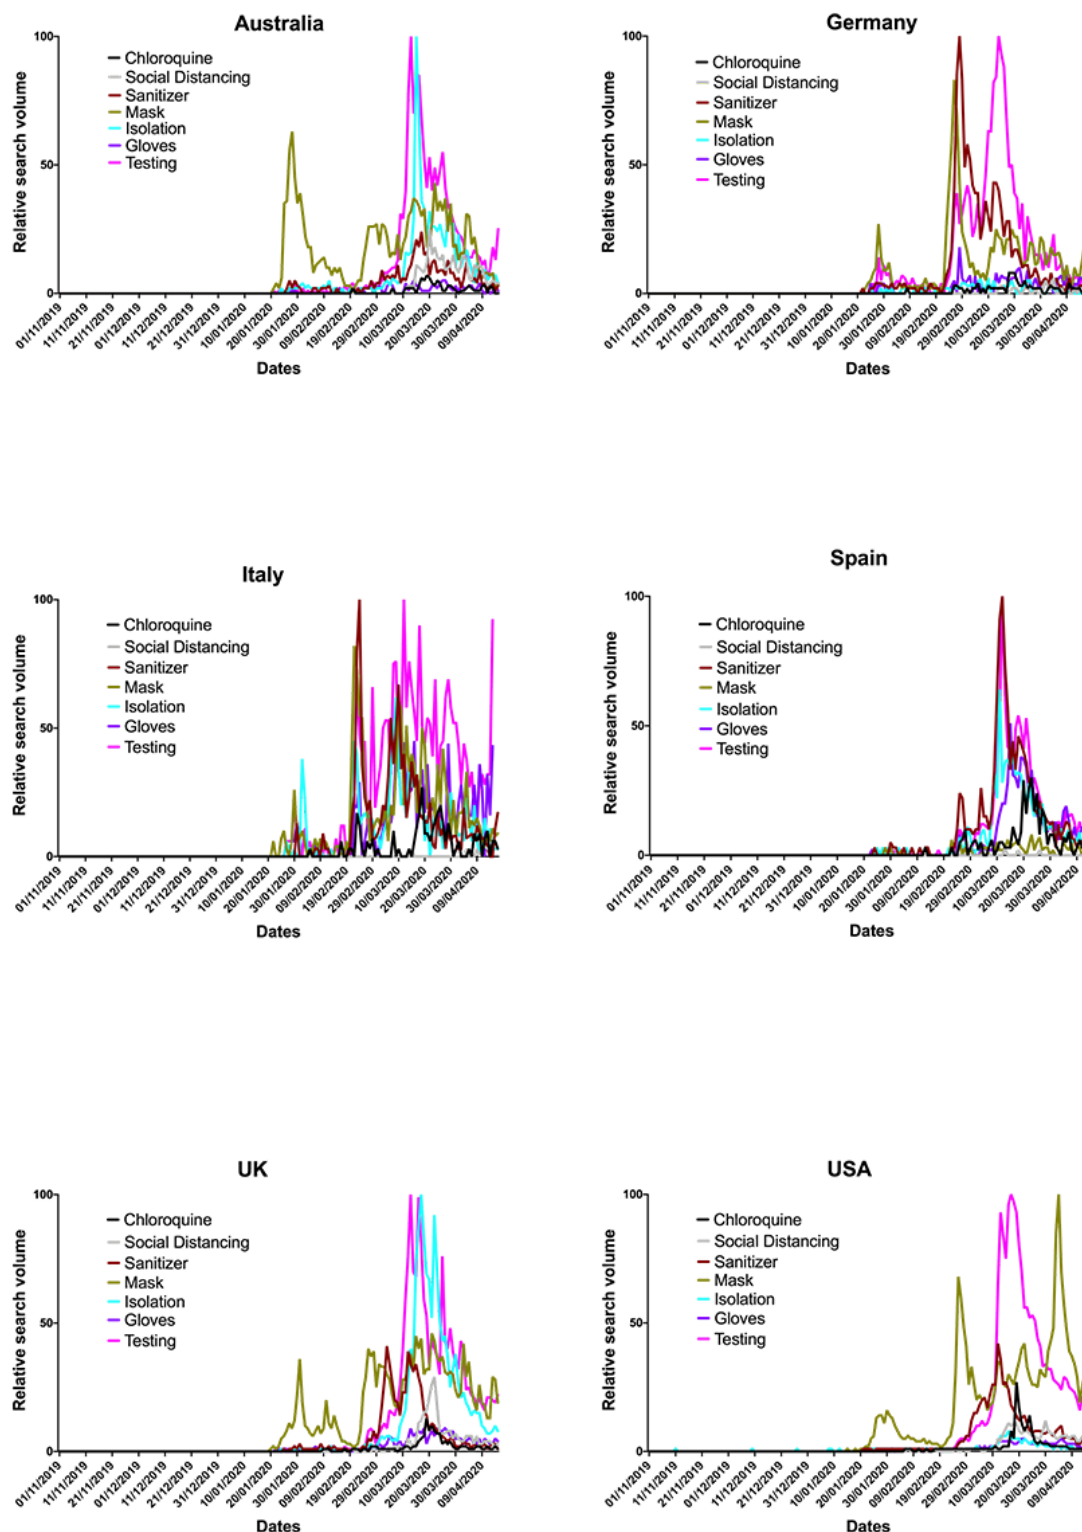

than a later peak coinciding with that of “testing” in other countries. In the United States, “gloves” was searched most at the end of February, but also with a second peak in early April, unlike the other countries. In Italy, searches of “testing” peaked sporadically from late February to mid-April (the end of the search period), with larger peaks spread further across the period.

Of the medical intervention search terms (Figure 6), “vaccine” was highly searched in all countries, peaking in late March, except in Germany, where it peaked in late February, and Italy, where it peaked sporadically from the end of January to mid-April (the end of the search period). In the United Kingdom, “vaccine” had a second peak in mid-April. The other medical interventions had relatively small peaks, often in mid- or late March. “Remdesivir” peaked higher in Italy relative to the other countries. “Chloroquine” peaked much higher in the United States relative to the other countries, also having a smaller peak in the United Kingdom. “Ibuprofen” had the highest peak in

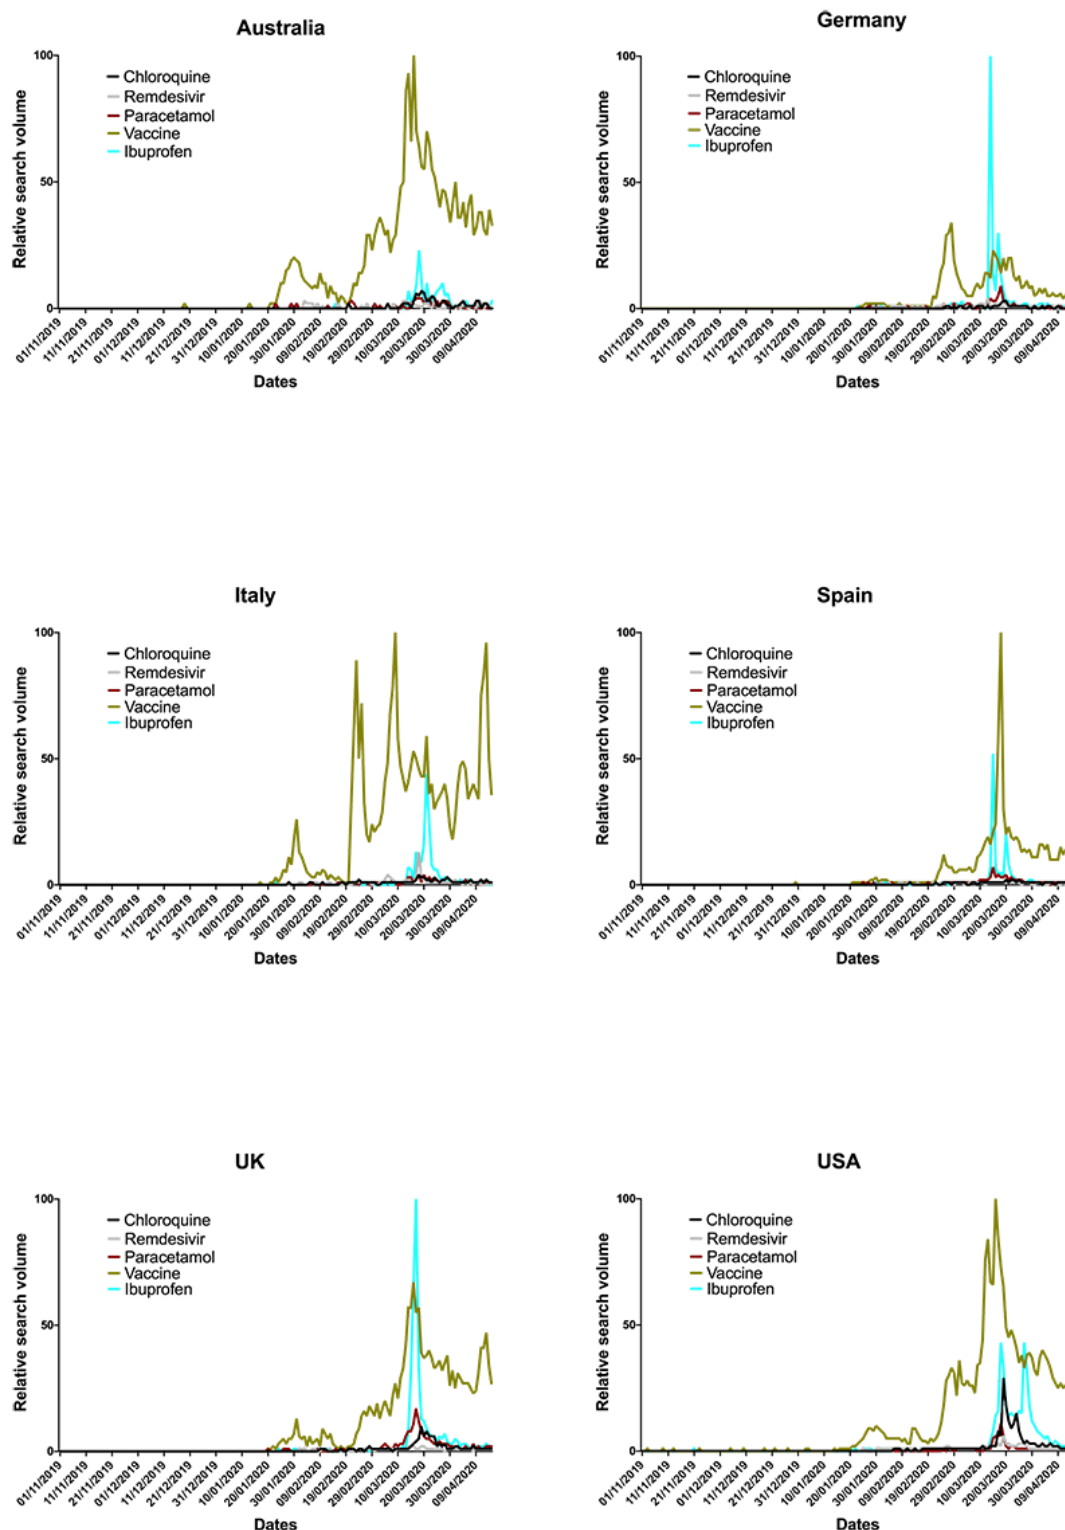

Germany and the United Kingdom, peaking in all countries in mid- or late March and having a second peak in early April in the United States.

Of the misinformation search terms (Figure 7), “5G” had erratic smaller peaks throughout mid- and late March but peaked in most countries in early April, with Germany and Spain displaying reduced peaks. “Man made” was mostly searched in mid-March, with some more widespread erratic peaks in all but the United Kingdom, and a substantial peak in late January and early February in Australia, Italy, and Spain. “Lab” was searched relatively little in Australia, the United Kingdom, and, to some extent, the United States. “Lab” was, however, highly searched in Italy and Spain in late March, with Italy also exhibiting large peaks in late January and late February, and was searched at similar intervals in Germany but never so proportionally high as Italy and Spain. In most cases, peaks of “lab” coincide with peaks of “man made.”

**Figure 5.** Government policy relative search volumes (RSVs) extracted from Google Trends (GT). Grouped RSV data, normalized to the highest RSV peak in the time period (represented as 100) were extracted from GT on April 17, 2020, for the period of November 1, 2019, to April 17, 2020. Search terms included “coronavirus chloroquine” (control term), “coronavirus social distancing,” “coronavirus sanitizer,” “coronavirus mask,” “coronavirus isolation,” “coronavirus gloves,” and “coronavirus testing,” with variations to reflect the language native to each country.

**Figure 6.** Medical intervention relative search volumes (RSVs) extracted from Google Trends (GT). Grouped RSV data, normalized to the highest RSV peak in the time period (represented as 100) were extracted from GT on April 17, 2020, for the period of November 1, 2019, to April 17, 2020. Search terms included “coronavirus chloroquine,” “coronavirus remdesivir,” “coronavirus paracetamol,” “coronavirus vaccine,” and “coronavirus ibuprofen,” with variations to reflect the language native to each country.

**Figure 7.** Misinformation relative search volumes (RSVs) extracted from Google Trends (GT). Grouped RSV data, normalized to the highest RSV peak in the time period (represented as 100) were extracted from GT on April 17, 2020, for the period of November 1, 2019, to April 17, 2020. Search terms included “coronavirus chloroquine,” “coronavirus remdesivir,” “coronavirus paracetamol,” “coronavirus vaccine,” and “coronavirus ibuprofen,” with variations to reflect the language native to each country.

## Correlation Analysis Results

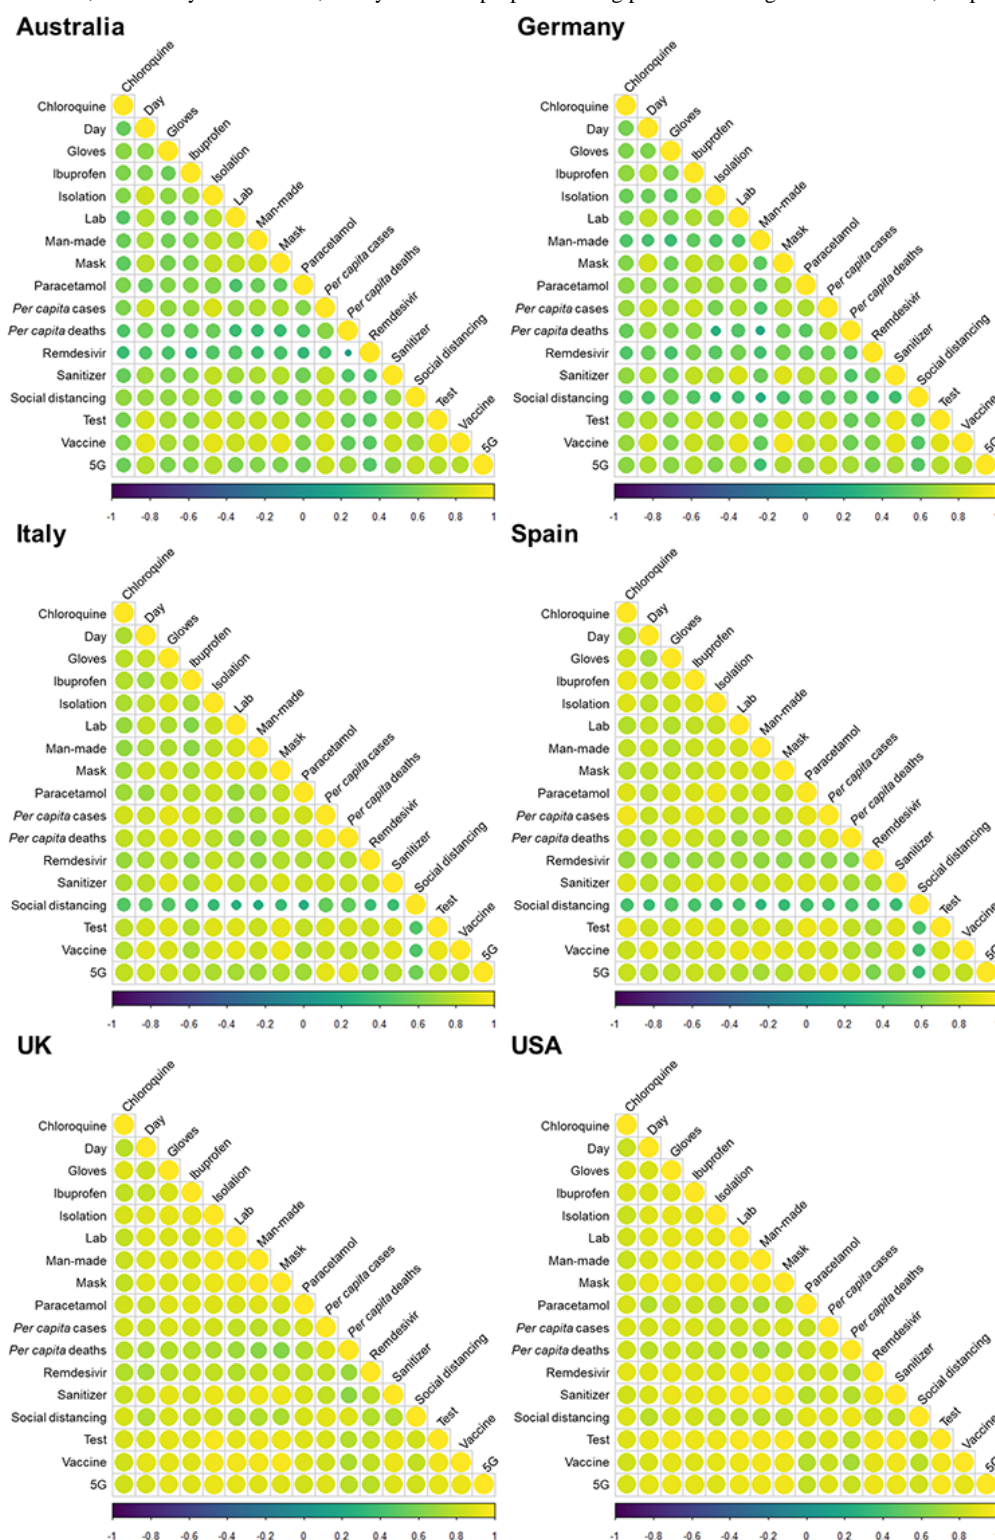

In all countries, almost all normalized search terms significantly positively correlated with one another (overall mean Spearman rho 0.753, SD 0.158) and *per capita* deaths (mean *per capita* deaths Spearman rho 0.690, SD 0.168) and cases (mean *per capita* cases Spearman rho 0.800, SD 0.112; [Figure 8](#), [Table 1](#),

and [Multimedia Appendix 1](#) Table S1); the only exception was the nonsignificant association between *per capita* deaths and remdesivir RSV in Australia (Spearman rho 0.134,  $P=.08$ ). Overall, stronger correlations were identified more universally for the United Kingdom (mean Spearman rho 0.851, SD 0.066) and the United States (mean Spearman rho 0.873, SD 0.058), while relatively weaker correlations were shown for Australia

(mean Spearman rho 0.641, SD 0.150) and Germany (mean Spearman rho 0.632, SD 0.157; Figure 8, Table 1, and Multimedia Appendix 1 Table S1). In Italy and Spain, the

weakest correlations were those between social distancing and all other variables.

**Figure 8.** Correlograms for the search factors and per capita case and death rates for each country. The size of each circle indicates the strength of the correlation as does the color, denoted by the scale bar, with yellow and purple denoting positive and negative correlations, respectively.

**Table 1.** Mean Spearman rho rank coefficients and their standard deviations are given for each country and overall results for all six countries.

Countries	Overall correlation, mean (SD)	Time correlation, mean (SD)	Cases correlation, mean (SD)	Deaths correlation, mean (SD)
All	0.753 (0.158)	0.769 (0.122)	0.800 (0.112)	0.690 (0.168)
Australia	0.641 (0.150)	0.701 (0.136)	0.732 (0.122)	0.495 (0.146)
Germany	0.632 (0.157)	0.681 (0.143)	0.719 (0.123)	0.535 (0.153)
Italy	0.753 (0.147)	0.772 (0.093)	0.819 (0.103)	0.796 (0.104)
Spain	0.766 (0.152)	0.764 (0.120)	0.826 (0.133)	0.762 (0.116)
UK	0.851 (0.066)	0.835 (0.052)	0.846 (0.037)	0.750 (0.075)
US	0.873 (0.058)	0.861 (0.047)	0.858 (0.024)	0.802 (0.056)

## Discussion

This study aims to identify any correlation between the internet searching of defined COVID-19–relevant search terms and the *per capita* cases and deaths in six countries. We identified a positive correlation between the cases and deaths relating to COVID-19 and online searches surrounding government policies, medical interventions, and scientific misinformation.

### Principal Results

Between November 1, 2019 and April 17, 2020, *per capita* deaths and cases showed a similar trend across the six countries, with all having reached or passed peak daily new cases during the first wave of the pandemic. However, Australia and Germany experienced fewer deaths during this time period, allowing for a direct comparison of the search trends across countries with high and low COVID-19 cases and deaths. Where the ratio of mortality to cases is higher, such as the United Kingdom, which had the highest excess deaths in Europe during this period [35], this could reflect strained health care provision, delayed or reduced effectiveness of preventative measures, a poorer testing effort, or a combination of all of these [36,37]. Disparity in testing across countries may also have exacerbated differences in mortality. The importance of testing is illustrated by its high RSV across all countries (Figure 5) and the finding that the greatest degree of testing (Germany) aligns with relatively low mortality and weak correlations between RSVs and caseload. Where testing and contact tracing have been employed (eg, Germany, South Korea), they have been undoubtedly effective in mitigating increases in cases and deaths [38,39], possibly leading to an increased media and public interest, predominantly, it seems, in countries where it is lacking.

Overall, stronger correlations were observed in the United Kingdom and the United States. The English-speaking majority of these countries could explain this, given the widespread use of English on social media and in international news. In direct contrast, Australia had some of the weakest overall correlations; the combined low *per capita* deaths and cases, and the earlier application of travel restrictions and a 2 week quarantine [40,41] may have fostered a greater sense of safety and, therefore, less need by individuals to focus on the pandemic, evidenced by reduced interest in medical interventions. The overall strength of correlations being weakest in Australia and Germany, where the case and death figures are lower, supports the association

between reduced public pressure and a less coordinated uptake of news and misinformation.

That, in almost all cases, *per capita* deaths and cases correlated with the search term RSVs further suggests a strong relationship between the pressure elicited upon the public and their receptibility to pandemic-related digital information. The virus was internationally recognized and regularly reported by January [2], with many of the proposed preventative measures and medical interventions being widely searched online before cases and deaths began to emerge (Figures 5 and 6). The peak of most RSVs in mid-March, aligning approximately with peak *per capita* deaths and cases (Figures 1 and 2), also coincides with the beginning of lockdown in many countries [42], suggesting that populations were well informed prelockdown and ready for substantial changes to living conditions. The more dramatic peaks of search term RSVs following the beginning of March may denote the public searching news-relevant topics in far greater volume due to their willingness to follow government guidance, increased anxiety, and free time. In Italy, however, RSV peaks arrived earlier, likely due to the earlier arrival of the virus. The later peaks, which are often larger, may be propagated by greater exposure to mainstream and social media while at home and increased levels of anxiety (Multimedia Appendix 1 Figure S1) [43,44] thus creating a “second wave.” This relatively erratic persistent search behavior, particularly surrounding misinformation, could indicate heightened public panic especially as *per capita* deaths increase.

The data in this study highlights the utility of infoveillance in assessing public readiness for and adoption of preventative measures. The early interest in masks observed in the United States and Australia could indicate a willingness for, or pre-emptive fear of, the use of PPE. Despite some antimask sentiment in politicians [45] and possible reluctance by governments to impose mask-wearing for fear of appearing dictatorial, the public may be more prepared for discourse surrounding PPE than expected given the high RSVs. Conversely, social distancing consistently correlated weakly with other search terms, specifically in Germany, Italy, and Spain, despite all three countries entering nationwide lockdowns and observing government-mandated social distancing rules. Given the use of translated search terms, where these received more searches than the English equivalent, this is unlikely to be due to linguistic differences, despite these comprising only the non-English-speaking countries. In some countries, strict enforcement of social distancing may not have been necessary

due to greater compliance with guidelines (Germany). Alternatively, social distancing may not have been so heavily emphasized or adhered to in some countries, resulting in government-enforced curfews with fines for noncompliance, as experienced in Italy [46,47]. Regardless, clear and repeated guidance should be provided by governments to ensure compliance by their citizens. Good government response has been credited with the rapid reduction of lockdown measures in some countries, but such responses need to be data driven [38,48], and GT can provide an effective proxy for the extent of public adherence to this guidance.

Public interest in medical interventions was similarly moderately consistent between countries, with ibuprofen and chloroquine being the most searched. Some of this search intensity likely arose from misinformation, for example, the high RSVs for ibuprofen coincided with a scientific correspondence to *The Lancet* hypothesizing a heightened risk to a subset of patients with hypertension and diabetes should they take ibuprofen to combat COVID-19 [21]. This correspondence became misrepresented on messaging platforms and in media [16,49] as “evidence” that ibuprofen worsened COVID-19 symptoms. Furthermore, a second ibuprofen RSV peak in April in the United States coincided with a viral social media message claiming that patients with COVID-19 using ibuprofen did not recover [16]. The European Medicines Agency and the US Food and Drug Administration quickly discredited this as misinformation, possibly explaining the ephemerality of the RSV peak [25,26]. Paracetamol was highly searched simultaneously with ibuprofen, suggesting that people were seeking alternatives [50]. That the ibuprofen RSV comprises the highest medical intervention search peak in the United Kingdom and Germany, and a relatively high peak in other countries, compared to lower RSVs for experimental COVID-19 disease-modifying drugs such as remdesivir [51], confirms the capacity of misinformation to penetrate the public consciousness. Although this may also reflect the less familiar names and scientific background of the experimental drugs. This is further evidenced by the much larger RSVs for *vaccine* across all countries, a term familiar with most people, yet a therapeutic option that is clearly much further from public availability than therapies such as remdesivir [52]. The second peak of interest in vaccines in the United Kingdom was likely propagated by UK media reporting the initiation of clinical trials at the University of Oxford [53]. It is worth noting, however, that one experimental drug, namely, chloroquine, was searched with far greater intensity in the United States. This is likely due to US government briefings that supported chloroquine as a potential treatment for COVID-19 [54] based on a small clinical study [55], which led to multiple larger studies that ultimately did not support the outcomes [55,56] with most trials now suspended as reviewed in [57] and following some reports of accidental self-poisoning [58]. The important role of clear guidance from government is further exemplified from the suggestion during US government briefings that consideration should be given to the internal use of disinfectant and UV light in combating COVID-19. This is a clear example of misinformation arising from misinterpreted scientific literature that led to widescale panic and increased calls to poison centers [59-61].

Similarly, mass media and elected representatives have also propagated theories that SARS-CoV-2 is either man-made or was leaked from a laboratory in Wuhan. A quickly retracted scientific preprint appeared to propagate this theory by providing it an undue sense of credibility [24]. Although the man-made theory was scientifically discredited [27], public discussion moved toward a “leak” of the virus [16,23], highlighting the evolution and adaptability of misinformation, especially when supported by public figures [62]. Editors, reviewers, and authors should maintain stringent safeguards to ensure appropriate publishing, even of preprints, especially regarding such sensitive topics [63]. Similar conspiracy theories with large RSVs (Figure 7) arose via mainstream and social media outlets suggesting the spread of COVID-19 by 5G towers. The theory itself was in early circulation and despite being discredited as misinformation in January, long before the search intensity peaked [22], it led to vigilante attacks on phone masts and engineers in uninformed attempts to arrest viral spread [3,16,22]. The danger of misguided intervention led by misinformation outlines a clear requirement for mechanisms to reduce the spread of, while rationally and widely discrediting, these theories via perceivably credible sources such as national governments or professional medical bodies [1]. That the search volume surrounding 5G and ibuprofen dissipated so rapidly after documented attempts made by public health authorities such as the World Health Organization to curb the spread of this misinformation [25,26] best illustrates this point. It is, therefore, clear that during this pandemic the consumption of mass media, social media, government announcements, and health organization releases has influenced the public perception around both the causes and treatments of COVID-19 and, as perhaps best evidenced by the high RSVs for ibuprofen and 5G, has contributed to both public panic and health care issues such as reduced stocks of essential medicines caused by stockpiling [50].

### Limitations of GT Data

This study used GT data for six countries in which it is the most popular, but not the only, internet search engine. However, as the most widely used, it provides the best snapshot of user searches so that appropriate statistical studies can be conducted. As with any searches, the data presented in this study do not confirm subscription of those searching the terms to the ideals, interventions, or policies that they represent; many of the queries that contribute to these data may have been submitted by critics and sceptics. Even such searches, however, ratify the increased public awareness, discussion, and spread of the information denoted by the search terms. A greater volume of people reached by the information will undoubtedly suggest a greater number subscribing to the theories and ideas. The progression of a global pandemic is incredibly complicated and unpredictable, and the findings of this study focus on GT data from just one time period in a currently ongoing situation. Although this study bears relevance primarily to the beginning of the pandemic, this is arguably the most critical point at which to limit spread; however, the findings may not prove as relevant to periods when the public have adjusted to the situation.

## Conclusions

Infoveillance has already proven to be a valuable tool during the COVID-19 pandemic through detection of novel symptoms [11], assessment of behaviors such as self-medication [64], and identification of outbreaks [65]. This study focuses on the public response during the early developing pandemic, particularly surrounding misinformation, government policy, and medical interventions.

A study exploring the use of GT for digital epidemiology found that search term RSVs were influenced far more by media clamor than by epidemiological burden [66]. This pandemic is unique in that rapidly emerging medical research deposited in preprint archives has been accessible and consumed by the media and public pre-peer review, leading to potentially dangerous misinterpretation, as has occurred with chloroquine [58]. Although our findings ratify this, we also identified a

positive correlation between internet searching and COVID-19 deaths and cases, indicating a more synergistic combined effect of epidemiological burden and media attention. The prevalence and online spread of misinformation has been reported previously for COVID-19 [1] with regard to social media platforms, and, as in this study, the findings ultimately identified an important role for public health organizations and governments in providing accessible online information and refutation of misinformation. Medical misinformation has drastic health care consequences and pre-existing misinformation, particularly that surrounding vaccines, will be a significant future obstacle in overcoming COVID-19 [6]. The presentation of accurate information, including infodemiology data as illustrated in this study, to maintain societal ease is vital, and there is an imperative for scientists, public health authorities, and governments to collaborate to rigorously maintain this.

## Acknowledgments

RABG was funded by Cardiff University. JPC was funded by the Biotechnology and Biological Sciences Research Council (BBSRC) through the South West Biosciences Doctoral Training Partnership (grant BB/M009122/1). BPK was funded by Idorsia Pharmaceuticals. HWE was funded by Cardiff University. Work in the ELE lab was supported by the BBSRC (BB/S002774/1).

## Authors' Contributions

RABG and JPC cowrote the manuscript, provided sources, extracted and prepared data, performed statistical analyses, and prepared figures. BPK provided sources and synthesis, and assisted with preparing the manuscript. HWE provided data, sources, and supervision, and assisted with preparing and writing the manuscript. ELE designed the study, provided early data searches, and contributed to writing the manuscript. All authors contributed to the editing of the manuscript and design of the study.

## Conflicts of Interest

None declared.

**Abstract**

**Background:** COVID-19 was first discovered in December 2019 and has since evolved into a pandemic.

**Objective:** To address this global health crisis, artificial intelligence (AI) has been deployed at various levels of the health care system. However, AI has both potential benefits and limitations. We therefore conducted a review of AI applications for COVID-19.

**Methods:** We performed an extensive search of the PubMed and EMBASE databases for COVID-19–related English-language studies published between December 1, 2019, and March 31, 2020. We supplemented the database search with reference list checks. A thematic analysis and narrative review of AI applications for COVID-19 was conducted.

**Results:** In total, 11 papers were included for review. AI was applied to COVID-19 in four areas: diagnosis, public health, clinical decision making, and therapeutics. We identified several limitations including insufficient data, omission of multimodal methods of AI-based assessment, delay in realization of benefits, poor internal/external validation, inability to be used by laypersons, inability to be used in resource-poor settings, presence of ethical pitfalls, and presence of legal barriers. AI could potentially be explored in four other areas: surveillance, combination with big data, operation of other core clinical services, and management of patients with COVID-19.

**Conclusions:** In view of the continuing increase in the number of cases, and given that multiple waves of infections may occur, there is a need for effective methods to help control the COVID-19 pandemic. Despite its shortcomings, AI holds the potential to greatly augment existing human efforts, which may otherwise be overwhelmed by high patient numbers.

**Introduction**

COVID-19, caused by SARS-CoV-2 [1], was first discovered in December 2019 and has since become a global pandemic [2]. An emerging viral pandemic like COVID-19 exerts significant pressure on limited health care resources [3]. To prevent human efforts of disease containment from being overwhelmed, we need tools that can streamline the diagnosis, surveillance, and treatment of COVID-19 [4]. This need is particularly pressing in relatively resource-scarce settings, such as low- or middle-income countries [5,6].

Digital methods such as artificial intelligence (AI) hold the potential to greatly enhance medical care [7]. AI implies the use of a computer to model intelligent behavior without human intervention [8]. It has been applied to many areas of medicine [9], especially to aid the detection and prevention of disease [10]. AI techniques being used in medicine are broad, ranging from computer vision to deep learning techniques [11]. Unlike the if-then rules used in traditional computer programming, AI methods emulate the decision-making process of humans via two major approaches. The first major approach is supervised machine learning, which aims to develop a predictive algorithm using regression (linear or multiple) or classification methods

(eg, decision trees, neural networks). The other major AI approach is unsupervised machine learning, which allows computers to explore large amounts of unclassified data and to discover novel disease or treatment patterns [12].

An example of how AI has been applied to COVID-19 is demonstrated by BlueDot, a Canadian company specializing in infectious disease forecasting [13]. Using an AI engine that continuously gathers data for a multitude of diseases from a range of different sources globally, BlueDot was able to predict the COVID-19 outbreak and alert its users even before the World Health Organization did [14]. Another example is an AI-powered chatbot named SGDormBot, which has been used for symptom-based mass screening of migrant workers for COVID-19 in Singapore [15].

Nonetheless, while AI has been promoted as a tool to help manage the COVID-19 pandemic, AI has both potential benefits and limitations. We therefore conducted a rapid review of AI applications for COVID-19. In our review, we sought to delineate the major categories of AI use, describe the limitations of AI, and identify areas for further development.

## Methods

We based our review on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [16], and extensively searched two databases (PubMed and EMBASE) for all English-language papers published from December 1, 2019, to March 31, 2020, using the search terms “novel coronavirus,” “2019 novel coronavirus,” “2019-nCoV,” “coronavirus disease 2019,” “COVID-19,” and “SARS-CoV-2.” The database search was supplemented by reference list checks. Papers reporting new data on AI applications for COVID-19

were included. Review papers and commentaries without new data were excluded.

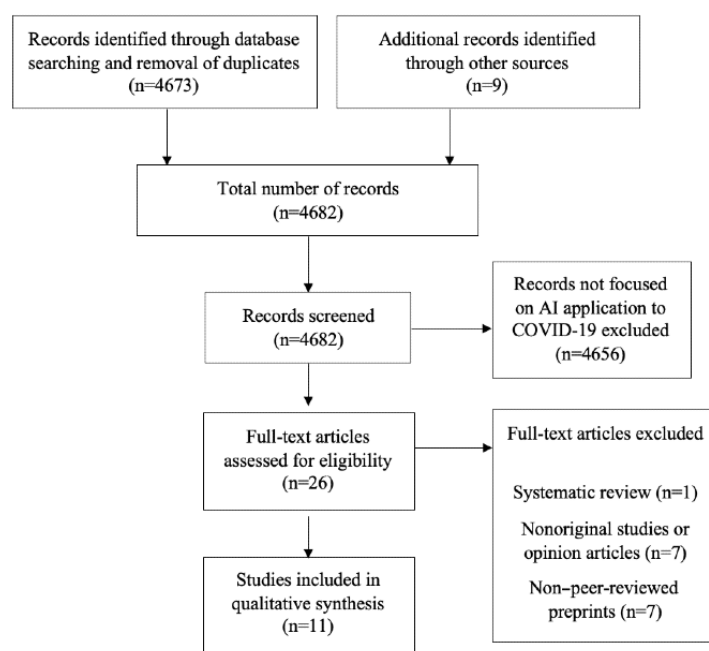

The quality of included studies was assessed using a modified TRIPOD (transparent reporting of a multivariable prediction model for individual prognosis or diagnosis) statement for adherence to reporting standards [17] and PROBAST (prediction model risk of bias assessment tool) for risk of bias [18]. A thematic analysis and narrative review of AI applications for COVID-19 was then conducted.

## Results

### Included Studies, Adherence to Reporting Standards, and Risk of Bias

Of 4682 articles, 11 articles were included for review (Figure 1, Table 1). The original TRIPOD statement consisted of a 22-category checklist with 37 items. However, items related to predictor variables were not relevant for studies assessing the performance of AI algorithms. The final components selected, as well as the degree of adherence in each category, are shown in Figure 2. Overall, adherence rates of publications to TRIPOD items ranged from 18.2% to 100%. Items concerned with data validation were reported in <50% of the 11 publications reviewed. Items related to clinical context, study methodology, and applicability were better reported, with >80% of the publications providing adequate information. For the assessment of risk of bias and applicability, we applied the PROBAST tool (Figure 3); as with TRIPOD, we did not assess predictors. Generally, risk of bias in the remaining three categories was low. We identified four areas where AI was applied to COVID-19: diagnosis, public health, clinical decision making, and therapeutics.

**Figure 1.** Study flow diagram.

**Table 1.** Studies included in the review.

First author (year)	Area or specialty of AI <sup>a</sup> application	AI application method	Clinical benefit shown	Internal or external validation done
Hurt (2020) [19]	Diagnosis and clinical decision making	Using a deep learning approach to augment radiographs with color probability	Improved diagnostic accuracy of pneumonia and COVID-19 at point of care, triaged patient for CT <sup>b</sup> scan, helped physicians track evolution of pulmonary manifestation over length of hospitalization	No
Li (2020) [20]	Diagnosis	Deep learning-based computer-aided diagnostic system for pneumonia trained with CT scans of patients with COVID-19 suggested pneumonia in patients who received a negative reverse-transcription polymerase chain reaction test result	Improved accuracy of diagnosis	No
Li (2020) [21]	Diagnosis	AI 3D deep learning model to analyze CT scan	Improved diagnostic accuracy and differentiated from non-COVID-19 lung pathologies	Yes
Yang (2020) [22]	Public health	Recurrent neural network for AI-based prediction of epidemic trend	Good epidemiological modeling and prediction of trends relating to COVID-19	Yes
Al-Najjar (2020) [23]	Public health	AI-based classifier prediction model to determine the outcome of patients	Identified key factors influencing clinical outcome, guided public health decision making	No
Jiang (2020) [24]	Clinical decision making	Tool with AI capabilities that will predict patients at risk for more severe illnesses based on clinical parameters	AI tool predicted patients at risk for more severe illness on initial presentation, provided clinical decision support	Yes
Beck (2020) [25]	Therapeutics	Used pretrained deep learning-based system to identify commercially available drugs that could act on the viral proteins of SARS-CoV-2	Used AI to discover that atazanavir, an antiretroviral medication, is the best chemical compound due to its high inhibitory potency, among several other antiviral agents that could be used in the treatment of SARS-CoV-2	Yes
Kadioglu (2020) [26]	Therapeutics	AI combined with molecular docking to identify candidates suitable for drug repurposing via in silico methods	Supervised machine learning was used to study drug likeliness of candidate compounds, helped with evaluation of the potential of various agents	Yes
Richardson (2020) [27]	Therapeutics	Use of BenevolentAI's knowledge graph to search for approved drugs that can help treat COVID-19	Baricitinib was identified as a viable drug with tolerable side effects and potential therapeutic use in patients with COVID-19	No
Ton (2020) [28]	Therapeutics	Use of Deep Docking for accelerated screening of large chemical libraries for potential drugs against COVID-19	Screened through 1.3 billion compounds from the ZINC15 library to identify the top 1000 potential ligands against the main protease (Mpro) of SARS-CoV-2 and made them publicly available	Yes
Zhang (2020) [29]	Therapeutics	Use of AI-based dock analysis to determine whether the compounds listed in Traditional Chinese Medicine databases had potential for direct SARS-CoV-2 protein interaction	Identified 26 herbal plants containing compounds potentially active against SARS-CoV-2	No

<sup>a</sup>AI: artificial intelligence.<sup>b</sup>CT: computed tomography.

**Figure 2.** Adherence of studies to reporting standards.**Figure 3.** Risk of bias and applicability assessment using PROBAST (Prediction model Risk Of Bias ASsessment Tool).

## Diagnosis

Radiological diagnosis relies on imaging data and is amenable to deep-learning techniques [30]. For COVID-19, features seen on computed tomography (CT) images include bilateral ground-glass opacification and consolidation [31]. One fully automatic 3D deep-learning framework developed for the detection of COVID-19 (COVNet) was able to extract relevant information from both 2D and 3D images obtained from a CT

scan to generate a probability score to distinguish patients with COVID-19 from patients with non-COVID-19 community-acquired pneumonia [21]. Once trained, COVNet could process each CT scan with high sensitivity (90%) and specificity (96%) for COVID-19 identification. In contrast to CT, real-time reverse-transcription polymerase chain reaction (RT-PCR), a technique frequently used for COVID-19 diagnosis, had a much lower sensitivity (71%-80%) [20,32]. Another AI system (InferRead CT Pneumonia), a deep learning diagnostic

system, was able to identify features of coronavirus infection in CT scans of patients with false-negative RT-PCR results [33]. Even without CT images, using only plain chest radiographs, a deep learning approach could improve diagnosis of COVID-19 pneumonia by augmenting radiographs with color probability [19].

Apart from superior sensitivity compared to RT-PCR, AI coupled with radiological investigations could be more efficient for COVID-19 diagnosis. For instance, COVNet could process each CT scan in under 5 seconds on average [21]. This could both decrease physician workload and allow a greater volume of patients to be evaluated, facilitating more rapid case detection [34].

## Public Health

AI has proven to be a valuable tool in public health efforts, helping to characterize the epidemiology of COVID-19 and model disease transmission, even in the early stages of the pandemic. The application of AI to this area would be particularly helpful for policy makers, in contrast to clinical decision making by individual clinicians.

Perhaps one of the most prominent examples of AI used in public health, BlueDot has demonstrated its effectiveness in predicting and monitoring infectious diseases like COVID-19. Other applications of AI gathered from our rapid review are discussed as follows. Yang et al [22] developed an AI-based model that used a form of recurrent neural network (RNN) for epidemiological modelling. The model was trained using the 2003 severe acute respiratory syndrome (SARS) epidemic data from China, while incorporating the epidemiological parameters of COVID-19 and public health interventions like the lockdown of Hubei province. Using the model, it was predicted that the number of cases in Hubei would peak in early February. When the number of predicted infections was plotted against real-time epidemiologic trends, there was considerable similarity between the actual numbers and predictions made by the AI, supporting the accuracy of such models for forecasting disease development. Similar work is in progress using a wide range of data sources.

An artificial neural network has also been used to build a classifier prediction model for patient outcomes in South Korea [23]. The Korea Centers for Disease Control and Prevention collected patient characteristics like age and gender, extracted the independent predictors, and classified patients with COVID-19 into 2 groups: deceased and recovered. This helped policy makers target the most vulnerable patients, directing attention and resources toward their care.

## Clinical Decision Making

AI can assist in clinical decision making regarding patients with COVID-19, including triage decisions for the optimal use of limited health care resources [24]. Hurt et al [19] used an AI-augmented system for plain chest radiographs to track and predict the pulmonary progression of COVID-19 among hospitalized patients, which helped to identify patients that needed critical care. Early identification of at-risk cases could further guide clinicians toward earlier intervention, which may result in improved outcomes. For instance, Jiang et al [24] took

multiple clinical parameters and constructed an AI framework that could predict deterioration even at initial presentation, with superior accuracy compared to logistic regression.

## Therapeutics

In silico screening with AI can help identify potentially effective therapeutic agents among existing drugs (ie, drug repurposing). Deep learning technology has been used to screen 1.3 billion compounds from the ZINC15 library for drug repurposing [28]. Molecule transformer-drug target interaction (MT-DTI) was a natural language processing (NLP) tool used to predict binding affinity values between commercially available antiviral drugs and target proteins on SARS-CoV-2. This led to the identification of atazanavir, an antiretroviral medication, which may also be effective against SARS-CoV-2 [25]. Similarly, using BenevolentAI's knowledge graph and a library of structured medical information, machine learning uncovered baricitinib, a Janus kinase inhibitor used for rheumatoid arthritis, as a safe candidate drug that could inhibit SARS-CoV-2 viral entry [27]. In another study, a similar process of virtual drug screening identified antiviral agents against hepatitis C as drugs that had high binding affinities to target proteins on SARS-CoV-2 [26].

Apart from the identification of conventional Western medications that may be applied to COVID-19, in silico screening with AI has also been applied to Chinese herbal medicines. Zhang et al [29] used molecular docking analysis to determine whether natural compounds listed in the Traditional Chinese Medicine (TCM) Systems Pharmacology Database, Encyclopedia of Traditional Chinese Medicine, and SymMap could interact directly with SARS-CoV-2 proteins. They eventually shortlisted 26 herbal plants containing potential SARS-CoV-2 antivirals for further trials.

## Discussion

### Limitations of AI Identified

Despite the many benefits that AI can bring to the table, there are some significant limitations to its use.

### Difficult Data Collection

AI needs large amounts of training data to generate accurate predictive algorithms [35]. For instance, the European Centre for Disease Prevention and Control requires a dedicated team of epidemiologists to screen, validate, and collate data from multiple international, regional, and local sources [36]. Even data collection for smaller geographical areas is far from easy. In the city-state of Singapore, a Health Ministry–helmed national consortium has been required to assemble detailed data from various health systems, hospitals, and clinics [37].

However, even if financial and logistical resources are plentiful, large volumes of information may not be available during the early stages of disease outbreaks, which is ironically the time when prediction is most required. Hence, relying on AI early in a disease outbreak may be impractical. Nonetheless, even if large amounts of data are available, AI is not infallible, as demonstrated by the failure of GoogleFlu, a big data analysis tool for epidemiological trending for influenza [38]. Similarly,

diagnostic AI tools like those applied to radiology require large volumes of both image- and non-image-based clinical data to achieve high accuracy [11].

Apart from the quantity of data, obtaining high-quality inputs can be particularly challenging. Informal data sources and news reports [39] provide heterogeneous data with inherent noise, resulting in biased results [40]. This is particularly concerning in the context of epidemiological trending and disease prediction, when inaccurate forecasting leads to incorrect calibration of public health responses and health care resourcing. Furthermore, the collection of data from hospitals can be complicated. Some countries, such as Singapore, achieved success with data collection efforts by having a nationwide standardized protocol and rigorous contact tracing [37]. Other countries, such as the United States, rely on individual jurisdictions to report case information to the Centers for Disease Control and Prevention (CDC), but not all jurisdictions provide daily updates. As a result, the case counts may increase at different intervals [41]. Based on a report published by the CDC COVID-19 Response Team in March, less than 6% of cases reported had information regarding the patients' comorbidities and risk factors and this incomplete data collection has limited research efforts [42].

### ***Lack of Multimodal AI Assessments***

Many studies used singular data types to perform AI-driven tasks, for instance only using radiological images for the diagnosis of COVID-19 [20,21]. Assessments of patients based on a single data type may be skewed, thus highlighting the need for a multimodal AI framework capable of analyzing different data types [35]. As there is significant overlap in how the lungs respond to different pathological insults [33], and as radiological presentation often depends on an interplay of multiple factors [21], the full potential of CT-based AI algorithms may be better realized by including non-image-based clinical data. For now, based on recommendations by the Italian Society of Medical and Interventional Radiology, CT should be used as a screening tool only for symptomatic patients with specific indications, and the use of CT with AI for screening or as a first-line test is not supported [43].

### ***Delay in Realization of Benefits***

As useful as AI may be in helping to identify drugs and vaccines against COVID-19, such treatments are unlikely to be made widely available in the immediate future, precisely when such treatments are needed the most. There is considerable delay caused by rigorous medical trials required before approval can be given to drugs or vaccines, and it can take 12-18 months just to develop a vaccine [44]. Even with a vaccine on the market, supply shortage will likely be an issue in the face of massive demand and limited initial production [45].

### ***Poor Internal Validation***

Another issue we noticed was the poor internal validation done in some of the studies, which makes it hard to determine the clinical or incremental value of AI over conventional methods. Studies that discussed the performance of AI augmentation of CT scans [21] and plain radiographs [19] did not compare AI with radiologists' evaluations, and did not describe data sets

used for validation [33]. Furthermore, confounding factors can affect the internal validity of such studies, such as how variation in respiratory effort, image contrast, technique, and the resolution of radiological images may affect the accuracy of AI-based radiological interpretation frameworks [19]. After completion of our review, we found one study that addressed our validity concerns. Bai et al [46] compared AI with radiologists and demonstrated that AI alone had higher accuracy, sensitivity, and specificity than radiologists, whereas the performance of radiologists was enhanced when AI was used to augment their evaluations.

### ***Poor External Validation***

External validation could also be improved. Many studies were only applied to patients seen at single centers, or populations within the same geographical region [20,22,23]. This could mean that algorithms shown to be accurate for the population studied may fare less well in other settings. Increasing the diversity of data sets from different populations and demonstrating the reproducibility of AI-based algorithms in different settings would be required if we are to generalize the usage of AI tools [11].

### ***Inability to Be Used by Laypersons***

While the use of AI technology in the clinical context may seem simple, the underlying theory and operating mechanisms of these algorithms are often opaque to the untrained layperson, which includes health care professionals unfamiliar with AI. For example, one of the intrinsic drawbacks of deep learning is the lack of interpretability, as it is "impossible to determine what imaging features are being used to determine the output" [21]. Physicians may not trust AI to evaluate clinical scenarios, and would not be able to troubleshoot incorrect AI-based assessments [11]. To avoid hindering AI's uptake, implementation frameworks need to be designed in a way that make AI easily operable and clearly understood by most health care professionals.

### ***Inability to Be Used in Resource-Poor Settings***

AI-based methods of disease detection, surveillance, and prognostication often require access to digital resources such as CT scanners, mobile phones, and internet access. Such resources may not be widely or consistently available in less developed regions [47]. Thus, the benefits of AI-based approaches may not be realized in resource-poor settings. Effort is needed to shift the reliance of AI from expensive technologies to cheaper and more readily accessible alternatives such as chest X-ray, point-of-care ultrasound, or even vital signs data alone.

### ***Ethical Pitfalls***

The use of AI may require access to personal information to generate trends, make predictions, and conduct assessments. Moreover, individual patient information has been placed online on multiple platforms [48]. The sharing of such information may lead to the infringement of privacy and personal rights. Although it may be acceptable to process personal data for disease containment in a pandemic, problems arise when the data are used for sinister purposes. As such, there need to be proper ethical guidelines and laws in place to govern the use of AI and big data. For example, the Australian Human Rights

Commission has set out practical steps for researchers to control the use of AI [49]. Overall, health care organizations can be viewed by patients as trustworthy, but it is important to remember that the confidentiality of the data obtained from the public should be respected, and that there should be transparency in how institutions handle the data obtained [50].

A more subtle type of ethical pitfall concerns the need for human input when programming AI tools. AI's superiority in calculation and computation does not necessarily translate into good decision making unless the machine has values that enable it to make an ethical choice, which requires input from a human programmer [51]. In other words, a particular AI program will make choices based on the programmer's morality. This raises an ethical concern, as difficult public health decisions like resource allocation are often multifaceted and based on more than just a single set of ethical guidelines conforming to the beliefs of a single person or single group of people. On a smaller scale, the decision to rely solely on the computer to make a unilateral judgment on how or whether a patient should be treated based on the machine's calculated benefit of treatment is also fraught with ethical concerns as there are some who believe that medical treatment should be discussed together with the patient [50]. As such, it is prudent to use AI only as a guide in decision making, rather than relying on it wholly.

Like all prediction methods, AI may unwittingly single out ethnic minority groups as being at high risk for disease. Unethical interpretation of prediction results may exacerbate ethnic tensions and lead to the stigmatization of and discrimination against specific ethnic groups. To illustrate, the US CDC has reported that African Americans and Hispanics have higher rates of hospitalization and mortality from COVID-19 than the White population [52]. Even though such a finding is likely to be due to differential access to health care [53], the same finding may lead to misconceptions about race and inherent disease susceptibility.

### **Legal Barriers**

Finally, there may be legal liabilities associated with adverse outcomes when human physicians use AI technologies for the care of their patients. When malpractice cases involving medical AI applications are involved, the legal system needs to be clear on which party holds the liability [30]. This is particularly worrisome given that the usability of AI, especially for the care of patients with COVID-19, is still relatively unknown due to the lack of sufficient evidence of its effectiveness over traditional methods. Consequently, medical professionals may hesitate when asked to use AI for patient management.

### **Areas for Further Work**

There are several other areas in which AI has shown significant promise.

#### **Surveillance**

Infrared thermal cameras used to screen the public for fever have been paired with AI-powered facial recognition systems to determine if individuals are wearing surgical masks [54]. A US-based computer vision startup has started offering a software that uses camera images to observe for compliance with social

distancing rules [55]. With the proliferation of such technologies, it is increasingly evident that AI-based surveillance can greatly help with public health interventions that slow the spread of infection.

Blockchain technology is a digital method that can be used in conjunction with AI, and it refers to a verifiable permanent ledger system that can be used to store health care-related information [7]. The coupling of AI with blockchain for self-testing and tracking systems has been proposed for the surveillance of COVID-19. Not only can such a system of self-testing overcome supply chain limitations in resource-scarce countries and achieve a higher rate of testing [5], it also gives real-time feedback on population health and allows for risk stratification of suspect cases.

AI can also potentially predict the occurrence of disease outbreaks early on, thus giving health authorities more time to act. Effenberger et al [56] have demonstrated the effectiveness of using internet relative search volume (RSV) indices for the forecasting of COVID-19 outbreaks in different geographical areas. Maximum public interest, and therefore maximum RSV indices, preceded peaks in case numbers. This meant that trending RSV indices can help public health authorities predict and respond to local surges of COVID-19 cases.

### **Combination With Big Data**

AI-based techniques like machine learning can be used to gather data from multiple sources for processing, which can provide novel insights. We have discussed how AI's ability to analyze large amounts of data swiftly makes it possible to use the data to predict the likelihood of new outbreaks, model successful disease containment strategies, and to find the most effective treatment protocols [9]. However, there are some other areas of application that have yet to be explored. Sun et al [57] demonstrated the value of using a Chinese health care-oriented social network that streamed reports from local or national health authorities—along with several other international media outlets—for epidemiological studies of the disease; AI can be used to facilitate this collection.

AI, when paired with big data, can find new drugs to treat COVID-19. Integrated AI-based drug discovery methods for novel drug compounds, such as deep generative models, can use large data sets to train and generate new drugs with optimized chemical properties. Such methods are often more time-efficient than traditional computational methods [58].

In addition, AI combined with big data can also be used to assess the accuracy of online information available to the public. Stratifyd, a US-based data analytics company, scans social media posts, cross-references them with data from official sources, and alerts users when false information is identified [59]. It can thus be applied to the current pandemic to prevent misinformation about the disease from spreading online. AI can also be used to analyze international air travel data. By doing so, AI can track disease spread between countries, allowing for an assessment of importation risk at a particular location and the latter's capacity to respond [60], estimation of disease spread from the epicenter of the outbreak [61], and identification of

areas that may have undetected cases imported from other countries [62].

### **Operation of Other Core Clinical Services**

As the COVID-19 pandemic exerts pressure on health care resources, institutions have had to reduce the provision of clinical services. The American College of Surgeons, for example, has provided guidelines for the management of nonemergency operations, recommending hospitals to “thoughtfully review all scheduled elective procedures” [63]. In Singapore, nonurgent medical appointments have been rescheduled and staff have been redeployed to help manage patients with COVID-19 [64]. To mitigate the impact on non-COVID-19 patients, AI can be used to augment their care.

With regard to medical investigations, AI-based radiological interpretation algorithms can be applied to read scans for non-COVID-19 diseases. With regard to medical consultations, AI-based conversational chatbots can assume some of the duties of the physician, such as symptom screening and patient education. Chatbots are already being used to combat the pandemic. Symptoma, a symptom-to-disease digital health assistant using AI, has been shown to be highly accurate when screening for COVID-19 [65]. Similarly, chatbots have been used to rapidly screen health care workers for COVID-19, facilitating staff movements and minimizing nosocomial transmission [66]. By extension, AI-based chatbots can provide a platform for patients with non-COVID-19 conditions to receive medical care at a time when clinical resources are limited. These chatbots can potentially be augmented by smartwatch-based health monitors (eg, heart rate and electrocardiogram monitoring using the Apple Watch [67]).

### **Clinical Management of Patients With COVID-19**

Studies have already established that AI can help guide management of patients with COVID-19 in general practice.

AI can also potentially help in the management of critically ill patients with COVID-19. For instance, given the uncertainty over the optimal management of COVID-19-related acute respiratory distress syndrome (ARDS) [68], AI methods like reinforcement learning could be used to determine management choices to achieve the best possible clinical outcomes [69]. Besides therapeutics, machine learning strategies can be used for vaccine development against COVID-19. They have already been applied to SARS-CoV-2 proteomes, and nonstructural proteins were found to be potential vaccine candidates [70].

### **Conclusion**

AI is no longer new in the field of medicine, and many studies have explored how its potential to enhance medical care of patients could be realized. Even as we see the situation improving in some countries, others are still struggling to contain the spread of COVID-19. In the face of growing pressure on limited health care resources, the use of AI-driven techniques to aid in diagnosis, surveillance, finding therapeutics, and public health decision making may help improve the efficiency and effectiveness of human efforts to combat the pandemic. Another recently published review found that AI could contribute to the prevention and control of the spread of COVID-19 via several important approaches: detecting suspected cases, large-scale screening, monitoring, determining interactions with experimental therapies, pneumonia screening, using the Internet of Intelligent Things for data and information gathering and integration, allocating resources; making predictions, models, and simulations; and using robotics for medical quarantine [71]. We hope that our rapid review can help highlight additional areas for more robust AI applications and studies in the later phases of the ongoing pandemic.

## Abstract

**Background:** Many factors involved in the onset and clinical course of the ongoing COVID-19 pandemic are still unknown. Although big data analytics and artificial intelligence are widely used in the realms of health and medicine, researchers are only beginning to use these tools to explore the clinical characteristics and predictive factors of patients with COVID-19.

**Objective:** Our primary objectives are to describe the clinical characteristics and determine the factors that predict intensive care unit (ICU) admission of patients with COVID-19. Determining these factors using a well-defined population can increase our understanding of the real-world epidemiology of the disease.

**Methods:** We used a combination of classic epidemiological methods, natural language processing (NLP), and machine learning (for predictive modeling) to analyze the electronic health records (EHRs) of patients with COVID-19. We explored the unstructured free text in the EHRs within the Servicio de Salud de Castilla-La Mancha (SESCAM) Health Care Network (Castilla-La Mancha, Spain) from the entire population with available EHRs (1,364,924 patients) from January 1 to March 29, 2020. We extracted related clinical information regarding diagnosis, progression, and outcome for all COVID-19 cases.

**Results:** A total of 10,504 patients with a clinical or polymerase chain reaction–confirmed diagnosis of COVID-19 were identified; 5519 (52.5%) were male, with a mean age of 58.2 years (SD 19.7). Upon admission, the most common symptoms were cough, fever, and dyspnea; however, all three symptoms occurred in fewer than half of the cases. Overall, 6.1% (83/1353) of hospitalized patients required ICU admission. Using a machine-learning, data-driven algorithm, we identified that a combination of age, fever, and tachypnea was the most parsimonious predictor of ICU admission; patients younger than 56 years, without tachypnea, and temperature <39 degrees Celsius (or >39 °C without respiratory crackles) were not admitted to the ICU. In contrast, patients with COVID-19 aged 40 to 79 years were likely to be admitted to the ICU if they had tachypnea and delayed their visit to the emergency department after being seen in primary care.

**Conclusions:** Our results show that a combination of easily obtainable clinical variables (age, fever, and tachypnea with or without respiratory crackles) predicts whether patients with COVID-19 will require ICU admission.

artificial intelligence; big data; COVID-19; electronic health records; tachypnea; SARS-CoV-2; predictive model

## Introduction

The unprecedented global spread of SARS-CoV-2, the virus that causes COVID-19, requires innovative approaches that deliver real-time results [1,2]. To date, big data analytics have been primarily used to assess SARS-CoV-2 transmission [3] and to indirectly estimate COVID-19 incidence using data from social media [4]. However, many factors involved in the onset and temporal distribution of the ongoing COVID-19 pandemic remain unknown. Similarly, both the individual and population burdens of COVID-19 are only beginning to be elucidated. Although big data analytics and artificial intelligence (AI) are widely used in the realms of health and medicine [5-7], researchers are only beginning to use these tools to explore the clinical characteristics and predictive factors of patients with COVID-19, including mortality [8-11].

Considering the unprecedented spread and severity of the ongoing COVID-19 outbreak, focus has been given to hospitals' unmet needs, particularly their ICU requirements [8,9,12]. Indeed, health systems have been or currently are near collapse, and independent modelling efforts have aimed at forecasting a number of epidemiological estimators, including ICU use [13-15].

Previously, our team reported that a combination of big data analytics and machine learning techniques helped better determine the quality of diagnosis and treatment of chronic obstructive pulmonary disease (COPD) via an analysis of hospital electronic health records (EHRs) using natural language processing (NLP) and validated algorithms [16,17].

As part of the BigCOVIData study, our primary objectives are to describe the clinical characteristics and determine the factors that predict ICU admission of patients with COVID-19. Determining these factors using a well-defined population can increase our understanding of the real-world epidemiology of the disease. To achieve this aim, we used a combination of classic epidemiological methods [18], NLP, and machine

learning (for predictive modeling) to analyze the clinical information contained in the EHRs of patients with COVID-19.

## Methods

The BigCOVIData study was conducted in compliance with legal and regulatory requirements and followed generally accepted research practices described in the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) Guideline for Good Clinical Practice, the latest edition of the Helsinki Declaration, the Guidelines for Good Pharmacoepidemiology Practices, and applicable local regulations. This study was classified as a "non-postauthorization study" by the Spanish Agency of Medicines and Health Products, and it was approved by the Research Ethics Committee at the University Hospital of Guadalajara (Spain). We and endorsed the STrengthening the Reporting of OBservational studies in Epidemiology (STROBE) guidance for reporting observational research [19].

### Study Design and Data Source

This was a multicenter, noninterventional, retrospective study using data captured in the EHRs of the participating hospitals within the Servicio de Salud de Castilla-La Mancha (SESCAM) Health Care Network in Castilla-La Mancha, Spain (Figure 1). Data captured in EHRs were collected from all available departments, including inpatient hospital, outpatient hospital, and emergency department (ED), for virtually all types of provided services in each participating hospital. The study period was January 1 to March 29, 2020.

The study database was fully anonymized in a structured format and contained no personal information from patients. Likewise, personal information was not accessed during either the application of automated and algorithmic methods (ie, NLP) or the conversion of unstructured data into the structured database. Importantly, given that clinical information was handled in an aggregate, anonymized, and irreversibly dissociated manner, patient consent regulations do not apply to the present study.

**Figure 1.** Map of the Castilla-La Mancha region (red) within the Spanish (blue line) and European territories. From a general source population of 2,035,000 inhabitants, we collected and analyzed the clinical information in the EHRs of 1,364,924 patients within the Servicio de Salud de Castilla-La Mancha (SESCAM) Health Care Network. EHR: electronic health record.

## Study Sample

The study sample included all patients in the source population who were diagnosed with COVID-19. Patients were identified on the basis of clinical diagnosis or microbiological test results. Clinical confirmation of COVID-19 cases was determined by observed symptomatology, imaging (mostly chest X-ray), and laboratory results, as captured in the unstructured, free-text information in the EHRs. Microbiological test result confirmation of COVID-19 cases involved reverse transcriptase–polymerase chain reaction (RT-PCR) or similar available tests. Our decision to consider cases confirmed both clinically and by RT-PCR was justified by the limited availability of routinely administered RT-PCR tests in the region during the study period and supported by recent discussions on the far-from-optimal sensitivity of RT-PCR for COVID-19 (ie, a single negative result from a single specimen cannot exclude the disease in suspected cases) [20,21]. Indeed, recent reports highlight the clinical validity and relatively high sensitivity of

symptom- and imaging-based identification of patients with COVID-19, especially in early stages of the disease [20,22,23].

## EHRead

To meet the study objectives, we used EHRead [24], a technology developed by Savana that applies NLP, machine learning, and deep learning to analyze the unstructured free-text information written in millions of deidentified EHRs. This technology enables the extraction of information from all types of EHRs and subsequent normalization of the extracted clinical entities to a unique terminology. This process enables further analysis of a descriptive or predictive nature. Originally based on Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) terminology, our unique body of terminology comprises more than 400,000 medical concepts, acronyms, and laboratory parameters aggregated over the course of five years of free-text mining, targeting the most common diseases (eg, respiratory diseases, cardiovascular diseases, and diabetes).

Using a combination of regular expression rules and machine learning models, the terminology entities are detected in the unstructured text and later classified based on sections typically contained in EHRs, hospital services, and other clinical specifications. Importantly, each detected term is described in terms of negative, speculative, or affirmative clinical statements; this is achieved by using deep learning convolutional neural network classification methods that rely on word embeddings and context information (for a similar methodological approach, see [25]). The limitations of case-by-case detection are also overcome with a similar approach to ensure that the detected concepts are used within the appropriate context for the descriptive and predictive analysis.

For particular cases where extra specifications are required (ie, to differentiate COVID-19 cases from other mentions of the term related to fear of the disease or to potential contact), the detection output was manually reviewed in more than 5000 reports to avoid any possible ambiguity associated with free-text reporting. All NLP deep learning models used in this study were validated using the standard training/validation/testing approach; we used a 75/12/13 split ratio in the available annotated data (between 2000 and 3000 records, depending on the model) to ensure efficient generalization on unseen cases. For all developed models, we obtained F scores greater than 0.89.

### Data Analyses

All categorical variables (eg, comorbidities, symptoms) are shown in frequency tables, whereas continuous variables (eg, age) are described via summary tables that include the mean, SD, median, minimum and maximum, and quartiles of each variable. To test for possible statistically significant differences in the distribution of categorical variables between study groups (ie, male vs female, ICU admission vs no ICU admission), we used Yates-corrected chi-square tests. For continuous variables, mean differences were tested using *t* tests. Given our general population approach and our unusually large sample size, we were interested in exploring sex-related differences in patients with COVID-19; therefore, most results were stratified by sex [26]. All statistical inferences were performed at the 5% significance level using 2-sided tests or 2-sided CIs.

### Predictive Model

We developed a decision tree to classify patients with COVID-19 according to their risk of being admitted to the ICU. The two types of patients or *classes* considered in the model were therefore “admitted to the ICU” and “not admitted to the ICU.” The model maps the characteristics of the patients (the *variables*) to their class in the shape of a tree. From a clinical perspective, this model contemplates all patient variables upon

admission; therefore, it is predictive from symptom debut until outcome. The tree is composed of nodes that branch to subsequent child nodes depending on the patient’s variables. The tree is built in such a way that each branch separates the two classes as much as possible. This separation is measured as the Shannon entropy, where a node with an entropy of zero indicates that the classification is perfect (either all or none of the patients were admitted to the ICU) and an entropy of one is the worst possible mix (50%/50%) [27].

### Model Training and Validation

The model was developed and tested on the available data from hospitalized patients who had or had not been admitted to the ICU; the latter were either discharged from the hospital or died in the course of the disease. This amounted to a total of 900 patients. We validated our algorithm by splitting our COVID-19 sample into a 70% training set and a 30% validation set. This means that the model was trained with 630 patients (582 who did not require intensive care vs 48 who did) and validated over the remaining 270 patients. Because the two classes were unbalanced (far fewer patients required ICU admission), we used the standard technique of oversampling the lower class to guarantee a balance of accuracy and recall (ie, the tradeoff between false positives vs false negatives). Further, we sought to replicate the results of this validation in an a posteriori sensitivity analysis, as per recent recommendations for predictive modeling in COVID-19 [28] and TRIPOD (Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis) guidance [29]. For this second validation, we trained the model with data from the provinces of Ciudad Real and Guadalajara (38% of the study sample from Castilla-La Mancha), and we used an independent set with combined data set from the other three provinces, namely Toledo, Cuenca, and Albacete, for validation.

Additional details regarding the development and validation of the predictive algorithm are included in the Supplementary Methods in [Multimedia Appendix 1](#). The workflow used for the generation of the predictive algorithm is summarized in Figure S1 in [Multimedia Appendix 1](#).

## Results

From a source general population of 2,035,000 inhabitants, we used NLP and machine learning to analyze the clinical information contained in the EHRs of 1,364,924 anonymous patients ([Figure 1](#)). Among these, we identified a total of 10,504 patients diagnosed with COVID-19 ([Figure 2](#)). The flowchart of participation in the study up to hospital admission, ICU admission, or discharge is presented in [Figure 2](#).

**Figure 2.** Patient flowchart depicting the total number of inhabitants in the source population, the number (%) of patients with available EHRs analyzed, the number of patients diagnosed with COVID-19, and of those, the number of hospitalizations and ICU admissions. EHR: electronic health record; ICU: intensive care unit.

Of the patients with COVID-19, 52.5% (5519/10,504) were male, with a mean age of 58.2 years (SD 19.7) (Table 1). Most patients with COVID-19 were aged  $\geq 50$  years (Figure 3). Upon diagnosis, the most common symptoms reported were cough, fever, and dyspnea (Table 1); notably, less than half of patients presented with all three of these symptoms. Further, respiratory crackles, myalgia, and diarrhea were identified in  $\geq 5\%$  of cases, while other respiratory and nonrespiratory signs and symptoms

were less common. Sex-dependent differences in sign and symptom frequencies upon diagnosis are shown in Table 1. Of note, we observed subtle increases in the frequency of diarrhea, myalgia, headache, chest pain, and anosmia in female patients with COVID-19, while male patients showed significant increases in fever, dyspnea, respiratory crackles, rhonchus, lymphopenia, and tachypnea (all  $P < .05$ ).

**Table 1.** Baseline demographics and clinical data of the patients in the study upon diagnosis (N=10,504).

Characteristic	Female	Male	Total	P value <sup>a</sup>
Sex <sup>b</sup> , n (%)	4984 (47.4)	5519 (52.5)	10,504 (100)	N/A <sup>c</sup>

<sup>a</sup>*P* values from Yates-corrected chi-square test on percentage difference of female vs male COVID-19 patients. All tests were performed individually for each variable (sign, symptom, or comorbidity, where applicable). For numerical values (ie, age), *t* tests of difference between means were used.

<sup>b</sup>The sex of one patient was listed as Unknown.

<sup>c</sup>N/A: not applicable.

<sup>d</sup>List of medical conditions according to Systematized Nomenclature of Medicine Clinical Terms terminology.

<sup>e</sup>CKD: chronic kidney disease.

<sup>f</sup>COPD: chronic obstructive pulmonary disease.

<sup>g</sup>OSA: obstructive sleep apnea.

**Figure 3.** Age distribution of incident cases of COVID-19 in females (left) and males (right) in the study population for the period comprised between Jan 1, 2020 and March 29, 2020.

Similarly, the most frequent comorbidities among the 10,504 patients were cardiovascular disease ( $n=5058$ , 48.2%), mainly arterial hypertension ( $n=3527$ , 33.6%); heart disease ( $n=2639$ , 25.1%); and diabetes ( $n=1646$ , 15.7%) (Table 1). Regarding respiratory diseases, COPD was present in 6.4% (675), asthma in 7.2% (759), obstructive sleep apnea (OSA) in 2% (212), and bronchiectasis in 1.2% (129) of the 10,504 patients. Sex-dependent differences in comorbidities upon diagnosis are also shown in Table 1; except for asthma, the frequency of all comorbidities was significantly higher in male than in female patients with COVID-19 (all  $P<.05$ ).

Next, we explored whether the distribution of comorbidities and signs and symptoms captured in the patients' EHRs upon diagnosis differed between patients with COVID-19 who were and were not admitted to the ICU (Table 2). Regarding comorbidities, diabetes, obesity, cardiovascular disease (mainly hypertension), heart disease (mainly ischemic heart disease), and renal dysfunction were more common among patients who were admitted to the ICU (all  $P<.01$ ). As for signs and symptoms, cough, fever, dyspnea, respiratory crackles, diarrhea, tachypnea, lymphopenia, and rhonchus were more frequent among ICU patients (all  $P<.05$ ). Interestingly, respiratory diseases were not more frequent among patients who were admitted to the ICU (Table 2).

**Table 2.** Associations of signs and symptoms and comorbidities with ICU admission upon diagnosis in patients with COVID-19 (N=10,504).

<sup>d</sup>COPD: chronic obstructive pulmonary disease.

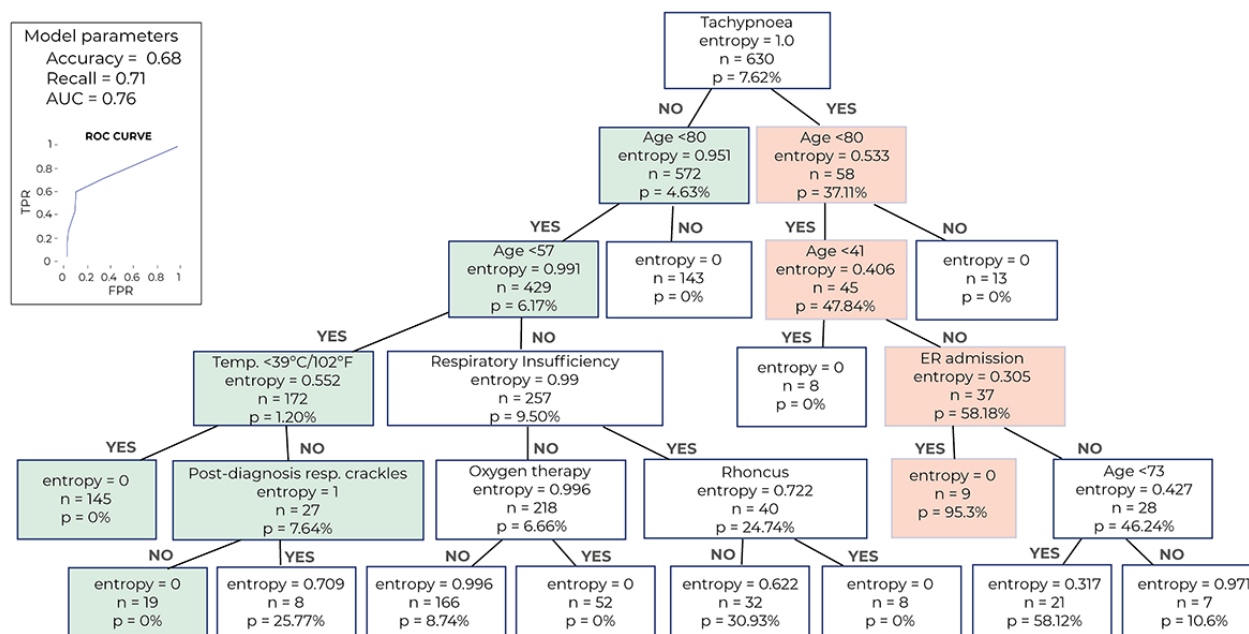

<sup>e</sup>OSA: obstructive sleep apnea.

<sup>f</sup>CKD: chronic kidney disease.

Finally, by using a machine-learning, data-driven algorithm, we identified that a combination of three easily available clinical variables, namely age, temperature, and respiratory frequency, was the most parsimonious predictor of ICU admission among patients with COVID-19 (Figure 4). For this model, age and temperature were captured as continuous variables, whereas tachypnea (yes/no) was defined as a respiratory frequency of more than 20 breaths per minute. With accuracy, recall, and area under the curve (AUC) values of 0.68, 0.71, and 0.76, respectively, the presented model reached optimal balance in terms of positive and negative predictive values for ICU admission. On the one hand, patients younger than 56 years, without tachypnea, and with temperature <39 °C (entropy=0, n=145) or >39 °C without respiratory crackles (entropy=0, n=18) were not admitted to the ICU. On the other hand, patients with COVID-19 aged 40 to 70 years were likely to be admitted in the ICU if they presented with tachypnea and delayed their visit

to the ED after being seen in primary care (entropy=0, n=104). As stated in the Methods section, we performed an additional sensitivity analysis with different data sets to further validate the results of our predictive model. The independent data set of two provinces (Ciudad Real and Guadalajara, including a total of 753,408 individual patients, or 38% of the entire study sample from Castilla-La Mancha; Figure 1 and Supplemental Table S1 in Multimedia Appendix 1), was used to retrain our algorithm to identify ICU admission at onset; validation was performed in the remaining three provinces. As shown in Supplemental Figure S2 in Multimedia Appendix 1, the new decision tree identified the same relevant clinical variables, that is age, tachypnea, temperature, and respiratory crackles/rhonchus, with similar (but not identical) thresholds in some variables. This additional model achieved accuracy, recall, and AUC values of 0.85, 0.57, and 0.84, respectively, providing additional proof of validity for our main findings.

**Figure 4.** Decision tree of relevant clinical variables for the prediction of ICU admission in patients with COVID-19. The combination of three easily available clinical variables, namely age, temperature, and respiratory frequency, was the most parsimonious predictor of ICU admission among COVID-19 patients. The number of patients, probability (p) of ICU admission predicted by the model, and level of entropy (a measure indicating how mixed or pure the classification is, where 0 indicates optimal separation of classes) are indicated in each box. The green pathway indicates that patients with no tachypnea, age <56 years, and temperature <39 °C (OR >39 °C without respiratory crackles) did not require ICU admission. In contrast, the red pathway indicates that patients aged 40-79 years, who presented with tachypnea, and who delayed their visit to the emergency department after being seen in primary care were likely to be admitted in the ICU. For this model, we obtained accuracy, recall, and AUC values of 0.68, 0.71, and 0.76, respectively (top right panel). AUC: area under the curve; FPR: false positive rate; resp.: respiratory; ROC: receiver operating characteristic; TPR: true positive rate.

## Discussion

### Principal Findings

By accessing the clinical information of more than 10,000 anonymous patients with COVID-19 (a number that largely

surpasses samples included in recent reports about the disease [30,31]), we were able to describe their demographic and clinical characteristics, their clinical journey, and the statistical relationship between the most common symptoms and comorbidities on admission, and COVID-19 prognosis (ie, ICU admission). There were subtle differences in clinical symptoms

at onset by sex, while all comorbidities (except asthma) were significantly more frequent in male than female patients with COVID-19. The variables identified in our ICU admission model (ie, age, temperature, and tachypnea) are clinically relevant, as they are readily available and easily observable in everyday practice for patients with COVID-19. Although tachypnea is not an exclusive manifestation of COVID-19 and can be present in patients suffering from other respiratory diseases (ie, pneumonia), our model suggests that this sign (in combination with age and temperature) is a more reliable predictor of ICU use than other common symptoms and signs, such as cough, dyspnea, or respiratory crackles.

The reported sex-dependent differences in the symptomatology of COVID-19 at onset have been further confirmed by our group using similar methods [32] and should be interpreted in light of data suggesting that female teenagers and young adult women are significantly more affected by the disease than their male counterparts [32]. In this regard, our results warrant further investigations aimed at closing the gender gap in the ongoing pandemic [33].

Given that the stability and capacity of ICUs worldwide is threatened by the rapid spread of COVID-19, the identification of individual factors that predict ICU admission may not only improve patient management but also optimize health care resource use and planning. Thus, recent studies using big data and machine learning have explored the prognostic factors of the disease, including ICU transfer, discharge, and mortality [8-11]. In line with our results, respiratory rate has also been identified as an important predictor of ICU transfer in patients with COVID-19 [9].

If further applied to other national and international health care networks, the tools and methodology presented in this study can potentially characterize and predict the prognosis of COVID-19 in a timely and unprecedented manner. As demonstrated in recent studies [34,35], there may be value in the application of AI to the current COVID-19 pandemic, not only to predict outbreaks [36] or read chest computed tomography scans [37] but also to elucidate the clinical onset and natural history of COVID-19 almost in real time. Indeed, classical methods would require months of questionnaire-based data collection and questionnaire validation along with multiple Ethics Board approvals and other practical hurdles; these steps can be avoided with our current approach.

In the race against COVID-19 [38], where the goal is to curb the pandemic, it is imperative to leverage big data and intelligent analytics for the betterment of public health. However, it is of the utmost importance not to neglect privacy and public trust, to apply best practices, and to maintain responsible standards for data collection and data processing on a global scale [39].

## Strengths and Limitations

To our knowledge, this is one of the first attempts to combine NLP and machine learning to access and analyze unstructured, free-text real-world data from EHRs in a large series of patients with COVID-19. Although recent studies have used machine learning to predict ICU admission in patients with COVID-19 [9], our approach takes this methodology one step further by

applying NLP to exclusively analyze unstructured information. Indeed, our state-of-the-art methodology enabled rapid analysis of the unstructured free-text narratives in the EHRs of 1 million patients from the general population of the region of Castilla-La Mancha (Spain).

Our methodology combined modules for sentence segmentation, tokenization, text normalization, acronym disambiguation, negation detection, and a multidimensional ranking scheme; the latter involved linguistic knowledge, statistical evidence, and continuous vector representations of words and documents learned via shallow neural networks. When applied to EHRs, NLP enables both access to longitudinal health records for *all* patients in the target population and the implementation of exploratory analysis to clarify associations between variables that have remained undetected with traditional research methods. By considering all possible patients with the target disease, the information and analyses used here (ie, real-world data and free-scale statistics) remained unbiased by the research question or the observers. Unlike classical statistical methods (eg, logistic regression), the main advantage associated with the use of machine learning in this context is that it enables the automatic detection of meaningful relationships between variables. For instance, if a given symptom (ie, fever) is only relevant for certain patients (ie, older than 50 years), techniques such as the classification trees used here are suitable to uncover this relationship. In this context, although the total number of patients who required ICU use in the training set was somewhat low (48 patients), the number of variables considered in the model was also very limited. In addition, the inclusion of a validation stage reduces the likelihood of overfitting. Ultimately, the use of classification trees in this study (as opposed to other models, such as artificial neural networks) is especially appropriate in the clinical context because they are easily interpretable.

Regarding the geographical location of our participating hospital sites, it is worth mentioning that with a total of 1,364,924 patients from the region of Castilla-La Mancha (SESCAM Health Care Network), our sample is representative of the Spanish population. Spain is among the countries that have been most affected by the pandemic in terms of both total cases and mortality rates [40,41]; the Castilla-La Mancha region in particular is the third most affected region in the country, just behind Madrid and Catalonia. For this reason, we anticipate that the clinical conclusions drawn here will be relevant for clinicians worldwide. Of note, the ICU capacity in the region during the study period had not yet been compromised, which protects against possible bias in our training data (all patients requiring intensive care were indeed admitted to the ICU).

The results and conclusions of the present study should be interpreted in light of the following limitations. First, we did not distinguish COVID-19 cases confirmed by laboratory results (ie, RT-PCR) from those exclusively diagnosed through clinical observation (ie, symptomatology, imaging and laboratory results). However, it should be noted that PCR and other rapid laboratory tests for the detection of SARS-CoV-2 were not routinely administered in Spain during the study period. In addition, this decision is supported by recent discussions on the clinical validity and relatively high sensitivity of symptom- and

imaging-based identification of patients with COVID-19, especially in early stages of the disease [20,22,23]. Second, independent replications by different research groups in larger patient sets are needed to further support the clinical validity of our results.

Finally, future reports from the BigCOVIData study may incorporate laboratory results and treatments and may contextualize the results presented here in a larger clinical picture [28].

## Conclusion

In this study, we found that in the largest series of patients with COVID-19 attended during the first three months of the pandemic in Spain, 6.1% of all hospitalized patients (83/1353) required ICU admission. We also found that a combination of easily obtained clinical variables, namely age, fever, and tachypnea, predicts whether patients with COVID-19 will require ICU admission.

## Acknowledgments

The members of the Savana COVID-19 Research Group are Ignacio H Medrano, MD; Jorge Tello; Alberto Porras, MD, PhD; Marisa Serrano, PhD; Sara Lumbreras, PhD; Universidad Pontificia Comillas; Carlos Del Rio-Bermudez, PhD; Stephanie Marchesseau, PhD; Ignacio Salcedo; Andrea Martínez; Claudia Maté, MD; Sergio Collazo, MD; Jesús Barea, MD; María Villamayor, MD; Antonio Urda, MD, PhD; Carolina de la Pinta, MD; Imanol Zubizarreta; Yolanda González, PhD; and Sebastian Menke, PhD. We thank all the Savaners for helping accelerate health science with their daily work. This study would have not been possible without every single team member. This study was sponsored by Savana [42]. We also thank the SESCAM Health Care Network in Castilla-La Mancha, Spain, for its participation in the study and for supporting the development of cutting-edge technology in real time.

## Abstract

**Background:** Internet hospitals show great potential for adequately fulfilling people's demands for high-quality outpatient services, and with the normalization of the epidemic prevention and control of COVID-19, internet hospitals play an increasingly important role in delivering health services to the public. However, the factors that influence patients' intention to use the online inquiry services provided by internet hospitals remain unclear. Understanding the patients' behavioral intention is necessary to support the development of internet hospitals in China and promote patients' intention to use online inquiry services provided by internet hospitals during the prevention and control of the COVID-19 epidemic.

**Objective:** The purpose of this study is to identify the determinants of patients' intention to use the online inquiry services provided by internet hospitals based on the theory of planned behavior (TPB).

**Methods:** The hypotheses of our research model were developed based on the TPB. A questionnaire was developed through patient interviews, verified using a presurvey, and used for data collection for this study. The cluster sampling technique was used to include respondents with chronic diseases. Structural equation modeling was used to test the research hypotheses.

**Results:** A total of 638 valid responses were received from patients with chronic diseases. The goodness-of-fit indexes corroborated that the research model was a good fit for the collected data. The model explained 45.9% of the variance in attitude toward the behavior and 60.5% of the variance in behavioral intention. Perceived behavioral control and perceived severity of disease had the strongest total effects on behavioral intention ( $\beta=.624$ ,  $P=.004$  and  $\beta=.544$ ,  $P=.003$ , respectively). Moreover, perceived convenience, perceived information risk, emotional preference, and health consciousness had indirect effects on behavioral intention, and these effects were mediated by attitude toward the behavior. Among the four constructs, perceived convenience had the highest indirect effect on behavioral intention ( $\beta=.207$ ;  $P=.001$ ).

**Conclusions:** Perceived behavioral control and perceived severity of disease are the most important determinants of patients' intention to use the online inquiry services provided by internet hospitals. Therefore, internet hospitals should further optimize the design of online service delivery and ensure a reasonable assembly of high-quality experts, which will benefit the promotion of patients' adoption intention toward online inquiry services for health purposes. Perceived convenience, emotional preference, and perceived risks also have effects on behavioral intention. Therefore, the relevant quality control standards and regulations for internet hospitals should be further developed and improved, and the measures to protect personal information should be

strengthened to ensure the patient safety. Our study supports the use of the TPB in explaining patients' intention to use online inquiry services provided by internet hospitals.

## Introduction

### Background

With the development of human society, an aging population with chronic and age-related diseases, and its increasing health care requirements have become a challenge for the governments of all countries worldwide, especially China [1,2]. In China, many people complain about the “difficulty of seeing a doctor” and tend to go to high-level hospitals even for mild symptoms [3]. It is difficult for patients in rural and remote areas to access high-quality health services owing to an uneven distribution of medical resources [4,5]; moreover, the time spent by physicians on communicating with each patient is limited, usually less than 3 minutes in outpatient departments in large hospitals [6]. A latest national health services survey showed the rate of chronic diseases in Chinese residents was up to 245.2 person per thousand population, and the majority of the common chronic diseases were hypertension, diabetes, and heart disease [7]. Patients with chronic diseases such as diabetes receive little education or information about their diseases in such a short time [8]; thus, their health service requirements are rarely fulfilled. Under such circumstances, inability of traditional medical resources to meet the increasing demands of health services for the public contributes to the emergence of internet hospitals [9].

Internet hospitals, a novel approach to health service delivery via internet technology [3,9,10], were developed as a potential solution to optimize the allocation of health resources and to meet people's demands for high-quality health services [3]. Compared with mobile health (mHealth), a technology integration of mobile computing, medical sensors, and portable devices for meeting the needs of consumers about health care or health information services [11], internet hospitals refer to one-stop online service platforms based on traditional hospitals, which integrate consultation, prescription, payment, and drug delivery; internet hospitals enable patients to communicate with skilled experts anytime and anywhere using a website or a smartphone app and gain access to health-related services such as online disease counseling, online guidance, electronic prescriptions, medical information, remote diagnosis, treatment and rehabilitation, chronic disease follow-up, and health education [3,9]. Several studies have shown that compared with traditional medical services, internet hospitals increased the time that the physicians spent with each patient, improved the accessibility to high-quality health care, alleviated the difficulty of “seeing a doctor” [3,12], promoted the rational distribution of health resources, and improved the balance between supply and demand of health resources in China [4,9]. In addition, the Chinese government has implemented an ambitious national

strategy called “Health China” since 2016, and this strategy is expected to solve the problem of “difficulty and expense of seeing a doctor” and improve the ability of medical resources to meet the increasing demands of the public health services in China [13]. Thus, the development of internet hospitals is crucial for implementing this national strategy.

Internet hospitals have also shown great potential for the epidemic prevention and control of COVID-19 in China [10,14]. During the COVID-19 epidemic, internet hospitals, which provide free COVID-19 consultation services and offer essential medical support to the public, have effectively reduced the probability of nosocomial cross-infections and fulfilled patients' demands for outpatient services, especially for patients with chronic diseases [10], and thus, have been further widely accepted by society. However, a latest research report in China in 2020 has highlighted that the users' acceptance of online inquiry services provided by different types of internet hospitals was relatively poor, with significant differences [15]. Among enterprise-led internet hospitals such as WeDoctor, Hao Yisheng, and AliHealth, more than half (53.4%) provided services to less than 1000 patients per day, whereas approximately one-third (26.6%) provided services to more than 3000 patients per day. Moreover, the number of daily outpatient visits of medical institution-led internet hospitals such as the internet hospital of People's Hospital of Zhejiang Province and the internet hospital of No.2 People's Hospital of Guangdong Province was generally lower, with two-thirds (66.7%) of the internet hospitals providing services to less than 100 patients per day.

With the normalization of prevention and control of the COVID-19 epidemic, internet hospitals play an increasingly important role in delivering health services to the public. Moreover, issues such as whether patients accept internet hospitals and what factors influence patients' decisions regarding the online inquiry services provided by internet hospitals should be considered for the long-term development of internet hospitals. Understanding the factors that affect patients' intention to use online inquiry services will help internet hospitals to further improve their service design, promote their development, and thus promote patients' health care-seeking intention to use online inquiry services during the prevention and control of the COVID-19 epidemic. However, the factors influencing patients' health care-seeking intention to use online inquiry services provided by internet hospitals remain unclear.

Previous studies on patients' health care-seeking behaviors of online inquiry focus on mHealth services, and theoretical models have been applied to identify the determinants of adoption intentions for mHealth services [8,13,16-18] or health technology [19-21]; however, few studies focus on patients'

health care-seeking intention to use the online inquiry service provided by internet hospitals. A theoretical model must be identified and tested to provide a context-related understanding of patients' intention to use the online inquiry services provided by internet hospitals. Internet hospitals have unique service delivery characteristics, and patients exhibit different degrees of acceptance for online inquiry services for different types of internet hospitals [15]. Thus, it is necessary to analyze the factors influencing the intention to use the online inquiry services provided by internet hospitals. To date, relevant theoretical models have not been applied to patients' intention to use the online inquiry services in the context of internet hospitals.

### Theory of Planned Behavior

The theory of planned behavior (TPB), an expansion of the theory of reasoned action, has been widely used as a classical theory in explaining and predicting various types of human behaviors [22,23]. The TPB mainly consists of five variables: attitude toward the behavior, subjective norm (SN), perceived behavioral control (PBC), behavioral intention, and actual behavior. According to TPB, whether individuals perform a certain behavior depends on their behavioral intention to perform the behavior. Behavioral intention is determined by the following factors: attitude toward the behavior, SN, and PBC, which is also called adoption intention [23]. Compared with the technology acceptance model, which has been widely applied to the acceptance and use of information technology [13,16], TPB considers both the subjective and social factors affecting patients' behavioral intention as well as external control conditions that are not affected by personal willingness [22,23]. In health care settings, patients' intention to perform a behavior for health purposes is often the result of an interaction between internal and external factors. The TPB has been frequently applied in the field of mHealth services [24-27], and these studies found that attitude toward the behavior, SN, and PBC are the major determinants of behavioral intention toward mHealth service adoption. However, to date, TPB has not been used in the study of the factors influencing patients' behavioral intention to use online inquiry services in the context of internet hospitals. Considering the uniqueness of mHealth service, Zhang et al [27] proposed the integration of TPB and protection motivation theory in the context of mHealth services and found an indirect effect of perceived severity of disease (PSD) on behavioral intention. Thus, patients' PSD should be considered. To date, China has not established an effective quality control system for internet hospitals [12,15]. Potential medical risks of the online inquiry services provided by internet hospitals threaten patients' health safety. Therefore, medical risks should also be considered.

Thus, in this study, we combined the TPB and patients' PSD and perceived medical risks (PMRs) to develop a theoretical model to identify the factors influencing patients' behavioral intention to use the online inquiry services provided by internet hospitals.

### Research Hypotheses and Model

In this study, the TPB model was adopted as the theoretical framework, where attitude toward the behavior refers to the

extent to which a patient has a favorable or unfavorable opinion of online inquiry behavior; SN is defined as a patient's perceived social pressure when performing online inquiry; and PBC is defined as a patient's perception of the degree of ease or difficulty when using the online inquiry services provided by internet hospitals, and it is generally equivalent to self-efficacy [23,27]. Several studies have shown that attitude toward the behavior, SN, and PBC are the positive determinants of patients' adoption intention toward mHealth services [24,26,27]. Therefore, three hypotheses were formulated as follows:

- Hypothesis (H)1: Attitude toward the behavior has a positive effect on the behavioral intention of patients to use the online inquiry services provided by internet hospitals.
- H2: PBC has a positive effect on the behavioral intention of patients to use the online inquiry services provided by internet hospitals.
- H3: SN has a positive effect on the behavioral intention of patients to use the online inquiry services provided by internet hospitals.

A previous study on the use of mobile technology demonstrated that perceived convenience (PC) positively affected attitude toward the behavior [28]. Internet hospitals not only save the time and effort that patients spend on seeking health services but also conveniently provide patients with health services via the internet anywhere and anytime. In this study, we define PC as patients' perceptions of saving time and effort when using the online inquiry services provided by internet hospitals. If patients find it convenient to access health service while having to spend less time and effort, they will have a positive attitude toward participating in telemedicine [29]. Thus, we posed the following hypothesis:

- H4: PC has a positive effect on the attitude of patients toward using online inquiry in internet hospitals.

A study concerning mobile commerce demonstrated the effect of perceived outcome (PO) on behavioral intention, and this effect was mediated by behavioral attitude [30]. In health care settings, the value of PO affects patients' choices to a certain extent, and patients in China tend to go to high-level hospitals rather than primary health care institutions even for mild symptoms [3]. If patients find that the service outcomes obtained from internet hospitals are consistent with or even better than those from traditional large hospitals, they may have a positive attitude toward online inquiry. In this study, PO refers to patients' perceptions of the degree to which online inquiry achieves the expected health outcome improvement. Thus, we posed the following hypothesis:

- H5: PO has a positive effect on the attitude of patients toward online inquiry in internet hospitals.

Although mHealth services may promote the accessibility of high-quality health services, alleviate the difficulty in "seeing a doctor," and thus improve patients' quality of life, they also lead to issues regarding quality control, information security, and privacy protection [31,32]. Likewise, internet hospitals were potentially puzzled by these issues. The potential risks of using the online inquiry services provided by internet hospitals include medical risk and information risk. Patients may want

to gain access to health services from internet hospitals but may not want to get involved in medical disputes for undesired outcomes or disclose their personal information resulting in online fraud. To date, China has not established an effective quality control system for internet hospitals [12,15], and their potential medical risks threaten patient safety, thereby possibly affecting patients' intention to use the online inquiry services of internet hospitals. In this study, we define perceived information risk (PIR) as patients' perception of lack of control over their personal information (ie, privacy information on health care-seeking data) after they have adopted the online inquiry services provided by internet hospitals. Information privacy concern is a core predictor of PIR [33]. A study by Deng et al [13] found that privacy risk was negatively correlated with adoption intention toward mHealth services, and a study by Zhang et al [8] on the intention to use diabetes management apps found that perceived privacy risk negatively influenced behavioral intention. Therefore, we formulated the following hypotheses:

- H6a: PMR has a negative effect on the behavioral intention of patients to use online inquiry in internet hospitals.
- H6b: PIR has a negative effect on the attitude of patients toward online inquiry in internet hospitals.

Emotional preference (EP) could be defined as emotions that individuals are motivated to experience; these emotions strongly influence various human behaviors [34]. In health care settings, a patient's EP needs to be respected and be inaccessible protection from society. Several studies regarding patients with mental health problems suggest that the requirements of patients associated with their EPs, owing to issues such as stigma and social discrimination, affected their intention toward seeking help in time [35,36]. In internet hospitals, patients equipped with mobile devices can communicate with physicians without the constraints of time and space, which help to meet the requirements associated with their EPs, for example, privacy protection and avoiding embarrassment and stress to a certain extent; thus, those with EP may have a positive attitude toward online inquiry services of internet hospitals. Therefore, we established the following hypothesis:

- H7: EP has a positive effect on the attitude of patients toward online inquiry in internet hospitals.

With the rapid development of internet hospitals, the issue of their medical liability comes to the fore, threatening patient safety [3,37,38]. In addition to patients, physicians, and hospitals, the stakeholders of internet hospitals also involve a third-party medical platform, which could cause a more complex medical dispute. However, to date, the complaint system established by the Chinese government for internet hospitals regarding medical accidents and medical disputes is imperfect,

and the related regulations from traditional hospitals are often used for the management of medical behaviors in internet hospitals [12,15]. If patients find it challenging to defend their rights and interests in internet hospitals, they may have a negative attitude toward online inquiry. Therefore, we posed the following hypothesis:

- H8: Perceived medical liability (PML) has a negative effect on the attitude of patients toward online inquiry in internet hospitals.

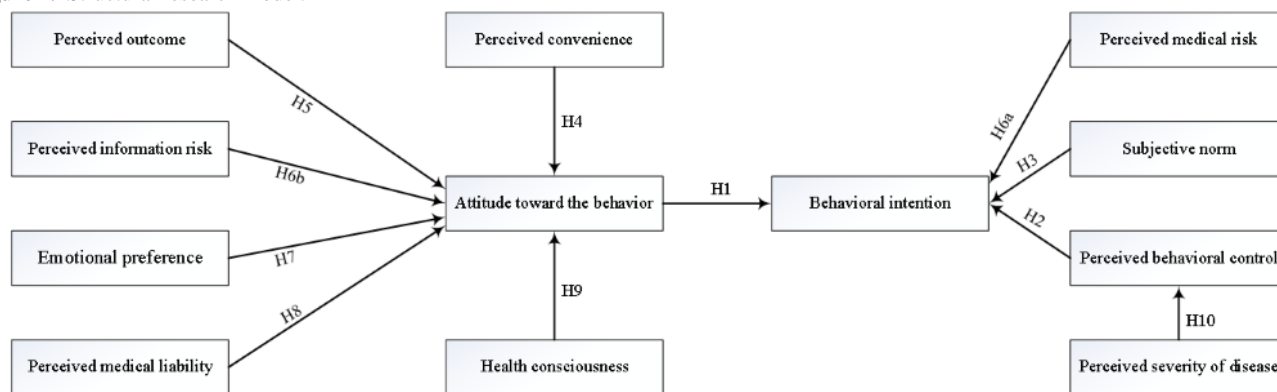

Health consciousness is defined as the degree to which health concerns are integrated into an individual's daily life, thus creating a motivation for health improvement [39]. A study by Guo et al [40] found such a moderation effect of health consciousness on behavioral attitude toward continuous use of mHealth services [40], and an investigation by Ahadzadeh et al [20] found that the partial effect of health consciousness on the intention toward health-related internet use was mediated by behavioral attitude [20]. Thus, we posed the following hypothesis:

- H9: Health consciousness has a positive effect on the attitude of patients toward online inquiry in internet hospitals.

As well as health consciousness, PSD is a driving factor for health-seeking behaviors [18]. PSD could be defined as patients' perception of the degree of seriousness of their untreated diseases, including opinions of clinical consequences and potential social consequences [27]. A higher perceived health risk of the disease consequences leads to a greater motivation to adopt a health-oriented behavior for access to health services. This hypothesis has been tested in several studies [19,20]. Several other studies on mHealth services also found that the PSD has a positive effect on behavioral intention [18,27]. In China, people usually tend to go to traditional high-level hospitals even for mild symptoms, owing to their lack of confidence in the quality of health care provided by primary care institutions [3]. When individuals perceive a more serious health threat, they might tend to consider the online inquiry service provided by internet hospitals challenging for the purpose of diagnosing or treating their diseases, and thus, they are likely to seek high-quality health services in traditional large hospitals rather than in internet hospitals. Thus, we posed the following hypothesis:

- H10: PSD has a negative effect on the patients' PBC of online inquiry in internet hospitals.

The 11 research hypotheses, with reference to the results of eliciting salient beliefs from patient interviews, are summarized in the research model (Figure 1).

**Figure 1.** Structural research model.

## Methods

### Development of the Study Questionnaire

We developed a survey questionnaire for the research model. We interviewed 19 patients effectively according to the connotation requirements of the TPB [41]; the results of eliciting

salient beliefs from patient interviews were used to design the questionnaire items, and the items were also discussed and approved by a focus group. The questionnaire items (Textbox 1) were measured with a 5-point Likert scale ranging from “strongly disagree” (1) to “strongly agree” (5). We then performed a presurvey to validate the designed questionnaire.

**Textbox 1.** Measurement items of the constructs.**Perceived convenience**

1. I think it is convenient to use the online inquiry services provided by internet hospitals anywhere without going to the hospital in person.
2. I think that internet hospitals could provide a vast amount of medical information and help me find well-known hospitals or doctors across the country.
3. I think it is time-saving to make an online inquiry through internet hospitals.
4. I think that using the online inquiry services provided by internet hospitals could be helpful to save expenses such as transportation and lodging fees.
5. I think that using the online inquiry services provided by internet hospitals could be helpful to decrease losses such as the loss of normal income due to sick leaves.

**Perceived outcome**

1. I think that the online inquiry services provided by internet hospitals are helpful to accurately understand the conditions.
2. I think that effective treatment recommendations could be obtained through the online inquiry services provided by internet hospitals.
3. I think that effective medication guidance could be obtained through the online inquiry services provided by internet hospitals.

**Perceived medical risk**

1. I am worried that physicians in internet hospitals pay less attention to my conditions.
2. I have doubts about the professionalism of internet hospitals or their physicians.
3. I have doubts about the authenticity of internet hospitals or their physicians.
4. I am worried that I may not be able to clearly explain my conditions to physicians when using online inquiry services provided by internet hospitals.
5. I am worried that, because the online inquiry services provided by internet hospitals cannot provide medical examinations, it may result in misdiagnosis and missed diagnosis.

**Perceived information risk**

1. I am worried that I would be deceived during the use of the online inquiry services provided by internet hospitals.
2. I am worried that the personal information could be disclosed after using the online inquiry services provided by internet hospitals.

**Emotional preference**

1. I think that using the online inquiry services provided by internet hospitals could avoid the tension associated with face-to-face communication with physicians.
2. I think that using the online inquiry services provided by internet hospitals could be helpful to protect personal information and avoid the embarrassment associated with face-to-face communication with physicians.

**Perceived medical liability**

1. I think the relevant laws and regulations about the online inquiry services provided by internet hospitals are at an imperfect stage.
2. I think it is difficult to divide the liability of medical accidents encountered between patients, physicians, hospitals, and network platforms when using the online inquiry services provided by internet hospitals.
3. I think it is difficult to protect my legal rights when a medical accident occurs while using the online inquiry services provided by internet hospitals.

**Attitude toward the behavior**

1. Overall, I think using the online inquiry services provided by internet hospitals is a better experience than those provided by traditional hospitals.
2. Overall, I think using the online inquiry services provided by internet hospitals is helpful for disease treatment.
3. Overall, I think it is meaningful to using the online inquiry services provided by internet hospitals.

**Subjective norm**

1. Both family and friends around me think that I should use the online inquiry services provided by internet hospitals.
2. Patients around me think that I should use the online inquiry services provided by internet hospitals.
3. Web friends think that I should use the online inquiry services provided by internet hospitals.

4. The government has been advocating the use of online inquiry services provided by internet hospitals.

#### Health consciousness

1. I am aware of and very concerned about my health problems.
2. I will try to manage and improve my wellness.

#### Perceived severity of disease

1. I do not think my health problems are serious.

#### Perceived behavioral control

1. I have appropriate hardware equipment (such as smartphone and computer) to use the online inquiry services provided by internet hospitals.
2. I could independently complete the online operation process of using the online inquiry services provided by internet hospitals.
3. I could clearly distinguish the valid and invalid information about the online inquiry services provided by internet hospitals.

#### Behavioral intention

1. If I am sick, I will choose an internet hospital for online inquiry.
2. If someone around me requires health services, I will recommend the online inquiry services provided by internet hospitals to them.

In the presurvey analysis, we selected the outpatients who visited a tertiary public hospital, patients who bought medicines in a large drugstore, and patients from communication groups with chronic diseases (including diabetes, hypertension, and heart disease) as respondents. The presurvey sample size was often suggested to be 5-10 times the number of observed variables of the scale, or greater than or equal to 100 [42], and thus, we selected 150 patients by convenience sampling, and 128 patients were volunteered to participate in the presurvey during December 2019. Finally, a validation sample of 117 patients was used for testing reliability and validity of the designed questionnaire. Reliability was measured using Cronbach alpha. If the Cronbach alpha of a construct increases significantly after the removal of an item, indicating that the item reduces the internal consistency of its measurement, the item should be further revised or removed. The Cronbach alpha of all constructs should be higher than .70 [43,44]. We used exploratory factor analysis with varimax-rotated components to measure the validity of the designed questionnaire, and its cumulative total of variance and factor loadings were used to assess the construct validity. If the cumulative total of variance of the principal components selected accounted for more than 70% of the total variance, the composition of the principal components as exogenous constructs was consistent with the constructs of the designed questionnaire, and if each item had a factor loading value of 0.50 or higher on one of the principal components but factor loading values below 0.50 on others, the validity of the designed questionnaire was considered acceptable, and no items were removed.

No items were revised or removed on the basis of the analysis result of the presurvey, and thus, the designed questionnaire with acceptable reliability and validity could be further used for data collection. Structural equation modeling (SEM) was then used to verify the research model. Data on participants' demographic characteristics such as gender, age, education level, marital status, living alone or with others, residence,

monthly average income, types of medical insurance, and online inquiry experience were also collected.

#### Data Collection

The target population included patients with chronic diseases including diabetes, hypertension, and heart disease, selected using the cluster sampling technique. We used the developed questionnaire to create an electronic questionnaire using the web-based survey tool wenjuanxing [45], a widely used website for conducting surveys in China. To collect enough sample data, the sample size was determined by general guidelines for SEM, and the samples were recommended to be at least 10-15 times as many as the items of the scale [46]. From February 12-29, 2020, we sent the survey link to Tencent QQ groups, WeChat groups, and Baidu Post Bar of patients with the aforementioned chronic diseases. Prior to the beginning of the survey, an informed consent of the managers of these patient social platforms was also requested and obtained. Moreover, we selected some general practitioners working in the community health center and physicians working in the tertiary hospital via convenience sampling, and these doctors were devoted to the treatment and management of the aforementioned chronic diseases. We then sent the survey website link to the doctors, and subsequently, they sent the website link to the targeted patient communication groups via WeChat. Participants could click on the website link using their phones to access and complete the electronic questionnaire. Before the survey, we introduced the purpose of the survey, provided the definition of internet hospitals, and guaranteed that the survey data would not be used for other purposes. After an individual's consent was obtained, the survey was conducted accordingly. A WeChat, Tencent QQ, or Baidu Post Bar account and mobile Internet Protocol address could be used to complete the questionnaire only once. The study was approved by the Medical Ethics Committee of Tongji Medical College of Huazhong University of Science & Technology.

## Statistical Analysis

Descriptive statistics were used to analyze the demographic characteristics of the respondents. Patients' intention to use the online inquiry services provided by internet hospitals was measured using two items (Textbox 1), with a higher score indicating elevated adoption intention. These respondents were divided into a younger group (younger than 50 years) and an older group. An independent *t* test was further used to evaluate the differences among adoption intention scores between the younger and the older groups.

SEM was used to verify the research model. Before evaluating the structural model, we assessed the measurement model to evaluate the reliability, convergent validity, and data fit indexes. We measured the reliability using the Cronbach alpha and composite reliability (CR). Values of .70 or higher for Cronbach alpha and values of 0.6 or higher for CR for all constructs were considered acceptable [8,43,44]. Convergent validity was measured using the average variance extracted (AVE) and standard loadings. The AVE of each construct and all the standard loadings should be greater than 0.50 [8,16,19]. The model fit was generally considered acceptable when the indexes met the criteria including  $\chi^2 / df < 3$ , root mean square error of approximation  $< 0.08$ , goodness-of-fit index (GFI)  $> 0.90$ , adjusted GFI  $> 0.90$ , Tucker-Lewis index  $> 0.90$ , comparative fit index  $> 0.90$ , and normed fit index  $> 0.90$  [13,27,47,48].

Otherwise, the research model was further revised. Moreover, we performed a bootstrap analysis with 1000 bootstrap bias-corrected samples to assess the direct, indirect, and total effect of variables (constructs) on the endogenous variables (ie, attitude and behavioral intention toward using online inquiry) [8,48]. Data analysis was done using SPSS V.24 and AMOS V.21 (IBM Corp).

## Results

### Sample Characteristics

In total, 812 responses (online survey) were received; of these, 174 responses were excluded because they contained identical answers to all questions, displayed certain logical contradictions, or because the time taken to answer the questionnaire was less than 100 seconds. The demographic characteristics of the 638 participants are shown in Table 1. Among these participants, 332 (52.0%) were aged 19-29 years, and 197 (30.9%) experienced the online inquiry services provided by internet hospitals. On average, the patients' intention to use the online inquiry services provided by internet hospitals (min 1, max 5) was moderate, with a mean score of 3.21 (SD 0.84), and differences were not observed between younger patients and older patients (mean 3.19, SD 0.84 vs mean 3.36, SD 0.82;  $P=.10$ ).

**Table 1.** Demographic characteristics of the participants (N=638).

Characteristics	Value, n (%)
<b>Gender</b>	
Male	241 (37.8)
Female	397 (62.2)
<b>Age (years)</b>	
≤18	14 (2.2)
19-29	332 (52.0)
30-39	109 (17.1)
40-49	110 (17.2)
50-59	62 (9.7)
≥60	11 (1.7)
<b>Education level</b>	
Up to secondary school	241 (37.8)
College	85 (13.3)
Undergraduate	206 (32.3)
Postgraduate and higher	106 (16.6)
<b>Marital status</b>	
Married	325 (50.9)
Unmarried	313 (49.1)
<b>Living alone or with others</b>	
Living alone	70 (11.0)
Living with family	510 (79.9)
Living with friends	58 (9.1)
<b>Residence</b>	
Rural	263 (41.2)
Urban	375 (58.8)
<b>Monthly average income, ¥ (US \$)</b>	
<2000 (285.40)	252 (39.5)
2000 (285.40)-5000 (713.60)	243 (38.1)
5001 (713.80)-8000 (1141.80)	91 (14.3)
>8000 (1141.80)	52 (8.2)
<b>Types of medical insurance</b>	
Basic medical insurance for urban and rural residents	362 (56.7)
Basic medical insurance for urban employees	196 (30.7)
Commercial medical insurance	24 (3.8)
Others	56 (8.8)
<b>Online inquiry experience</b>	
Yes	197 (30.9)
No	441 (69.1)

## Measurement Model Testing

Table 2 shows the results of the measurement model. The Cronbach alpha and CR of each construct were higher than the

recommended values, indicating excellent reliability. The AVEs of constructs, except PMR, SN, and PBC, and all the standard loadings were greater than the recommended values, indicating acceptable convergent validity. Specifically, for example, the

values of Cronbach alpha and CR in PC were .866 and .877, respectively, and higher than the recommended values of .70, indicating the measurement model had excellent reliability; moreover, the AVE was 0.597 and greater than the threshold value of 0.50, indicating the measurement model had acceptable convergent validity.

The goodness-of-fit results of the research model are shown in [Table 3](#). All fit indexes were below the recommended values, indicating that the data collected did not fit with the research model, and thus further revision of the research model was needed.

**Table 2.** Statistical results of the research model

Constructs and items	Standard loadings	<i>P</i> value	Score, mean (SD)	Cronbach alpha	CR <sup>a</sup>	AVE <sup>b</sup>

<sup>a</sup>CR: composite reliability.

<sup>b</sup>AVE: average variance extracted.

<sup>c</sup>PC: perceived convenience.

<sup>d</sup>Numbers refer to the numbered lists under each construct in [Textbox 1](#).

<sup>e</sup>N/A: not applicable.

<sup>f</sup>PO: perceived outcome.

<sup>g</sup>PMR: perceived medical risk.

<sup>h</sup>PIR: perceived information risk.

<sup>i</sup>EP: emotional preference.

<sup>j</sup>PML: perceived medical liability.

<sup>k</sup>AB: attitude toward the behavior.

<sup>l</sup>SN: subjective norm.

<sup>m</sup>HC: health consciousness.

<sup>n</sup>PSD: perceived severity of disease.

<sup>o</sup>Not available because of only an item.

<sup>p</sup>PBC: perceived behavioral control.

<sup>q</sup>BI: behavioral intention.

**Table 3.** Goodness-of-fit results of the research model.

Fit indexes	$\chi^2$ / df	RMSEA <sup>a</sup>	GFI <sup>b</sup>	AGFI <sup>c</sup>	TLI <sup>d</sup>	CFI <sup>e</sup>	NFI <sup>f</sup>
Research model	5.185	0.0813	0.767	0.732	0.786	0.803	0.768
Recommended value	<3	<0.08	>0.90	>0.90	>0.90	>0.90	>0.90

<sup>a</sup>RMSEA: root mean square error of approximation.

<sup>b</sup>GFI: goodness-of-fit index.

<sup>c</sup>AGFI: adjusted goodness-of-fit index.

<sup>d</sup>TLI: Tucker-Lewis index.

<sup>e</sup>CFI: comparative fit index.

<sup>f</sup>NFI: normed fit index.

## Model Modification

To improve the goodness of fit of the research model, hypothesis paths of H3, H5, H8, and H10 were removed. Furthermore, the constructs including PML, PO, and SN were removed. Considering that the AVEs of the constructs PMR and PBC were considerably lower than the recommended values, indicating the measurement indexes with interference, the items including PMR2, PMR3, and PBC3 were removed. Moreover, the items including attitude toward behavior 1, PC4, and PC5

were removed on the basis of a focus group discussion. Additionally, the relationships between PBC and PC, between PBC and PMR, between PSD and PMR, between PSD and PBC, between PMR and PIR, between PMR and EP, and between EP and PC were established.

As shown in [Table 4](#), after modification, the goodness of fit of the research model was improved. All fit indexes were greater than the recommended values, indicating that the eight-construct model was a good fit for the data collected.

**Table 4.** Goodness-of-fit results of the revised research model.

Fit indexes	$\chi^2 / df$	RMSEA <sup>a</sup>	GFI <sup>b</sup>	AGFI <sup>c</sup>	TLI <sup>d</sup>	CFI <sup>e</sup>	NFI <sup>f</sup>
Research model	2.837	0.054	0.942	0.920	0.933	0.946	0.920
Recommended value	<3	<0.08	>0.90	>0.90	>0.90	>0.90	>0.90

<sup>a</sup>RMSEA: root mean square error of approximation.<sup>b</sup>GFI: goodness-of-fit index.<sup>c</sup>AGFI: adjusted goodness-of-fit index.<sup>d</sup>TLI: Tucker-Lewis index.<sup>e</sup>CFI: comparative fit index.<sup>f</sup>NFI: normed fit index.

## Structural Model Testing

Table 5 shows that three (H3, H5, and H10) of the eleven research hypotheses were rejected. The standardized path

coefficients of all other relationships were significant at  $P < .05$ . The relationships among constructs in the final research model are illustrated in Figure 2.

**Table 5.** Hypothesis testing results of the research model

Hypothesis paths	Standardized path coefficients	<i>P</i> value	Results
H1 <sup>a</sup> Attitude toward the behavior (+ <sup>b</sup> ) → Behavioral intention	0.394	<.001	H1 supported
H2 Perceived behavioral control (+) → Behavioral intention	0.624	<.001	H2 supported
H3 Subjective norm (+) → Behavioral intention	— <sup>c</sup>	—	H3 not supported
H4 Perceived convenience (+) → Attitude toward the behavior	0.525	<.001	H4 supported
H5 Perceived outcome (+) → Attitude toward the behavior	—	—	H5 not supported
H6a Perceived medical risk (– <sup>d</sup> ) → Behavioral intention	–0.192	<.001	H6a supported
H6b Perceived information risk (–) → Attitude toward the behavior	–0.182	<.001	H6b supported
H7 Emotional preference (+) → Attitude toward the behavior	0.206	<.001	H7 supported
H8 Perceived medical liability (–) → Attitude toward the behavior	—	—	H8 not supported
H9 Health consciousness (+) → Attitude toward the behavior	0.243	<.001	H9 supported
H10 Perceived severity of disease (–) → Perceived behavioral control	—	—	H10 not supported

<sup>a</sup>H: hypothesis.<sup>b</sup>+: positive effect.<sup>c</sup>Hypothesis paths of H3, H5, H8, and H10 were removed in the revised model.<sup>d</sup>–: negative effect.

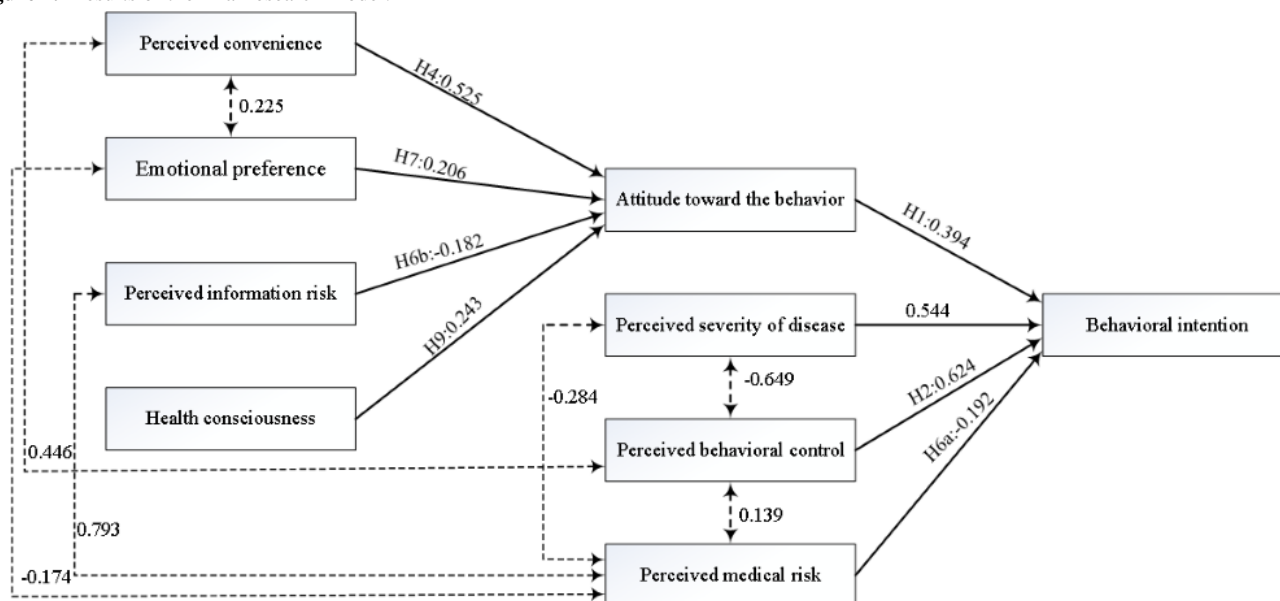

**Figure 2.** Results of the final research model.

Table 6 shows the total, direct, and indirect effects (standardized path coefficients) of the model variables (constructs) on attitude toward the behavior and behavioral intention, respectively. PC, PIR, EP, and health consciousness explained 45.9% of the variance in attitude toward the behavior. Among these four variables, PC had the strongest effect on attitude toward the behavior ( $\beta=.525$ ,  $P=.002$ ). EP and health consciousness had moderate effects on attitude toward the behavior ( $\beta=.206$ ,  $P=.002$  and  $\beta=.243$ ,  $P=.002$ , respectively). Additionally, PIR had a slightly negative direct effect on attitude toward the behavior ( $\beta=-.182$ ,  $P=.001$ ).

Further, PC, PIR, EP, and health consciousness had indirect effects on behavioral intention, and these effects were mediated by attitude toward the behavior. PC had the highest indirect effect on behavioral intention ( $\beta=.207$ ,  $P=.001$ ) among the four constructs.

Overall, attitude toward the behavior, PMR, PSD, and PBC explained 60.5% of the variance in behavioral intention. PBC and PSD had the highest total effects on behavioral intention ( $\beta=.624$ ,  $P=.004$  and  $\beta=.544$ ,  $P=.003$ , respectively). Attitude toward the behavior had a moderate total effect on behavioral intention ( $\beta=.394$ ,  $P=.002$ ), whereas PMR had a slightly negative total effect on behavioral intention ( $\beta=-.192$ ,  $P=.005$ ).

Within expectations, PMR had the strongest positive relationship with PIR ( $r=0.793$ ,  $P=.001$ ). Moreover, PMR had a slightly negative relationship with EP and PSD ( $r=-0.174$ ,  $P=.002$  and  $r=-0.284$ ,  $P=.002$ , respectively) but a positive relationship with PBC ( $r=0.139$ ,  $P=.002$ ). Additionally, PBC had a moderate positive relationship with PC ( $r=0.446$ ,  $P=.001$ ) but was strongly and negatively correlated with PSD ( $r=-0.649$ ,  $P=.002$ ). PC also had a slightly positive relationship with EP ( $r=0.225$ ,  $P=.002$ ).

**Table 6.** Total, direct, and indirect effects of the model variables.

Variables	AB <sup>a</sup> ( $R^2=45.9\%$ )		BI <sup>b</sup> ( $R^2=60.5\%$ )

<sup>a</sup>AB: attitude toward behavior.<sup>b</sup>BI: behavioral intention.<sup>c</sup>PC: perceived convenience.<sup>d</sup>Not available.<sup>e</sup>PMR: perceived medical risk.<sup>f</sup>PIR: perceived information risk.<sup>g</sup>EP: emotional preference.<sup>h</sup>HC: health consciousness.<sup>i</sup>PSD: perceived severity of disease.

<sup>j</sup>PBC: perceived behavioral control.

## Discussion

### Principal Findings

Our study shows that the patients' intention to use the online inquiry services provided by internet hospitals was relatively low, with room for development. Internet hospitals in China show an emerging trend for adequately fulfilling people's demands for health services [9,10]. Thus, the determinants of patients' intention to use online inquiry services provided by internet hospitals are needed that help provide opportunities to promote the development of internet hospitals. Our findings show the patients' intention to use the online inquiry services provided by internet hospitals was determined by the following factors: attitude toward the behavior, PBC, PSD, PC, PIR, PMR, health consciousness, and EP.

Our study found that two TPB factors (ie, attitude toward the behavior and PBC) had significant effects on patients' intention to use the online inquiry services provided by internet hospitals, whereas the factor (ie, SN) had an insignificant effect on behavioral intention. PBC was the most important determinant of patients' intention to use the online inquiry services provided by internet hospitals. Several studies on mHealth services also indicated PBC was the major determinant of behavioral intention [24,26,27]. If patients find it easy to use online inquiry services, their willingness toward online inquiry services provided by internet hospitals will be stronger. Many studies found that the perceived ease of use of mHealth technology is a determinant of patients' adoption intention toward mHealth services [8,21,49,50], especially among older adults [16]. Similar to mHealth service, the ease of using online inquiry services provided by internet hospitals must be promoted, thereby potentially improving the PBC of users in using these services. Therefore, internet hospitals should be patient-centered, further optimize online service delivery process to improve the ease of using online inquiry services, and provide patients with multiple convenient and easy-to-use channels for online inquiry, such as mHealth service apps and WeChat official accounts.

PSD had a strong positive total effect on patients' intention to use the online inquiry services provided by internet hospitals, and this effect was also direct but not mediated by PBC. This finding is consistent with the findings of a study by Zhang et al [27] regarding mHealth service adoption in China. Another study by Liu et al [51] also found a positive effect of PSD on propensity of users in online health care communities to seek health information. This finding suggests that perceived disease severity motivates patients to adopt online inquiry services provided by internet hospitals. Internet hospitals, owing to the integration of a large number of high-quality medical resources across the country could competently fulfill the increasing patient demands for high-quality health services. It is difficult for patients in rural and remote areas of China to access high-quality health services [4,5]. Thus, internet hospitals should be dedicated to enhance the awareness of individuals regarding disease vulnerability and emphasize the advantages of online inquiry services to change the indifferent attitude and distrust of certain people toward the online inquiry services provided

by internet hospitals. With the increasing health service requirements of patients, physicians tend to have a heavier workload [44], and unreasonable expectations regarding online services may further increase the physicians' workload. Therefore, internet hospitals should also ensure a reasonable assembly of high-quality experts and coordinate their online and offline medical resources. Ensuring a reasonable assembly of high-quality medical resources in internet hospitals will not only optimize the physicians' workload but also meet the increasing patient demands for renowned experts, thereby promoting patients' willingness toward online inquiry services provided by internet hospitals.

PC also had a moderate positive total effect on patients' intention to use online inquiry services provided by internet hospitals. This finding is in line with the findings of a study of Valikodath et al [29] on patients' willingness toward telemedicine for diabetic retinopathy. Another study by Clevenger et al [52] also demonstrated that PC was positively associated with acceptance of adolescent vaccination outside of the traditional medical home. This finding suggests the need for internet hospital managers to identify the gaps in convenience of health care service delivery and further improve the organizational service delivery design. During the special survey time called "Wuhan on lockdown," this policy might contribute to a greater intention of patients in the Wuhan area to use online inquiry services provided by internet hospitals owing to the inconvenience of seeking health services in traditional hospitals. With the normalization of the prevention and control of the COVID-19 epidemic, service convenience has become an important topic in the context of health care, and internet hospitals play an increasingly important role in delivering health services to the public. Therefore, internet hospitals should also promote and achieve one-step health care services via the integration of medical service, medicine, and medical insurance. Improving service convenience will help people reduce the risks of nosocomial cross-infection and, thus, benefit the promotion of patients' intention to use the online inquiry services provided by internet hospitals.

Although the indirect effect of PIR on patients' intention to use online inquiry services provided by internet hospitals was weak (and this effect was mediated by attitude toward the behavior), PMR had a significantly negative stronger direct effect on behavioral intention. Similarly, several studies on mHealth services found the negative effect of perceived privacy risk on behavioral intention [13,53]. Another study by Zhang et al [8] also demonstrated the negative effect of perceived privacy risk on patients' intention to use diabetes management apps. With the rapid development of health information technology, patients are increasingly aware of and concerned about their personal information protection such as privacy protection on health care-seeking data. Although our research found that PIR had only a weak effect on patients' intention to use the online inquiry services provided by internet hospitals, solid patient measures to protect patient information are needed. Additionally, our research found that PMR had a stronger effect on patients' intention to use online inquiry services provided by internet

hospitals. However, to date, the Chinese government has not established an effective quality control system for internet hospitals, and related regulations from traditional hospitals are often used for the management of medical behaviors in internet hospitals, although the government have realized the problem [12,15], which could lead to an increase in probability of medical risks, threatening patient safety [38], thereby potentially affecting risk-conscious patients' intention to use the online inquiry services. Thus, to ensure patient safety regarding the use of online inquiry services provided by internet hospitals, the relevant quality control standards and regulations for internet hospitals should be further developed and improved.

Health consciousness had slightly positive indirect effects on patients' intention to use the online inquiry services provided by internet hospitals, and these effects were mediated by attitude toward the behavior. A previous study by Ahadzadeh et al [20] suggested that health consciousness positively affected patients' intention of the internet use for health-related purposes. Several studies concerning disease information-seeking behaviors also demonstrated an effect of health consciousness on behavioral intention [54,55]. Patients with a higher level of health consciousness are more likely to be aware of and concerned about their wellness [56], and if they believe that their health service requirements can be adequately fulfilled by the online inquiry services provided by internet hospitals, their willingness toward online inquiry will be stronger. With the increasing health awareness of people in China, their willingness toward online inquiry services provided by internet hospitals will be further improved.

Our study also found that EP had a slightly positive total effect on patients' intention to use the online inquiry services provided by internet hospitals. Emotion is an essential element of human behavior. Regarding health behaviors, some patients with genital diseases or patients who are sensitive about a certain disease have more awareness about self-precautionary measures and privacy protection or are more unwilling to disclose their condition to others, eventually affecting their help-seeking intentions. Such unfavorable results have been found in several studies on patients with mental health problems [35,36]. With internet hospitals, such patients could be provided with a more confidential approach of seeking health services through graph-text, voice, and video services [9], which protects their privacy and fulfills their emotional requirements to a certain extent; thus, patients with EPs would be more willing to gain access to the online services provided by internet hospitals.

## Limitations

This study has several limitations. First, among the twelve constructs, PSD included only one item, which may have resulted in a measurement error. Second, although the research model was developed based on the TPB, some factors influencing patients' intention to use online inquiry services provided by internet hospitals may not have been identified; for example, "medical expenses" was included in PC but deleted in the revised model; the medical service price is an important determinant of patients' intention to accept a medical service in traditional hospitals, especially whether this service is covered by medical insurance payment [57], but was not as a factor included into the research model, and thus, continuous research is needed to help further explore these determinants. Third, online survey was used as the data collection method owing to the COVID-19 epidemic, and the target population included individuals with chronic diseases such as diabetes, hypertension, and heart disease; although the age of patients with chronic diseases was usually old, the younger patients in targeted patient communication groups might be more willing to participate in the online survey; moreover, we used cluster sampling rather than proportional sampling, and although differences were not observed between younger patients and older patients, our results may have been biased by the age distributions. Further, data collection was self-reported by patients via online survey, which might have a recall bias. In addition, to improve the goodness of fit of the research model, a few constructs including PML, PO, and SN were removed, which may have produced an insignificant result; therefore, further research is necessary to identify whether these constructs significantly affect patients' intention to use online inquiry services provided by internet hospitals.

## Conclusions

PBC and PSD are the most important determinants of patients' intention to use online inquiry services provided by internet hospitals. Therefore, internet hospitals should further optimize the design of online service delivery and ensure a reasonable assembly of high-quality experts, which will benefit the promotion of patients' adoption intention toward online inquiry services for health purposes. PC, EP, and perceived risks also have effects on behavioral intention. Therefore, the relevant quality control standards and regulations for internet hospitals should be further developed and improved, and the measures to protect personal information should be strengthened to ensure patient safety. Our study supports the use of the planned behavior theory in explaining patients' intention to use the online inquiry services provided by internet hospitals.

## Acknowledgments

We thank all respondents for voluntarily participating in the survey. This study was supported by the National Natural Science Foundation of China (Grant Number 71774062) and the Fundamental Research Funds for the Central Universities (Grant Number 2018KFYYXJJ065).

## Abstract

**Background:** Real-time polymerase chain reaction (RT-PCR) testing for the identification of viral nucleic acid is the current standard for the diagnosis of SARS-CoV-2 infection, but technical issues limit its utilization for large-scale screening. Serological immunoglobulin M (IgM)/IgG testing has been proposed as a useful tool for detecting SARS-CoV-2 exposure.

**Objective:** The objective of our study was to compare the results of the rapid serological VivaDiag test for SARS-CoV-2-related IgM/IgG detection with those of the standard RT-PCR laboratory test for identifying SARS-CoV-2 nucleic acid.

**Methods:** We simultaneously performed both serological and molecular tests with a consecutive series of 191 symptomatic patients. The results provided by a new rapid serological colorimetric test for analyzing IgM/IgG expression were compared with those of RT-PCR testing for SARS-CoV-2 detection.

**Results:** Of the 191 subjects, 70 (36.6%) tested positive for SARS-CoV-2 based on RT-PCR results, while 34 (17.3%) tested positive based on serological IgM/IgG expression. Additionally, 13 (6.8%) subjects tested positive based on serological test results, but also tested negative based on RT-PCR results. The rapid serological test had a sensitivity of 30% and a specificity of 89% compared to the standard RT-PCR assay. Interestingly, the performance of both assays improved 8 days after symptom appearance. After 10 days had passed since symptom appearance, the predictive value of the rapid serological test was higher than that of the standard molecular assay (proportion of positive results: 40% vs 20%). Multivariate analysis showed that age >58 years ( $P<.01$ ) and period of >15 days after symptom onset ( $P<.02$ ) were significant and independent factors associated with serological test positivity.

**Conclusions:** The rapid serological test analyzed in this study seems limited in terms of usefulness when diagnosing SARS-CoV-2 infection. However, it may be useful for providing relevant information on people's immunoreaction to COVID-19 exposure.

SARS-CoV-2; COVID-19; serological test; RT-PCR

## Introduction

Recently, a novel coronavirus, which was first reported in China, capable of interperson transmission has been causing lethal pneumonia in humans [1]. Subsequent molecular studies confirmed that the origin of this transmissible pneumonia was the novel SARS-CoV-2 virus, which causes the new COVID-19 disease [2].

As the COVID-19 disease rapidly spread to other Asian and European countries, the Italian Government had to take drastic measures to contain the outbreak, including establishing strict criteria to define patients from whom oropharyngeal swabs should be collected for the molecular polymerase chain reaction (PCR) diagnosis of COVID-19 and quarantining individuals who may have been in contact with SARS-CoV-2-infected people [3]. These measures were active for weeks, during which the number of new SARS-CoV-2 infection cases in Italy continued to increase, with more than 4000 new cases being reported daily [4]. Several attempts have been made to interpret the epidemiological trend of COVID-19 in Italy, and experts have focused on the limitations of early SARS-CoV-2 infection diagnosis [5] and the detection of SARS-CoV-2 infection in asymptomatic people [6].

The real-time PCR (RT-PCR) test for identifying viral nucleic acid is the current standard for the diagnosis of COVID-19. However, this assay has some practical limitations [3], such as the unpleasantness of obtaining biological material from the nasopharynx, the relatively long time required to generate results, and the need for certified laboratories and specific expertise. These limitations make RT-PCR unsuitable for quick and simple patient screening. Therefore, the search for a precise, rapid, simple, and large-scale screening test for quickly identifying SARS-CoV-2-infected patients has become urgent to prevent virus transmission and ensure timely treatment of patients.

The Saw Swee Hock School of Public Health at the National University of Singapore recently reviewed the diagnostic tests for COVID-19 infection currently undergoing clinical validation, including dozens of assays based on RT-PCR, next-generation sequencing, and microfluidics [7]. Additionally, 12 immunoassays based on evidence that COVID-19 is related to immunoglobulin G (IgG) and immunoglobulin M (IgM) expression were also listed. It has been argued that, based on previous experiences with viral SARS infection epidemics, specific IgM antibodies against SARS-CoV-2 could be detected in blood by performing immunoassays 3-6 days after symptom onset, while IgG detection could occur some days later [4]. It has also been speculated that, since SARS-CoV-2 belongs to the same large family of viruses that caused the Middle East Respiratory Syndrome and SARS epidemics, SARS-CoV-2 antibody seroconversion should be similar to that of other coronaviruses [5].

A report from the National University of Singapore has described the VivaDiag SARS-CoV-2 IgM/IgG Rapid Test kit as an immunoassay with available information regarding sensitivity and specificity [8] and a potential candidate for reliable and rapid (15 minutes) testing, according to the preliminary data available [6]. The test is based on the utilization of antihuman IgG and IgM against the recombinant antigen that represents the receptor-binding domain of the COVID-19 spike protein.

The aim of our study was to compare the results provided by the rapid serological VivaDiag test with those of standard RT-PCR testing for SARS-CoV-2 detection in swab specimens. The two tests were simultaneously performed on subjects with COVID-19 symptoms. We setup a prospective, mono-institutional, ad hoc, blinded, and independent study that enrolled a series of 191 subjects who were admitted to the Emergency Department of the Policlinico University Hospital in Bari, Italy.

## Methods

### Recruitment

Between March 23, 2020 and March 29, 2020, we enrolled a consecutive cohort of 191 patients who were admitted to the Emergency Department of the Policlinico University Hospital in Bari, Italy for COVID-19-related symptoms or because they were quarantined for previous exposure to COVID-19-positive individuals. Oropharyngeal swabs for standard SARS-CoV-2 RT-PCR analysis and venous blood samples for VivaDiag tests were simultaneously collected from each subject, and the tests were immediately performed in reference laboratories. Registries containing patients' main clinical data, including date of symptom onset (self-reported), were created. Informed written consent was obtained from all patients. Oropharyngeal swab samples were immediately analyzed for SARS-CoV-2 by RT-PCR at the Laboratory of Molecular Epidemiology and Public Health of the Hygiene Unit of the Policlinico University Hospital (Bari, Italy), the regional reference laboratory for SARS-CoV-2 identification. The venous blood samples were analyzed at the Clinical Pathology Laboratory (Certified ISO-9001/2015; Head E. Savino) and the Institutional BioBank (Certified ISO-9001/2015; Head A. Paradiso) of the IRCCS Istituto Tumori Giovanni Paolo II (Bari, Italy). This study was approved by the Ethical Committee of the IRCCS Istituto Tumori Giovanni Paolo II, Bari (Protocol number CE 870/2020).

### Molecular Detection of SARS-CoV-2

Nasopharyngeal/oropharyngeal swabs were subjected to nucleic acid extraction with the MagNA Pure System (Roche Diagnostics), in accordance with the manufacturer's instructions. The presence of the *E* gene, *RdRP* gene, and *N* gene of the SARS-CoV-2 virus were identified by a commercial RT-PCR assay (Allplex 2019-nCoV Assay; Seegene). Samples were considered positive at molecular screening if all three genes

were detected. The Centers for Disease Control and Prevention RT-PCR protocol was used to confirm the presence of SARS-CoV-2 [9]. To date [10,11], this methodology is considered the gold standard for the detection of SARS-CoV-2 infection.

### SARS-CoV-2 IgM/IgG Rapid Test

The SARS-CoV-2 IgM/IgG combined antibody rapid test kit, VivaDiag, (VivaChek Biotech) is a lateral flow qualitative immunoassay used for the rapid determination of the presence or absence of both anti-SARS-CoV-2-IgM and anti-SARS-CoV-2-IgG in human specimens (whole blood, serum, and plasma). A surface antigen from SARS-CoV-2, which can specifically bind to SARS-CoV-2 antibodies (including both IgM and IgG), is conjugated to colloidal gold nanoparticles and sprayed onto conjugation pads. The rapid SARS-CoV-2 IgG/IgM combined antibody test strip has two mouse antihuman monoclonal antibodies (anti-IgG and anti-IgM) on two separate test lines.

When testing, 10-15  $\mu$ L of a specimen was inserted into the sample port, and then the sample dilution buffer was added. As the specimen flowed through the device, anti-SARS-CoV-2 IgG and IgM antibodies, if present in the specimen, were bound by the SARS-CoV-2 antigens (ie, the gold colorimetric reagent fixed on the conjugate pad). As the conjugated sample continued to travel up the strip, the anti-SARS-CoV-2 IgM antibodies were bound on the M (IgM) line, and the anti-COVID-19 IgG antibodies were bound to the G (IgG) line. If the specimen did not contain SARS-CoV-2 antibodies, no labeled complexes were bound. The presence of SARS-CoV-2 IgG and IgM antibodies was indicated by a red/purple line on a specific region of the device. Each test was evaluated by two readers, and a picture was taken of the result. In case of disagreement, the picture was evaluated by a third party.

### Statistical Analysis

The performance of the VivaDiag tests was compared to that of the RT-PCR tests using the caret R package, which computed

all the parameters needed (sensitivity, specificity, accuracy, and Cohen  $\kappa$ ). The performance evaluation was carried out using RT-PCR as the gold standard. Both tests were performed on the same subjects. Univariate and multivariate logistic regression were performed. Age was dichotomized by using the median age as a cutoff, and the number of days after the onset of symptoms was used as a categorical variable (0-5 days, 6-8 days, 9-10 days, 11-15 days, >15 days). All analyses were carried out in R version 3.6 (The R Foundation), and results were considered to be significant when the  $P$  value was <.05.

## Results

All 191 subjects enrolled in the study underwent a SARS-CoV-2 RT-PCR test and IgM/IgG rapid test. The cohort had a median age of 58.5 years, and 60.6% (116/191) were male. Subjects were admitted to the emergency room at different times after the onset of symptoms. A description of symptoms was available for 160 (83.8%) of the 191 patients. Of these 160 subjects, 14 (8.7%) were in quarantine and asymptomatic at the time they arrived to the emergency room.

Of the 191 patients, 70 (36.6%) tested positive for SARS-CoV-2 based on RT-PCR results, while 34 (17.8%) tested positive based on serum IgM/IgG rapid test results. Compared to the RT-PCR test, the serological test had an accuracy of 67% (95% CI 60-74), a sensitivity of 30%, and a specificity of 89%. The Cohen  $\kappa$  value was 0.21, meaning that the strength of agreement was, according to Altman [12], considered fair. Notably, 13 patients (6.8%) tested positive based on serological test results, but also tested negative based on RT-PCR results (Figure 1). Of these 13 subjects, 7 (54%) obtained positive IgG/IgM test results at different times after symptom onset (range 10-27 days), while 6 (46%) only obtained positive IgM results at various times after symptom appearance (range 4-25 days). The distribution of the percentage of positive results detected by both tests broken down by days from symptom onset is shown in Figure 2.

**Figure 1.** Comparison of RT-PCR and VivaDiag results from a series of 191 subjects ( $P=.001$ ). Compared to RT-PCR, VivaDiag had a sensitivity of 30%, specificity of 89%, accuracy of 67% (95% CI 60-74), and Cohen  $\kappa$  value of 0.21. RT-PCR: real-time polymerase chain reaction.

		RT-PCR	
		Negative, n (%)	Positive, n (%)
VivaDiag	Negative, n (%)	107 (56)	49 (29)
	Positive, n (%)	13 (7)	21 (11)

**Figure 2.** Bar plot depicting the distribution of the proportion of positive results from the VivaDiag serological test and those from RT-PCR testing for SARS-CoV-2 detection on oropharyngeal swab specimens according to time after symptom onset to test performance. RT-PCR: real-time polymerase chain reaction.

A clear increase in the number of positive serological tests was observed as more days elapsed from symptom appearance, reaching 66.7% at 15 days after symptom onset. Conversely, the highest likelihood for a positive RT-PCR test result was seen from 9 to 10 days after symptom onset, and it decreased rapidly afterwards over time. Of the 14 asymptomatic individuals, 4 (29%) had positive RT-PCR test results, while only 1 (7%) had a positive serological test result.

Further analysis regarding the behavior of IgM and IgG according to the time after symptom onset is described in [Figure 3](#). Only minimal differences in the behavior of the two immunoglobulins with respect to the time of symptom appearance became evident. However, all 13 patients with positive VivaDiag tests and negative RT-PCR results had positive IgM results, while only 7 (54%) of them also had positive IgG results.

**Figure 3.** Bar plot depicting the distribution of the proportion of positive IgG and IgM VivaDiag test results according to time after symptom onset to test performance. IgG: immunoglobulin G; IgM: immunoglobulin M.

Univariate and multivariate logistic regressions were performed to identify independent predictive variables for positive VivaDiag and RT-PCR test results (Tables 1-2). Both univariate and multivariate analyses showed that age >58.5 years and

period of >15 days from symptom onset were significantly associated with VivaDiag positivity, while 9-10 days after symptom onset was independently associated with a positive RT-PCR test result.

## Discussion

### Principal Results

When we compared the performance of the rapid serological test to that of RT-PCR for the detection of SARS-CoV-2 infection, our findings showed that 17.8% (34/191) of the subjects tested positive based on serum IgM/IgG expression, whereas 36.6% (70/191) of the subjects tested positive based on SARS-CoV-2 RT-PCR test results, leading to a sensitivity of 30% and a specificity of 89% for the serological test.

The clinical relevance of so-called rapid serological testing is still an open issue, since the data currently available are still scarce [13]. For this reason, we compared its performance to that of standard RT-PCR testing and analyzed performance with respect to the time of COVID-19–related symptom onset. To this end, we set up a mono-institutional consecutive cohort of patients who were tested with both assays at a single qualified laboratory.

The design of our study allowed us to specifically analyze two aspects of the open issue: (1) the concordance of the rapid serological test results with those of standard molecular testing and (2) the relationship between IgG/IgM expression and the onset of clinical symptoms.

With regard to the degree of concordance between the two tests, the results reported in Figure 1 clearly show that the precision of the VivaDiag rapid test is unsatisfactory. Notably, only 11% (21/191) of the patients that tested positive for COVID-19 based on the molecular test results also tested positive based on the

serological test results. This percentage is impressively similar to the performance reported for serological tests in Spain [14] and Germany [15]. However, the first important finding from our study concerns the 6.8% (13/191) of subjects that tested negative based on RT-PCR results, but tested positive based on serological results. The two tests did not produce similar results, which is obvious for assays that are designed to analyze different aspects of COVID-19; the molecular test detects the presence of SARS-CoV-2 in samples based on specific anatomical parts of the respiratory system, while the serology test reveals the kinetics of immunoglobulins as the body reacts to viral infection. Negative serological test results in patients with a positive molecular test could mean that the patients are infected, but have not yet reached the stage of immunoglobulin reaction development. Conversely, subjects who have negative molecular test results, but also have serological test results showing the presence of specific IgG/IgM antibodies, may be recovering from COVID-19. The data shown in Figure 2 seem to confirm these assumptions, as the molecular test yielded more positive results during the early symptomatic phases of the disease in our subjects, while the serological test performed better later on (ie, 10 days after symptom appearance).

The second aspect we were able to analyze in our study was seroconversion and the kinetics of immunoglobulins with respect to the onset of COVID-19–related symptoms. Figure 3 shows the behavior of the two immunoglobulins according to symptom appearance. Interestingly, IgG and IgM did not seem to behave differently based on the number of days elapsing from symptom appearance, but they clearly and progressively increased along the course of the disease. This unexpected finding, in contrast

with common knowledge concerning the kinetics of the two immunoglobulins, is supported by the results presented by Zhang et al [16] and Lou et al [17]. Both authors reported that the detectable serology markers, IgG and IgM, had similar seroconversions in COVID-19 patients, with antibody levels increasing rapidly at 6 days after exposure, and this trend occurred with a concomitant decline in viral load. Such behavior in the 6-10-day time window after symptom appearance is typically accompanied by an improvement in serological test sensitivity compared to standard molecular testing.

Very recently, Whitman et al [18] evaluated the performance of 11 SARS-CoV-2 serological assays in a multicentric study that enrolled a cohort of subjects with positive RT-PCR test results. For the serological tests, the incidence of IgG/IgM positivity in the RT-PCR SARS-CoV-2-positive samples ranged from 26.9% to 0%. In particular, the incidence of positive results with the VivaDiag test was 8.2%, which is significantly lower than the value we found in our study. However, the enrollment criteria in the Whitman et al study were very different from ours. In our study, the subjects were consecutively recruited from a single institution, and the tests were performed simultaneously on fresh biospecimens. Interestingly, Whitman et al reported that among the SARS-CoV-2 RT-PCR-positive individuals, the percent seropositivity increased with time, peaking at 81.8%-100.0% in samples taken >20 days after symptom onset. The same trend of increased seropositivity with increased time from symptom onset was observed in our cohort of subjects.

### Limitations

Our study had some important limitations. First, the VivaDiag test was based on the colorimetric evaluation of the IgG and IgM bands performed by the operator, thus implying that all the limitations that a qualitative inter-intra-operator evaluation

produces in terms of variability are present in this study [19]. In our study, this was partially solved by resorting to double operator evaluation and taking pictures of all test results to be reanalyzed by a third-party reader in the case of first level evaluation disagreement. Therefore, our next step will be to use quantitative immunoassay methods to analyze SARS-CoV-2-specific immunoglobulins [20] to overcome these issues.

Second, the neutralizing antibodies used in the VivaDiag test might cross-react with other coronavirus antigens, such as those of the SARS-CoV. The recombinant antigen utilized in VivaDiag is the receptor-binding domain of the SARS-CoV-2 spike protein, for which information on possible cross-reactivity with other coronaviruses and flu viruses has not yet been studied [13]. Further studies are urgently needed to definitively clarify this point.

### Conclusions

Our study analyzed the clinical performance of the rapid serological test, VivaDiag, and confirmed the test's limited applicability for the diagnosis of SARS-CoV-2 infection by comparing its performance to that of standard molecular testing. However, this rapid serological test seems to provide important information concerning individuals' immunoreaction to the infection, and more importantly, it may detect previous exposure to the virus in currently healthy persons. A trial, recently registered in ClinicalTrials.gov (NCT04316728), will specifically address this issue by investigating the monitoring of seroconversion of COVID-19 IgG/IgM in healthy subjects who may develop COVID-19-related symptoms. In essence, our real-world results should be considered hypothesis-generating findings that warrant further examination in a controlled clinical trial in order to be confirmed [21].

## Abstract

**Background:** Essential workers have been shown to present a higher prevalence of positive screenings for anxiety and depression during the COVID-19 pandemic. Individuals from countries with socioeconomic inequalities may be at increased risk for mental health disorders.

**Objective:** We aimed to assess the prevalence and predictors of depression, anxiety, and their comorbidity among essential workers in Brazil and Spain during the COVID-19 pandemic.

**Methods:** A web survey was conducted between April and May 2020 in both countries. The main outcome was a positive screening for depression only, anxiety only, or both. Lifestyle was measured using a lifestyle multidimensional scale adapted for the COVID-19 pandemic (Short Multidimensional Inventory Lifestyle Evaluation–Confinement). A multinomial logistic regression model was performed to evaluate the factors associated with depression, anxiety, and the presence of both conditions.

**Results:** From the 22,786 individuals included in the web survey, 3745 self-reported to be essential workers. Overall, 8.3% (n=311), 11.6% (n=434), and 27.4% (n=1027) presented positive screenings for depression, anxiety, and both, respectively. After adjusting for confounding factors, the multinomial model showed that an unhealthy lifestyle increased the likelihood of depression (adjusted odds ratio [AOR] 4.00, 95% CI 2.72-5.87), anxiety (AOR 2.39, 95% CI 1.80-3.20), and both anxiety and depression (AOR 8.30, 95% CI 5.90-11.7). Living in Brazil was associated with increased odds of depression (AOR 2.89, 95% CI 2.07-4.06), anxiety (AOR 2.81, 95% CI 2.11-3.74), and both conditions (AOR 5.99, 95% CI 4.53-7.91).

**Conclusions:** Interventions addressing lifestyle may be useful in dealing with symptoms of common mental disorders during the strain imposed among essential workers by the COVID-19 pandemic. Essential workers who live in middle-income countries with higher rates of inequality may face additional challenges. Ensuring equitable treatment and support may be an important challenge ahead, considering the possible syndemic effect of the social determinants of health.

**KEYWORDS**

COVID-19; depression; anxiety; lifestyle; Brazil; Spain

**Introduction**

The prevalence of COVID-19 continues to increase in Brazil [1], and mental health is recognized as an important challenge ahead worldwide [2-4]. Several studies have used web surveys to screen for common mental health disorders (mainly depressive and anxiety disorders) among the general population [5-8]. Some of these studies, but not all [9,10], have shown that essential workers, such as health care workers (HCWs), had an increased likelihood of anxiety and depression compared to other workers [11,12]. Essential workers may have increased workload and working hours during the pandemic [13], struggle with the lack of adequate personal protective equipment [14], and may be isolated from friends and families [15]. Burnout symptoms [16], emotional exhaustion [17], and fear of transmitting the virus [18] are commonly reported.

The first study investigating mental health problems among essential workers during the COVID-19 pandemic was conducted in China and found the prevalence of anxiety and depressive symptoms to be at 20.1% and 12.7%, respectively [19]. In two subsequent systematic reviews, HCWs presented increased depression/depressive symptoms, anxiety, psychological distress, and poor sleep quality [20,21]. The first meta-analysis evaluating the prevalence of mental health problems among HCWs (up to April 13, 2020) found 13 studies (N=33,062 participants), of which 12 were conducted in China. The pooled prevalence of a positive screening for anxiety was 23.2% (95% CI 17.8-29.1) while depression was estimated at 22.8% (95% CI 15.1-31.5) [22]. Evidence from outside of China is still scarce [23-30], and it is difficult to estimate the overall prevalence of common mental health disorders due to methodological issues, heterogeneity in study populations and sizes, and differences in criteria used to define a case (eg, different instruments and cut-offs). For instance, the prevalence of depression was as low as 10% among HCWs in Singapore and India [23] to as high as 64.7% among physicians in Turkey [31].

Four major groups of variables have been associated with an increased likelihood of having a positive screening for anxiety and/or depression among essential workers during the COVID-19 pandemic: demographic, professional/financial worries, COVID-19 exposure factors, and personal health factors. In terms of demographics, being female and younger were more frequently associated with depression [31,32] while a higher education level and residing in areas or provinces with a greater number of cases have been associated with anxiety [19,33,34]. Worrying about adequate training, knowledge, preparedness, and finances, as well as self-efficacy and career phase, were some of the professional/financial variables analyzed under this domain [34]. COVID-19 exposure variables

included being a frontline worker [31,33,34]; fear, suspicion, or diagnosis of COVID-19 for oneself and/or their significant other [19,32,33,35]; and having a deceased colleague [32]. Finally, regarding personal health factors, included variables were perceived stress [19], poor sleep [19,26], presence of a previous medical or psychiatric disorder [31,35], and a history of alcohol consumption [35]. Of note, good social support was frequently associated with a decreased likelihood of anxiety and depression among essential workers [19,36].

The fast growing field of lifestyle psychiatry [37] has been providing evidence on how health behaviors (eg, diet, physical activity, smoking, and sleep) relate to the prevalence, incidence, and adverse outcomes of mental health disorders [38-40]. For instance, consistent results point to the beneficial effects of physical activity in preventing the onset of depression as well as improving its symptoms [40]. As many people around the world are under confinement due to the COVID-19 pandemic, changes in lifestyle behaviors have attracted more research interest [41]. Behaviors, such as sleep quality [36,42], were assessed among HCWs instead of using a comprehensive, multidimensional approach to lifestyle. Multidimensional evaluations of lifestyle are still scarce [41], although it is possible that different health behaviors share a common pathway to improve mental health, such as anti-inflammatory effects [43,44]).

Considering the social determinants of health [45,46], it is possible that countries presenting poor social and health indicators may present a higher prevalence of unhealthy outcomes, which could include both COVID-19-related and mental health problems. Herein, we have included two countries with different social and health indicators, and at different stages of the COVID-19 pandemic, as summarized in Figure 1 [47-50]. Brazil has roughly 4.5 times the population of Spain, but 0.4 times the GDP (gross domestic product) and 0.4 times the expenditure on health. In addition, Brazil is considered one of the countries with the greatest inequalities in income/wealth globally, with a Gini index of 53.9. The first COVID-19 case was diagnosed on January 31, 2020, in Spain and on February 26, 2020, in Brazil, respectively. On May 2, 2020 (the midpoint of our data collection period), there were almost 25,000 deaths in Spain and 6000 deaths in Brazil. At that time, Spain was under a strict lockdown policy while the lockdown in Brazil was implemented partially and in select cities and counties.

So far, we are unaware of studies that have investigated mental health problems among essential workers from two countries presenting such different social and epidemic profiles. Thus, our major aim is to describe the prevalence of depression, anxiety, and the comorbidity of both, as well as their associated factors, among self-reported essential workers during the COVID-19 pandemic in Brazil and Spain.

**Figure 1.** Select social and health indicators (2017) and the COVID-19 situation (as of May 2, 2020) for Brazil and Spain. GDP: gross domestic product. Data sources: Institute from Health Metrics and Evaluation [47], \*World Health Organization [48,49], \*\*World Bank 2017-2018 [50].

## Methods

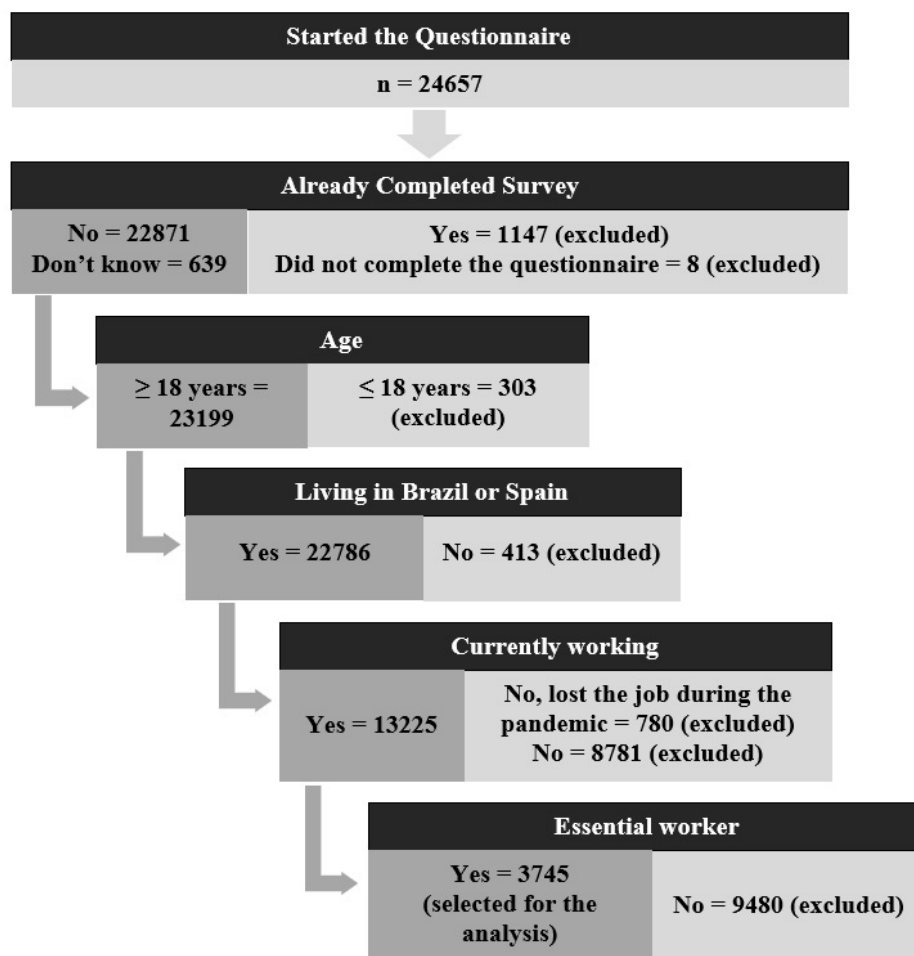

### Study Design

A web survey was conducted from April 15 to May 15, 2020, in Spain and April 20 to May 20, 2020, in Brazil. The online questionnaire was created using SurveyGizmo and included questions about demographics, COVID-19 experience, lifestyle behaviors, self-rated health, and previous diagnosed conditions. The questionnaire comprised 101 questions, and skips, when appropriate, were implemented to decrease the time of completion (Multimedia Appendix 1). The usability and technical functionality were tested before launching the survey in both countries. In addition, participants could read information regarding ways to maintain a healthy lifestyle during the pandemic while they were answering the questionnaire, and were provided with additional websites and telephone numbers to find reliable information regarding COVID-19. This information was compiled from the COVID-19-related

webpages of the Centers for Disease Control and Prevention, the National Institute of Health (United States), the Oswaldo Cruz Foundation, the Brazilian Ministry of Health, and the Spanish Ministry of Health.

### Study Population

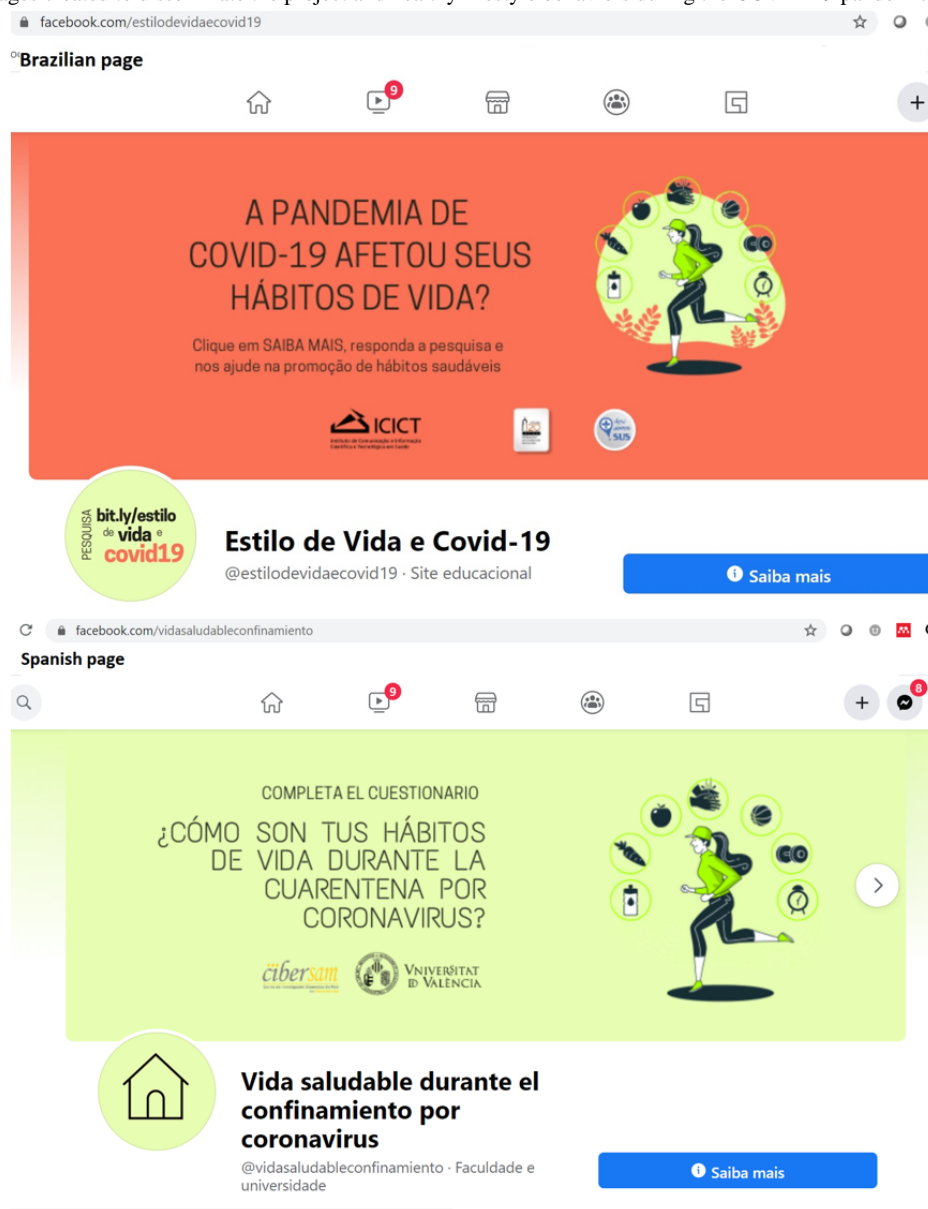

The study population included adults from both sexes living in Spain or in Brazil, who had access to the internet, and agreed to participate in the study after reading the informed consent form. Herein, we selected individuals who reported to be essential workers. Essential workers were considered all participants who answered “yes” to the following question: “Are you currently working as a health care worker or as a professional of other essential services (transportation, food, cleaning)?” To avoid duplicated responses, individuals who reported having previously completed the questionnaire were excluded (Figure 2) as no identification data (nor IP [Internet Protocol] address) were collected.

**Figure 2.** Inclusion flowchart.

### Sample and Recruitment

A convenience sample of participants was recruited via social networks (Facebook, WhatsApp, and Twitter) using a snowball technique and sponsored social network advertisements. A Facebook page for each country (Figure 3) was created and boosted using the following words: “healthy lifestyles,” “sad,” “happiness,” “fear,” “emotion,” “stress,” “well-being,” “self-esteem,” “quality of life,” “motivation,” “mind,” “boredom,” “panic,” “interpersonal relationship,” “life,”

“emotional intelligence,” “physical fitness,” and “physical exercise.” According to Facebook, the page would reach 87 million people in Brazil and 290,000 individuals in Spain. Fundamental parameters were unknown when the sample size was defined, such as the possible participation of superrecruiters [51] with the potential to skew the sampling process, or whether or not there would be structural bottlenecks. Therefore, the sample size was not defined a priori; instead, a 30-day period of data collection was specified.

**Figure 3.** Facebook pages created to disseminate the project and healthy lifestyle behaviors during the COVID-19 pandemic in Brazil and Spain.

## Response Rates

Response rates were not estimated in the study since the study denominator is unknown (ie, we were unable to estimate how many individuals had sent the survey link via different—and probably overlapping—social networks).

## Variables and Measurements

### Study Outcome (Dependent Variable)

The main outcome is a positive screening for depression and/or anxiety. Depression was screened using the Patient Health Questionnaire-2 (PHQ-2 [52-55]; cut-off  $\geq 3$ ), and anxiety was screened using the Generalized Anxiety Disorder 7-item scale (GAD-7 [56]; cut-off  $\geq 10$ ). Subsequently, two dichotomous variables were created: “Positive Depression” and “Positive Anxiety.” The outcome was a composite variable created using the aforementioned variables with the following categories: negative screening for both depression and anxiety, positive

screening for depression only, positive screening for anxiety only, and positive screening for both depression and anxiety.

### Independent Variables

Demographic information included sex, age, educational level (aggregated as primary/secondary education, a professional degree, a university degree, or a master’s/PhD degree), number of people living in the household, frontline worker (yes/no), and country of residence (Brazil/Spain). Social distancing/self-isolation was considered as a dichotomous variable (yes/no).

Questions related to COVID-19 were as follows: “Have you been diagnosed with COVID-19?”; “Have you been admitted to a hospital or hospitalized due to COVID-19?”; and “Have you lost a significant other?” Possible answers were yes or no.

Lifestyle habits were assessed using the Short Multidimensional Inventory Lifestyle Evaluation–Confinement (SMILE-C) [41]. This scale was developed specifically to allow a multidimensional measure of lifestyle during the COVID-19

pandemic. It comprises 27 items made up of 7 domains (diet and nutrition, substance abuse, physical activity, stress management, restorative sleep, social support, and environmental exposures), with response options measured using a 4-point Likert scale. The SMILE-C has an overall Cronbach  $\alpha=0.75$  and Kaiser-Meyer-Olkin Measure=0.77. The higher the score, the healthier the lifestyle pattern. In this study, the SMILE-C total score was dichotomized at the 75th percentile (up to 85%).

Self-rated health was measured using the question “How would you rate your health in general?” with possible answer choices of “very bad,” “bad,” “neither good nor bad,” “good,” and “very good” [57]. Response options were aggregated into very good/good and neither good nor bad/bad/very bad.

Previously diagnosed conditions were investigated using the question “In the last 12 months, have you been diagnosed by a medical doctor or health professional, or received treatment for any of the following conditions?” Conditions included diabetes, heart disease, hypertension, stroke, anemia, asthma, depression, anxiety, bipolar disorder, schizophrenia, anorexia/bulimia, HIV/AIDS, cancer, tuberculosis, cirrhosis, and renal disease [58]. The conditions were then aggregated as chronic diseases, mental health disorders, and infectious diseases.

Screening for alcohol abuse was performed using the Alcohol Use Disorder Identification Test (AUDIT-C; cut-off  $\geq 3$  [59]).

Changes in the SMILE-C domains during the pandemic were evaluated using questions like “Did you change your nutritional habits and diet during the COVID-19 pandemic?” Response options were measured using a 4-point Likert scale (completely, moderately, mildly, not at all) and aggregated into completely/moderately and mildly/not at all.

### Statistical Analysis

Nonresponse treatment is described in [Multimedia Appendix 2](#). Independent variables were described by outcome and proportions compared using chi-squared tests. Taking into consideration the complex, multiple associations of the different covariates with the outcomes under analysis (screening for depression and anxiety), preliminary analyses using Least Absolute Shrinkage and Selection Operator (LASSO [60, 61]), a simple machine learning procedure, were employed. LASSO is a penalized regression analysis method that helps to optimize variable selection and regularization in order to enhance the accuracy of the model to be implemented. The subset of factors (variables) that did not contribute to the hypothetical model

under assessment yield zero coefficients [62]. Such variables were excluded from subsequent multivariable analyses ([Multimedia Appendix 2](#)).

The second procedure to optimize variable selection was based on the simulation of different modeling strategies with the subsequent choice of the best subset of variables to be included in a parsimonious model based on the best  $R^2$  coefficient [63, 64]. The glmnet library and the regsubsets function from R 4.0.2 (The R Foundation) were used.

Using this subset of variables, a multinomial logistic regression was fitted, taking as the reference category “negative screening for both depression and anxiety.” Analyses used the backward strategy, with the progressive elimination of variables based on the results of the Wald test and maximum likelihood estimation of fitness, considering a significance level of 5.0%. The model fitness was evaluated using different diagnostic tools, such as the Hosmer-Lemeshow statistics, the Pearson chi-squared test, as well as the deviance information criterion. Additionally, an analysis of residuals was performed ([Multimedia Appendix 2](#)). The model yielded adjusted odds ratios (AORs) with their respective 95% CIs.

### Ethical Aspects

The study was approved by the Ethics Committee at the Hospital Universitari i Politècnic La Fe in Valencia, Spain, and by the Comissão Nacional de Ética em Pesquisa (CONEP, Brazil – 3.968.686). The survey was anonymous (no identifying data like name, zip code, or IP address were collected), and participants read the consent form and confirmed their interest in participating before starting the questionnaire. As mentioned before, as a direct benefit, participants were provided with tips on healthy lifestyles and reliable websites and telephone numbers for additional information regarding COVID-19.

## Results

Overall, 24,657 questionnaires were initiated, and 22,786 were eligible for the main study. Of those, 3745 reported to be working as an essential worker during the COVID-19 pandemic and comprised the study sample ([Figure 2](#)). In total, 2842 participants were from Brazil and 903 from Spain. Most were female (Brazil:  $n=2052$ , 72.2%; Spain:  $n=640$ , 70.9%;  $P=.44$ ), with a median age of 39 (IQR 32–51) years for Brazil versus 43 (IQR 32–52) years for Spain ( $P=.07$ ). Half of the sample ( $n=457$ , 50.6%) reported being a frontline personnel in Spain compared to 28.9% ( $n=822$ ) in Brazil ( $P<.001$ ) ([Table 1](#)).

The prevalence of positive screenings for depression, anxiety, and comorbidity of both was 8.3% (n=311), 11.6% (n=434), and 27.4% (n=1027), respectively. All were higher in Brazil compared to Spain (Table 1). Table 2 describes the

sociodemographic and clinical characteristics of the sample across the outcome categories (negative for depression and anxiety, positive for depression only, positive for anxiety only, and positive for both depression and anxiety).

In the multinomial model, living in Brazil was associated with an AOR of 2.89 (95% CI 2.07-4.06) for a positive screening for depression, an AOR of 2.81 (95% CI 2.11-3.74) for anxiety, and an AOR of 5.99 (95% CI 4.53-7.91) for both conditions compared to living in Spain. An unhealthy lifestyle was associated with an AOR of 4.00 (95% CI 2.72-5.87) for depression, an AOR of 2.39 (95% CI 1.80-3.20) for anxiety, and an AOR of 8.30 (95% CI 5.90-11.7) for both conditions. Interestingly, being a frontline worker was not associated with depression only (AOR 0.81, 95% CI 0.60-1.08), although it

increased the likelihood of having anxiety (AOR 1.49, 95% CI 1.18-1.87) and both conditions (AOR 1.25, 95% CI 1.02-1.53). Additionally, we found that being female, being younger, presenting moderate or substantial changes in sleep patterns during the COVID-19 pandemic, being diagnosed with or treated for mental health disorders in the last year, and reporting a reduction in self-rated health were all associated with a higher likelihood of having depression, anxiety, or both conditions (Figure 4 and Multimedia Appendix 2).

**Figure 4.** Factors associated with depression or anxiety or both (multinomial model) among essential workers from Brazil and Spain (n=3745). April-May, 2020. Note: (1) Age was dichotomized by the sample median age. (2) The SMILE-C (Short Multidimensional Inventory Lifestyle Evaluation-Confinement) was dichotomized at the percentile 75%, the higher the score, the healthier the lifestyle).

## Discussion

In a web survey of 3745 essential workers from Brazil and Spain, we showed 8.3%, 11.6%, and 27.4% presenting positive screenings for depression, anxiety, and both conditions, respectively. As in previous studies conducted during the COVID-19 pandemic, we found that women, younger workers, frontline workers, those reporting a mental health diagnosis or treatment in the last 12 months, and those reporting changes in sleep patterns presented a higher likelihood of a positive

screening for anxiety and/or depression. Most importantly, higher odds ratios were observed in those living in Brazil and in those following an unhealthy lifestyle.

During data collection, Spain had 4 times the number of COVID-19 deaths than Brazil and had adopted a strict lockdown policy. It could be expected that essential workers under these conditions would be more prone to present anxiety and depressive symptoms. However, Brazil has additional social, structural, and political problems that may affect mental health. Recently, Baqui et al [65] reported on the higher mortality risk

among “pardo” and Black Brazilians admitted to hospital due to COVID-19; ethnicity was the second most important risk factor for death (after age). In addition, the authors highlighted that comorbid diseases and death were more common among Brazilians from the North region compared to the Central-South (except for Rio de Janeiro). Ribeiro et al [66] highlighted that the worst public health and socioeconomic scenarios were present in the northern regions of Brazil; higher proportions of individuals living in substandard housing (slums), with reduced schooling and a lack of sanitation and piped water, may interfere with adherence to hygiene recommendations. Although both papers discussed intracountry inequalities, social and health inequalities may be even higher between different countries [67] (Figure 1). In addition, the political instability and the government’s failure to acknowledge the seriousness of the pandemic (eg, official data on COVID-19 was not being published) [68] may be worsening the consequences of COVID-19 in Brazil, including repercussions concerning the mental health of essential workers. These workers may be seeing a high number of casualties, and working under intense fear and feelings of impotence, which may be related to the higher odds for anxiety and depression observed in our study.

Self-reported unhealthy lifestyle behaviors during confinement were associated with an increased likelihood of presenting a positive screening for both anxiety and depression in our study. Several studies have assessed psychological distress in HCWs during COVID-19, but its association with lifestyle remains underresearched. To our knowledge, the present study is the first web survey designed to assess a wide range of lifestyle changes and its relationship with anxiety and depression among essential workers during the pandemic. Among HCWs from New York, where almost half screened positive for depression, and one third for anxiety [30], physical activity/exercise was the most commonly endorsed solution to cope with COVID-19–related psychological distress, but its relationship with anxiety and depression was not explored. Our results are consistent with those pertaining to the general population and clinical studies. For instance, in Australia, adults who reported negative changes in physical activity, sleep, smoking, and alcohol intake after the onset of COVID-19 were more likely to have higher rates of depression, anxiety, and stress symptoms [69]. In the same way, individuals with anxiety and depression have shown higher ratios of unhealthy lifestyle habits, including poor diet quality, impaired sleep, reduced physical activity, smoking, and substance and/or alcohol misuse [39]. Based on the present results, the relationship between anxiety/depression and lifestyle as a multidimensional construct applies also to essential workers during the COVID-19 pandemic.

Our findings regarding sleep changes are also in accordance with a meta-analysis that showed that about 50% of HCWs have poor sleep quality in general (ie, during nonpandemic times) [36]. Subjective sleep quality, defined by the satisfaction with one’s overall sleep experience, may worsen among frontline HCWs treating patients with COVID-19 [42]. The present study expands the association between changes in sleep and anxiety/depression to a wider group of essential workers. This concurs with evidence supporting a bidirectional relationship between sleep disturbances and anxiety/depression [70].

Moreover, a reduced quality of sleep was associated with higher levels of depressive and anxiety symptoms during the COVID-19 lockdown in Italy [71].

Our results are in accordance with most of the literature: women and youth [17,31,32,72], frontline workers [31,33,34], a diagnosis of or treatment for mental health disorders in the past 12 months, and self-rated poor health [17] all increased the likelihood of depression and anxiety. Mental health disorders are associated with higher mortality rates and shorter life expectancies [73]. Our results, which support that of The Lancet Commission on Global Mental Health and Sustainable Development [74], showed the importance of social and environmental factors in mental health and highlighted the additional challenges experienced by populations living in countries with higher rates of inequality.

Consistent with other web surveys, where the population is recruited through social networks, our sample is not probabilistic and may therefore not represent the entire population of essential workers from Brazil and Spain [75]. Additionally, in 2018, 67% of Brazilian households had internet access (48% among the lower economic strata) [76] compared to 86.4% in Spain [77]. Although this difference may not have contributed to the different prevalence found between the countries (as we may have surveyed individuals with age, income, and schooling more similar to the Spanish population), we may be overrepresenting the highest socioeconomic strata in Brazil. Women were also overrepresented in both countries, as in many other web surveys conducted during the COVID-19 pandemic [18,23,32,34,72]. Due to the length of the original questionnaire, we did not include questions regarding gender and ethnicity/race, which may be associated with higher vulnerability to COVID-19 [65] and mental health outcomes. Additionally, we did not ask about the specific profession of essential workers and were not able to assess which professional groups were more vulnerable to mental health problems. In the United States [78], over 75% of Americans were estimated to work in occupations (including health care, manufacturing, retail, and food services) that are challenging to do from home. It was suggested that those workers may receive low wages and be subjected to stress due to the lower income and job insecurity, which could result in a large burden of mental health disorders.

One important strength of our survey was to disseminate reliable information on COVID-19 and strategies to maintain a healthy lifestyle. Considering the massive amount of information available, including fake news, and all the technology available for creating and disseminating online surveys, we believe that researchers can contribute to society by providing valuable information to respondents while obtaining data. Studies addressing participants’ opinions and effectiveness, when appropriate, on this information should be considered in the future.

Finally, our results provide additional support for The Lancet COVID-19 Commission [79], and are in accordance with Vigo et al [80], showing that countries with higher rates of inequality may be facing an important mental health burden in the forthcoming months.

## Acknowledgments

We would like to thank Gabriel Madeira and Ronaldo I Moreira for their assistance in creating and testing the online questionnaire; Thais Martini for social media management; Juliana Krapp and Daniele Souza for communications advice; all the institutions and individuals who promoted the survey; and all the individuals who answered it. RBDB is grateful for long-term funding from the Fundação de Amparo à Pesquisa do Estado do Rio de Janeiro (FAPERJ) (E-26/203.154/2017) and the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) (310541/2017-4). FIB acknowledges funding from FAPERJ (Health Networks; E-26/010.002428/2019). FK acknowledges funding from the Fundação de Amparo à Pesquisa do Estado de São Paulo (INCT 2014, 2014/50891-1), CNPq (INCT 465458/2014-9), and the Fundação de Amparo à Pesquisa do Estado do Rio Grande do Sul (47177.584.16785.16042020).

Funding sources had no role in the study design, data collection, analysis, interpretation of data, writing of the report, or in the decision to submit the paper for publication.

## Authors' Contributions

RBDB, VBM, and FK conceived and designed the study. JCM, TDAC, and PB analyzed the data and created the figures. RBDB and FIB supervised data analysis. RBDB, VBM, and BC revised the literature. RBDB wrote the first draft, and all authors revised and provided significant intellectual contribution. All the authors approved the submitted version.

## Conflicts of Interest

VBM has been a consultant, advisor, or Continuing Medical Education speaker over the last 3 years for the following companies: Angelini, Ferrer, Lundbeck, Nutrición Médica, and Otsuka. The remaining authors have no conflicts to declare.

## Abstract

**Background:** Wearable sensors have been used successfully to characterize bradykinetic gait in patients with Parkinson disease (PD), but most studies to date have been conducted in highly controlled laboratory environments.

**Objective:** This paper aims to assess whether sensor-based analysis of real-life gait can be used to objectively and remotely monitor motor fluctuations in PD.

**Methods:** The Parkinson@Home validation study provides a new reference data set for the development of digital biomarkers to monitor persons with PD in daily life. Specifically, a group of 25 patients with PD with motor fluctuations and 25 age-matched controls performed unscripted daily activities in and around their homes for at least one hour while being recorded on video. Patients with PD did this twice: once after overnight withdrawal of dopaminergic medication and again 1 hour after medication intake. Participants wore sensors on both wrists and ankles, on the lower back, and in the front pants pocket, capturing movement and contextual data. Gait segments of 25 seconds were extracted from accelerometer signals based on manual video annotations. The power spectral density of each segment and device was estimated using Welch's method, from which the total power in the 0.5- to 10-Hz band, width of the dominant frequency, and cadence were derived. The ability to discriminate between before and after medication intake and between patients with PD and controls was evaluated using leave-one-subject-out nested cross-validation.

**Results:** From 18 patients with PD (11 men; median age 65 years) and 24 controls (13 men; median age 68 years),  $\geq 10$  gait segments were available. Using logistic LASSO (least absolute shrinkage and selection operator) regression, we classified whether the unscripted gait segments occurred before or after medication intake, with mean area under the receiver operator curves (AUCs) varying between 0.70 (ankle of least affected side, 95% CI 0.60-0.81) and 0.82 (ankle of most affected side, 95% CI 0.72-0.92) across sensor locations. Combining all sensor locations did not significantly improve classification (AUC 0.84, 95% CI 0.75-0.93). Of all signal properties, the total power in the 0.5- to 10-Hz band was most responsive to dopaminergic medication. Discriminating between patients with PD and controls was generally more difficult (AUC of all sensor locations combined: 0.76, 95% CI

0.62-0.90). The video recordings revealed that the positioning of the hands during real-life gait had a substantial impact on the power spectral density of both the wrist and pants pocket sensor.

**Conclusions:** We present a new video-referenced data set that includes unscripted activities in and around the participants' homes. Using this data set, we show the feasibility of using sensor-based analysis of real-life gait to monitor motor fluctuations with a single sensor location. Future work may assess the value of contextual sensors to control for real-world confounders.

## Introduction

### Background

The core treatment of patients with Parkinson disease (PD) is symptomatic and consists of dopamine replacement therapy. Although motor symptoms such as bradykinesia and rigidity can be well controlled in early disease stages, most patients experience motor fluctuations in symptom severity after a few years of treatment with levodopa [1]. The pattern of these motor fluctuations varies between patients and may include wearing off, unpredictable off phases, peak-dose dyskinesias, and diphasic dyskinesias. Therefore, optimal management of motor fluctuations requires a highly personalized approach. The current evaluation of motor fluctuations involves paper diaries, such as the Hauser diary, which are burdensome to complete and which demonstrate reduced compliance when used for more than three days [2]. Moreover, patients are not always able to accurately recognize their own symptoms (eg, dyskinesia is often confused with tremor and vice versa). A more objective and unobtrusive way to assess motor fluctuations over longer periods of time in daily life could shed light on the real-world presentation of PD and benefit both individual patient care and follow-up in clinical trials.

Wearable movement sensors could potentially address this need. It is important to distinguish between active monitoring (ie, the analysis of specific tasks, such as the timed up and go [TUG] test [3]) and passive monitoring (ie, the analysis of natural behavior of daily living). Although active monitoring has received by far the most attention [4,5], this approach is susceptible to attrition in patient compliance [6]. By contrast, excellent long-term compliance can be achieved when patients are only asked to wear an unobtrusive sensor, such as a smartwatch, as they go about their daily activities [7]. Passive monitoring can also provide more continuous insights into symptom fluctuations throughout the day. However, these benefits come at a cost: it is challenging to develop algorithms that can cope with the large variation in signals encountered in daily life, of which only a small proportion may be explained by PD-related impairments. Since obtaining accurate labels in daily life environments is difficult and costly, most of the currently available reference data sets have been collected in the lab and involved patients performing a standardized set of tasks and activities. Algorithms trained on these data sets are unlikely to perform well in real-life settings [8]. Some studies have simulated a home environment in the lab and included unscripted behavior [9,10]. Although this is more realistic, all

data are still collected in the same environment, so the expected variation in activities and symptom severity is much reduced compared with real life. Consequently, the real-life performance of new sensor-based methods to assess motor fluctuations remains largely unknown.

Another challenge is finding the best strategy to derive meaningful and interpretable outcome measures from daily life sensor data. One approach is to detect and quantify a specific behavior that probes the presence of PD symptoms. Gait is a promising candidate in this regard for three reasons. First, gait is highly stereotypic, allowing for accurate detection in daily life signals. Second, gait becomes abnormal even in very early stages of the disease, likely already in the prodromal phase [11], and gait impairments worsen as the disease progresses [12,13]. Recording and analyzing gait is therefore useful across a wide spectrum of disease severities. Third, even among patients with PD without freezing of gait, the gait pattern changes in response to dopaminergic medication. Specifically, the step length and arm swing are reduced in the off state, which is known as bradykinetic gait [14,15]. However, these findings are based on data collected during standardized tasks (typically the TUG test) in highly controlled laboratory environments. It is not self-evident that these effects directly translate to daily life [16]. Various behavioral and environmental factors may influence gait in daily life. In addition, patients with PD show different gait patterns when they are aware that they are being evaluated (partially a Hawthorne effect and partially the phenomenon of *kinesia paradoxa*, the sudden transient ability of patients with PD to perform a task due to increased alertness or arousal) [17,18]. Indeed, gait patterns as measured in the lab and in real life (using accelerometry) are only weakly correlated [19,20].

Empirical evidence that underlines the value of analyzing real-life gait in PD is emerging. This approach may discriminate better than lab-based gait analysis between patients with PD and controls [19]. Similarly, real-life gait variability, derived from an accelerometer worn on the lower back, may predict the time to first fall better than various in-lab measurements, including gait speed in the off state [21]. In addition, a pilot study showed that at-home gait speed, measured using a radio wave-based monitor, correlates with PD severity [22]. However, studies that have examined how on-off changes are reflected in real-life gait patterns are scarce. Moore et al [23] suggested that step length derived from an ankle sensor could be used to monitor on-off changes in real life but illustrated this in only one patient. Sama et al [24] proposed that the energy in the 0- to 10-Hz frequency band during gait, obtained using a

waist-worn sensor, could predict the patient's motor state. When tested in daily life, the algorithm's predictions demonstrated high agreement with on-off diaries completed by the patients [25]. We conclude that analyzing real-life gait to monitor motor fluctuations has thus far shown promising results, but developments remain in the early stages. This is reflected by the lack of consensus on the best sensor location [26]. The field would benefit from an objective comparison of commonly used sensor locations on labelled data collected in the patients' home environments.

## Study Objective

In the Parkinson@Home validation study, we collected data from multiple wearable sensors during unscripted activities in and around the participants' homes and recorded the activities on video. The objective of this publication is twofold. First, we aim to describe this new reference data set, which will be made available to the research community in collaboration with the Michael J Fox Foundation. Second, using this data set, we aim to assess whether real-life gait analysis can be used to obtain a digital biomarker for motor fluctuations in PD. Specifically, we will assess how well various sensor locations can discriminate between gait performance before and after intake of dopaminergic medication and explore which factors complicate gait analysis in daily life.

## Methods

### Study Sample

We included a group of 25 patients with PD and 25 age-matched participants without PD (controls). Patients were recruited using various strategies, including advertisements in the Dutch Parkinson Patient Association's magazine and on social media, visits to support groups, and through physiotherapists specialized in the treatment of PD. Controls were recruited from partners and acquaintances of the participating patients and by advertisements on social media. The inclusion criteria were (1) aged  $\geq 30$  years, (2) in possession of a smartphone running on Android 4.4 or higher, and (3) living within travelling distance from the study center. Additional inclusion criteria for the PD group were (1) Parkinson disease diagnosed by a neurologist, (2) currently using levodopa and/or a dopamine agonist, (3) experiencing at least slight motor fluctuations (Movement Disorders Society Unified Parkinson's Disease Rating Scale [MDS-UPDRS] part IV item 4.3  $\geq 1$ ), and (4) experiencing at least some Parkinson-related gait impairments (MDS-UPDRS part II item 2.12  $\geq 1$  and/or item 2.13  $\geq 1$ ). The exclusion criteria were (1) any type of advanced treatment (deep brain stimulation or intestinal levodopa or apomorphine infusion) and (2) psychiatric or cognitive impairments that may hinder successful completion of the study protocol (based on judgement of the assessor running the recruitment). We did not exclude patients with PD or controls who used assistive devices or reported other medical problems affecting their movements. We refer to

[Multimedia Appendix 1](#) for a flow diagram of the inclusion procedure.

### Data Collection Procedure

Data were collected during single visits to the participants' homes from July 2017 to July 2018. A visit consisted of 2 parts: an unscripted free-living part and a standardized clinical assessment. In the PD group, both parts were conducted twice during the same visit, once in the morning after overnight withdrawal of dopaminergic medication (premedication) and once after intake of the patient's prescribed dopaminergic medication (postmedication).

During the free-living part, the assessors encouraged the participants to perform habitual activities in and around their house for at least one hour. In order to capture natural behavior, there was no script for this part of the visit. Instead, the assessors used a checklist to ensure that essential behaviors were captured, such as doing normal morning routines, preparing and having breakfast, walking indoors, walking in the neighborhood, walking up and down the stairs, sitting down, standing up, and doing some household chores. It should be noted that the participants' normal routines were leading; for example, if participants hardly did any household chores themselves, we did not ask them to do so during the visit.

The clinical assessments were also conducted in the participants' homes and included the TUG test, the Abnormal Involuntary Movement Scale, and the complete MDS-UPDRS, except for the self-reported items of part I and II, which were completed through an online survey after the visit. In the PD group, the clinical assessments were performed before and after medication intake, except for part I (assessor-rated items) and part IV of the MDS-UPDRS, which were only performed after medication intake. In addition, both the patient and the assessor scored the disease state (as off, on without dyskinesia, or on with dyskinesia) for every 30-minute epoch after medication intake. All assessments were conducted by a single assessor who had received appropriate prior training. [Multimedia Appendix 1](#) provides an overview of the events during the home visits.

During the full duration of the visit, participants wore lightweight sensors on both wrists, both ankles, the lower back, and in the front pants pocket, containing movement, contextual, and physiological sensors ([Table 1](#)). Except for the smartphone, all devices were attached using adjustable straps. In addition, the entire visits were recorded on video using a handheld high-definition video recorder by one of the assessors following the participant. To put the patient at ease and make the setting more naturalistic, the other assessor helped to comfort the patient and shift the focus from being recorded to performing habitual activities together. To allow for time synchronization between all sensors and the video recordings, all devices were triggered (hit simultaneously against the table 10 times) in front of the camera at the beginning and end of the recordings.

**Table 1.** Overview of the wearable sensors used during the study visits.

Device	Locations	Collected sensor data
Gait Up Physilog 4 <sup>a</sup>	Both ankles, both wrists, lower back (strap around waist)	Accelerometer, gyroscope, magnetometer, barometer
Android Wear smartwatch <sup>b</sup>	Wrist (PD <sup>c</sup> group: self-reported most affected side; control group: most comfortable side)	Accelerometer, gyroscope, barometer, light
Android smartphone <sup>d</sup>	Pants pocket (same side as Android Wear smartwatch)	Accelerometer, magnetometer, light, proximity, GPS, Wi-Fi, and cellular networks
Empatica E4 <sup>e</sup>	Wrist (opposite wrist to Android Wear smartwatch)	GSR <sup>f</sup> , PPG <sup>g</sup> , skin temperature, accelerometer

<sup>a</sup>Gait Up SA.<sup>b</sup>Motorola Moto 360 Sport (Motorola Inc) with custom application collecting raw sensor data.<sup>c</sup>PD: Parkinson disease.<sup>d</sup>Various models with the HopkinsPD app collecting raw sensor data.<sup>e</sup>Empatica Inc.<sup>f</sup>GSR: galvanic skin response.<sup>g</sup>PPG: photoplethysmogram.

After the home visits, all participants continued to use a subset of the sensors (smartphone and smartwatch) for 2 weeks and completed symptom diaries as reference. As this part of the data set is not used in the current analyses, we refer to [Multimedia Appendix 1](#) for a detailed description of the corresponding protocol.

The study protocol was approved by the local medical ethics committee (Commissie Mensgebonden Onderzoek, region Arnhem-Nijmegen, file number 2016-1776). All participants received verbal and written information about the study protocol and signed a consent form prior to participation, in line with the Declaration of Helsinki.

## Data Availability

The full data set as described in the “Methods” section, with the exception of the raw video recordings and absolute GPS coordinates, will be made available to the worldwide research community in collaboration with the Michael J Fox Foundation. To protect participant privacy, manual annotations are available from the video recordings, and the GPS data will be deidentified before sharing. A subset of the data is being used in the international Biomarker and Endpoint Assessment to Track Parkinson’s Disease (BEAT-PD) Challenge [27]. The full curated and deidentified data set will be released when this data challenge is completed. The specific data and analysis scripts that support the findings of this study are available from the corresponding author upon reasonable request.

## Data Processing

### Video Annotations

To provide ground truth labels for algorithm development and validation, the video recordings were annotated by trained research assistants for (1) the protocol structure (ie, when the clinical assessments and free-living parts were performed), (2) the occurrence of general behaviors during the free-living parts (such as standing, walking, and sitting), and (3) the presence and severity of tremor and the presence and manifestations of freezing of gait during the free-living parts. Annotations from the last category were checked by a physician with experience

in movement disorders. In addition, those items of the MDS-UPDRS part III that can be evaluated from video were assessed by a second, independent rater (physician with experience in movement disorders). The annotations were created using ELAN (The Language Archive), an open source program for creating annotations in video recordings [28]. For a detailed description of the video annotation protocol, we refer to [Multimedia Appendix 1](#).

### Sensor Data Preprocessing

In the current analysis, we used the triaxial accelerometer data (in m/s<sup>2</sup>) from all Physilog devices and the smartphone worn in the pants pocket. First, data were interpolated to a uniform sample rate of 120 Hz using piecewise cubic interpolation. Next, the effects of gravity were removed by applying an  $\ell_1$  trend filter to each of the 3 axes separately (MATLAB implementation by Kim et al [29]). For each device, we used the 3 resulting dynamic acceleration signals,  $a_x$ ,  $a_y$ , and  $a_z$ , to compute the magnitude of dynamic acceleration (ie, the square root of [ $a_x^2 + a_y^2 + a_z^2$ ]).

### Frequency Analysis of Gait Segments

Various approaches have been used to quantify the gait pattern in patients with PD using accelerometer data. Some studies rely on the detection of the initial and final contact of the feet, from which temporal gait features such as the step and swing time can be derived [30]. Based on the exact sensor positioning and some assumptions derived from the biomechanics of gait, location-specific algorithms can be used to estimate spatial gait features. For example, having identified the initial and final contact, one can use the inverted pendulum model to estimate the step length using a sensor on the lower back [31]. Although this approach produces outcome measures that directly relate to the way gait is evaluated by clinicians, its location dependency complicates the comparison of different sensor locations. Additionally, detecting the initial and final contact is more challenging in real-life circumstances [32]. Other studies analyze the periodicity of the accelerometer signal during gait based on the power spectral density (PSD) or autocorrelation

[21,33]. Since it does not rely on location-specific assumptions, we used this approach in our analysis.

The video annotations were used to locate periods of gait (defined as five or more consecutive steps) during the free-living parts. From these, we extracted nonoverlapping gait segments of equal length (3000 samples, corresponding to 25 seconds). This length was selected because prior research showed that using shorter free-living gait segments discriminated less well between patients with PD and controls [19] and in order to achieve sufficient resolution in the frequency domain. To be included in the analyses, participants needed to have at least 10 gait segments of 25 seconds. In addition, patients were required to have at least 5 segments before and 5 segments after medication intake. The PSD of each gait segment and sensor location was estimated using Welch's method [34] (with, per segment, Hamming windows of 1024 samples with approximately 50% overlap). From each of the 6 sensor locations, we extracted 4 different signal properties, resulting in 24 features. We computed the total power in the 0.5- to 10-Hz interval, which captures practically all contributions from human gait [35]. In addition, we extracted the frequency, height, and width (at half the height) of the dominant peak in the PSD. The frequency of the dominant peak was used to derive the participants' cadence (the method is described in [Multimedia Appendix 1](#)).

## Evaluation

For the main objective of this study, we compared real-life gait segments before and after medication intake. Since we expected that the relative differences within subjects are most relevant in this context, we normalized each feature using  $z$  scores based on each patient's mean and standard deviation. In addition, we compared gait segments between patients with PD and controls. For these analyses, we rescaled each feature using its between-subject standard deviation in order to aid the comparison of effect sizes between features and to obtain a common scale for regularization (see "Classification").

## Individual Features

First, we examined the effect of medication intake on the individual features. To deal with the varying number of gait segments between participants, we used linear mixed effect models with the normalized features as dependent variables. For each feature, we estimated a fixed effect of the timing of the gait segment (premedication/postmedication) and random intercepts and slopes per patient. We used separate linear mixed effect models to estimate fixed effects of the group (patients with PD premedication, postmedication, or controls) and random intercepts per participant. Because we aim to show the magnitude and spread of the individual fixed effects rather than testing overarching hypotheses based on multiple comparisons, we report the unadjusted 95% confidence intervals of the estimated effects, as recommended by Gelman et al [36].

## Classification

Next, we evaluated whether combinations of features could be used to predict whether a gait segment occurred before or after medication intake. For this, we used logistic LASSO (least absolute shrinkage and selection operator) regression with

uniform prior class probabilities. To account for the varying number of gait segments per patient, we weighted each gait segment by the inverse of the number of gait segments per patient. We evaluated the performance using leave-one-subject-out nested cross-validation (CV), with the LASSO regularization hyperparameter being selected in the inner CV loops. The main performance measure was the mean area under the receiver operator curve (AUC). In addition, we evaluated the performance of logistic LASSO regression to predict whether a gait segment was from a patient with PD (premedication) or control. We used nested cross-validation for this as well, leaving 1 patient and 1 control out in each fold. To avoid information leakage, normalization was performed separately for each fold using only training data.

For both problems, we trained one classifier for each sensor location and one for all sensor locations combined. To prevent the patient with PD or control classifiers from learning the differences between the dominant and nondominant side, we ensured that the proportion of participants with measurements from the dominant side was always equal in the PD and control group. We tested whether the AUCs of the individual sensor locations were lower than the AUC of all sensor locations combined using the Wilcoxon matched pairs signed rank test ( $P < .05$  considered statistically significant). The results of the individual comparisons were then used to test the overarching null hypothesis that using all sensor locations combined is superior to using any of the single sensor locations (we rejected this hypothesis if three or more individual comparisons were nonsignificant, which corresponds to a significance level  $\alpha$  of approximately .01; for the calculation, see [Multimedia Appendix 1](#)).

Using the trained classifiers of the sensor location with the highest AUC, we constructed continuous scores that could serve as digital biomarkers for the response to medication intake (premedication/postmedication classifier) and PD gait impairment severity (PD/control classifier). For this, we used the classifiers' decision values (linear combinations of feature values), which, in the case of logistic regression, correspond to the logarithm of the odds (logit) of the posterior class probabilities. We then examined their correlation with relevant clinical measures (Spearman  $\rho$ ). Specifically, using the "best" classifier for predicting premedication and postmedication in the PD group, the patients' mean changes in decision values after medication intake (corresponding to the patients' mean log odds ratio) were correlated to the changes in the TUG score and the subtotal of the items related to mobility of the MDS-UPDRS part III (items 3.9, 3.10, 3.11, 3.12, and 3.13). Using the same sensor location's classifier for predicting patient with PD or control, the patients' mean decision values were correlated to the absolute TUG score, time since diagnosis, and the subtotal of the MDS-UPDRS part III mobility items. All analyses were performed in MATLAB 2018a (MathWorks).

## Qualitative Evaluation

To explore which factors unrelated to PD may disturb gait analysis in real-world settings, we inspected individual patients and sensor locations in which the classifier performed worse than random classification in predicting premedication and

postmedication (AUC <0.5). This was done by visually identifying change points in the PSDs and evaluating the corresponding video recordings for potential explanations. If an identified factor was also present in the video recordings of another patient, we evaluated whether it had a similar impact on the PSD (regardless of the patient's AUC).

## Results

### Participant Characteristics

A minimum of 10 gait segments of 25 seconds were available in 18 patients with PD (median 46.5 segments, range 14-95) and 24 controls (median 31 segments, range 11-61). These participants' demographic and clinical characteristics are presented in [Table 2](#). Reasons for collecting an insufficient number of gait segments included rainy weather (n=4), a desire not to be filmed in the neighborhood (n=1), use of a wheelchair

for longer distances (n=1), fatigue (n=1), and technical problems with the video recordings (n=1). The included patients did not differ substantially from the excluded patients in terms of disease severity ([Multimedia Appendix 1](#)). In 9 participants, there were technical problems with the sensor worn on the lower back. Therefore, we excluded this sensor location from the analyses combining multiple sensor locations (we refer to the [Multimedia Appendix 1](#) for the results of the 33 patients for whom the lower back sensor data were available). In addition, technical problems caused data loss for 1 ankle sensor in 1 participant; this participant (control) was excluded from the analyses combining multiple sensor locations. The distribution of the length of the analyzed gait segments was similar among patients with PD (premedication and postmedication) and controls ([Multimedia Appendix 1](#)). The experiences of participants during the home visit collected by the online exit survey are included in [Multimedia Appendix 1](#).

**Table 2.** Demographics and clinical characteristics of patients included in the analyses.

Characteristic	Patients with PD <sup>a</sup> (n=18)	Controls (n=24)

## Comparison of Before and After Medication Intake

Figure 1 shows all individual changes in the signal properties after medication intake. For illustration, Figure 2 displays the power spectral density of one of the patients who demonstrated a clear response to medication intake (PD\_14). At the group level, the total power and height of the dominant peak increased in all sensor locations after medication intake, whereas the width

of the dominant peak did not change significantly in any sensor location (Figure 3). Cadence increased in some patients but markedly decreased in others, resulting in a nonsignificant change at the group level for all sensor locations (Figure 3). Because of the high correlation between changes in the height of the dominant peak and total power (mean Pearson  $r$  of 0.80) and the clearer response of the latter across the sensor locations, the height was not included in subsequent analyses.

**Figure 1.** Changes in the 4 signal properties after medication intake, expressed in z scores (color bar). The x-axis displays the various sensor locations; the y-axis shows all individual patients (sorted on the values of the ankle sensor of the most affected side). The figure highlights that the total power and height of the dominant peak increase after medication intake in most patients (with considerable variation between sensor locations), the cadence increases in some but decreases in others (with high agreement between sensor locations), and the width of the dominant peak does not change considerably. Grey areas indicate missing data. la: least affected; ma: most affected; PD: Parkinson disease.

**Figure 2.** Visualization of the PSD of one of the patients who shows a clear response after medication intake (PD\_14). x-axis: nth gait segment of 25 seconds (the white line indicates intake of dopaminergic medication). y-axis: frequency (Hertz). Color bar: PSD in  $(\text{m/s}^2)^2/\text{Hz}$ . PD: Parkinson disease; PSD: power spectral density.

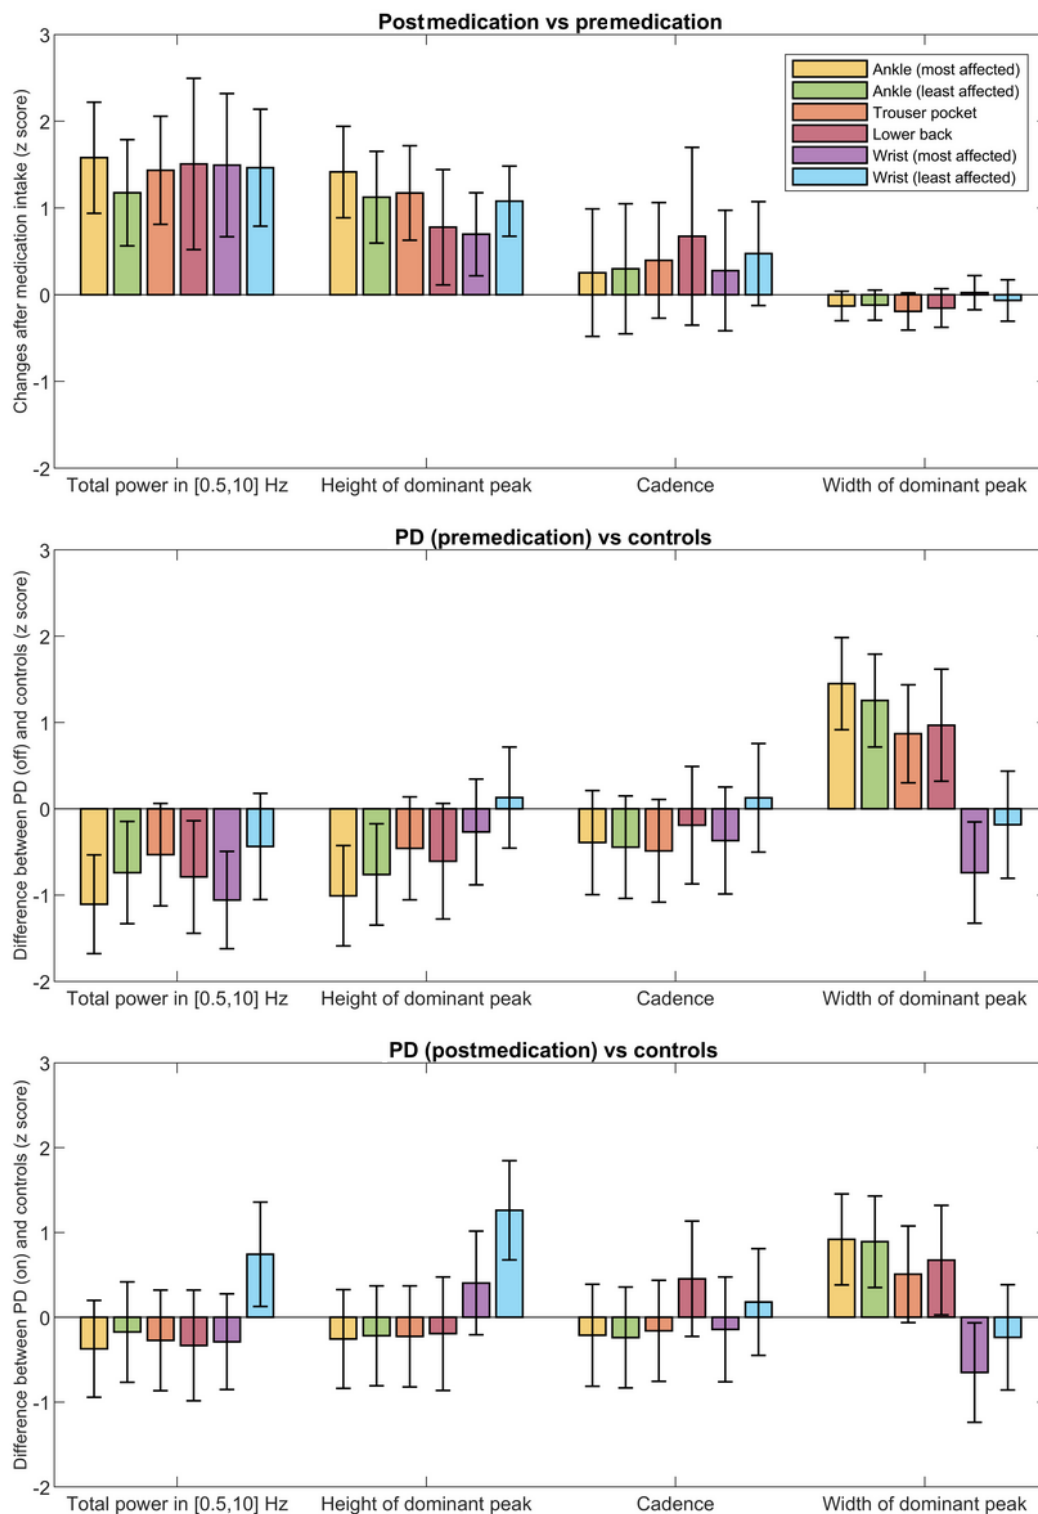

Figure 4 displays the receiver operator curves (ROCs) of the logistic classifiers trained using the various sensor locations and signal properties. The mean AUC for all sensor locations and signal properties combined was 0.84 (95% CI 0.75-0.93). The mean AUCs of the ankle of the most affected side (0.82, 95% CI 0.72-0.92), the wrist of the most affected side (0.76, 95% CI 0.66-0.87), and the wrist of the least affected side (0.79, 95% CI 0.69-0.88) were not significantly worse than using all sensor locations combined. Based on this, we reject the overarching hypothesis that using all sensor locations combined is superior to using any of the single sensor locations. Of the signal properties, the total power was most informative to discriminate between before and after medication intake, with a mean AUC of 0.80 (95% CI 0.69-0.91). The mean AUC of the width of the dominant peak (0.51, 95% CI 0.45-0.58) and cadence (0.55, 95% CI 0.43-0.66) were by themselves not significantly different from 0.5 (random classifier), although the width of the dominant peak resulted in a modest (but statistically significant) improvement in AUC when combined with the total power (Figure 4). The AUC and balanced accuracy

(based on an equal class prior) of all locations and signal properties are presented in Table 3. Multimedia Appendix 1 includes a sensitivity analysis on the effects of the choice of per-subject normalization.

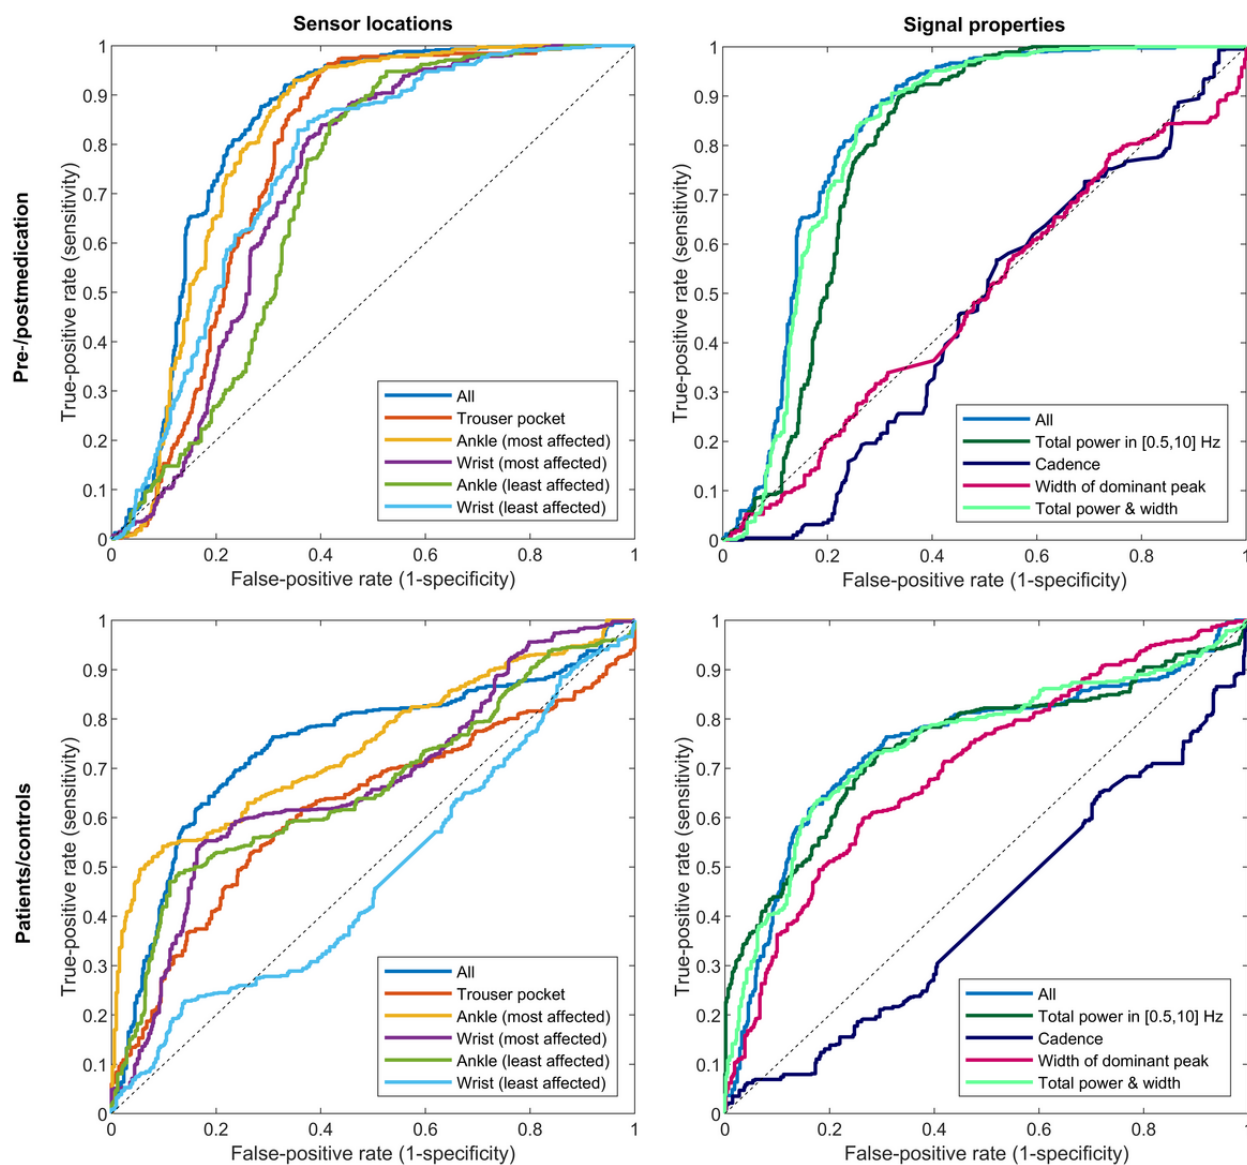

Both the TUG (−1.51, 95% CI −2.29 to −0.73) and the subtotal of the MDS-UPDRS part III mobility items (−1.31, 95% CI −2.13 to −0.48) decreased after medication intake. However, the patients' mean changes in decision values, obtained from the classifier based on the ankle sensor of the most affected side, did not correlate with changes in the TUG ( $p=0.02$ , 95% CI −0.49 to 0.45), nor with changes in the subtotal of the MDS-UPDRS part III mobility items ( $p=0.11$ , 95% CI −0.38 to 0.45).

Based on the video recordings, freezing of gait (FOG) was observed in 2 patients (PD\_1 and PD\_4). However, no FOG episodes occurred during any of the gait segments of at least 25 seconds, so FOG is not expected to have influenced the observed changes.

**Figure 3.** Top: changes after medication intake on a group level (mean and 95% CI). Middle: differences between patients with PD (premedication) and controls (mean and 95% CI, positive means higher in patients). Bottom: differences between patients with PD (postmedication) and controls (mean and 95% CI, positive means higher in patients). All estimates are based on linear mixed effects models for each sensor location and signal property. PD: Parkinson disease.

**Figure 4.** Receiver operating characteristic curves of the logistic classifiers, averaged over the cross-validation folds. Top half: premedication and postmedication classification. Bottom half: patients and controls classification. Left half: comparison between different sensor locations. Right half: comparison between different signal properties, based on all sensor locations combined.

**Table 3.** Performance of the logistic classifiers (mean, SE 1.96 over the cross-validation folds). Accuracies are based on the optimal classifier for each fold with equal misclassification costs and equal class prior (also referred to as balanced accuracy).

<sup>a</sup>PD: Parkinson disease.<sup>b</sup>AUC: area under the receiver operator curve.

## Comparison of Patients and Controls

The width of the dominant peak differed between patients and controls in most sensor locations, both premedication and postmedication ([Figure 3](#)). Interestingly, the PD patients' width was elevated in the ankle, pants, and lower back sensors but lowered in the wrist of the most affected side. The estimated cadence did not differ between patients (pre- and postmedication) and controls, regardless of the sensor location used. The total power and height of the dominant peak were lower in patients with PD (premedication) compared with controls in most sensor locations, but this difference was not present after medication intake, with the exception of the wrist of the least affected side, which showed elevated values after medication intake and no differences before medication intake. The ROCs for the various sensor locations and signal properties ([Figure 4](#)) show that it was generally more difficult to discriminate between the gait of patients with PD and controls than between before and after medication intake within patients with PD. The AUC and balanced accuracy of all locations and signal properties are presented in [Table 3](#).

The patients' decision values obtained by the classifier based on the ankle of the most affected side demonstrated low to moderate correlations with the time since diagnosis ( $p=0.55$ , 95% CI 0.11 to 0.78), the absolute subtotal of the MDS-UPDRS part III mobility items ( $p=0.41$ , 95% CI -0.07 to 0.81), and the absolute TUG score ( $p=0.33$ , 95% CI -0.16 to 0.69).

## Impact of Real-world Factors

We observed considerable variation in the premedication and postmedication classification performance (AUC) between

individual patients ([Multimedia Appendix 1](#)). This may be partly explained by variation in the strength of the response to dopaminergic medication. In addition, real-world factors unrelated to PD may negatively impact the classification performance in uncontrolled settings. By inspecting the video recordings and PSDs, we identified various factors that may have influenced the PSD of devices worn on the wrist and in the pants pocket.

## Wrist-Worn Devices

For the wrist-worn devices, the positioning of the hands (eg, in or out of the pocket of the pants or jacket) appeared to have a significant impact on the PSD during gait. To explore this, we evaluated the video recordings and PSDs of all patients ( $n=5$ ) who changed the position of their hands within either the premedication or postmedication free-living part (to be able to rule out that the observed difference was caused by the effects of medication). In all 5 patients, we found an association in time between changes in the position of the hands and changes in the PSD (examples are shown in [Figure 5](#)). One patient (PD\_9) changed the position of his hands from the pants pocket to the pocket of his jacket, which was associated with changes in the PSD. In the other 4 patients, the nature of the changes in the PSD was associated with the amplitude of the arm swing; in one patient with a pronounced arm swing (based on the video recordings), the total power clearly increased when removing the hand from the pocket (PD\_10). In 3 patients with a reduced arm swing, the contribution from the harmonic frequency components changed without an increase or even with a decrease in the total power (PD\_3, PD\_11, and PD\_18).

**Figure 5.** Visualization of the PSD of the devices worn on the wrist (most affected side) and in the pants pocket of 6 illustrative patients. x-axis: nth gait segment of 25 seconds (the white line indicates intake of dopaminergic medication). y-axis: frequency (hertz). Color bar: PSD in  $(\text{m/s}^2)^2/\text{Hz}$ . PD\_9: blue line with arrow indicates when patient moved his hand from his pants pocket to the pocket of his jacket (during the premedication part, his hand was in his pants pocket). PD\_10: blue line with arrow indicates when patient removed her hand from the pocket of her jacket (during the premedication part, her hand was outside the pocket). PD\_18: blue line with arrow indicates when patient put his hand in his pants pocket (during the premedication part, his hand was outside the pocket). PD\_4: after medication intake, the patient presented with choreic dyskinesias in both arms and legs, which were most severe on his most affected side. PD\_8: before medication intake, the arm swing on his most affected side was practically absent. After medication intake, he showed an arm swing with a small amplitude and started to make occasional gestures. PD\_3: before medication intake, the arm swing on his most affected side was practically absent (hand was outside the pocket). After medication intake, first he had his hand in the pocket of his jacket. Blue line with arrow: patient removed his hand from the pocket and demonstrated an arm swing with a small amplitude, and he started to make occasional gestures.

The effect of an (almost) absent arm swing in patients with PD may closely resemble the effect of putting the hand in the pants pocket. This is illustrated by patients PD\_3 and PD\_8 (Figure 5). Before medication intake, their arm swing was practically absent, while after medication intake, these patients showed an arm swing with a small amplitude and started to make occasional gestures (eg, point at things). Similar to the patients who removed their hands from their pockets and demonstrated a modest arm swing, the contribution from the harmonic frequency components changed without an increase in the total power (Figure 5).

The video recordings provided no explanation for the low performance of the wrist-worn sensor (most affected side) in PD\_7 and PD\_15.

### **Pants Pocket**

The positioning of the hands also appeared to be relevant when using the pants pocket as a sensor location. Two patients removed their hand from the pants pocket containing the smartphone during one of the free-living parts (PD\_9 and PD\_18). In both patients, this was not only reflected in the PSD of the wrist-worn device, but also in the PSD of the smartphone (Figure 5). Given the observed changes, we hypothesize that the presence of the hands in the pants pocket reduces the total power measured by the smartphone, which might be explained by reduced freedom of movement of the smartphone. There were other patients with low classification performance in the smartphone (PD\_10 and PD\_15), but the video recordings provided no explanation.

## **Discussion**

### **Principal Findings**

This work presents a new reference data set for the development of wearable sensor algorithms that can passively monitor persons with Parkinson disease in daily life. The novelty of this data set consists of (1) the inclusion of unscripted daily activities in and around the participants' own homes in combination with a simultaneous video reference that was later used to annotate specific activities and symptoms, (2) the combination of multiple movement sensors positioned on 6 different body locations and 8 different contextual and physiological sensors (eg, GPS, light, photoplethysmogram), (3) objective monitoring of these everyday activities during both a practically defined off state and a subjective optimal on state, allowing for testing of responsiveness, (4) the addition of a subsequent longitudinal follow-up with a more limited set of sensors on 2 body positions for 2 weeks, and (5) the principle of data sharing, such that this rich and versatile data set will be made openly available to the scientific community.

We have also explored this data set ourselves, with the main aim of assessing whether analysis of free-living gait can be used to obtain a digital biomarker for motor fluctuations in PD. We demonstrated that, despite the natural variation that is inevitably present in unscripted gait, it is feasible to measure the response to dopaminergic medication using simple signal properties derived from the PSD of accelerometer signals. Moreover, we present the first simultaneous evaluation of multiple sensor

locations in this context. This is a highly relevant issue in the field of wearable sensors, where much uncertainty exists about the ideal sensor placement to obtain the most sensitive and reliable markers for any specific sign of PD [26]. Our results indicate that the effects of dopaminergic medication on gait can be detected in all tested sensor locations (ie, both ankles, both wrists, the lower back, and the pants pocket). Combining multiple sensor locations did not improve classification significantly, suggesting that 1 individual sensor is a reasonable setup, from both an algorithmic and a usability perspective, to monitor on-off changes in free-living gait. Based on the used signal properties, it was generally more difficult to distinguish between patients with PD and age-matched controls than between premedication and postmedication among patients with PD. This may be explained by the fact that, in addition to the presence of PD, other factors also influence a person's gait pattern (eg, idiosyncrasies, age, comorbidities). When studying within-subject changes, many of these factors remain stable and hence do not introduce variability that is unrelated to PD. Finally, the qualitative analysis using the video recordings and PSDs revealed that the positioning of the hands has a significant impact on the PSD of both the wrist and the pants pocket in real-world settings, highlighting potential points of improvement for future research. Note that we illustrate this approach here for gait, but the data set lends itself well to future analyses by other groups who may want to study the optimal composition of sensor types and positions for a wide range of other symptoms or unscripted daily activities.

### **Limitations**

Before sensor-based gait analysis can be recommended to clinicians and researchers as a tool to assess therapy responses in real life, it is important to consider this study's limitations. First, we only included patients with at least some motor fluctuations and PD-related gait impairments. Although motor fluctuators may also be the main target group for such an objective evaluation tool, the generalizability to fluctuators who do not report any gait impairments remains to be evaluated. Second, differences in gait pattern between on and off periods might be less pronounced in daily life because most patients do not withhold their medication for as long as they did in this study. We purposely included a practically defined off assessment (ie, after overnight withdrawal of all dopaminergic medication) to assess which sensor locations and signal properties would be most responsive. Nevertheless, our findings remain to be confirmed on truly real-life data, where fluctuations can be more subtle. We should also note that, for practical reasons, we could not randomize the order of the premedication and postmedication parts (the premedication session was always performed first), so we cannot rule out that fatigue influenced the measured postmedication performance (although we minimized its effects by including a break between both parts). Third, the presented assessment of motor fluctuations depends on the occurrence of gait segments of at least 25 seconds. This limits the potential target group to patients who are able to walk during both on and off periods, excluding patients with Hoehn & Yahr stage 5. However, most fluctuators with a lower Hoehn & Yahr stage can still walk when the medication effects have worn off [37]. Finally, the presented analysis depends on

accurate localization of gait segments in time. In this study, we used the available video annotations for this, which enabled us to focus on how well the different sensor locations capture on-off changes in the gait patterns without introducing additional variability in how well the different sensor locations can detect gait. Several methods have been proposed for the detection of gait based on accelerometer data, with accuracies varying across sensor locations and techniques [38,39]. We are currently working on the implementation and evaluation of a novel probabilistic gait segmentation framework, which localizes gait segments in time with stationary (periodic) behavior [40].

### Comparison With Other Strategies

In contrast to the analysis of a specific behavior, such as gait, others have proposed activity-independent algorithms to monitor motor fluctuations in daily life. These algorithms typically assume that whenever the patient is wearing the sensor, it is possible to estimate the disease state. For example, Hammerla et al [8] used deep learning to predict the patient's motor state (ie, asleep, off, on without dyskinesias, or on with dyskinesias) every 5 minutes based on the accelerometer signal from 2 wrist-worn devices. The resulting performance was suboptimal (sensitivity for off detection: 0.50; for on detection: 0.52). This suggests that it may be too ambitious to predict the patients' motor state regardless of the activities performed.

Another consideration is the interpretability of such activity-independent algorithms. Because it is unclear what the algorithms' predictions are based on, it is challenging to relate the outcomes to clinical impairments. This might form a barrier to use in clinical practice and makes it difficult to form hypotheses about potential covariates and confounders in daily life. In our approach, it is transparent that the outcomes relate to (changes in) the gait pattern. This means that we can predict circumstances in which the algorithm will fail (eg, when a patient only uses a wheelchair to travel longer distances) and that we can use our knowledge about gait to interpret the results.

### Clinical Interpretation

Our results show that the total power in the 0.5- to 10-Hz interval of the PSD during gait increases in response to dopaminergic medication, whereas the cadence increases in some but decreases in other patients. The width of the dominant peak does not change. The finding related to cadence contrasts with earlier lab-based findings showing an increase in cadence after intake of levodopa [14]. We demonstrated that, because of its marked variability between patients in real life, cadence is not a useful signal property for patient-independent algorithms. A likely explanation for this variability is that the ability to modulate cadence is intact in persons with PD, and some patients use this as compensation for reduced step length [41].

Whereas the clinical meaning of cadence is clear, the clinical meaning of the total power and width of the dominant peak are less straightforward. Sama et al [24] refer to the total power in the 0- to 10-Hz interval as the "fluidity of patients' movements during gait." However, the most pronounced clinical changes after medication intake are an increase in step length and arm swing [14,15]. Since it is reasonable to assume that an increased

step length and arm swing are reflected in an increased power of acceleration, the total power in the 0.5- to 10-Hz interval is most likely sensitive to these changes in gait pattern. The finding that the total power of the least affected arm is elevated in patients with PD after medication intake in comparison with controls may be explained by excessive movements (including dyskinesias) caused by dopaminergic medication. The width of the dominant peak in the PSD has been referred to as a measure for the inconsistency or variability of gait [21,42]. Weiss et al [21] showed that it predicts the fall risk in patients with PD. Interestingly, although the width of the dominant peak did not change after medication intake in this study, it was elevated in patients with PD compared with controls for the sensors worn on both ankles, the pants pocket, and the lower back. This might be explained by the insensitivity of balance impairments to levodopa [15]. The finding that the width of the dominant peak is lowered in the wrist of the most affected side, pointing to less variability, can possibly be attributed to reduced or absent arm swing and gestures, resulting in a less variable PSD (which matches with our observations, described in "Impact of Real-world Factors").

We observed absent or weak correlations between the sensor-based predictions and currently used clinical assessments (TUG and MDS-UPDRS part III mobility items). There are multiple explanations for this. The measurement modality is different (for the TUG, it is time versus acceleration-based measures), and the measured construct is related but not identical (for the TUG, postural transitions and gait versus only gait). Perhaps the most important difference is the measurement setting. There is growing evidence that following instructions in a standardized track results in different gait patterns compared with walking freely in a natural environment [16,18-20]. It can be argued that measurements in daily life are more valid, if the aim is to know how the patient performs in the presence of real-life facilitators and challenges. Since free-living assessments are inherently different from clinical assessments, alternative methods to establish validity may be more appropriate. The predictive power (eg, the ability to detect the effect of dopaminergic medication) and, in the end, the clinical utility (eg, whether the information helps clinicians to provide better treatments) might serve as reasonable alternatives.

### Future Directions

The combined inspection of the video recordings and PSDs highlighted some factors other than PD that may impact the (within-subject changes in the) gait pattern in real life, such as putting the hands in the pocket and making gestures. This part of the study was exploratory, and the effects of these factors need to be examined quantitatively in independent experiments. Other potential time-varying factors include voluntary changes in the walking pace [12], the type of shoes worn, carrying objects, the ground type, the location (eg, crowded city versus countryside), and other factors in the physical environment [43]. This area of research has not received much attention so far, largely due to a lack of available data sets. However, controlling for important covariates and confounders could be a significant step forward in the analysis of free-living gait. The inclusion of multiple sensor types that measure context in this study (eg, GPS, Wi-Fi, barometer) and the emergence of smart home

sensors [22,44] provide an opportunity to further examine the added value of a multimodal gait pattern analysis. Finally, real-life gait analysis in patients with PD may not only be useful to monitor motor fluctuations but could also yield much-needed digital biomarkers to quantify disease progression in clinical trials testing new disease-modifying therapies. Future studies

that include long-term passive monitoring with wearable sensors (such as the Personalized Parkinson Project [45]) will reveal whether the promising results of lab-based gait analysis in this context [12,13] can be further improved by using highly frequent measurements obtained in the patients' natural environment.

## Acknowledgments

The authors wish to thank all participants for their enthusiasm to contribute to this study and for welcoming us in their own homes. We are grateful to the Michael J Fox Foundation for Parkinson's Research, UCB Biopharma, Stichting ParkinsonFonds, UCB, the Dutch Ministry of Economic Affairs (PPP Allowance made available by the Top Sector Life Sciences & Health to stimulate public-private partnerships), and ZonMw (91215076 "Big Data for Personalised Medicine") for financially supporting both the data collection and analyses efforts of the Parkinson@Home validation study. We also thank Tim Hahn for his help with setting up and executing the study, as well as all involved research assistants and physicians for creating the detailed annotations of the video recordings.

## Abstract

**Background:** Digital pain mapping allows for remote and ecological momentary assessment in patients over multiple time points spanning days to months. Frequent ecological assessments may reveal tendencies and fluctuations more clearly and provide insights into the trajectory of a patient's pain.

**Objective:** The primary aim of this study is to remotely map and track the intensity and distribution of pain and discomfort (eg, burning, aching, and tingling) in patients with nonmalignant spinal referred pain over 12 weeks using a web-based app for digital pain mapping. The secondary aim is to explore the barriers of use by determining the differences in clinical and user characteristics between patients with good (regular users) and poor (nonregular users) reporting compliance.

**Methods:** Patients (N=91; n=53 women) with spinal referred pain were recruited using web-based and traditional in-house strategies. Patients were asked to submit weekly digital pain reports for 12 weeks. Each pain report consisted of digital pain drawings on a pseudo-three-dimensional body chart and pain intensity ratings. The pain drawings captured the distribution of pain and discomfort (pain quality descriptors) expressed as the total extent and location. Differences in weekly pain reports were explored using the total extent (pixels), current and usual pain intensity ratings, frequency of quality descriptor selection, and Jaccard similarity index. Validated e-questionnaires were completed at baseline to determine the patients' characteristics (adapted Danish National Spine Register), disability (Oswestry Disability Index and Neck Disability Index), and pain catastrophizing (Pain Catastrophizing Scale) profiles. Barriers of use were assessed at 6 weeks using a health care-related usability and acceptance e-questionnaire and a self-developed technology-specific e-questionnaire to assess the accessibility and ease of access of the pain mapping app. Associations between total extent, pain intensity, disability, and catastrophizing were explored to further understand pain. Differences between regular and nonregular users were assessed to understand the pain mapping app reporting compliance.

**Results:** Fluctuations were identified in pain reports for total extent and pain intensity ratings ( $P<.001$ ). However, quality descriptor selection ( $P=.99$ ) and pain drawing ( $P=.49$ ), compared using the Jaccard index, were similar over time. Interestingly, current pain intensity was greater than usual pain intensity ( $P<.001$ ), suggesting that the timing of pain reporting coincided with a more intense pain experience than usual. Usability and acceptance were similar between regular and nonregular users. Regular users were younger ( $P<.001$ ) and reported a larger total extent of pain than nonregular users ( $P<.001$ ).

**Conclusions:** This is the first study to examine digital reports of pain intensity and distribution in patients with nonmalignant spinal referred pain remotely for a sustained period and barriers of use and compliance using a digital pain mapping app. Differences in age, pain distribution, and current pain intensity may influence reporting behavior and compliance.

## Introduction

### Background

The term *spinal pain* refers to pain in the cervical, thoracic, and low back areas of the spine [1,2]. Spinal pain can remain localized to the spine and refer to other areas. Cervical and thoracic spinal pain may refer to one or both the upper limbs [2], whereas low back spinal pain may refer to one or both of the lower limbs [2]. Chronic spinal pain is a common reason for clinical consultation [3,4] with an increasing prevalence [5,6] and associated high levels of disability [7].

Pain is a subjective sensory and emotional experience [8], and patients' self-reported measures of pain, such as pain intensity and quality descriptors, are common during pain assessment [9]. In addition, self-reports of pain distribution can improve the understanding of pain mechanisms [10-12]. Therefore, more efficient patient-clinician communication is paramount to optimize pain management. Traditionally, numerical rating scales capture pain intensity, whereas pain drawings capture pain distribution that is expressed by area (extent) and location [13].

Among the self-reported methodologies, ecological (from the patients' environment) momentary (in real time) assessment (EMA) methods can help to repeatedly collect information about the patient's pain condition [14,15]. In the clinical pain field, EMA methods can be used to minimize pain recall bias and assess pain within the patients' real-world context [14,16] to provide detailed spatiotemporal information and support pain management [12,17-21]. For example, repeated pain intensity reports of patients with musculoskeletal spinal pain may present a stable or fluctuating temporal pattern [22-27]. Similarly, spatiotemporal patterns of pain may present a stable (localized or widespread) or a variable course [28,29]. However, there is little knowledge about the relationship between the course of pain intensity and extent.

Digital biomarkers are defined as objective and quantifiable physiological and behavioral data acquired and measured using digital devices, such as smartphones, tablets, or computers. Thus, digital pain mapping can acquire time-stamped digital pain biomarkers (pain intensity, distribution, and quality). When acquired over multiple time points, a more detailed overview of a patient's pain experience can be achieved, thereby improving the clinician's understanding of the patient's pain [12].

The feasibility of health apps is mostly dependent on its usability and reporting compliance [30,31]. Usability is a broad term that defines the appropriateness of a technology to fit its purpose [32]. A good compliance rate ensures that the requested information is collected [33-38]. However, little is known about the influence of user characteristics and symptom severity on compliance.

### Objectives

This feasibility study aims to map and track pain intensity (current and usual), distribution (extent and location), and quality of pain and discomfort in patients with nonmalignant spinal referred pain for a duration of 12 weeks using a digital pain mapping app. The secondary aim is to determine the barriers to use and individual and clinical factors influencing a patient's pain reporting compliance using the digital mapping app.

The study aims to address 3 main hypotheses: (1) fluctuations in pain intensity, distribution, and quality over 12 weeks would be identified; (2) pain extent would be associated with current pain intensity and levels of disability; and (3) better reporting compliance would be more likely in patients with more severe pain symptoms.

## Methods

### Overview

This web-based prospective observational cohort study recruited people with nonmalignant spinal referred pain (somatic and radicular) and asked them to submit a weekly pain report for 12 weeks using a web-based pain mapping app. At baseline, all participants completed standardized e-questionnaires about demographics, primary pain site (cervical and thoracic pain or low back pain), disability, and pain catastrophizing. Six weeks into the study, patients were invited to participate in a battery of health care-related usability and acceptance (HUX) e-questionnaire and a self-developed technology-specific e-questionnaire to gain insight into the appropriateness and ease of use of the pain mapping app.

### Participants and Recruitment

The inclusion criteria were kept broad to obtain a general impression of the weekly differences in pain intensity, extent, and quality in patients with nonmalignant spinal referred pain. Men and women (aged 18-85 years) living in Denmark and able to communicate in Danish or English were recruited. Pregnant or breastfeeding women and people with drug abuse and addiction problems were not included. People with a cognitive deficiency, those who lack necessary computer skills (self-assessment or inability to create a password), and/or those who do not have regular internet access were excluded from the study.

In total, 2 recruitment strategies were designed. The traditional strategy consisted of recruiting patients referred to the Neurosurgical Department at Aalborg University Hospital (Denmark). The web-based recruitment strategy consisted of posting a 1-min video on social media platforms (Facebook, LinkedIn, and Twitter) with a call-to-action requesting those interested in taking part in the study to contact the researchers directly via email. Screening was carried out via email correspondence. Additional screening for all patients was carried out by phone interviews, where information about medical

history, diagnoses, and current treatment was collected. The patients' pain management was not monitored or affected during the study.

Patients received detailed information about the study via email, including technical information about registration to the pain mapping app and how to complete the digital pain reports. Subsequently, the researcher (MG) emailed the link to the demographic questionnaire related to their primary pain site (cervical and thoracic or low back). The links to the remaining e-questionnaires (disability and pain catastrophizing) were emailed individually on completion of the previous questionnaire. Each questionnaire took 2 to 3 min to complete.

Furthermore, 6 weeks after the first pain report was submitted, patients completed HUX e-questionnaires, such as the System Usability Scale (SUS) [32] and the modified Technology Acceptance Model (mTAM) questionnaire [39] and a self-developed technology-specific questionnaire.

### Baseline Patient Profile

Baseline e-questionnaires collected information about the patients' general demographics, walking distance ability, health and social information, disability, and pain beliefs. A maximum of 3 reminders were emailed to the patients, each 1 week apart. If a questionnaire was not completed following the 3 reminders, the patient received a final direct email reminder. Questionnaires were delivered using the SurveyXact software (Ramboll). Permission was obtained to use and adapt all the paper-format questionnaires to the electronic versions used in this study.

The general information questionnaire, adapted from the Danish National Spine Register's (DaneSpine) basic information questionnaire for degenerative spinal disorders, was used to collect information regarding demographics, walking distance ability, health, and social status. Disability was measured by the Oswestry Disability Index (ODI) in patients whose primary pain site was low back and by the Neck Disability Index (NDI) in patients whose primary pain site was the cervical or thoracic spine. The ODI and the NDI have been used since 1990 and are recommended tools for evaluating self-rated disability in spinal disorders [40,41]. The Pain Catastrophizing Scale (PCS) was used to evaluate pain-related catastrophizing thoughts. Catastrophizing is a negative anticipatory response associated with higher pain intensity [42,43].

### Quantification of Pain Intensity, Extent, and Distribution Consistency

Navigate Pain (Aglance Solutions) allows for the EMA of the temporal development of pain intensity and extent, thereby facilitating an objective and easy visualization of pain changes over time [44,45]. The web-based digital pain mapping app allows users to complete individual pain reports. The pain mapping app had a zoom feature and the option of moving the body chart on the screen to facilitate the visualization and capturing of pain. In each pain report, users indicated their pain area and location on a pseudo-three-dimensional body chart avatar in different views (anterior, posterior, lateral right, and lateral left) and provided a usual and a current pain intensity rating. Usual pain intensity was defined as the pain felt most of

the time, whereas current pain intensity was defined as the pain experienced at the time of reporting.

Patients received an email with a link to create a password for accessing the pain mapping app free of charge. Patients used a computer mouse or a touch screen device (ie, smartphone or tablet) to report the distribution of pain and discomfort on a male or female body chart. Patients selected among 11 color-coded pain and discomfort quality descriptors: tingling, throbbing, stabbing, dull aching, numbness, itchy, electric, cold, burning, other, and the general descriptor *pain*. The number of pixels was extracted from the drawn areas in the body charts, including the different views, to quantify the total pain and discomfort extent (total extent). Only one pain report was used to determine the extent and distribution of pain and discomfort each week. If patients submitted more than one weekly pain report, the first pain report following the weekly reminder or the report closest to a 7-day interval was selected. Weekly pain intensity ratings were calculated using all reports for each week.

Patients rated their overall usual and current pain intensity using 2 electronic Color Analogue Scales (eCASs). The eCAS is a colored line (green, yellow, and red) accompanied by the words *no pain*, *moderate pain*, and *severe pain* [46,47].

The consistency of pain distribution may assist in a more objective decision-making process. To assess the consistency of pain and discomfort distribution, 1 pain drawing in the posterior view for each of the 12 weeks was extracted from the weekly pain reports. The similarity of degree of distribution among the weekly pain drawings was calculated and expressed using the Jaccard similarity coefficient, also known as the Jaccard index [48]. The Jaccard indices were calculated between consecutive pain drawings (week to week) during the 12-week period. A higher Jaccard index represents a greater pixel overlap between drawings and is a proxy measure to determine the degree of changes in the distribution (ie, combination of the location and area) of pain and discomfort between weekly pain reports [11,12,48]. Owing to the inconsistent use of the anterior and lateral body chart views, only the posterior view was used to calculate the Jaccard index. The posterior view was used in all the weekly pain reports and was found to be the most relevant view to capture changes in spinally referred pain.

### Assessment of Pain and Discomfort Quality Descriptors

Pain and discomfort quality descriptors are clinically useful during the differential diagnosis process, especially for neuropathic pain [49-52]. The frequency of pain and discomfort quality descriptor selection was calculated by normalizing the number of times a quality descriptor was selected. Therefore, a selected descriptor was only accounted for once weekly for each patient.

### Health Care–Related Usability, Acceptance, and Technology-Specific Questionnaires

To explore the barriers of use, patients who had completed at least one pain report at 6 weeks were deemed as users and invited to complete a battery of electronic questionnaires, including HUX questionnaires and a technology-specific questionnaire. The HUX questionnaires consisted of SUS and

mTAM questionnaires to assess the usability and acceptance of the pain mapping app among patients.

The SUS is a simple 10-statement questionnaire evaluating the user experience before any discussion with the researcher. There are alternating positive and negative statements. The version used here replaced the term *the product* to the name of the digital body mapping software *Navigate Pain*. An SUS score over 68 is considered above average [32]. The Technology Acceptance Model (TAM) [39] was modified (mTAM) with the term *digital body chart* to describe the technology. The mTAM consisted of a total of 9 statements—4 of these rated perceived usefulness and 5 rated perceived ease of use. Both questionnaires use a 5-point Likert scale, ranging from 1 for *strongly disagree* to 5 for *strongly agree*.

A Navigate Pain Specific (NPS) questionnaire was developed to examine user behavior, particularly accessibility and ease of access. Patients were asked to answer 5 questions. Of these questions, 2 questions assessed point of access to the mapping app (computer or laptop, tablet, or smartphone) and the access pathway to the pain mapping app (reminder email or direct URL link). One question used a 5-point Likert scale, ranging from 1 for *very helpful* to 5 for *not at all helpful*, to explore the helpfulness of the weekly pain report reminder. The last 2 questions also used a 5-point Likert scale, ranging from 1 for *very easy* to 5 for *very difficult* to assess the registration process and the general patients' perspective of ease of use.

### Differences Between Regular and Nonregular Users

Patient characteristics were assessed in relation to pain reporting compliance. Regular users completed weekly pain reports, whereas nonregular users did not fulfill this criterion. In the NPS questionnaire, nonregular users received an additional question asking for reasons for the lack of regular pain reporting, such as "I didn't have time," "I forgot to do it," "I am in too much pain to do it," "I don't have pain," "I'm not interested in using Navigate Pain any more," and "Other."

### Statistical Analysis

Descriptive statistics were used to describe demographics and baseline characteristics and quality descriptor selection. Data distribution was assessed with histograms and quantile-quantile plots for pain intensity ratings, total extent (pixels), and pain distribution (Jaccard index). For nonparametric data, Friedman tests were used to assess the pain intensity ratings (usual and current) and the total extent between weeks. A Wilcoxon signed-rank test was used to compare the differences between current and usual pain intensity ratings. The consistency of pain distribution was determined by comparing the Jaccard indices

each week using a Friedman test. A logistic multiple regression analysis was carried out to explore the influence of reporting compliance on pain distribution consistency. A chi-square test was used to assess differences in weekly pain and discomfort quality descriptor selection during the 12 weeks.

Spearman correlation was used to determine the associations between the pain intensity ratings and the total extent for each patient and the baseline disability and PCS scores.

Mann-Whitney *U* tests were used to examine the differences in baseline characteristics between regular users and nonregular users, such as age, gender, primary pain site, usual and current pain intensity, total extent, disability, PCS scores, and HUX and NPS questionnaire results. A chi-square test was used to explore recruitment differences between regular and nonregular users. A logistic multiple regression analysis was carried out to explore the probability of better reporting compliance in relation to the severity of the pain symptoms. The assessment of pain severity included current pain intensity ratings, extent of pain quality (posterior view) from the first submitted pain report, and baseline disability (ODI or NDI) scores.

Statistical analyses were performed using SPSS 25 (SPSS Statistics, 2018). The Jaccard indices were calculated using MATLAB R2017b (The MathWorks, Inc). Correlation coefficients, means, SD values, median, and IQR were reported where relevant. *P* values of less than .05 were considered statistically significant, and Bonferroni adjustment was used in multiple analyses.

In Denmark, observational studies using surveys and questionnaires are not required to obtain ethical approval but are required to be registered with the Danish Data Protection Agency (journal numbers 2017-899/10-0159 and 2017-509-00011). This study adhered to ethical data privacy and storage General Data Protection Regulation requirements and was conducted according to the Declaration of Helsinki. The study is registered with ClinicalTrials.gov (NCT03926364).

## Results

### Baseline Patient Profile

A total of 91 patients (mean age 51.8, SD 13.5 years; 53 women) were willing to participate in the study. Recruitment methods included a traditional in-house strategy and a web-based strategy. Following screening and early dropouts, a total of 78 patients were recruited to participate in the study (Figure 1). Overall, 92% (12/13) of the early dropouts were due to technical difficulties with creating a password that limited access to the pain mapping app.

**Figure 1.** CONSORT (Consolidated Standards of Reporting Trials) flow diagram, showing the complete recruitment process.

Overall, 64% (50/78) of the participants were recruited using the web-based strategy. Only an age difference was identified between the patients recruited through the web-based strategy (mean age 48.7, SD 12.1 years) and the traditional in-house strategy (mean age 59.2, SD 13.4 years;  $P<.001$ ).

A total of 3863 pain reports were submitted (mean 59, SD 66, per patient). All the patients recruited for this study had pain for longer than 6 months, with 79% (60/76 completed questionnaires) of patients having pain for over 12 months (Table 1), thus fulfilling the criteria of chronic or persistent pain. Walking ability distance, disability, and catastrophizing scores at baseline are shown in Table 2.

### Quantification of Pain Intensity, Total Extent, and Distribution Consistency

Current pain intensity ratings (median 6.3, IQR 4.5) were greater than usual pain intensity ratings (median 5.4, IQR 4.0;  $Z=-18.0$ ;  $P<.001$ ) when compared over the 12 weeks. Furthermore, fluctuations were identified in terms of usual pain intensity

ratings ( $\chi^2_{11}=145.3$ ;  $P<.001$ ), current pain intensity ratings ( $\chi^2_{11}=105.7$ ; same  $P<.001$ ), and total extent ( $\chi^2_{11}=48.7$ ;  $P<.001$ ) over the 12 weeks (Figure 2). Comparisons of subsequent pain drawings showed similar Jaccard indices ( $P=.52$ ) for the study cohort. The logistic regression model was not statistically significant ( $\chi^2_{11}=8.1$ ;  $P=.70$ ).

**Figure 2.** Median (IQR) pain and discomfort extent (A) and usual (B) and current (C) pain intensity ratings, increased and decreased as a group ( $n=65$ ), in comparison with baseline and throughout the 12 weeks. The lower and upper quartiles, representing observations between the 25th and 75th percentile range, show the median for a month. The whiskers are drawn down to the 10th percentile and up to the 90th. Points below and above the whiskers are drawn as individual dots.  $*P<.001$  adjusted for multiple comparisons. NRS: numerical rating scale.

### Frequency of Pain and Discomfort Descriptors

A chi-square test revealed that the selection of quality descriptors remained stable over the 12 weeks ( $P=.99$ ; Figure

3). However, individual variations in pain and discomfort quality descriptor selection were observed (Figure 4).

**Figure 3.** The most frequently selected pain and discomfort quality descriptors over 12 weeks were pain (39%) and dull (20%). The qualities numbness (9%), burning (8%), and stabbing (6%) were also chosen frequently. The least frequently selected quality descriptors were throbbing (3.2%), other (2.8%), itchy (0.8%), and cold (0.4%).

**Figure 4.** Examples of individual pain reports illustrating fluctuations in pain and discomfort intensity, total extent, and quality, spanning 12 weeks. The red line represents the weekly average current pain intensity rating. The pain drawings were selected every second week to capture the general overview of the changes in pain and discomfort quality descriptors selection and the fluctuations in pain and discomfort extent over the 12 weeks. NRS: numerical rating scale.

### Relationship Among Pain Intensity, Total Extent, Disability, and Pain Catastrophizing

Usual and current pain intensities were associated with the total extent ( $r=0.23$  and  $r=0.25$ , respectively;  $R^2=3\%$ ;  $P<.001$ ). Disability, as rated by the ODI and NDI, was not associated with the current and usual pain intensities ( $P=.29$  and  $P=.09$ , respectively), total extent ( $P=.31$ ), and pain catastrophizing ( $P=.83$ ). Similarly, pain catastrophizing was not associated with usual and current pain intensities ( $P=.89$  and  $P=.71$ , respectively) and the total extent ( $P=.29$ ).

### Differences Between Regular and Nonregular Users

Regular users ( $n=35$ ; mean age 48.7, SD 11.2 years) and nonregular users ( $n=30$ ; mean age 55.8, SD 15.3 years) differed in age ( $P<.001$ ). Interestingly, nonregular users had more intense current pain (median 6.4, IQR 3.2) than the regular users (median 6.1, IQR 5.1;  $U=3306.7$ ;  $P<.001$ ). However, regular users had a greater total extent (regular users 4063, IQR 8075.5; nonregular users 3221, IQR 4925.0;  $U=2,775,320.5$ ;  $P<.001$ ). In addition, 80% (28/35) of the regular users were recruited through the web, as opposed to 56% (17/30) of the nonregular ( $\chi^2_2=28.9$ ;  $P<.001$ ). Current pain intensity, pain extent, and disability did not influence reporting compliance between regular and nonregular users ( $P=.96$ ).

### HUX Analyses

HUX questionnaires were completed by 94% (33/35) of the regular and 73% (22/30) of the nonregular users. The total mean SUS score was 70, giving it a marginal usability score [53] with no difference between regular and nonregular users ( $P=.45$ ).

Regular users rated acceptable usability [54] with a mean SUS score of 71.5 points, whereas nonregular users rated marginal usability [53] with a mean SUS score of 68 points. There were no differences in mTAM scoring between the regular and nonregular users, with both groups having similar acceptance scores in each of the questionnaire statements ( $P$  value range for each statement=.12-.97).

Of the regular users, 49% (17/35) accessed the pain mapping app from a computer or laptop and did not need the weekly reminder to submit the pain reports; nonregular users accessed the pain mapping app using a variety of devices, and 82% (20/30) depended on the weekly reminder to submit the pain reports. Furthermore, 45% (10/30) and 41% (9/30) of the nonregular users reported forgetfulness and *other* as the reasons for poor reporting compliance. The remaining 13% of nonregular users reported too much (2/30) or no pain (1/30). None of the patients selected *I am not interested anymore* or *I did not have time*.

Regular users rated the general use of the pain mapping app as easy or very easy (15/35, 45% and 8/30, 27%, respectively). Similarly, nonregular users rated the general use of the pain mapping app as *easy* and *very easy* (11/30, 50% and 4/30, 18%, respectively). Only 6% (6/35) of the regular and 9% (2/30) of the nonregular users rated the general use of the pain mapping app as *difficult*.

## Discussion

### Principal Findings

This is the first pragmatic observational study using a web-based app to map, track, and quantify pain and discomfort remotely in patients with nonmalignant spinal referred pain over a sustained period. The results show fluctuations in current and usual pain intensities over 12 weeks for the group of patients recruited for this study. In addition, the results show fluctuations in pain and discomfort extent (total extent) on a group level. However, the pain drawings and the quality descriptor selection remained consistent on a group level. HUX scores were similar between regular and nonregular users. The regular users were generally younger, had a greater total extent, and accessed the app differently than the nonregular users.

Fluctuations in current and usual pain intensities and in total extent occurred over the 12-week observation period, suggesting that spatiotemporal patterns of chronic spinal referred pain may increase and decrease over time. These fluctuations may be related to the heterogeneity of the study cohort in which participants had different primary pain sites, differences in pain management, and differences in reporting compliance. Thus, there is no rationale for why the group pain intensity and total extent varied on any given week over the 12-week observation period. An interesting observation in this study was that current pain intensity ratings were greater than usual pain intensity ratings, suggesting that patients completed pain reports when their pain was more intense than usual. The reasons for this reporting behavior are unclear and should be further explored. However, the difference between current and usual pain intensity ratings was small ( $<1$  of 10) and may not be clinically meaningful [54].

The selection of pain and discomfort quality descriptors remained consistent over time, which can be expected for a group with chronic pain. Interestingly, pain distribution also remained consistent. In this study, pain distribution consistency was calculated by comparing the similarity of consecutive weekly pain drawings. Therefore, the study's results do not imply that pain distribution was consistent throughout the 12-week study period. It is possible that fluctuations in pain distribution may occur over longer periods ([Multimedia Appendix 1](#)). The Jaccard index has primarily been used to assess the ability of patients to reliably draw and redraw pain areas [48,55]. Therefore, the Jaccard index may only be appropriate to assess distribution consistency over shorter periods.

The study's findings align with previous studies [56-59] showing a weak and positive association between the pain intensities (usual and current) and the total extent. These results suggest that pain extent is related to pain intensity but do not explain the intensity variance. Therefore, capturing changes in clinical pain extent and distribution may add additional value to clinical interpretation.

The relationships of pain intensity and extent with disability and catastrophizing scores are contradictory. Similar to our study, studies on chronic low back pain [60,61] and knee

osteoarthritis [59] have shown that pain intensity and total extent were not associated with disability and pain catastrophizing. However, other studies have shown a positive relationship of the total extent with disability scores [11,62-66] and pain catastrophizing [43,62,67-69]. The relationship between catastrophizing and disability scores has been widely described in musculoskeletal shoulder and low back pain [70-72]. However, patients in our study reported high levels of disability but not high levels of catastrophizing, showing no association between disability and catastrophizing at baseline.

The HUX results demonstrated that the pain mapping app was considered a good pain communication tool by patients and therefore may be relevant for clinical practice. However, the HUX assessment failed to identify compliance differences, as represented by the similar results between regular and nonregular users.

Most of the regular users were recruited using the web-based strategy. Patients recruited through the web were younger (approximately by 3 years) and may already be more technically competent [73] than those recruited using the traditional strategy. A limited number of studies have assessed users' characteristics influencing the use and acceptance of pain technology [74]. Overall, regular users were younger (approximately by 7 years) and reported a larger pain extent than nonregular users, suggesting that reporting compliance of the pain mapping app may be based on an inherent need to communicate the pain extent [75]. Interestingly, the total extent differences between regular and nonregular users (approximately 850 pixels) represents a very small area on a pain drawing and may be insufficient to be clinically relevant. In a short period, the 7-year age gap between regular and nonregular users will become irrelevant as technical savviness increases among older adults [76]. Therefore, it is possible that in the future, only relevant baseline differences influencing compliance may be based on the recruitment method.

### Limitations

EMA can induce bias because of the lack of standardization of pain reporting in terms of context (location and environment), timing, and frequency [15,77]. This study lacks contextual information about, for example, type or change in pain management and activity levels. Therefore, it is not known whether the fluctuations in total extent reporting may be due to a change in experienced pain or a change in the number of pain report submissions over time. Furthermore, fluctuations could also be due to a change in the drawing skills, as the patients' drawing confidence may have increased with repetition or even whether patients used different accessing devices affecting their technical skills.

Technical limitations influenced the total extent results and the distribution consistency index. First, the total extent may be overestimated, as it is the sum of all the quality descriptors used in a pain report. Second, only the Jaccard index was used as a measure of distribution consistency. Using one single index, the Jaccard index, to measure pain distribution consistency, carries potential risks for misinterpretation, as it will miss similarities between 2 pain drawings with equal pain areas but

different locations, representing a small analytical variation, but with clinical implications.

Technical and interpretation barriers of use were identified. Technical barriers caused most of the early dropouts, likely because of using an old version of a browser, and may have biased the usability ratings. Interpretation barriers led to different drawing behaviors despite receiving the same instructions, highlighting different ways of understanding the provided pain reporting instructions or perceiving the individual pain experience ([Multimedia Appendix 2](#)).

### Future Perspectives

The digital pain biomarkers acquired from the app can assist in a more objective diagnostic process and monitor the outcomes following treatment. An example of outcome monitoring could be useful following spinal surgery or a conservative approach, such as exercise therapy, where the pain mapping app can be used to monitor changes in pain intensity and referred arm and leg pain distribution [78]. New metrics for assessing consistency

over a longer period may prove clinically valuable as fluctuating and stable pain reports may require different pain management approaches.

The usefulness and advantages of digital pain mapping to track digital pain biomarkers, combined with machine learning, have already revealed spatiotemporal patterns of pain and discomfort [10]. These patterns have the potential to become a game changer and may be able to predict those patients more likely to respond to treatments or assist in the prognosis of pain conditions [79].

### Conclusions

This is the first study to remotely track pain intensity and distribution and examine barriers of use and compliance using a digital mapping pain app for a sustained period. Differences in age and pain distribution may influence reporting behavior and compliance and recruitment strategies that may play a role in the success of future web-based studies.
