This review identified that parents are looking online on major search engines and social media platforms for vaccine information. It was identified that locating accurate information online regarding the benefits and risks of vaccines is challenging for parents given the low number of sources that contain accurate information [42]. There was conflicting evidence about how parents utilize information found online to inform their vaccine choices. However, vaccine-hesitant parents who have access to accurate online vaccine information have significant improvement in attitudes regarding vaccination benefits and reduction in parental concerns about vaccination risks [28]. Given the plethora of misinformation perpetuated online, clinicians may want to provide "information prescriptions" to parents regarding the search terms they use and encourage parents to access websites moderated by health care experts. The interactive component to the websites would provide an opportunity for parents to ask questions of vaccination experts. Health care providers should discuss with parents the nature of online vaccine discussions. Reviewing with parents the utilization of hierarchical and scientific language utilized by some to promote antivaccine messaging. Further discussion focused on search terms and even providing parents suggestions for vaccine-positive or neutral terminology that will allow them access to a more balanced discussion of vaccine benefits and risks online.

Parents identify trust as a fundamental part of the vaccine decision-making process. This importance placed upon perceived trust in the source of information reinforces the importance of relational care practices, and a trusting relationship with a health care provider is a priority. Developing and fostering trust between primary care providers and parents may be a strategy to increase vaccine uptake by parents.

## Abstract

**Background:** Over half of men who have sex with men (MSM) use geosocial networking (GSN) apps to encounter sex partners. GSN apps' users have become a unique large subpopulation among MSM for interventions concerning HIV prevention and control. Pre-exposure prophylaxis (PrEP) is a promising measure for HIV prevention, especially for MSM, but its effectiveness largely depends on medication adherence. However, little is known about PrEP adherence among GSN apps' users, which is critical to addressing the overall optimization of PrEP compliance outside of clinical trials in the context of large-scale implementation.

**Objective:** The objective of this study is to understand the correlation between GSN apps' use and medication adherence among MSM receiving PrEP, with the aim to increase their awareness about PrEP use in order to increase adherence.

**Methods:** This study based on the China Real-world Oral intake of PrEP (CROPrEP) project, a multicenter, real-world study of Chinese MSM on daily and event-driven PrEP. Eligible participants completed a detailed computer-assisted self-interview on sociodemographic, GSN apps' use, and sexual behavior. Then participants were followed up for 12 months and assessed for various characteristics (eg, PrEP delivery, adherence assessment, PrEP coverage of sexual activities, and regimens switch). A

generalized estimation equation was used to analyze the predictors of medication adherence and regimen conversion among GSN apps' users and nonusers.

**Results:** At baseline, 756 of the 1023 eligible participants (73.90%) reported primarily using GSN apps to seek sexual partners, and GSN apps' users are more likely to have high-risk behaviors such as multiple sex partners and condomless anal intercourse than other nonusers (all  $P < .05$ ). During follow-up, GSN apps' users had a significantly low level of pill-counting adherence than nonusers (adjusted odds ratio [aOR] 0.8, 95% CI 0.6-1.0,  $P = .038$ ). In the event-driven group, GSN apps' users had marginally lower levels of self-reported adherence (aOR 0.7, 95% CI 0.4-1.0,  $P = .060$ ) and lower PrEP coverage of sexual practices (aOR 0.6, 95% CI 0.4-1.0,  $P = .038$ ). Additionally, GSN apps' users seemed more likely to switch from event-driven to daily regimen (aOR 1.8, 95% CI 0.9-3.3,  $P = .084$ ).

**Conclusions:** GSN apps' users are highly prevalent among MSM, despite their higher sexual risk and lower adherence levels, suggesting that eHealth needs to be introduced to the GSN platform to promote PrEP adherence.

## KEYWORDS

men who have sex with men (MSM); MSM; HIV/AIDS prevention; Pre-exposure prophylaxis (PrEP); geosocial networking app; dating app; adherence; regimen switch

## Introduction

Men who have sex with men (MSM) are estimated to have a 20-fold higher risk of new HIV infections than the general population on average, with MSM contributing to more than half of new HIV infections in western and central Europe and North America, and 30% in Asia and the Pacific [1]. Digital technology has changed the way MSM lives and seeks sexual partners, and a meta-analysis estimated that 50%-80% of MSM reported using geosocial networking (GSN) apps for sexual encounters [2,3]. Recent studies indicate an increase in GSN app users with high-risk sexual behaviors (ie, condomless and multisex partners); however, effective interventions for HIV prevention among this group remain an underexplored topic [2-7].

Pre-exposure prophylaxis (PrEP) is a promising novel HIV prevention method, and its coverage continues to expand globally [8]. Adherence is probably the strongest determinant of effectiveness for PrEP based on evidence from existing clinical trials and real-world studies [9-12], and optimizing adherence has become a common goal across various settings globally. Recent studies have found that GSN apps may facilitate the roll out of PrEP programs [13-15], though more information is needed on the role of GSN apps in PrEP initiation and adherence. In 2017, a large-scale survey of GSN apps' users among MSM in Europe and Central Asia reported that 10% of MSM were using PrEP in the last 3 months, and 33% were planning to start PrEP in the next 6 months [16]. A study on Grindr use among MSM from the United States found that those with recent GSN apps' use had a higher percentage of initiating PrEP compared with nonusers (24.6% vs 14%,  $P < .001$ ) [15]. The above evidence suggests that MSM with GSN apps' use experience may comprise a sizeable proportion of PrEP users, but we do not know exactly the size and risk level they occupy among PrEP users in China. In addition, despite the importance of adherence for PrEP effectiveness based on existing clinical trials and real-world studies among the overall MSM population,

there is little information on these outcomes for MSM who are using GSN apps. In 2019, the updated WHO guidelines for PrEP recommended both daily and event-driven regimens for PrEP among MSM [17], raising concerns about regimen switches. The limited available research evidence suggests that the switch between daily and event regimens is more common when 2 regimens are available [18]. Understanding adherence and regimens switch among GSN apps' users and addressing the barriers preventing adherence will be crucial to the long-term success of PrEP interventions in the Chinese MSM population. Discontinuation of PrEP is another concern and may hinder its prevention effect [19,20]. However, research has only scarcely explored the effect of app use behavior on PrEP discontinuation.

Therefore, this study aims to understand the behavioral characteristics of GSN apps' users among PrEP users and assess their adherence, regimen conversion, and discontinuation in a real-world study in China with options for daily and event-driven PrEP regimens, to explore new directions for improving adherence.

## Methods

### Study Design and Participants

This study was based on the China Real-world Oral intake of PrEP (CROPrEP) project [21], a multicenter, real-world study of daily or event-driven emtricitabine/tenofovir disoproxil fumarate (TDF/FTC) PrEP regimens among HIV-negative MSM at high risk of HIV infection in China. From December 2018 to October 2019, participants were recruited from 4 cities including Shenyang (First Affiliated Hospital of China Medical University), Beijing (Beijing You An Hospital of Capital Medical University), Shenzhen (Shenzhen Third People's Hospital), and Chongqing (Chongqing Public Health Medical Treatment Center). Eligible participants reported GSN apps' use and sexual characteristics at baseline and then began quarterly follow-up visits (eg, free PrEP distribution, medication adherence assessments, and computer-assisted self-interview [CASI]) over 12 months. The expected follow-up time was from

October 2019 to October 2020. Other methodological considerations, such as inclusion and exclusion criteria for eligible participants, are detailed in this study protocol paper [21].

## Procedures

Data analysis for this study was conducted from December 2018 to January 2020. Eligible participants completed 6 follow-up visits at baseline, 1, 3, 6, 9, and 12 months. At enrollment, after receiving professional medication counseling from doctors on daily and event-driven regimens, participants received free TDF/FTC as PrEP and chose between taking PrEP on a daily basis, or following an event-driven regimen (consisting of 2 pills 2-24 hours before sexual intercourse or 1 pill if the last medication was taken 1-6 days ago, and a pill every 24 h from the first drug intake during the period of sexual activity) [18]. Participants were permitted to change regimens during the study. A detailed computer-assisted self-administered questionnaire on GSN apps' use (referring to using GSN apps as the main venue for seeking sexual partners during the previous 3 months), sociodemographic information, sexual behavior, and substance use was also filled out by eligible participants to understand the distribution and characteristics of GSN apps' users among MSM on PrEP.

At each clinical follow-up visit, participants completed assessments of adherence through pill counts and CASI. Regimen switching events were measured in the CASI. Participants were required to return the remaining pills at each visit in exchange for a dose of TDF/FTC that would cover the next visit, and the pills were counted by study staff. Participants who tested positive for HIV discontinued TDF/FTC and were offered counseling and referral services. A unique 6-digit number was assigned to participants in place of their real names to protect privacy throughout the study. For each follow-up visit, participants receive 50 RMB (about US \$7.07) as compensation for travel and missed work.

## Outcomes and Core Variables

### Primary Outcomes

In our study, the primary outcomes were pill-counting adherence and regimen switches for PrEP. Participants were asked to return surplus pills at each follow-up, and adherence was calculated by counting the number of pills actually taken and dividing by the number of theoretical pills to be taken during that period. For the event-driven group, the theoretical number of pills to be taken is calculated according to the medication regimen: 2 pills of TDF/FTC orally 2-24 hours before sex, 1 pill 24 and 48 hours after the first dose (if the interval between the last dose is within 1-6 days, take 1 pill before sex), and 1 pill every 24 hours during continuous sex. The total number of pills taken in a week does not exceed 7. The numbers of drug taking days and sex days of the drug users were collected via the questionnaire; pill-counting adherence greater than 90% was defined as an adherence to PrEP. Participants were allowed to change regimens, and the date and direction of medication regimens switching from an event-driven regimen to a daily regimen or vice versa were collected through self-administered questionnaires during follow-up.

### Secondary Outcomes

Secondary outcomes included self-reported adherence, PrEP coverage of last sex events, and PrEP discontinuation. Self-reported adherence was assessed by a questionnaire on whether the medication was missed. We calculated recent sexual behavior with PrEP based on self-administered questionnaires and adjusted the data based on weekly records of pill taking and sexual practices. PrEP discontinuation excludes those who discontinue PrEP due to seroconversion to HIV positivity.

### GSN Apps' Use, Sexual Behaviors, and Other Observation Variables

The GSN app platforms mentioned in the questionnaire included *Blued*, *Jacked*, *Momo*, and other common gay social apps with geographical networking. Other adherence-related variables were also gathered via questionnaires. Specifically, questionnaires collected data on sociodemographics (eg, age, occupation, education), sexual behavior (ie, sexual role, number of sexual partners, type of sexual partners, condomless anal intercourse, and rectal douching), and substance use during the past 3 years. For sexual partners, casual partners were defined as one-night stands, as opposed to regular partners. Substance use was defined as the use of rush (poppers or alkyl nitrites), MDMA (3,4-methylenedioxymethamphetamine; ecstasy), ice, amphetamines, tramadol, or ketamine.

### Statistical Analysis

The distribution of demographic, behavioral, and PrEP-related characteristics of GSN apps' users and nonusers among MSM on PrEP (such as sexual behavior, substance use, and the choice of regimen) was compared using chi-square analysis or Fisher exact test, as appropriate. To clarify the determinants of PrEP adherence and regimen switches, generalized estimation equation with logistic models was used for analysis to obtain robust results by controlling for the correlation between observed variables [22,23], given that adherence, PrEP coverage of last sex events, and regimen switches were evaluated at each follow-up among GSN apps' users and nonusers. In this model, at each follow-up, data on time-dependent variables such as sexual behavior, drug use, and psychological factors were analyzed, and only variables statistically significant at the  $P < .20$  level were entered into the multivariate analysis with adjustment for demographic confounding factors including ethnicity, monthly income, and residence. All analyses were performed using SPSS version 24.0 (IBM). All  $P$ -values and confidence intervals were 2-sided.

### Ethics Statement

This study was approved by the Institutional Review Board at the 4 research centers and research procedures were carried out strictly in accordance with relevant guidelines ([2018]2015-139-5) and the Declaration of Helsinki. Written informed consents were obtained from participants prior to starting any study procedure. This study is registered with the Chinese Clinical Trial Registry (Trial registration number ChiCTR-IIN-17013762).

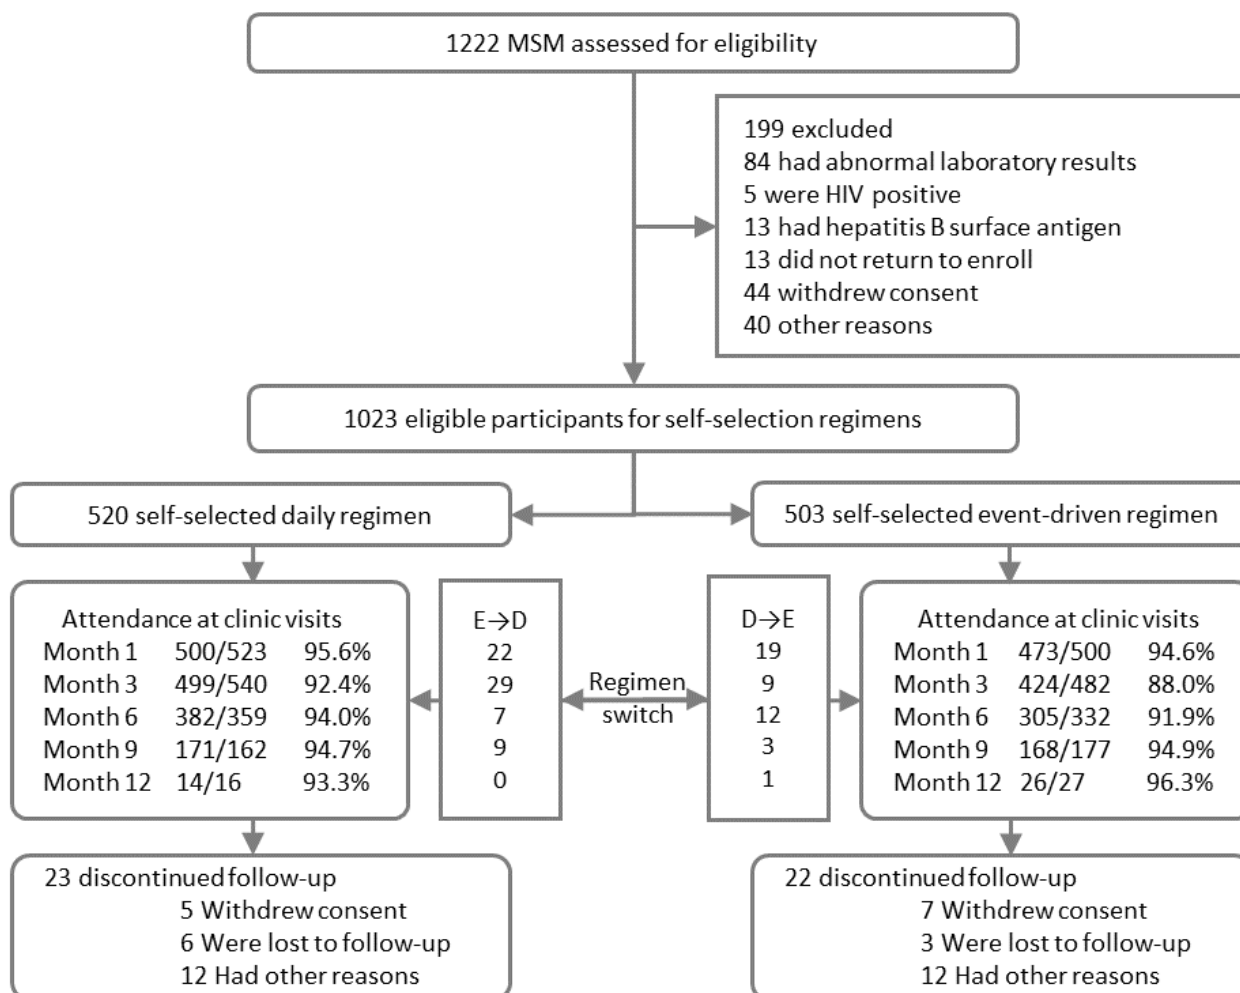

## Results

### Participant Demographics

Of the 1222 MSM screened, 1023 eligible participants were enrolled, including 520 MSM who chose daily PrEP and 503

MSM who chose event-driven PrEP at baseline (Figure 1). At PrEP initiation, the median age was 29 years (IQR 25-35), 81.23% (831/1023) of participants self-reported having a university degree or above, and 54.55% (558/1023) of participants self-identified as single.

**Figure 1.** Enrollment and follow up of the study participants. D→E: switching from daily to event-driven regimen; E→D: switching from event-driven to daily regimen; MSM: men who have sex with men.

### GSN Apps' Usage and Characteristics of GSN App Users

As much as 73.90% (756/1023) of eligible participants reported primarily using GSN apps to seek sexual partners in the past 3 months. GSN apps' users were younger and had higher education. A detailed distribution of sociodemographic characteristics is shown in Table 1.

Participants who use GSN apps were more likely to engage in risk behaviors than those not using GSN apps. Specifically, GSN apps' users had more male casual sexual partners ( $\geq 4$ : 34.9% [264/756] vs 21.7% [58/267],  $P<.001$ ) and more condomless anal intercourse (CAI; 1-2: 19.6% [148/756] vs 14.2% [38/267],  $\geq 3$ : 42.2% [319/756] vs 39.3% [105/267],  $P=.034$ ) than nonusers. However, there was no statistical difference between GSN apps' users and nonusers in the choice of medication regimens.

**Table 1.** Baseline characteristics of MSM on PrEP who did and did not report mainly seeking partners through geosocial networking apps during the past 3 months (N=1023).

<sup>c</sup>PrEP: pre-exposure prophylaxis.

<sup>d</sup>CAI: condomless anal intercourse.

<sup>e</sup>STI: sexually transmitted infection.

### GSN Apps' Use, Adherence, and Regimen Switches for PrEP

By January 2020, 97.07% (993/1023) of participants completed at least one clinical visit, with a total of 2962 follow-up visits, and the median follow-up time was 0.50 person-years, equivalent to 513.07 person-years.

As shown in [Figure 2](#), according to adherence assessments by pill count and questionnaires at each visit, the proportion of adherence greater than 90% was lower and the rate of switching from event-driven to daily regimen was higher for GSN apps' users than nonusers. As shown in [Table 2](#), in the multivariable analysis of generalized estimation equation with logistic regression, GSN apps' use was also found to be a significantly independent predictor of adherence over 90% with adjusted odds ratio (aOR) of 0.8 (95% CI 0.6-1.0;  $P=.037$ ). In terms of the medication regimen, the adherence to the daily regimen was higher than that to the event-driven regimen (aOR 3.8, 95% CI 3.1-4.6). The subgroup analysis of different regimens showed that the adherence of GSN apps' users to the event-driven PrEP was lower than that of nonusers (aOR 0.7, 95% CI 0.6-0.9). Other independent predictors of adherence included age (vs 18-24 years; 25-34: aOR 1.3, 95% CI 1.0-1.7; 35-65 years: aOR 1.4, 95% CI 1.0-1.8), college education and above (aOR 1.3, 95% CI 1.0-1.7), daily regimen (vs event-driven regimen; aOR 3.8, 95% CI 3.1-4.6), having multiple male sex partners (vs 0-1

male sex partners; 2-3: aOR 1.2, 95% CI 1.0-1.5;  $\geq 4$ : aOR 1.3, 95% CI 1.1-1.7), multiple casual male sex partners (vs 0; 1-3: aOR 1.1, 95% CI 0.9-1.3;  $\geq 4$ : aOR 1.3, 95% CI 1.0-1.6), number of CAI instances of 3 or more (vs no CAI; aOR 1.2, 95% CI 1.0-1.5), and substance use (vs no substance use; aOR 0.7, 95% CI 0.5-0.9; [Table 2](#)).

For self-reported adherence measures, GSN apps' users showed a statistically marginally lower level of adherence than nonusers in the event-driven regimen (aOR 0.7, 95% CI 0.4-1.0,  $P=.060$ ). PrEP coverage of last sex events was significantly lower with GSN apps' users than with nonusers on the event-driven regimen (aOR 0.6, 95% CI 0.4-1.0,  $P=.038$ ; [Table 3](#)).

As much as 9.7% (96/993) of PrEP users switched regimens, including 82 who switched once and 14 who switched more than once. Of the 111 regimen-switching events, 67 (60.4%) were from event-driven to the daily regimen, and 44 (39.6%) were from event-driven to the daily regimen. Interestingly, based on the above multivariable analysis, GSN apps' users were more likely to switch regimens from event-driven to daily use, compared with nonusers (aOR 1.8, 95% CI 0.9-3.3,  $P=.084$ ; [Table 3](#)).

Additionally, 4.40% (45/1023) of participants discontinued PrEP and dropped out of the study, and there were no significant differences in rates of discontinuation between GSN apps' users and nonusers (4.4% [23/520] vs 4.4% [22/503],  $P=.796$ ).

**Figure 2.** Pill-counting adherence and regimen switches for PrEP among GSN users and nonusers during follow-up. The difference in the rate for pill counting adherence and regimen switching between GSN users and nonusers at each follow-up visit was marked as  $*P<.20$ ,  $**P<.05$ . E→D: Switching from event-driven to daily regimen; GSN: geosocial networking; PC: pill counting; PrEP: pre-exposure prophylaxis.

**Table 2.** Generalized estimated equation analysis of behaviors during follow-up as predictors of over 90% adherence to pre-exposure prophylaxis by pill counting (N=993).<sup>a</sup>

## Discussion

### Principal Findings

These study results represented, to our best knowledge, the first evidence on the correlation between GSN apps' use and PrEP adherence in a real-world setting with options for daily or event-driven regimens to address bottlenecks in order to optimize PrEP adherence. Our results revealed that a high proportion of PrEP users mainly seek sexual partners through GSN apps, and GSN apps' users are at a higher sexual risk than other PrEP users. Worryingly, GSN apps' users had lower levels of medication adherence and higher rates of regimen switching during follow-up than GSN apps' nonusers. These data suggest the importance of reaching MSM at high risk through GSN platforms and providing them with education and interventions to improve PrEP adherence.

In this study, nearly three-quarters of MSM on PrEP reported seeking sexual partners mainly via GSN apps at baseline, which was higher than those reported in the general MSM population (56.0%) [2]. A study on American MSM found that those using GSN apps seemed more likely to start PrEP (aOR 1.6) compared with non-GSN apps' users, which seems to partly explain the high level of GSN apps' usage among MSM on PrEP [15]. Additionally, our results are similar to those from previous studies that found a higher proportion of HIV-related high-risk sexual behaviors among GSN apps' users compared to nonusers [4,7,24,25]. GSN apps offer many advantages not available with other traditional ways of encountering a sexual partner and making it easier to locate and screen via the app itself [4,7,24].

Medication adherence and regimen switching are important factors affecting the effectiveness of PrEP; however, there has been a lack of evidence on the effect of GSN apps' use on the above outcome variables. Our results found that although GSN apps' users were at a higher sexual risk than non-GSN apps' users, they had lower level of medication adherence to PrEP,

and higher rate of regimen switches during follow-up. The observed decrease in PrEP adherence among GSN apps' users could be attributed to their higher frequent substance using behaviors than nonusers. Previous research had demonstrated that substance use with sex is strongly associated with poor adherence to HIV treatments [26]. Additionally, this study observed a potential decline in the adherence of GSN users during the 6-12-month study period, which may be explained by the higher proportion of younger MSM among GSN users compared with nonusers. Our results also found a lower PrEP coverage of sex events among GSN apps' users compared with nonusers to further support this hypothesis. Furthermore, this study found that GSN apps' users were prone to transition from event-driven PrEP to daily dosing regimen than nonusers, although there was no statistically significant difference between the 2 groups in the choice of regimen at initiation. Additional work is needed to address the high rate of regimen switching among GSN apps' users, and response recommendations should be added to the WHO and country PrEP guidelines that recommend MSM currently using GSN apps to choose a more appropriate daily regimen based on their active sexual behavior. Daily dosing regimens are recommended by guidelines and some trial evidence for MSM with more frequent and irregular sexual behaviors due to the regimen's simplicity and ease of operation [17,27,28]. Given that GSN apps' users have a high conversion rate for medication regimens, they should be provided with timely education on new medication regimens, not only when PrEP is initiated, but also when they switch regimens. Because of the low dropout rate in this study, no significant difference was found in the termination rate of PrEP between GSN users and nonusers, and the outcome remains to be further observed and confirmed in a larger population with low cohort retention rate in the future.

Given that the GSN platforms cover most MSM using PrEP with high risk levels but low adherence, adherence intervention through eHealth on the GSN platforms may be an ideal way to

optimize adherence in the large-scale implementation of PrEP. The soaring number of dating app users offers unique opportunities to reach out to at-risk MSM for a broad range of health education and interventions [20,29]. GSN app-based advocacy has proven effective in expanding HIV testing and prevention interventions recruitment [30-35]. However, how to effectively deliver eHealth of PrEP adherence on GSN apps needs to be further explored [36]. Although banner ads in apps may be expensive [29,37,38], they can be used to effectively educate the public about PrEP and raise awareness, such as about different PrEP regimens. Pop-up ads in apps appear to be suitable for use as a just-in-time adherence intervention that can be set up on the dating apps to improve PrEP medication adherence [39]. A study conducted in the United States suggests that detailed user profiles on social platforms could help increase sexual health awareness of MSM [40]. This experience could be extended to reduce HIV high-risk behaviors of PrEP users by adding this setting to the GSN platform in China and other countries with similar HIV rates. Offline adherence support also must provide specific assistance to MSM with GSN apps' usage by providing counseling on medication regimens and switching regimens during PrEP initiation to minimize regimen switching.

### Strengths and Limitations

A major strength of this study was the assessment of adherence and regimen switches among MSM who reported using GSN apps, which increased our awareness of the correlation between GSN apps' use and adherence to PrEP. Furthermore, this study was based on a national multicenter real-world study that simulated real-world scenarios in which participants were able to choose their regimens and to switch between daily and event-driven dosing regimens if desired. However, there were also several limitations in this study. The follow-up time was

relatively short, and long-term outcomes may not be observed. Medication adherence may be overestimated to some extent due to the free availability of the PrEP and certain incentives in this demonstration study. This study did not further analyze the effect of GSN apps on HIV-prevention efficacy and drug concentration for PrEP, which future studies should examine. Although this study tries to simulate real-world scenarios as much as possible, compliance may be overestimated to some extent due to the free drug supply and the limited amount of incentive costs used to motivate PrEP use, as PrEP is not yet available in China. This study used a variety of methods to supervise the return of medicines, and pill counting remains inevitably affected by uncontrollable reasons such as forgetting to take them. Therefore, our study also uses questionnaires to comprehensively evaluate PrEP adherence from multiple perspectives. Although this study used flexible online and offline recruitment methods to reach all levels of MSM, similar to previous studies, the very high proportion of MSM with university degrees who start PrEP may not be representative of the entire MSM population in China. Therefore, further research is necessary to examine the causality between app use and the PrEP adherence of MSM.

### Conclusions

This study found that GSN apps' users who account for a large proportion of daily and event-driven oral PrEP users have lower adherence and are more likely to switch regimens despite their higher sexual risk than GSN apps' nonusers. Based on these results, GSN platforms provide a unique opportunity to reach high-risk MSM for promoting PrEP outreach, and it is also necessary to customize medication adherence interventions for GSN apps' users to improve the preventive effect of PrEP.

### Acknowledgments

This work was supported by the Mega-Projects of National Science Research (13th Five-Year Plan [2017ZX10201101]) and the National Natural Science Foundation of China (Grant No. 81872674). The authors are very grateful to all members of the CROPrEP study team for their contribution. Members not included in the authors' list include Yao Li, Fang Zhao, Yonghui Zhang, Zhu Mei, Yueru Jia, Rui Li, Yanni Ma, Xin Ma, and Xiaoyun Shi. We also thank the MSM who participated in this study and the staff of community-based organizations who contributed to its success. Gilead Sciences donated the research drug and is gratefully acknowledged.

### Authors' Contributions

HW, JX, and HS conceived and designed the study; HW, JX, JZ, ZC, QH, XH, YC, HW, XH, LZ, ZH, RB, SL, HL, XJ, HD, WG, and YJ performed the study and experiments; HW and JX analyzed the data; HW, JX, and SC drew the figures and tables; HW, JX, HS, and WD wrote and revised the manuscript; and JX and HS contributed equally as corresponding authors. All authors reviewed and approved the final manuscript.

### Conflicts of Interest

None declared.

## Abstract

**Background:** AIDSVu is a public resource for visualizing HIV surveillance data and other population-based information relevant to HIV prevention, care, policy, and impact assessment.

**Objective:** The site, AIDSVu.org, aims to make data about the US HIV epidemic widely available, easily accessible, and locally relevant to inform public health decision making.

**Methods:** AIDSVu develops visualizations, maps, and downloadable datasets using results from HIV surveillance systems, other population-based sources of information (eg, US Census and national probability surveys), and other data developed specifically for display and dissemination through the website (eg, pre-exposure prophylaxis [PrEP] prescriptions). Other types of content are developed to translate surveillance data into summarized content for diverse audiences using infographic panels, interactive maps, local and state fact sheets, and narrative blog posts.

**Results:** Over 10 years, AIDSVu.org has used an expanded number of data sources and has progressively provided HIV surveillance and related data at finer geographic levels, with current data resources providing HIV prevalence data down to the census tract level in many of the largest US cities. Data are available at the county level in 48 US states and at the ZIP Code level in more than 50 US cities. In 2019, over 500,000 unique users consumed AIDSVu data and resources, and HIV-related data and insights were disseminated through nearly 4,000,000 social media posts. Since AIDSVu's inception, at least 249 peer-reviewed publications have used AIDSVu data for analyses or referenced AIDSVu resources. Data uses have included targeting of HIV

testing programs, identifying areas with inequitable PrEP uptake, including maps and data in academic and community grant applications, and strategically selecting locations for new HIV treatment and care facilities to serve high-need areas.

**Conclusions:** Surveillance data should be actively used to guide and evaluate public health programs; AIDSvu translates high-quality, population-based data about the US HIV epidemic and makes that information available in formats that are not consistently available in surveillance reports. Bringing public health surveillance data to an online resource is a democratization of data, and presenting information about the HIV epidemic in more visual formats allows diverse stakeholders to engage with, understand, and use these important public health data to inform public health decision making.

## KEYWORDS

HIV; surveillance; infodemiology; data visualization; infectious disease; health policy; data dashboard; health department data; dashboard; data

## Introduction

Public health surveillance is the basis of effective public health decision making [1], and surveillance data have been called “the conscience of an epidemic” [2]. Defined as “the ongoing, systematic collection, analysis, and interpretation of health-related data essential to planning, implementation, and evaluation of public health practice” [3], surveillance data have a critical role to play in monitoring and protecting the health of individuals and populations. More specifically, surveillance is critical to delineate patterns of disease and to evaluate population-level health data and the impact of public health interventions and policies.

Dissemination of data is a critical aspect of surveillance practice: making public health data available broadly helps to raise awareness of public health threats, promotes the efficient targeting of resources and testing programs, supports evidence-based legislation to provide for prevention and care services, and enables the monitoring of progress in disease prevention and care [4]. Historically, surveillance data have been disseminated through reports, published at least annually [5], and at varying geographic levels (ie, national, state, and local) [4]. More recently, the broad availability of the internet and increasing data transfer speeds have enabled the online dissemination of reports; in many health jurisdictions, surveillance reports are now only available online.

The US case-based surveillance system for HIV is one of the largest, most well-resourced, and comprehensive infectious disease surveillance systems in the world [6]. The US Centers for Disease Control and Prevention (CDC) administers funding for the system, which is implemented by all US states and selected US cities. The CDC is responsible for processing surveillance data and deduplicating records and for producing national surveillance reports; the CDC does not report or map HIV surveillance data at geographic levels finer than at the county level. State and local health departments are responsible for producing local surveillance reports for jurisdictions smaller than counties. Surveillance reports have traditionally largely comprised tabular presentations of data [7]. Typical surveillance reports include only summary data and are not necessarily geared to lay audiences without technical backgrounds. Data visualizations are generally lacking from surveillance reporting, although more recently, some state and local health departments have incorporated choropleth maps to illustrate variations in

levels of disease by smaller geographic areas within states [8] or cities [9,10]. Despite these welcome additions, the types of data released and formats of visualizations vary across states, and the methods used to develop them may also vary among states.

We describe the development, implementation, methods, governance, and impact of AIDSvu.org, a free public data source created to visualize and disseminate HIV surveillance data. Launched in 2009, the resource is a cooperative private-public-academic partnership. We also summarize the reach and utilization of AIDSvu and its service and data resources.

## Methods

### Overview of AIDSvu and Statement of Purpose

AIDSvu was created in 2009 as an interactive online mapping platform to visualize the impact of the HIV epidemic on communities across the United States and to improve access to surveillance data at granular geographic levels. The goals of AIDSvu are to make HIV-related data widely available, easily accessible, and locally relevant to inform public health decision making. Improved accessibility and use of HIV surveillance data promotes disease awareness among the general public, media professionals, and medical practitioners and informs data-driven public health decision making. Local relevance refers to publishing data at the finest possible geographic levels, so that public health decisions can be made with awareness of heterogeneity of needs within states or cities. The platform also promotes the wide availability of multiple types of data, including surveillance data, census data on social determinants, locations of HIV-related service providers, and data on the uptake of key HIV services (eg, pre-exposure prophylaxis [PrEP] and HIV testing). Researchers have used AIDSvu’s data and tools to conduct analyses and evaluate public health interventions; in addition, advocates and community leaders have used AIDSvu’s maps and other tools to educate their audiences and support funding applications.

### Principles of Data Inclusion

With assistance from an advisory committee of key stakeholders in HIV and a technical advisory group that includes HIV surveillance technical experts, AIDSvu’s scientists have established firm principles of data inclusion to guide the scope

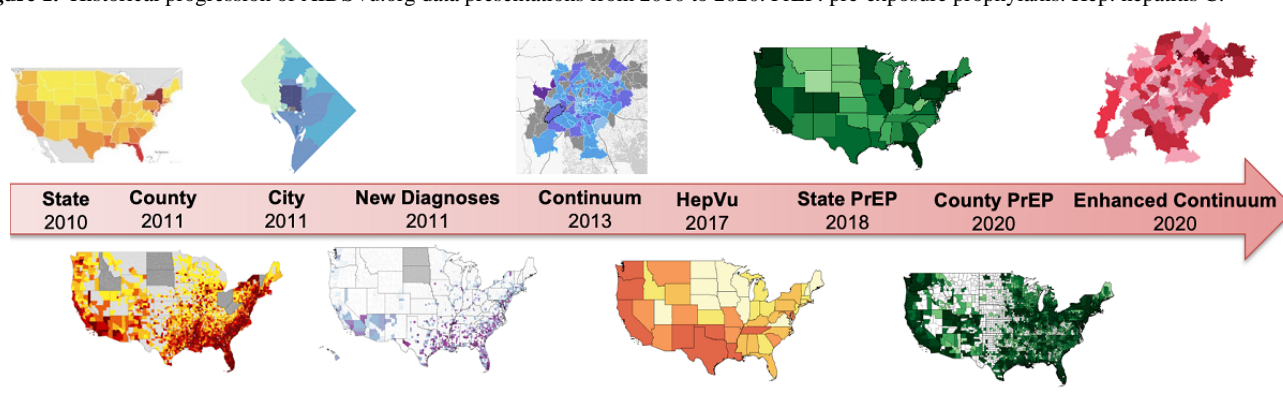

of data to be included on the site. First, all sources must be publicly available or fully transparent to allow replication. Second, all metrics must be consistently defined and standardized to enable meaningful comparisons across geographies. Third, data presented on the site are required to be substantially population based; for example, case-based surveillance data, other data sources that represent a census of outcomes (eg, PrEP utilization data from pharmacy sources), and population-based survey data. Fourth, data must be timely; AIDSvu's scientific team aims to provide data on the site as quickly as possible after they have been released and reviewed for data quality. Fifth, in recognition of privacy concerns and data suppression requirements set by health departments and the CDC, data are suppressed when indicated by either small numbers of cases or small populations (see [Multimedia](#)

[Appendix 1](#) for details). Within these criteria, the AIDSvu team continuously aims to release finer geographic levels of data to increase relevance to prevention and care activities in local communities.

### Overview of Data and Sources

AIDSvu presents HIV-related metrics from a variety of sources, including the US CDC, state and local health departments, health care claims databases, and public data such as US Census data. The elements presented on AIDSvu have expanded since the platform's inception. AIDSvu's first HIV surveillance map released in 2010 included only state-level data, and over time AIDSvu's team has added additional data elements at finer geographic levels, including county- and ZIP Code-level data for selected states and jurisdictions beginning in 2011 (see [Figure 1](#)).

**Figure 1.** Historical progression of AIDSvu.org data presentations from 2010 to 2020. PrEP: pre-exposure prophylaxis. Hep: hepatitis C.

The HIV surveillance data presented on AIDSvu are updated annually or as the data become publicly available from the data sources. HIV surveillance maps can be viewed by demographic breakdowns and can be overlaid with three types of service locations—PrEP, HIV testing, and HIV treatment—to enable examination of these resources relative to HIV prevalence and diagnosis data at different geographic levels [11].

Infographics and city and state profile pages provide supplementary visualizations and information, and complement

the data presented in the maps and existing surveillance reports. Other public data, such as US Census data on social determinants of health (ie, poverty, high school education, median household income, income inequality, health insurance, etc) can be viewed alongside interactive maps to provide context. [Table 1](#) displays the availability of data by visualization type [12,13]. [Table 2](#) displays the availability of data by geographic level.

**Table 1.** Availability of data by visualization type from the AIDSvu Project, July 2020.

Geographic level	Profiles	Prevalence	Diagnoses	Mortality	PrEP <sup>a</sup> use [12]	PrEP-to-need ratio [13]	SDH <sup>b</sup>	Continuum	Data sources
National	X <sup>c</sup>	X	X	X	X	X	X	X	CDC <sup>d</sup> and Symphony Health
Regional	X	X	X	X	X	X	X		CDC
State	X	X	X	X	X	X	X	Select states	CDC
County	X	X	X	X		X	X	Select counties	CDC
ZIP Code	X	X	X				X	Select cities	City and state health departments
3-digit ZIP Code					X				Symphony Health
Census tract, neighborhood, and community area		Select cities	Select cities						City and state health departments

<sup>a</sup>PrEP: pre-exposure prophylaxis.<sup>b</sup>SDH: social determinants of health.<sup>c</sup>X: Data are presented on AIDSvu. Empty cells: data are not presented on AIDSvu.<sup>d</sup>CDC: Centers for Disease Control and Prevention.**Table 2.** Availability of data by geographic level from the AIDSvu Project, July 2020.

Available data	State	Region	County	City	ZIP Code
HIV prevalence	X <sup>a</sup>	X	X	Select cities	Select cities
HIV diagnoses	X	X	X	Select cities	Select cities
PrEP <sup>b</sup> use	X	X	X		
PrEP-to-need ratio	X	X	X		
Mortality	X	X	X	Select cities	
Social determinants of health	X	X	X	Select cities	
Testing	X		Select counties		
Late diagnoses	X	X		Select cities	Select cities
Linkage to care	X			Select cities	Select cities
Viral suppression	X			Select cities	Select cities
Receipt of care	X			Select cities	Select cities
Federal funding	X	X			
Sexually transmitted diseases	X	X	Select counties	X	

<sup>a</sup>X: Data are presented on AIDSvu. Empty cells: data are not presented on AIDSvu.<sup>b</sup>PrEP: pre-exposure prophylaxis.

AIDSvu currently maps HIV prevalence and new diagnoses data at state and county levels in addition to the ZIP Code level for 50 cities and community areas and wards, and maps them at the census tract level for a subset of three of those cities. At the county level, AIDSvu maps data on prevalence (see [Figure 2](#)) and new diagnoses plus PrEP use [12] and PrEP-to-need ratio [13]; at the state level, AIDSvu maps all of the prior indicators

plus HIV mortality data and HIV testing data (see [Table 1](#)). For US cities, data are available at the ZIP Code level for HIV prevalence and 5-year risk of HIV diagnosis for 45 cities; data are available for the HIV continuum (eg, late diagnosis, prompt entry to care, retention in care, and viral suppression) for 35 cities.

**Figure 2.** AIDSvu map of HIV prevalence at the county level, 2018.

Regarding the intended audiences, AIDSvu's content was developed to meet the needs of several types of users: high-interest users (eg, health department staff, academic researchers, advocacy organizations, and community-based organizations), medical providers (eg, practicing clinicians and clinic staff), policy makers, the media, and the public. Different areas of the site are targeted primarily at different combinations of user audiences; for example, state profile pages might be relevant for both high-interest users and the public, data downloads are of most relevance to researchers, and infographic panels are of high relevance to all groups.

### Governance and Organizational Structure

AIDSvu is the result of a unique partnership between the academic community; governmental organizations, including federal, state, and local health agencies; and private industry. AIDSvu is led by Emory University's Rollins School of Public Health in partnership with Gilead Sciences, Inc, and the Center for AIDS Research at Emory University. The leadership team of AIDSvu is composed of the Advisory Committee, the Technical Advisory Group (TAG), and the Prevention and Treatment Advisory Committee (PTAC), as well as a core team of staff who manage daily activities. The Advisory Committee meets annually and consists of key stakeholders who provide oversight and guidance for the project, including members from federal government agencies such as the US Department of Health and Human Services and the CDC, as well as state departments of health, academic research institutions, health-focused not-for-profit organizations, and industry. AIDSvu's technical advisory teams (ie, TAG and PTAC) consist of HIV surveillance experts who provide input regarding data and other technical issues and HIV prevention professionals who advise AIDSvu's team on how the tool can be utilized in

HIV prevention efforts. TAG and PTAC members meet at least annually and include representatives from federal government agencies, state and city departments of health, and health-focused not-for-profit organizations. This shared responsibility of AIDSvu among public, private, and academic institutions improves ongoing sustainability, agility, and relevance to various audiences.

### Other Content Types

AIDSvu data are presented to optimize utility for the intended audiences. To do this, AIDSvu's team provides a variety of content and visualizations, including infographics to support HIV awareness days, blog posts, downloadable map images, HIV service and clinic locators, side-by-side maps of social determinants of health data, state and local profile pages, and downloadable datasets. These have been used to support user presentations [14], research [15,16], grant applications [17], and the development of educational and advocacy materials that have been presented to stakeholders at conferences, such as the American Public Health Association, the US Conference on AIDS, the Texas HIV Prevention Conference, Fast-Track Cities, Adherence, and the International AIDS Conference.

### Awareness Day Infographics

Annually, in observance of national HIV awareness days, AIDSvu releases a series of infographics highlighting key statistics for various populations, including gay men, women and girls, Black people, Asian and Pacific Islander populations, Native people, Latinx people, Youth, and Transgender people. These are made available to the public via Facebook, Twitter, and AIDSvu.org. The data that inform these graphics are calculated from data available on AIDSvu and from the CDC (see Figure 3).

**Figure 3.** Examples of infographics for national HIV awareness days.

## Blog Posts

Throughout the course of the year, AIDSVu develops and publishes blog posts on various topics, including HIV awareness days, the release of new data or a manuscript, a question-and-answer session on a particular issue (eg, Medicaid

expansion and health inequities in the South), and years in review. Since 2010, AIDSVu has published over 160 blog posts to the website, many of which have featured some of the leading experts in HIV surveillance, research, and advocacy (see [Figure 4](#)).

**Figure 4.** Examples of AIDSVu question-and-answer (Q&A) posts.

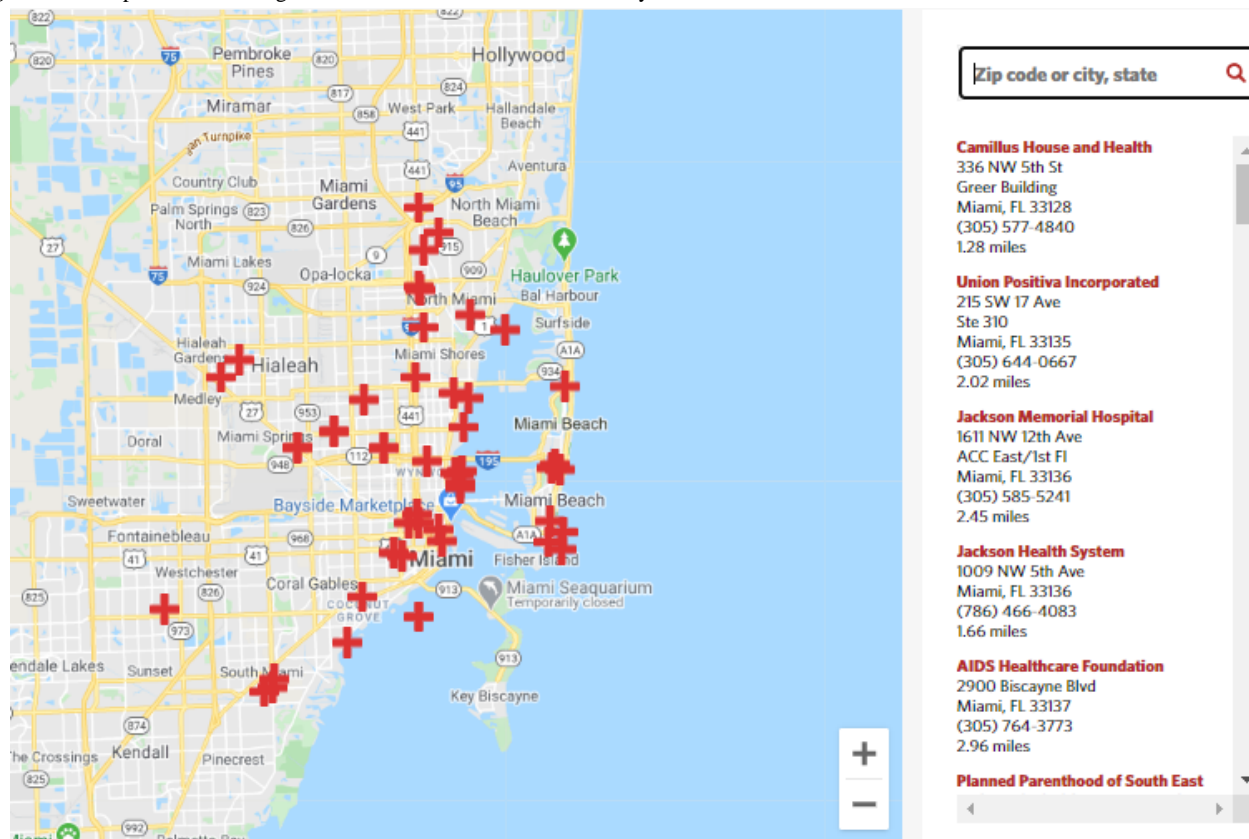

## Service and Clinic Locators

AIDSVu provides users with service locators for HIV prevention, testing, and care. Data for testing, PrEP [18], and care services are obtained from the National Prevention

Information Network through an application programming interface, so these data are as current as possible. In addition, for the nine states in the Deep South, users can locate services for stigma reduction, overdose prevention and reversal, harm reduction, and trauma-informed care (see Figure 5).

**Figure 5.** Example of HIV testing service locator for Miami Dade County.

## Overlays

Users are also able to overlay service provider locations directly onto AIDSVu's maps to illustrate how services are distributed in relation to the burden of HIV. The services available for overlay include HIV testing sites, PrEP services, Ryan White HIV/AIDS Program medical care providers, the Housing Opportunities for Persons with AIDS program, National Institutes of Health (NIH)-funded HIV Prevention Trials Network sites, NIH-funded HIV Vaccine Trials Network sites, and NIH-funded HIV treatment trial sites (see Figure 6).

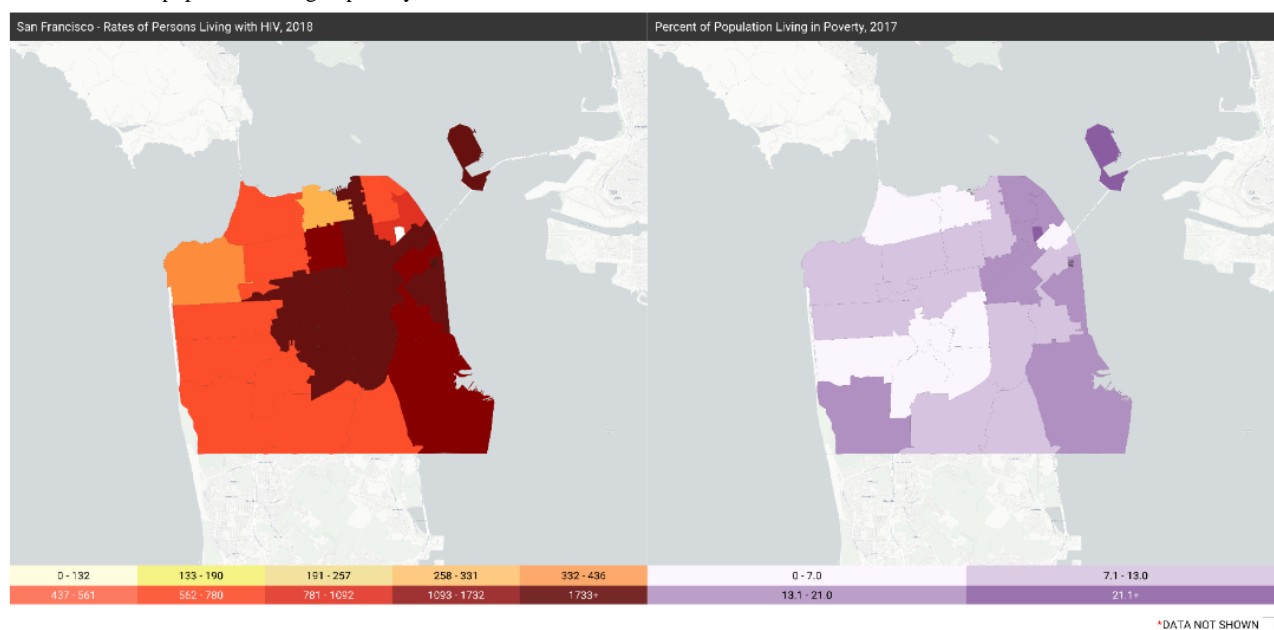

Social determinants of health can be displayed side by side on a secondary map to visualize the relationships between HIV and social determinants. The five social determinants included in AIDSVu are drawn from the US Census and are as follows: (1) poverty (percent of population living in poverty), (2) high school education (percent of population with a high school degree or equivalent), (3) median household income, (4) income inequality (measured by the Gini coefficient, a measure of income inequality where 0 reflects complete equality and 1 reflects complete inequality), and (5) people without health insurance (percent of population lacking health insurance) (see Figure 7).

**Figure 6.** Overlay of pre-exposure prophylaxis (PrEP) services on the Atlanta ZIP Code map of the 5-year risk of new HIV diagnoses, 2014-2018.

**Figure 7.** Percent of population living in poverty, San Francisco.

## Profile Pages

The site has unique pages with profiles for over 40 US cities and 48 counties prioritized for Phase 1 of the *Ending the HIV*

*Epidemic: A Plan for America* initiative [19]; 50 states; Washington, DC; Puerto Rico; four regions; and the nation, offering easy-to-understand, printable snapshots that summarize the impact of HIV in each of these jurisdictions. The pages

enhance the maps and display data and infographics for HIV prevalence, HIV prevalence rate ratios, new HIV diagnoses, new HIV diagnoses by transmission category, HIV mortality, AIDS diagnoses, the total population, and sexually transmitted diseases data. In some cases, AIDSvu serves as a public face

for data that are routinely reported by the CDC for all jurisdictions; for example, in 2018 some cities began reporting diagnosed HIV cases in male-to-female and female-to-male transgender people (see Figure 8).

**Figure 8.** A portion of the Atlanta city profile page in AIDSvu, 2020.

### Downloadable Data and Printable Maps

Data for the overall national level, along with those at regional, state, and county levels, are available for download. Select cities also provide their data for download. The latest national, regional, state, and county data are available for HIV new diagnoses, prevalence, and mortality; social determinants of health; PrEP utilization; and PrEP-to-need ratio. PrEP data are notable because they are a resource that was developed specifically for mapping and dissemination, to meet an urgent public health need [12,20]. Users can freely download these datasets for a number of years (2008-2018) to conduct their own analyses for use in reports, publications, grant applications, etc. Users do not need to submit a data request or obtain permission to use the available data.

Similarly, users are able to download printable maps. These maps can be customized to display a toggled area, titles, and legends, and at different resolutions and transparency levels.

### Results

AIDSvu's scientific team collects metrics to evaluate utilization over time by key audiences, including data on number of users, social media reach, and academic publications that reference AIDSvu. All data below are as of the end of 2019 unless otherwise noted.

#### Website Sessions and Users

Since 2010 (ie, the first full year of data reporting), the number of unique website users increased from 1852 in 2010 to 501,527 in 2019 (see Figure 9). Most users (96.8%) originated in the United States, and users from five states—Georgia, Texas,

Florida, California, and New York—accounted for 43.8% of all sessions in 2019; these states represented 36% of the US population in 2019.

**Figure 9.** Total number of AIDSVu users by year, 2010-2019.

### Social Media Reach

AIDSVu's team also uses various social media platforms to reach key audiences. Key metrics include impressions, defined as the number of times content has been displayed on a screen, and engagements, defined as the number of actions that users take involving posts or tweets. In 2019, AIDSVu generated 3,955,972 impressions on social media—1,928,029 on Facebook and 2,027,943 on Twitter—and 113,444 engagements—48,614 on Facebook and 64,830 on Twitter. Moreover, AIDSVu's Facebook page was followed by 10,440 users, and AIDSVu's Twitter page was followed by 4751 users. Based on organizational types derived from IP addresses, many AIDSVu users are *high-interest* audiences (eg, health department staff, government workers, and academics). For 2019, the distribution of user types included 22,710 academic users, 5274 government users, and 6511 nonprofit users.

### Academic Publications

Given that one of AIDSVu's major objectives is to increase the availability of HIV surveillance data and related information for research purposes, the number of academic papers that cite AIDSVu is a critical metric for evaluation. As of August 22, 2020, 249 peer-reviewed journal articles, 27 academic dissertations or theses, and 6 book chapters had used AIDSVu data or cited AIDSVu's resources. Among uses of AIDSVu in these scholarly products, common uses included use of maps or visual products (136 uses), downloading and using AIDSVu data for analyses (115 uses), citation as a public health tool (46 uses), and use of locator data for research or program purposes (3 uses). Uses of AIDSVu in academic products increased steadily from 2012 through mid-2020 (see Figure 10).

**Figure 10.** Number of academic uses of AIDSvu.org by year and use, 2012-2020.

## Public Health Applications and Use Cases

Examples of how the data on AIDSvu.org are used in public health practice have been recently reviewed [11]. AIDSvu maps have been used to develop targeting for door-to-door testing campaigns, identify areas of high need for telemedicine HIV care facilities [21], and identify service gaps for HIV prevention services [11]. Funders, such as the Elton John AIDS Foundation and the Gilead COMPASS initiative, have used data on the burden of HIV diagnoses to prioritize highly impacted areas for grant funding [22]. Academic researchers have used AIDSvu data to justify the selection of study sites in grant proposals [17].

## Discussion

The US HIV surveillance system is the most comprehensive and well-funded, country-specific surveillance system for any infectious disease in the world, and the quality of the data generated by the system is unparalleled in public health surveillance activities [6]. The data have been used over the course of decades of response to the US HIV epidemic to document health disparities, to argue for resources for care, for treatment and prevention, to serve as the basis for equitable resource allocation, and to identify specific cities and facilities in need of additional resources to provide services.

Although the HIV surveillance system and quality of its data are longstanding, the development and uptake of AIDSvu is a reflection of a growing culture of access to digital data, improved computing capacity and data bandwidth to deliver dynamic content, and an emerging appetite for consuming data through visualization and interaction, in addition to, or in preference to, tabular formats. The platform builds on a

substantial and well-justified public investment in surveillance data and increases the use of those data by presenting data in a way that may be more accessible to some users. This idea—the democratization of data—drives our efforts to make data on the US HIV epidemic widely available and understandable to different types of users.

One of the major enabling factors for the development and growth of AIDSvu has been the collaboration of public health colleagues at all levels of government, as detailed in the Methods section. These advisors promote appropriate uses and interpretations of data, provide advice about the best ways to display data, identify potential weaknesses in data elements or caveats to the interpretation of data, suggest emerging needs that could be met by surveillance data, and prioritize the types of information and formats that would be most useful to the public that they serve. Where possible, AIDSvu attempts to develop resources (eg, local profiles, data overlays, and map views) that reflect questions commonly asked of surveillance programs, so that routine inquiries to these programs can be referred to the website. Surveillance programs for most cities mapped by AIDSvu have agreed to release aggregated datasets for public use, fueling academic analyses and publications by facilitating ready access to data. One of the major lessons learned is that a broad collaboration of data providers and community partners has resulted in broad trust and in having data from many local health departments that are calculated using common definitions and codes and are, therefore, directly comparable to each other.

We acknowledge that surveillance data are available through multiple channels and believe that it is important that these critical data be available in many formats and through different types of partnerships. In 2012, the CDC launched the NCHHSTP

(National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention) AtlasPlus [23], which also offers mapping capabilities at the state and county levels and custom data tabular requests. The NCHHSTP AtlasPlus also provides similar mapping and data functions for related infectious disease surveillance data, including sexually transmitted infections, tuberculosis, and viral hepatitis, which AIDSvu does not include. Conversely, AIDSvu offers some features, like ZIP Code-level mapping, HIV care continuum mapping, infographics and messaging, blog posts to facilitate data interpretation, and service provider overlays, which NCHHSTP AtlasPlus does not offer. Different platforms for presenting and facilitating the understanding of public health surveillance data are needed to serve the broad range of people who can use the data for research, program, policy, and care-planning purposes.

One of the major lessons learned in the development of AIDSvu has been the progression to displaying data at increasingly finer levels of geographic resolution. At the time of AIDSvu's launch of county-level data in 2011, national maps of HIV case counts and prevalence were only available at the state level. The first consolidated depiction of county-level data (see Figure 2) revealed the striking heterogeneity of the impact of HIV within states, and the regional patterns of highly impacted counties in the South. The understanding of the geographic concentration within, and heterogeneity between, counties brought focus to the HIV epidemic in the US South and anticipated the national *Ending the HIV Epidemic* plan's focus on highly impacted urban counties [19]. With the launch of ZIP Code-level data and maps on AIDSvu, geographic disparities within highly impacted cities were apparent. Some cities have agreed to map HIV prevalence data at the census tract level, providing even more precision to inform targeting of prevention and care needs.

AIDSvu has also moved to develop data sources when there was not an existing public data resource that met AIDSvu's strict criteria for inclusion on the site. For example, AIDSvu supported the use of commercial data to develop systematic estimates of PrEP use at the state level in 2019 and accompanied the development of the data with online mapping and public-use datasets for PrEP use at the state level [12]. In 2020, AIDSvu developed and published methods to allow for county-level estimates of PrEP use, in response to the *Ending the HIV Epidemic* initiative's programmatic focus on highly impacted counties [19,20]. This allowed for the assessment of county-level progress toward earlier goals of PrEP uptake developed under the National HIV/AIDS Strategy [24]. Further, the city-level data on AIDSvu are compiled with standardized methods and are publicly available only on AIDSvu.

The AIDSvu platform has several strengths. The strengths include the ability of the platform to provide a common platform to allow cities to display their own surveillance data. Many health departments do not have resources to build and maintain online data visualization platforms, so it makes sense to have a shared resource. Jurisdictions do not report data on ZIP Codes of reported HIV infections to the CDC, so producing city-level resources cannot be done centrally by the federal government. AIDSvu staff can develop and share code to generate local resources such as ZIP Code-level HIV continuum estimates, which is more efficient than having individual health

departments develop such code. This also means that all city-level data presentations are prepared with the same methods so that data are directly comparable across cities. At the time that AIDSvu first displayed county-level data, these data were not publicly available in a single repository, but many states published their own county-level data, sometimes using different methods and assumptions. AIDSvu advanced the field in this area by making county-level estimates public that were directly comparable across state lines. AIDSvu also provides a platform to provide tools that can help interpret, visualize, and translate data to promote public health decision making (eg, map overlays to show areas in need of additional PrEP providers). Finally, AIDSvu has been a robust platform to make population-based data other than surveillance data available to researchers for academic purposes [12,25].

There are also challenges with the AIDSvu platform. The reporting of surveillance data typically lags 12-18 months between the end of a reporting period and the availability of state- and county-level data. Processing for these data includes deduplication of reports across states. In cases where health departments provide data directly to AIDSvu for city-level data displays, the cycle time is faster and data can be made available within 6-9 months, albeit without interstate deduplication and without complete ascertainment of deaths. AIDSvu has been supported for 10 years by a public-private-academic partnership, in which monetary resources are provided by Gilead Sciences and Emory University's Center for AIDS Research; staff effort and data reporting are contributed by public health organizations. Thus, the maintenance of the website, updating of data, and development of new resources are supported with annual commitments, and are not assured in the long term.

Looking forward, AIDSvu will continue to be guided by input on the data needs and priorities of local health programs. We expect to continue moving to display more data at the most granular levels, including expansion to more US cities. Data at the city and ZIP Code level are unique data resources and will be prioritized. Similarly, we will continue to explore ways to make data on PrEP use available with more stratifications where possible, including expanding the stratification of PrEP data to include race and ethnicity. Considering other data platforms like NCHHSTP AtlasPlus, we will continue to reassess the features of AIDSvu that are value added and prioritize the development of new data resources and presentations at finer geographic levels. The AIDSvu platform, which has already been extended to map hepatitis C data [26] and SARS-CoV-2 data [27], may also be used for visualization of other diseases in the future.

Over the past decade, AIDSvu has moved to make HIV surveillance data more accessible and easy to use through innovative visualizations and tabular displays, finer levels of geography, a broad array of indicators (eg, continuum indicators and PrEP use data), and targeted dissemination for multiple stakeholders. Its impact is seen in the utilization of data resources and the growing use of AIDSvu data to support academic research and to inform policy, programmatic, and educational efforts. Surveillance data are intended to inform local responses and are most powerful when they are available for use at the city and county level.

## Acknowledgments

AIDSVu is supported by an unrestricted grant from Gilead Sciences. This work was supported by the Center for AIDS Research at Emory University (P30AI050409). We acknowledge Irene Hall, Anna Satcher Johnson, the US state and city HIV surveillance coordinators, as well as members of our TAG and PTAC: Anna Satcher Johnson, MPH; Becky Grigg, PhD; Dan O'Connell, MA, MLS; Debbie Wendell, MPH, PhD; Eve Mokotoff, MPH; Jacob Dougherty; Jeff Hitt, MEd; Jeff Lauritsen, MPH; Kathleen Brady, MD, PhD; Lorene Maddox, MPH; Margaret Vaaler, PhD; Michael McFadden; Miranda Fanning, MPH; Natalie Cramer, MS; Pascale Wortley, MD, MPH; Pat Young, BS, RN; Richard Aleshire, MSW; Stacy Cohen, MPH; Steve Saunders, MS; and Virginia Hu, MPH.

## Abstract

**Background:** The COVID-19 outbreak was designated a global pandemic on March 11, 2020. The relationship between vaping and contracting COVID-19 is unclear, and information on the internet is conflicting. There is some scientific evidence that vaping cannabidiol (CBD), an active ingredient in cannabis that is obtained from the hemp plant, or other substances is associated with more severe manifestations of COVID-19. However, there is also inaccurate information that vaping can aid COVID-19 treatment, as well as expert opinion that CBD, possibly administered through vaping, can mitigate COVID-19 symptoms. Thus, it is necessary to study the spread of inaccurate information to better understand how to promote scientific knowledge and curb inaccurate information, which is critical to the health of vapers. Inaccurate information about vaping and COVID-19 may affect COVID-19 treatment outcomes.

**Objective:** Using structural topic modeling, we aimed to map temporal trends in the web-based vaping narrative (a large data set comprising web-based vaping chatter from several sources) to indicate how the narrative changed from before to during the COVID-19 pandemic.

**Methods:** We obtained data using a textual query that scanned a data pool of approximately 200,000 different domains (4,027,172 documents and 361,100,284 words) such as public internet forums, blogs, and social media, from August 1, 2019, to April 21, 2020. We then used structural topic modeling to understand changes in word prevalence and semantic structures within topics around vaping before and after December 31, 2019, when COVID-19 was reported to the World Health Organization.

**Results:** Broadly, the web-based vaping narrative can be organized into the following groups or archetypes: harms from vaping; Vaping Regulation; Vaping as Harm Reduction or Treatment; and Vaping Lifestyle. Three archetypes were observed prior to the emergence of COVID-19; however, four archetypes were identified post-COVID-19 (Vaping as Harm Reduction or Treatment was the additional archetype). A topic related to CBD product preference emerged after COVID-19 was first reported, which may be related to the use of CBD by vapers as a COVID-19 treatment.

**Conclusions:** Our main finding is the emergence of a vape-administered CBD treatment narrative around COVID-19 when comparing the web-based vaping narratives before and during the COVID-19 pandemic. These results are key to understanding how vapers respond to inaccurate information about COVID-19, optimizing treatment of vapers who contract COVID-19, and possibly minimizing instances of inaccurate information. The findings have implications for the management of COVID-19

among vapers and the monitoring of web-based content pertinent to tobacco to develop targeted interventions to manage COVID-19 among vapers.

## KEYWORDS

vaping; COVID-19; topic modeling; web-based narrative; modeling; trend; narrative; social media; internet; web-based health information

## Introduction

COVID-19 is spreading rapidly and has been declared a global pandemic [1]. COVID-19 was first reported in Wuhan, China, in December 2019 [2], and it was declared a pandemic by the World Health Organization (WHO) on March 11, 2020 [3]. With the pandemic currently in progress, research on the determinants of disease progression and communities that may be more vulnerable to COVID-19 is of key importance [4].

There is some scientific knowledge that vaping cannabidiol (CBD) or other substances may be associated with more severe manifestations of COVID-19 [5,6]. Use of electronic cigarettes (e-cigarettes) has been associated with a reduction in the ability of the lungs to respond to infection [5,6]; thus, people who use e-cigarettes may be at increased risk of contracting COVID-19 [4,7]. Several studies have indicated that smokers, including vapers, are more vulnerable to COVID-19 infections or more likely to develop serious complications after contracting SARS-CoV-2, the virus that causes COVID-19 [8-10]. Vaping devices may also be possible sites of COVID-19 transmission [9]. However, inaccurate information that vaping can aid COVID-19 treatment is also circulating [9], and experts have expressed the opinion that CBD, which can be administered through vaping, can mitigate COVID-19 symptoms [11,12].

For example, some Twitter posts around vaping indicated that e-cigarette devices may increase lung humidity and prevent COVID-19, and other posts stated that these devices can be used to administer COVID-19 medication to the lungs and possibly destroy the virus [9]. It has also been suggested that CBD products, often delivered through vaping, can be used to treat COVID-19, perhaps by augmenting the immune system [11,12]. Much of the information around vaping and other tobacco products is disseminated through the internet [13,14] and can affect health outcomes [15,16]. For example, vapers who develop COVID-19 may mistakenly believe that vaping CBD or other substances can alleviate COVID-19 symptoms; however, it may instead create additional disease complications. Thus, it is necessary to study the spread of inaccurate information to better understand how to promote scientific knowledge and curb misinformation, which may be critical to vapers' health [17].

A previous study analyzed Twitter content around COVID-19 and vaping [9]. The indicated study surveilled vaping tweets and detailed conversations around COVID-19 and vaping. The web-based conversations centered on the possibly heightened risk of COVID-19 for vapers and how vaping could potentially protect against COVID-19 [9]. However, past work did not use web-based vaping-related data from a range of sources or

detailed data from before the COVID-19 pandemic and through its progression. Detailing a large scope of sources is necessary to document the broad range of web-based vaping conversations, and collecting data from both before and during the COVID-19 pandemic is key to understanding the narrative prior to the emergence of COVID-19 and how it is changing as the pandemic progresses. Our study builds on previous work by using a large data set to represent the web-based vaping narrative (August 1, 2019, to April 21, 2020) that combines analysis of a multitude of sources, such as blogs, forums, and social media posts; also, we used novel computational techniques to examine how the vaping narrative has changed from before to during the COVID-19 pandemic.

Using the novel computational technique of structural topic modeling (STM), we mapped temporal trends in the web-based vaping narrative (a large data set comprising web-based vaping chatter from several sources) to show how discourse differed before versus during the COVID-19 pandemic. Topic modeling is a computer-aided content analysis technique where texts are organized into themes known as topics. These topics are not provided to the machine prior to modeling but emerge inductively as the algorithm learns patterns within the texts. The model assumes a relational theory of meaning by identifying structures of co-occurrence of words in individual texts and across all the texts. The model thus provides content analysis of text data sets that are too large to code by hand. Topic models use machine learning to uncover patterns and relationships that may be omitted by hand coding or traditional content analysis. Unsupervised machine learning methods have performed similarly to human coders on identical documents [18]. Unsupervised machine learning is a variant of machine learning that looks for new patterns in a data set without pre-existing labels and with limited human supervision. We used an approach to topic modeling known as STM [19,20]. STM enables discovery of topics and their prevalence based on document metadata, such as dates, or other important attributes, such as the number of new COVID-19 cases worldwide per day. Adding this metadata is useful, as the data are obtained over several months (August 2019 to April 2020), and the web-based vaping narrative may be susceptible to thematic change based on the progression of the COVID-19 pandemic. STM has been used to address several social scientific research questions around areas such as climate change [21,22] and web-based drug marketplaces [23]. As vapers may be at greater risk for contracting SARS-CoV-2 and COVID-19 disease progression [8-10], and CBD, which is often administered through vaping, may have interactions with COVID-19 treatment outcomes, we hope to provide insight on how vapers are responding to the pandemic. This may help improve the treatment outcomes of vapers who develop COVID-19.

## Methods

### Ethics Statement

Approval and informed consent were not needed because the data were collected using publicly available textual query techniques. All data are publicly available and can be accessed by anyone. The data were provided to the research team with all identifiers removed.

### Data Acquisition and Processing

Data were obtained using a textual query that scanned a data pool of approximately 200,000 different domains, such as public forum posts, blogs, news articles, message boards, health care provider forums, and social media (see [Multimedia Appendix 1](#) for the full list of sources). Textual queries were used to automatically search the indicated sources for text fragments related to keywords such as *vape*, *vaping*, and *e-cigarette*. The data that comprised vaping-related text fragments were collected from August 1, 2019, to April 21, 2020. As the data set represents a multitude of sources for web-based chatter related to vaping, our data set is likely representative of the web-based vaping narrative during the indicated period. The start date for the COVID-19 pandemic was denoted as December 31, 2019, when the Chinese government disclosed the existence of COVID-19 to the World Health Organization (WHO) [3]. Although the date of the first COVID-19 case is prior to December 31, 2019 [2], COVID-19 is unlikely to have influenced vaping-related discourse in the United States prior to December 31, 2019, due to low global awareness. The time period of August 1, 2019, to April 21, 2020, was chosen to provide sufficient data to detail the vaping narrative prior to the COVID-19 pandemic. Given that the date demarcating pre- and post-COVID-19 is December 31, 2019, our time period allowed for approximately four months before and approximately the same period after the first report of COVID-19 to the WHO.

### Word Prevalence and Topic Modeling

To prepare the data for word prevalence and topic modeling analysis, English stop words such as “the,” “a,” and “an” were removed, along with abbreviations, and terms were stemmed using Porter’s stemming algorithm [24]. Stemming converts words with the same “stem” or root (eg, “innovative” and “innovator”) to a single word type (eg, “innovate”). As our study centered on the intersection of vaping and COVID-19, it was expected that words such as “cigarette,” “vape,” and “coronavirus” would dominate our findings. However, these terms may crowd out other words, perhaps causing us to miss key topics occurring in the text. For example, if we were interested in understanding different cooking techniques such as roasting and frying, and we sourced data from web-based forums frequented by amateur chefs, the most frequent words in the data might be “cook” and “recipe.” However, these words might obscure information around the cooking techniques we were interested in. Thus, in some cases, such as our study, it may be necessary to remove frequently occurring words to detail underlying themes in the data. All data were first processed to remove mentions of COVID-19, tobacco, and vaping. These data were used to generate word clouds by word prevalence. As we will later detail, the word clouds generated by word

prevalence contained significant mentions of CBD after the emergence of COVID-19. When conducting topic modeling, mentions of CBD may crowd out other words and reduce our ability to identify salient topics. As such, we further processed the data set for topic modeling by removing mentions of cannabis, inclusive of CBD.

We first generated word clouds based on the top 200 terms ranked by prevalence before and after COVID-19 was reported to the WHO. In a word cloud, a larger font size indicates a greater prevalence of a single word. Word clouds thus provide a relative yardstick of the importance of a word in a particular time period. This visualization enabled us to qualitatively assess words by importance. Documents were processed (words removed) for mentions of cannabis, COVID-19, tobacco, and vaping. References to cannabis were determined using these search terms: [*bud OR cannabis OR cannabidiol OR cbd OR ganja OR hash OR hashish OR hemp OR indica OR joint OR marijuana OR mary jane OR ruderalis OR pot OR sativa OR weed OR THC*]. References to COVID-19 were determined using these search terms: [*COVID-19 OR covid 19 OR novel coronavirus OR coronavirus OR sars cov-2 OR sars cov 2 OR sars-cov-2 OR n-cov OR cov OR covid*]. References to tobacco were determined using these search terms: [*baccy OR bidi OR cig OR cigar OR cigarillo OR cigarette OR ciggy OR fag OR hookah OR pipe OR shag OR sheesha OR shisha OR snuff OR snus OR tobacco*]. References to vaping were determined using these search terms: [*e-cig OR electronic cigarette OR vape OR vaper OR vaping OR vapelife OR vapist OR vapiin OR vapylyfe*].

We then used topic modeling to understand changes in word prevalence within topics around vaping and COVID-19. Topic modeling is a computer-aided content analysis technique in which texts are organized into themes known as topics [25,26]. In topic modeling, a topic is a distribution over a vocabulary of words that represent semantically interpretable themes [19]. For example, in a topic denoted “vape,” the terms “smoke” and “device” are more likely to occur than the words “peanut” and “tomato.” “Smoke” may appear in both “vape” and “cooking” topics with different contextual meanings. Given that the topic is a distribution, “smoke” may appear with other high-probability terms such as “roast” and “fry” in the “cooking” topic but may appear with terms such as “nicotine” and “device” in the “vape” topic. Thus, topics can be understood by considering that a person who was talking about the topic of “cooking” would tend to use some words more frequently than others compared to if they were talking about the topic of “vape.” Topic models are suitable for analyzing large quantities of textual data via an automated technique for providing context.

We used an approach to topic modeling known as STM [18,20]. STM [18,20] enables the generation of topics regarding document metadata such as date and source as well as other covariates relevant to the research question, such as new COVID-19 cases. This is vital to understanding how the narrative and topic proportions change over time. This enabled a robust quantitative analysis of how the COVID-19 pandemic has shaped the web-based narrative on vaping [19]. The key innovation of STM is that it can incorporate metadata or information about each document. This allows metadata covariates, such as new COVID-19 cases per day, to influence

topic discovery. Metadata can affect both the prevalence and content of a topic. Metadata covariates for topical prevalence allow the metadata to affect topic frequency. Similarly, covariates in topical content allow the metadata to affect the word rate within a topic or how a topic is discussed [20]. The STM process will output documents and vocabulary for analysis [20]. This output can be investigated in a range of ways, such as detailing words associated with topics or the relationships between metadata and topics. Model output can be used to conduct hypothesis testing around these relationships. STM [18,20] was applied to the whole data set (August 1, 2019, to April 21, 2020); the data prior to the reporting of COVID-19 to the WHO only (August 1 to December 31, 2019); and the data after COVID-19 was reported to the WHO only (January 1 to April 21, 2020). We subsetting the data to see if the vaping narratives were different before and after COVID-19 was reported to the WHO. We used the following metadata covariates for the STM models. For the full data set, the covariates were the binary variable for before and after COVID-19 was reported to the WHO, COVID-19 content covariate (variable to control for COVID-19-related content), date (the first day was denoted as 1, and the days were numbered sequentially after), source (0=social media, 1=news), new COVID-19 cases per day worldwide, and new COVID-19 deaths per day worldwide. For the pre-COVID-19 data set, the covariates were the date and source. For the post-COVID-19 data set, the covariates were the date, source, new COVID-19 cases per day worldwide, and new COVID-19 deaths per day worldwide.

Because STM is an unsupervised approach, the number of topics to estimate ( $k$ ) is key to the analysis. We first estimated several models ranging from 5 to 200 topics. These models were then evaluated qualitatively by their ability to produce coherent topics and capture topics regarding vaping and COVID-19 [27]. The number of topics was based on our understanding of the data set and how other researchers interpreted STM results [27,28]. The choice of the number of topics was also influenced by postestimation validation outcomes and past work [27]. As per standard content analysis [29], topic model validation also requires qualitative review, where researchers assess the interpretability and relative efficacy of models based on their subject matter expertise and data context. Our final models ( $k=15$  for the whole data set;  $k=20$  for the pre-COVID-19 report data set;  $k=20$  for the post-COVID-19 report data set) provided the greatest external validity and the most semantically coherent output of distinctive topics. When the number of topics was greater than indicated above, there were diminishing returns for solutions, as the substantive meaning and coherence of categories started to break down [21]. When the number of topics was lower, variation decreased and specific topics were placed into more generic categories. Validating a topic model is not the same as evaluating a statistical model regarding a population sample [30]. The goal is to identify the framework that best describes the data, not to estimate population parameters [30].

We conducted qualitative analysis to determine the number of topics based on past social science studies in which topic modeling was used to extract meaning from large text samples.

These studies [21,31] determined topics by qualitative coding based on word prevalence and researchers' topic expertise. We applied similar techniques in this study. Methods such as interrater reliability ratings may guard against subjective bias based on subject matter expertise and data context [32]. Adding interrater reliability to the qualitative component of topic modeling may improve data quality. However, we sought to use topic modeling to answer a specific research question, not to improve on methodological techniques. Thus, we used best practices implemented in previous studies regarding topic interpretation but did not advance these methods.

Topic interpretation was influenced by prior knowledge about why texts were written and what they sought to accomplish. Most of the text was produced and consumed by people who engaged in vaping and other forms of tobacco use, and this lens was used to interpret the presence or absence of topics and words. Most of the topic labels were straightforward and did not require much interpretation. To characterize topics in the vaping narrative, we qualitatively coded each topic by investigating word clouds based on each topic and reviewing exemplar documents which detailed high proportions of each topic [19]. The topic we classified as "tobacco company merger called off" had the following most frequently occurring words: "sue," "analyst," "halt," "1st," "imperial," "judge," "backlash," "advisor," "merger," "stake," "acquire," "outbreak," "carolina," "confirm," and "mint." Exemplar documents that exhibited high proportions of this topic indicated a preoccupation with these words. This detailed a topical preoccupation with a tobacco firm merger being called off. Thus, the interpretation of the topic was clear, given the genre of the narrative and the reliance on research regarding prominent topics around vaping. Two authors assigned the topics, and a third author resolved disagreements when they arose.

Topic validation is key to assessing whether the substantive meaning of the topic and its words are parallel with the qualitative meaning of the text, and we used methodological guidance from past research for this purpose [19,26]. Past work advocated the use of sample documents to validate the substantive meaning of each topic. Determining the number of sample documents to use is based on the amount of resolution needed by a social scientist to answer the research question using topic modeling methods [33]. Thus, determining the number of sample documents is a largely qualitative process that is dependent on the research question at hand. To determine the appropriate number of documents to sample, we searched the social science literature for studies that used topic modeling based on whether they asked similar research questions to our study, addressed similar topic areas to our study, and drew their study data from similar sources to those used in our study. We searched databases such as Web of Science Core Collection, Embase, PsycINFO, MEDLINE, and Sociological Abstracts. We used keywords such as *contrarian*, *polarized*, and *topic modeling*. The 2016 paper by Farrell [21] was determined to be the most similar to our study based on the assessed characteristics. Farrell explored ideological polarization in climate change and used a broad range of sources, such as press releases, published papers, and website articles. Based on the nature of the research question and large range of sources,

Farrell determined that a sample of 50 documents was sufficient to validate the substantive meaning of the topic output. Given the similarities between Farrell's 2016 study and ours in a range of characteristics, we similarly determined that a sample of 50 documents was adequate to validate the topics. We used `findThoughts` and `plotQuote` within the STM package to examine the top 50 associated documents for each topic to validate a topic's substantive meaning. Determination of the top 50 documents was based on ranking topics by the maximum a posteriori estimate of the topic's theta value, which represents the modal estimate of the proportion of word tokens assigned to the topic with the model. These top 50 documents were read by two of the authors to determine validity. A third author resolved disagreements where necessary. As indicated above, interrater reliability was not determined; however, we believe our methods were sufficiently robust.

Finally, word clouds were again generated, this time to visualize topics with the top 100 words ranked by STM-generated weights per topic, for the models representing the full data set and the data sets from before and after COVID-19 was reported to the WHO. In these word clouds, a larger font size indicated a greater weight, with word clouds indicating the importance of a word within a topic. We then grouped topics and their associated word clouds into larger categories or archetypes based on shared concepts across topics [34]. All analysis was conducted using R with the following packages: `dplyr`, `quanteda`, `textclean`, `tm`, and `stm` [20,24,35-37].

## Results

### Data

We collected 4,027,172 documents (361,100,284 words) comprised of text from blogs (86.01%, N=310,546,244), news articles (11.02%, N=39,721,031), forums (3.01%, N=10,833,008), comments (<1%), professional reviews and Facebook posts (both <1%).

### Word Prevalence

The most frequently observed words in the data set were "ban" (216,735/361,100,284 words, 0.06%, rank 1), "product" (135,607/361,100,284 words, 0.04%, rank 2), and "make" (115,413/361,100,284 words, 0.03%, rank 3).

Figure 1 shows a word cloud displaying the 200 most frequently featured words in the data sets divided by time period. The words are colored, sized, and positioned radially based on frequency of appearance, with larger, more central words appearing most frequently. In the period before COVID-19 was reported to the WHO (prior to December 31, 2019), commonly featured words included "ban," "lung," and "quit." Over the next four months, mentions of "CBD" and "oil" increased, along with positive words such as "good" and "best." There was a clear shift in word prevalence before COVID-19 was reported to the WHO compared to after the COVID-19 report. Word prevalence shifted from words related to the vaping ban to positive words and words associated with CBD. The vaping ban was a move by the US government on September 11, 2019, to remove all flavored vaping products from the market [38].

**Month 2 (February 1 2020 – February 28 2020)**

Figure 2 (all observations), Figure 3 (before COVID-19 was reported to the WHO), and Figure 4 (after COVID-19 was reported to the WHO) detailed results of the topic modeling analysis. Topics not directly relevant to our analysis were not indicated in the figures, such as the Australian bushfires and

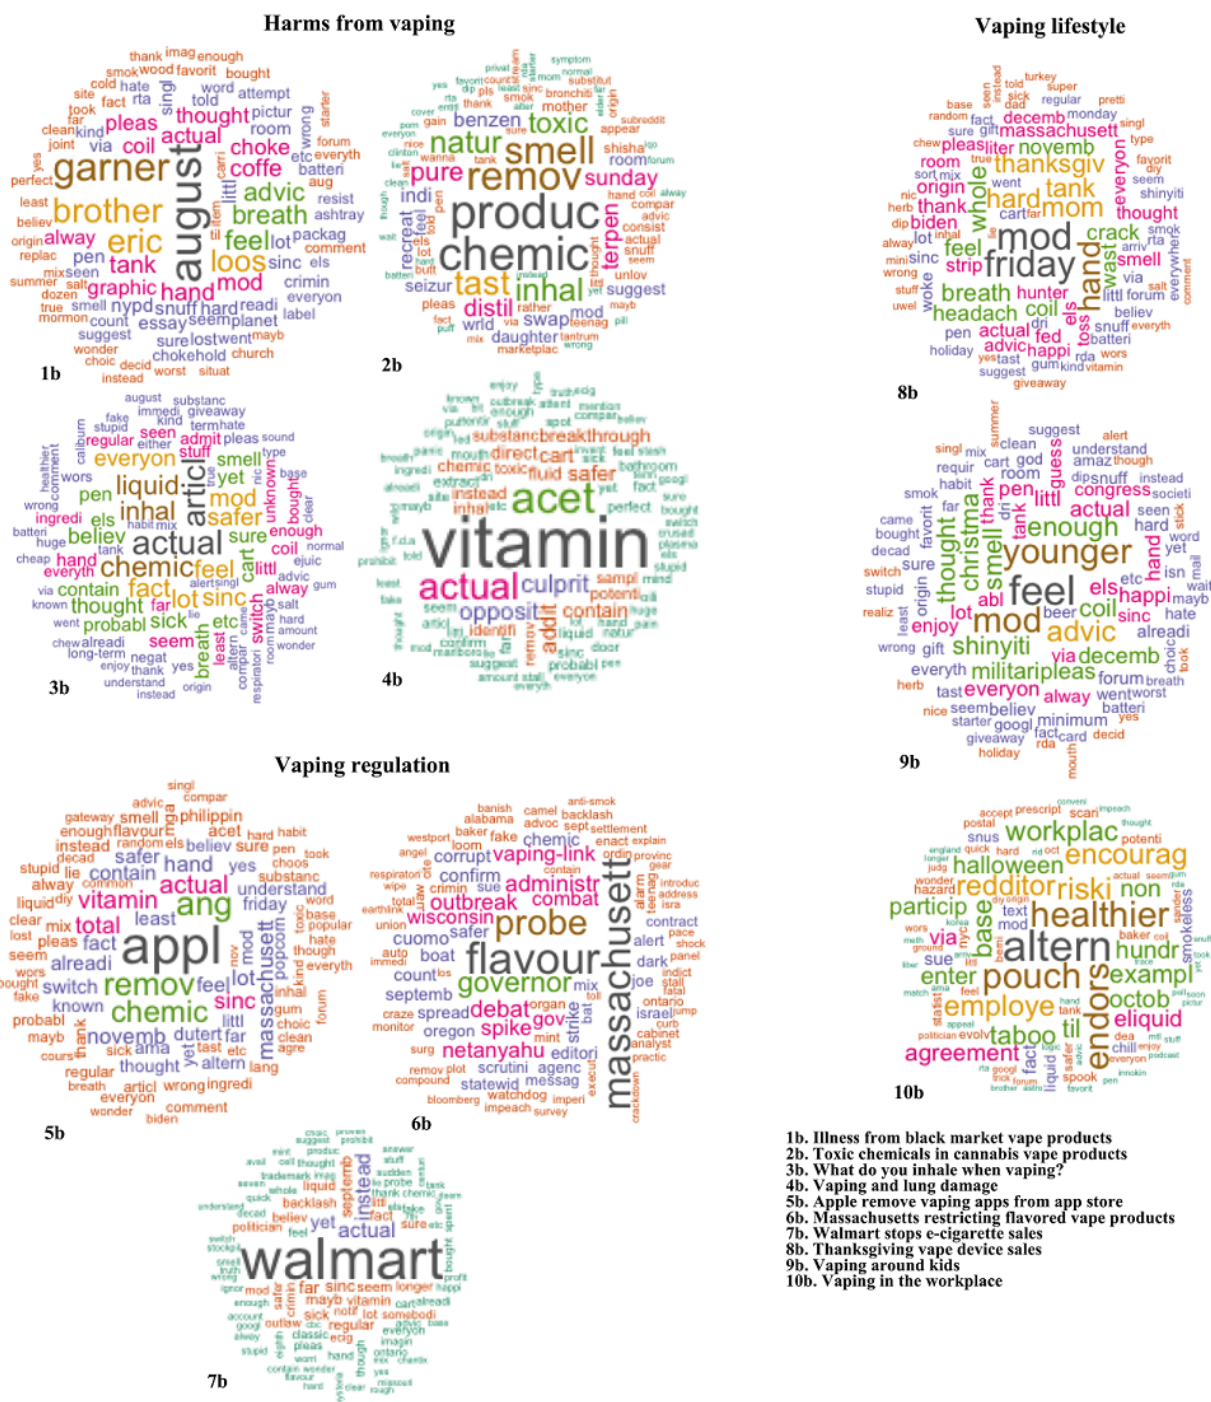

J Med Internet Res 2020 | vol. 22 | iss. 10 | e21743 | p.991  
(page number not for citation purposes)

**Figure 2.** Major archetypes of vaping-related topics with example topics per archetype obtained by structural topic modeling for all observations (August 1, 2019, to April 21, 2020). The word clouds are generated from the weights of the top 100 terms within a topic. Terms with larger weights are depicted in larger font sizes. Terms with approximately the same weight are depicted in the same color.

**Figure 3.** Major archetypes of vaping-related topics with example topics per archetype obtained by structural topic modeling before COVID-19 was reported to the WHO (August 1 to December 31, 2019). The word clouds are generated from the weights of the top 100 terms within a topic. Terms with larger weights are depicted in larger font sizes. Terms with approximately the same weight are depicted in the same color.

**Figure 4.** Major archetypes of vaping-related topics with example topics per archetype obtained by structural topic modeling after COVID-19 was reported to the WHO (January 1 to April 21, 2020). The word clouds are generated from the weights of the top 100 terms within a topic. Terms with larger weights are depicted in larger font sizes. Terms with approximately the same weight are depicted in the same color.

Topic modeling captured significant events in the vaping environment, such as the vaping health crisis and Walmart stopping e-cigarette sales. The vaping health crisis referred to the 2019 emergence of vaping-associated pulmonary injury (VAPI) in the United States [39]. Walmart stopping e-cigarette sales denoted the September 2019 termination of vape sales at Walmart after the advent of VAPI [40]. These were likely significant events in the vaping narrative, as they emphasized the possible harms of vaping and were highly prominent in US media. Accordingly, these events were identified as individual topics. We organized the topics into the following groups or archetypes: Harms from Vaping; Vaping Regulation; Vaping as Harm Reduction or Treatment; and Vaping Lifestyle. We

generated word clouds from the weights of the top 100 terms within each topic, and Figures 2–4 show sample word clouds for each of the three archetypes. Broadly, across the whole time period (Figure 2), the web-based vaping narrative was centered around harms from vaping and vaping regulation. Archetypes pre-COVID-19 (Figure 3) versus during COVID-19 (Figure 4) were largely similar, except that three archetypes were identified pre-COVID-19 (Harms From Vaping; Vaping Regulation; Vaping Lifestyle) but four archetypes were identified post-COVID-19 (Harms From Vaping; Vaping Regulation; Vaping as Harm Reduction or Treatment; Vaping Lifestyle). This suggests that the emergence of COVID-19 is related to the appearance of topics around vaping as a form of harm reduction

or treatment. There was also variation in the topics within an archetype. For example, pre-COVID-19, the Harms From Vaping archetype included topics such as “illness from black market vape products” and “toxic chemicals in cannabis vape products.” After COVID-19 was reported to the WHO, example topics in the same archetype were “vaping and dental health” and “vaping and lung damage.” This suggests that while underlying themes in the vaping narrative are largely stagnant, specific topics in an archetype may vary over time. In line with the difference in archetypes before and during the COVID-19 pandemic, there were also different event-based topics before and during COVID-19. Before COVID-19, several topics represented events significant to vapers in that time period, such as “Walmart stops e-cigarette sales” and “Thanksgiving vape device sales.” These event-related topics were not present after COVID-19 was reported to the WHO. Instead, we noticed new event-based topics, such as “Rush Limbaugh supports vaping” and “disposable vape devices not covered by ban.” After COVID-19 was reported to the WHO, we noticed the emergence of topics specific to COVID-19 that were not present pre-COVID-19. These topics were “vape stores as essential service” (vape stores not being designated as essential services when COVID-19 lockdowns occurred in the United States) and “sharing vapes in COVID-19” (vape devices being possible sites of SARS-CoV-2 transmission). Similarly, a “CBD product preference” topic emerged after the COVID-19 report (Figure 4, word cloud 8c) under the Vaping as Harm Reduction or Treatment archetype that may be related to the advent of the pandemic. As indicated in the Methods section, we removed words around cannabis to provide for more nuanced analysis; accordingly, CBD and other related terms did not appear in the topic-based word clouds. This CBD topic was not present pre-COVID-19. The appearance of the “CBD product preference” topic may be related to vapers using CBD as a treatment for COVID-19. As a validity check, we examined the top 50 associated documents for the “CBD product preference” topic to validate the substantive meaning of the topic. Convenience sampling was not used to sample the top 50 topics; instead, we used the theta values of the topics, as detailed earlier. The number of top-ranked documents to be sampled was based on the methodology outlined earlier. There were 114,622 documents in total for the “CBD product preference” topic. These documents were read by two of the authors to determine validity. A third author resolved disagreements where necessary. As indicated above, interrater reliability was not used. We found that a majority of these top 50 documents (31, 62%) detailed CBD administered through vaping as a possible COVID-19 cure or protective agent. Example text fragments regarding how vaping CBD can prevent or treat COVID-19:

*Pot smoke is the best expectorant I've ever used and fresh cbd oil or weed brownies are verrrrrrrry healing, promotes good sleep and good healing. If you are a non-smoker, tobacco smoke should help you clear out your lungs if you have nothing else.* [March 10, 2020]

*COVID-19 deaths invariably involve a "cytokine storm," an excessive, un-checked immune system response. Cannabinoids from cannabis, cbd in*

*particular, can lower cytokine production naturally. research needed asap!* [March 25, 2020]

Example text fragments regarding websites marketing CBD for COVID-19 prevention or treatment:

*Why hemp cbd flowers and a vaporizer are the best COVID-19 coronavirus prepping tools.* [February 18, 2020]

*REDACTED COMPANY NAME applauds the use of cbd during the coronavirus outbreak* [March 30, 2020]

*Toronto-based cannabis seller testing cbd's effectiveness on reducing symptoms of coronavirus.* [April 1, 2020]

## Discussion

### Principal Findings

Our main finding was the emergence of discourse around vape-administered CBD treatment for COVID-19 when comparing web-based vaping narratives before and after the outbreak of COVID-19. Recent work suggested that CBD use may increase COVID-19 risks [41]. Other studies indicated that CBD may aid COVID-19 treatment outcomes [12,42]. Vaping CBD products as a treatment for COVID-19 is still largely unsubstantiated. Beliefs around CBD as a COVID-19 treatment, bolstered by marketing campaigns and early-stage research [11,12,42], may be responsible for the emergence of discussion around CBD.

There is limited empirical research on the intersection of the vaping narrative and COVID-19, especially around the emergence of CBD-related COVID-19 treatments and comparing the narratives before and during the COVID-19 pandemic. The role of web-based narratives in tobacco control, especially within social media, is a growing field of study [43]. We expand on past work that used novel computational approaches to examine trends in digital media to understand how these web-based behaviors may influence health behaviors [44,45]; our results indicate that the web-based environment is key to comprehending vaping and related health outcomes, especially in response to public health events. Previous research suggested the need to monitor social media content around tobacco to protect youth and mitigate tobacco use [43]. We expand on these studies, bolstering the need to surveil web-based tobacco content given our findings around increased discussion of inaccurate COVID-19 vape-administered treatments that are not evidence-based and may worsen health outcomes. A recent review detailed the role of misinformation in public health outcomes [17], and we expand on past work by providing evidence of how large-scale events may create misinformation in the health sphere. The strength of this study is our use of innovative computational methods to explore the content of the vaping narrative and how it is affected by COVID-19, comparing narrative content before the COVID-19 outbreak and after the pandemic took shape. This outcome measurement is key to understanding how vapers respond to COVID-19, enabling optimized treatment of vapers who develop COVID-19, and possibly minimizing instances of inaccurate information.

Our findings around the use of CBD as a non-evidence-based and possibly injurious COVID-19 treatment, likely administered through vaping, are indicative of the earlier discussed point. Inaccurate information on the internet may create complications in COVID-19 treatment. Vapers who develop COVID-19 may use vape-administered CBD treatments; meanwhile, CBD is associated with reduced immune system functioning [41] and may heighten the disease progression of COVID-19. It is possible that upon contracting COVID-19, people may use vape devices to administer medication to themselves. Given the possibility of device malfunction [46,47], some individuals may further harm their health if they develop COVID-19 symptoms. As levels of misinformation around devices as a means to administer purported COVID-19 treatments increases, more people may share these modified devices; this creates possible sites of transmission [9,48] and may further increase SARS-CoV-2 transmission rates.

If health care professionals are aware that vapers with COVID-19 may use CBD as a treatment based on inaccurate information, these professionals may be better able to respond to vapers with COVID-19 who demonstrate CBD-related complications. Professionals can provide accurate information regarding COVID-19 to vapers who seek health care. Misinformation can also be combated with trusted information. Public health authorities can include COVID-19-specific information in targeted vaping-related messaging, perhaps mitigating consumption of inaccurate web-based information. Information-based campaigns can target inaccurate information in line with the topics identified by our results, such as vaping CBD as a COVID-19 treatment. There are several experimental interventions around reducing levels of inaccurate information [49,50], with some centering specifically on COVID-19 [51] and other health issues [17]. Interventions that harness similar techniques, such as asking respondents to judge information accuracy, may nudge individuals toward obtaining accurate information around COVID-19 and vaping. Interventions can also center on vaping-related health literacy in various media outlets, which may reduce misinformation about the topic [52]. Thus, our results may improve COVID-19 treatment for individuals who may have received inaccurate information around COVID-19 and vaping; they may also provide insight on reducing levels of misinformation among vapers during the pandemic.

Our findings have several implications. From a policy standpoint, we suggest that vaping forums be mandated to provide accurate data around the interactions between vaping and COVID-19. These efforts may reduce levels of inaccurate information around COVID-19 and vaping and may minimize any COVID-19 complications associated with vaping. Future research can identify changes in the vaping narrative as the pandemic progresses further, allowing public health authorities to adjust treatment provision for vapers at risk of contracting COVID-19. Future work can also address how inaccurate information on the internet can be mitigated, especially as the pandemic progresses.

### Limitations

Our results depended on the validity of the data collected through our textual query. We searched a wide range of web-based media and identified key themes that validated our results (eg, Walmart stops e-cigarette sales, Vitamin E acetate and vaping illness), and we are thus confident in the comprehensiveness of our data. We may have overlooked some slang terms for vaping and thus underestimated the web-based narrative. We did not obtain location data for individual text fragments; thus, we were not able to determine how COVID-19 cases in certain areas affected the narrative. Our data were drawn from August 1, 2019, to April 21, 2020, and we were not able to determine changes in the narrative after April. We were not able to collect all web-based vaping chatter and may have missed some themes. In future research, we will collect qualitative and survey data from vapers to enhance the current findings. We did not use interrater reliability for our qualitative analysis, and we will use such methods in future research.

### Conclusions

We demonstrated the advent of discourse around vape-administered CBD treatment for COVID-19 by comparing the web-based vaping narratives before and during the COVID-19 pandemic. The increase in CBD-related discussion within the vaping narrative may be due to the marketing of CBD products consumed through vaping as a COVID-19 treatment [11]. Our findings have implications for the management of COVID-19 among vapers and for monitoring of web-based content pertinent to tobacco.

### Acknowledgments

This study was funded by The Foundation for a Smoke-Free World. The funding body had no role in the design, analysis, or interpretation of the data in the study. This study was preregistered on the Open Science Framework (DOI 10.17605/OSF.IO/XBVF2).

## Abstract

**Background:** One of the key mandates of the World Health Organization (WHO) is to develop guidelines, defined as “a document containing recommendations for clinical practice or public health policy.” Guidelines represent the global standard for information sources shaping clinical practice and public health policies. Despite the rigorous development process and the value of guidelines for setting standards, implementing such standards within local contexts and at the point of care is a well-documented challenge. Digital technologies enable agile information management and may facilitate the adaptation of guidelines to diverse settings of health services delivery.

**Objective:** The objective of this paper is to detail the systematic and iterative process involved in transforming the WHO Antenatal Care (ANC) guidelines into a digital decision-support and patient-record application for routine use in primary health care settings, known as the WHO digital ANC module.

**Methods:** The WHO convened a team of clinical and digital health experts to develop the WHO digital ANC module as a tool to assist health care professionals in the implementation of WHO evidence-based recommendations for pregnant women. The WHO digital ANC module's creation included the following steps: defining a minimum viable product (MVP), developing clinical workflows and algorithms, algorithm testing, developing a data dictionary, and the creation of a user interface or application development. The overall process of development took approximately 1 year to reach a stable prototype and to finalize the underlying content requirements of the data dictionary and decision support algorithms.

**Results:** The first output is a reference software reflecting the generic WHO ANC guideline content, known as the WHO digital ANC module. Within it, all actionable ANC recommendations have related data fields and algorithms to confirm whether the associated task was performed. WHO recommendations that are not carried out by the health care worker are saved as pending tasks on a woman's health record, and those that are adequately fulfilled trigger messages with positive reinforcement. The second output consists of the structured documentation of the different components which contributed to the development of the WHO digital ANC module, such as the data dictionary and clinical decision support workflows.

**Conclusions:** This is a novel approach to facilitate the adoption and adaptation of recommendations through digital systems at the health service delivery level. It is expected that the WHO digital ANC module will support the implementation of evidence-based practices and provide information for monitoring and surveillance; however, further evidence is needed to understand how the WHO digital ANC module impacts the implementation of WHO recommendations. Further, the module's implementation will inform the WHO's ongoing efforts to create a pathway to adaptive and integrated (Smart) Guidelines in Digital Systems to improve health system quality, coverage, and accountability.

## Introduction

One of the key mandates of the World Health Organization (WHO) is to develop guidelines, defined as “a document containing recommendations for clinical practice or public health policy” [1]. These recommendations aim to assist policymakers and clinicians in making an informed decision on whether to undertake specific interventions based on an assessment of the anticipated impact, values and preferences, and use of resources [1]. For WHO and other institutions, such as the Institute of Medicine (IOM) and the National Institute for Health and Care Excellence (NICE), the development of guidelines entails a structured process and an underlying evidence base to support the formulation of recommendations [1,2]. As such, guidelines often represent a global standard and credible information sources for shaping clinical practice and public health policies.

Despite the rigorous development process and the value of guidelines for setting standards, applying global recommendations within local contexts and at the point of care is a well-documented challenge [2-9]. These challenges arise from both systemic issues (such as a lack of supplies, poor staff training, excessive workload, high staff turnover, lack of quality data collection, and difficulty monitoring clinical practice [7]) and barriers in accessing and interpreting recommendations during routine clinical and public health practice. Furthermore, a guideline alone is not sufficient for changing entrenched practices and often requires a combination of implementation strategies, including educational and training materials, convening conferences and meetings, auditing and providing feedback, encouraging the participation of opinion leaders, and other approaches [10]. Lastly, the variability and complexity of local conditions require significant adaptations of global guidelines, thus driving a push towards more agile, adaptive, and efficient approaches enabled by digital technologies to implement guidelines at local levels.

A complementary approach to overcoming some of the constraints associated with diffusing and incorporating static guideline recommendations into the delivery of health services is to utilize digital technologies. In particular, digital

decision-support systems have emerged as an innovative mechanism to facilitate the uptake of guideline recommendations and reinforce adherence to clinical practices at the point of care [3,11-13]. Digital decision support consists of digitized job aids that can combine an individual's health information with the health worker's knowledge and clinical protocols to assist health workers in making diagnosis and treatment decisions [11,14,15]. Different forms of digital decision support include prompts and alerts based on a clinical algorithm, checklists according to a clinical protocol, and screening tools to identify risk and prioritize patients. Increasingly, digital decision support tools are being integrated with patient record systems to promote continuity of care and provide a more comprehensive history of the patient to bolster clinical decision-making. Despite the increasing availability of decision support systems, the accuracy of the underlying health content and adherence to the WHO (or other national bodies) guideline recommendations cannot always be verified. As such, WHO's role in monitoring the adaptation of guidelines in digital form is a necessity.

In November 2016, the WHO published the first evidence-based guideline on antenatal care (ANC), entitled “WHO Recommendations on Antenatal Care for a Positive Pregnancy Experience” [16]. This guideline is a comprehensive document with 49 recommendations, encompassing nutritional interventions, maternal and fetal assessment, preventative interventions, common physiological symptoms, and health system interventions [17]. The recommendations ensure quality care throughout pregnancy and are based on a holistic consideration of comparative effects, values, resources, equity, acceptability, and feasibility [17].

While this guideline serves as the global standard for managing routine ANC, the guideline development team recognized that its adoption and uptake would be limited without effective implementation strategies. Considering the increasing ubiquity of mobile devices [18] and emerging uses of decision support tools, the guideline development team embarked on developing a digital decision support and health record module, which would contain the recommendations for routine use at the point of care. However, the structure of the ANC guideline, as with many other guidelines, did not readily lend itself for directly

encoding into a digital system and therefore required an additional year-long process to extract the recommendations for use in a point-of-care digital system [3,6].

This paper details the systematic and iterative process involved in translating the WHO ANC guidelines into a digital decision-support and patient-record software intended for routine use in primary health care settings, hereafter referred to as the WHO digital ANC module. By describing the methods and outputs, this paper aims to offer a replicable model for distilling and optimizing guideline content for digital systems.

## Methods

### The Process

The distillation of the ANC guideline content for a digital decision-support and client-record tool required a multidisciplinary team and a series of sequential but iterative steps. These steps, detailed below, include defining a minimum viable product (MVP), developing clinical workflows and algorithms, algorithm testing, developing a data dictionary, and the creation of a user interface or application development. The overall process of development took approximately 11 months to reach a stable prototype and finalize the underlying content requirements of the data dictionary and decision support algorithms.

### Establishing Fundamental Principles

The WHO convened a team of clinical and digital health experts (henceforth called “the team”) to lead the process of developing the WHO digital ANC module. In addition to WHO staff representing maternal health and digital health expertise, the team comprised obstetrician/gynecologists from the Brazilian Center for Research in Reproductive Health of Campinas (CEMICAMP, the University of Campinas’ research arm), digital and public health-implementation experts from the SUMMIT Institute for Development, and a technology social enterprise, Ona, which is the lead technology partner developing Open Smart Register Platform (OpenSRP) open-source software. The team worked mostly virtually and held 2 in-person meetings (in November 2017 and February 2018) throughout the development process.

The team’s aim was to develop a tool that assists health care professionals in implementing WHO evidence-based recommendations when providing quality medical care to pregnant women. Initially, the team established fundamental requirements for the digital tool, which would provide decision support and a longitudinal patient record of ANC based on WHO’s evidence-based recommendations. These overarching requirements included being user-friendly and applying human-centered design principles, adaptability to a wide range of contexts (ie, based on the availability of supplies, equipment, and human resources), and the ability to monitor pregnancy progression. Further, the team sought to create a comprehensive digital tool that would be able to link with existing health and logistical management information systems (Health Management Information Systems and Logistics Management Information Systems) and local electronic medical records (EMRs). Additionally, the tool would need to generate information and

monitor the health care process during the pregnancy of all women.

### Defining the Minimum Viable Product (MVP)

To set the parameters for the software’s MVP, the first iteration is designed for the primary health care (PHC) level to generate individual patient information (simple EMR) and to monitor the health care process as services are provided to all women during pregnancy. In line with the WHO recommendations for optimizing health worker roles for maternal and newborn health through task shifting, the ANC module was designed for the health worker cadre at the PHC level, namely, auxiliary nurse midwives, nurses, and midwives [19]. Future iterations, however, will be comprised of interlinked modules for community-level service provision and a patient version for women, allowing for management, feedback, and information exchange.

The first MVP provides decision support through prompts and alerts, checklists, and risk screening by health status based on WHO guidelines and clinical protocols. The WHO digital ANC module is a generic digital tool broadly applicable across all 49 ANC WHO recommendations, focusing on routine ANC (including screening and referral but not treatment for complications). Furthermore, the software documents whether required measures were implemented, and if they were not, then why not, which is important for decision-making, real-time feedback, and quality control. It is, however, customizable to diverse country contexts.

In addition to providing decision support (2.3 of WHO’s Classification of Digital Health Interventions), the module will help PHC workers identify, register, and longitudinally track pregnant women’s health status and services (2.1 & 2.2), as well as support their activity planning, scheduling (2.7), and referral coordination (2.6) [15]. Additionally, in planning for the future, the tool would be established in a way that could eventually employ machine learning algorithms, in anticipation of subsequent incorporation of artificial intelligence and predictive analytics.

### Developing Clinical Workflows and Algorithms

To better understand the standard patient and health worker’s actions during routine ANC contacts, the team developed relevant business processes and workflows (Figure 1) conducted by the PHC worker during ANC service delivery. The WHO’s *Pregnancy, Childbirth, Postpartum, and Newborn Care Guideline: A Guide for Essential Practice* served as a basis for this process, as it describes which procedures should be performed in clinical sequence [20]. While it is expected that each countries’ ANC workflows will vary from this generic idea, the team applied the Pareto principle, in which 80% of the content applies to all settings and 20% must be modified to local needs. Additionally, the workflows and the contact schedule (Figure 2) served as a framework for the module’s content and design.

Initially, for algorithm development, the WHO ANC recommendations were analyzed by 2 independent reviewers (SMH and RTS). Recommendations were identified, extracted, and split into spreadsheets according to their respective areas:

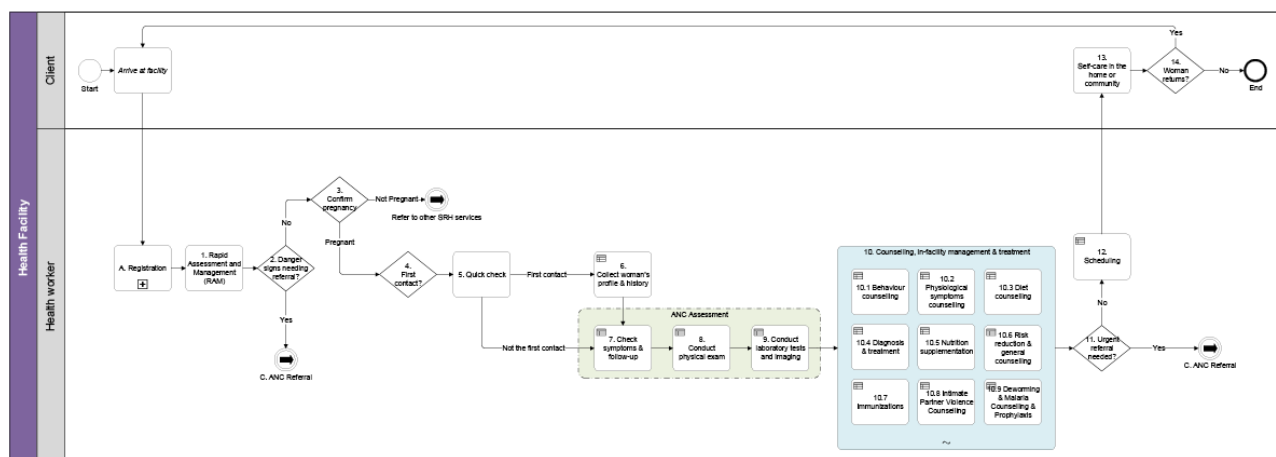

nutritional interventions, maternal and fetal assessment, preventive measures, common physiological symptoms, and health care system interventions. Recommendations were classified in line with the ANC guideline's categorizations: "universal" when they could be implemented in any scenario; "context-specific" when characteristics of the population were necessary to trigger the actions; "context-specific research"

when further studies were needed to formalize the recommendation; and "not recommended" when the action should be avoided due to a lack of a sufficient scientific basis to support its performance.

Upon further review, the team removed the "context-specific research" recommendations from the MVP.

**Figure 1.** The antenatal care (ANC) contact business process. ANC: Antenatal care, SRH: sexual and reproductive health.

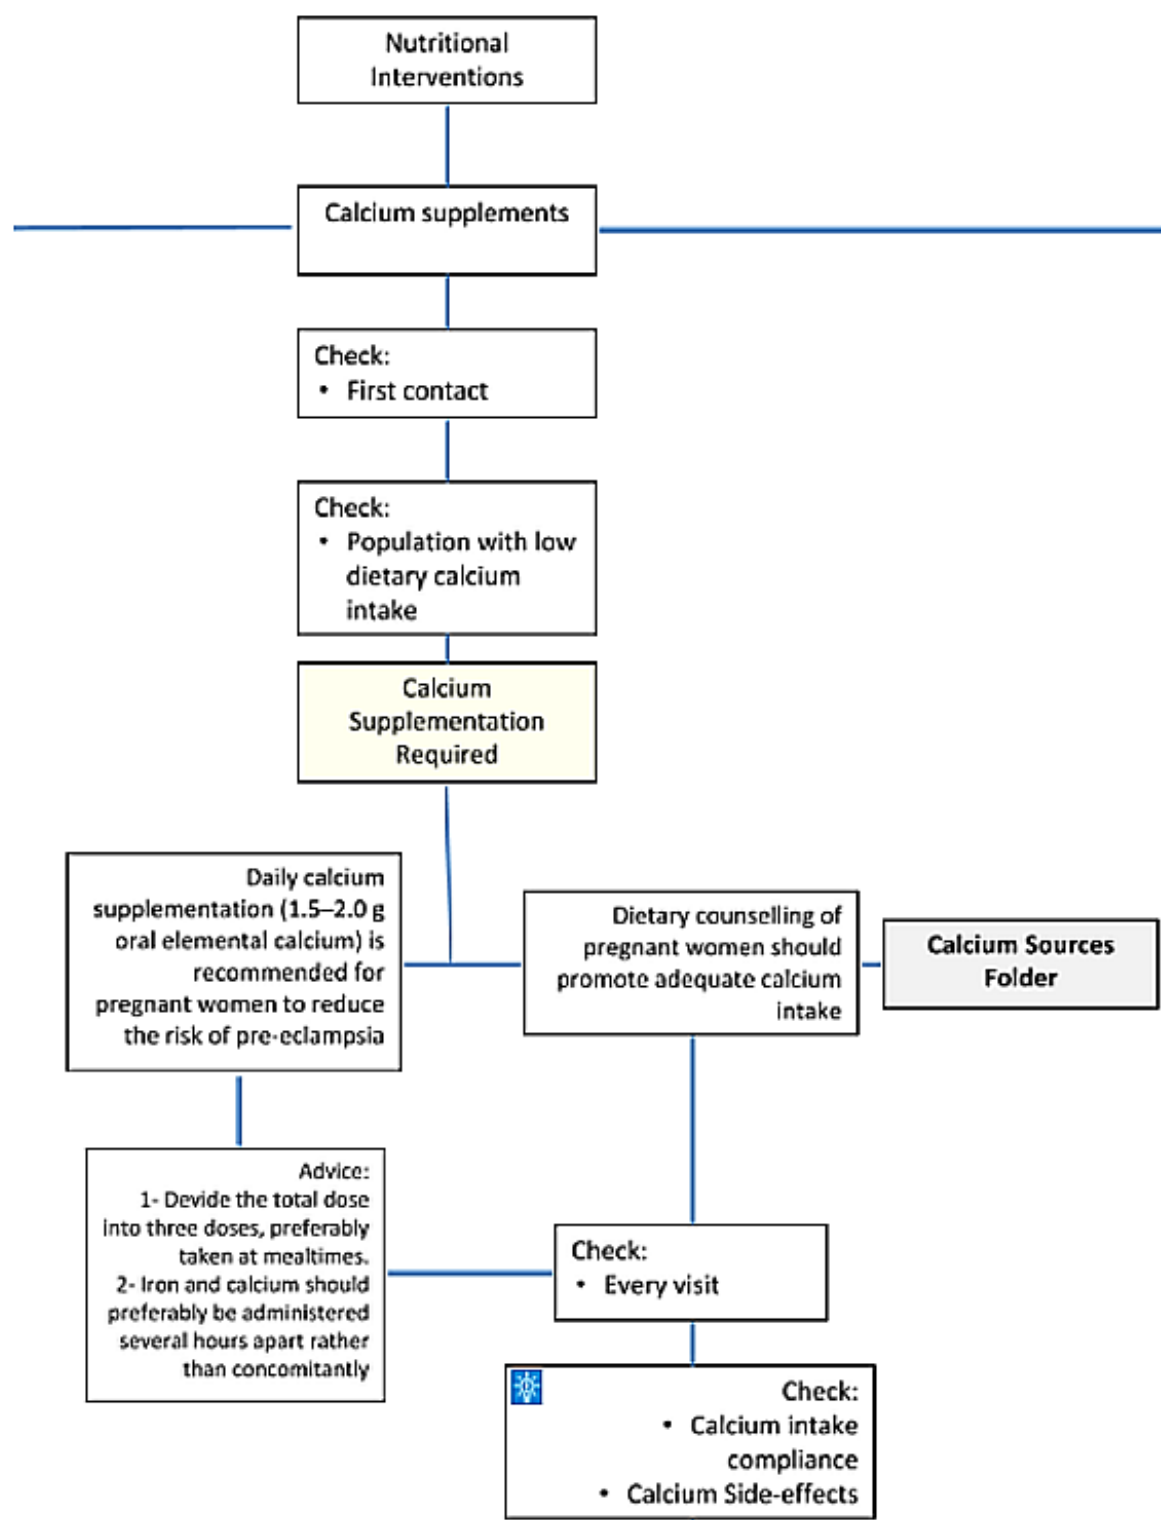

Other official WHO guidelines were consulted for clarification or for additional recommendations considered important for routine ANC (ie, influenza vaccination, pre-eclampsia screening, and hepatitis B and C testing [21-24]). When necessary, some adaptations were made to align with the clinical logic of the ANC service delivery process. These suggestions were assessed and agreed upon by the team. Decision trees were then created for each of the ANC and additional recommendations, considering parameters that trigger action during an ANC contact (for example, calcium supplementation after 20 weeks

gestation in women at high-risk for pre-eclampsia). Decision trees were also shaped by population-level characteristics (eg, folic acid and elemental iron supplementation according to the prevalence of anemia in the population), the local availability of health care equipment (eg, type of urine or syphilis tests depending on the laboratory facilities), and individual-level variables (eg, hepatitis C testing, if injectable drug user). Thus, a single algorithm structure or decision tree was developed to take all of these elements into consideration (Figure 3).

**Figure 2.** Antenatal care (ANC) 8-contact delivery schedule.

Interval Rules & Deviations										
Rule 1	< 20 weeks, contacts should be scheduled every 8 weeks									
Rule 2	≥ 20 weeks, contacts should be scheduled every 6 weeks									
Rule 3	≥ 26 weeks, contacts should be scheduled every 4 weeks									
Rule 4	≥ 34 weeks, contacts should be scheduled every 2 weeks									
Rule 5	if the logic skips the 40 weeks contact, she must come in, so add									
Rule 6	the woman MUST come in at 41 weeks if she hasn't given birth already (however this does not count as an official contact)									
Rule 7	if the woman comes in for the first time at 22 weeks or later, we have changed the logic to increase the number of visits, especially those in the 3rd trimester, as follows: - for women who come in at 22 and 23 weeks (they have one visit added) by increasing visits to every 2 weeks after 30 weeks (rather than 34 weeks) - for women who come in at 28 and 29 weeks (they have one visit added) by increasing visits to every 2 weeks after 32 weeks (rather than 34 weeks) - for women who come in after 30 weeks all her visits are every 2 weeks

### Algorithm Testing

Prior to the software's development, a test version was constructed (by SMH) using Excel resources that included diverse functions linking variables across different worksheets. The first version of the system design was outlined in the Excel testing form, creating an interactive spreadsheet (Figure 4). The testing form displayed real-time clinical diagnoses, the ANC recommendations, and additional guidance on the health care

process, all automatically elaborated by the system during data entry and guided by the logic underlying the clinical algorithms. Initial tests were performed using fabricated patient cases that explored data relative to all algorithms, probing all decision trees. The logic of the algorithm was thus reviewed and corrected, where necessary. Furthermore, the Excel prototype was helpful to visualize how the system could interact with the user in real time as a tool for support in clinical decisions in ANC.

## Development of the Data Dictionary

After a detailed review of the algorithms, the data elements which comprised them were separated into sections, including population and local setting characteristics, socio-demographic data, information on current pregnancy, medical (including immunization) and obstetric history, lifestyle and habits, physiological symptoms of pregnancy, physical examination and laboratory tests, counseling, and treatment. Initially, only data elements required to trigger recommendation-related algorithms were included in the data entry forms. As an example, basic variables for the early identification of sexually transmitted infections (STIs) were included, without further development of the complete algorithm for the differential diagnosis and management of these conditions (except syphilis and HIV, which are included in the ANC guidelines). For STIs as well as other issues, algorithms allow for the health worker to identify risk and subsequently support referral for further investigation or treatment.

From these efforts, the team constructed the data dictionary, which is a shared Google spreadsheet that contains all the clinical content and decision-support logic to be used to create

the data entry forms and decision-support workflows in the WHO digital ANC module (Figure 5). At this stage, the team also incorporated additional content in the data dictionary for the complete provision of routine ANC (eg, fetal heart rate, vaginal examination, maternal pulse, blood pressure, and temperature measurement), which are assumed standard clinical practices and therefore are not part of the ANC guidelines. The data dictionary served as the primary technical requirement for the software developers to build the MVP.

Additionally, all the variables in the data dictionary were mapped to standardized medical terminology codes, such as the International Classification of Diseases (ICD), Logical Observation Identifiers Names and Codes (LOINC), and Systematized Nomenclature of Medicine (SNOMED). Thus, the team also sought to standardize terminologies to ensure interoperability and ease of data aggregation for future integration with databases. For clinical care, terminologies are structured vocabularies covering health related concepts, such as diseases, diagnoses, laboratory tests, and treatments, to enable the storage, analysis, and exchange of data in a consistent and standard way [25,26].

**Figure 5.** Data Dictionary - Profile Tab. ANC: antenatal care; GA: gestational age; HIV: human immunodeficiency viruses, LMP: last menstrual period; MC: multiple choice; NA: not applicable; SFH: symphysis fundal height; STI: sexually transmitted infection.

Label	Info Icon	Due	Relevance	Name	Description	Type	Choices	Calculation
<b>CURRENT PREGNANCY</b>								
LMP known?	LMP = first day of Last Menstrual Period. If the exact date is unknown, but the period of the month is known, use day 5 for beginning of the month, day 15 for middle of the month and day 25 for end of the month. If completely unknown, select "No" and calculate GA from ultrasound (or SFH or abdominal palpation as a last resort).	First contact		lmp_known	Whether woman's LMP date is known or not.	MC (select one)	Yes No	
Specify date		First contact	[lmp_known] = "Yes"	lmp	The woman's Last Menstrual Period (LMP) date. This is defined as the first day of her most recent period.	Date		
NA		NA		lmp_edd	Expected Date of Delivery (EDD) calculated from LMP.	Calculation		[lmp] + 280 days
NA		NA		lmp_gest_age	Gestational age (GA) calculated from LMP.	Calculation		(today's date - [lmp]) / 7, shown in weeks and days
Ultrasound done?	An ultrasound is recommended for all women before 24 weeks gestation or even after if deemed necessary (e.g. to identify the number of fetuses, fetal presentation, or placenta location).	First contact		ultrasound_done	Whether or not the woman has had an ultrasound scan done at any point in this pregnancy.	MC (select one)	Yes No	
Ultrasound recommended	An ultrasound is recommended for all women before 24 weeks gestation or even after if deemed necessary (e.g. to identify the number of fetuses, fetal presentation, or placenta location).	NA	[ultrasound_done] = "No" and [site_ultrasound] = 1	NA	An ultrasound is recommended for all women before 24 weeks gestation or even after if deemed necessary (e.g. to identify the number of fetuses, fetal presentation, or placenta location). This informs the health worker to conduct the ultrasound at the health facility.	Toaster Message		
Refer for ultrasound in facility with U/S equipment	An ultrasound is recommended for all women before 24 weeks gestation or even after if deemed necessary (e.g. to identify the number of fetuses, fetal presentation, or placenta location).	NA	[ultrasound_done] = "No" and [site_ultrasound] = 0	NA	An ultrasound is recommended for all women before 24 weeks gestation or even after if deemed necessary (e.g. to identify the number of fetuses, fetal presentation, or placenta location). This informs the health worker to refer the woman to a facility where an ultrasound machine is available.	Toaster Message		
Ultrasound date		NA	[ultrasound_done] = yes	ultrasound_date	Date that the ultrasound was done.	Date		
GA from ultrasound - weeks		NA	[ultrasound_done] = yes	ultrasound_gest_age_wk	Gestational age in weeks from ultrasound.	Integer		
GA from ultrasound - days		NA	[ultrasound_done] = yes	ultrasound_gest_age_days	Gestational age in days from ultrasound.	Integer		
NA		NA	[ultrasound_done] = yes	ultrasound_gest_age_concept	Gestational age (in weeks) calculation used for GenIRS concept mapping. Decimal field.	Calculation		[ultrasound_gest_age_wk] * 7 + [ultrasound_gest_age_days] / 7

## Creation of User Interface and Application Development

As content was being developed in the data dictionary, the team also began creating mockups of the module's user interfaces, which allowed team members to collaboratively discuss, iterate on, and come to a consensus on the design and workflows required for the MVP. As the data dictionary content was completed over time, the team was able to enrich the interface designs with plausible clinical content, which further allowed for testing the designs with additional collaborators, including medically trained colleagues at the WHO and the Center for Research in Reproductive Health of Campinas (CEMICAMP), to elicit better feedback. During this iterative process, mockups were shared and discussed on Marvel [27]. After several rounds of feedback and iteration, the data dictionary and mockups were approved, which allowed the software development of the module to begin building it.

## Results

### Outputs

The methods described above resulted in 2 outputs. The first output is a reference software reflecting the generic WHO ANC guideline content, known as the WHO digital ANC module. The second output consists of the structured documentation of the different components which contributed to the development of the WHO digital ANC module, such as the data dictionary, clinical decision-support workflows, and mockups.

### WHO Digital ANC Module

The current version (1.0) of the WHO digital ANC module allows health workers to manage their patients' records as well as filter for women diagnosed with certain conditions, view attention flags, easily identify women overdue for contacts, and sort entries for gestational age, due date, and first and last name

(Figure 6A). Health workers can also see a summary of a woman's prior contacts and any attention flags; prompts noting conditions for close follow-up (eg, advanced maternal age, twin pregnancy) are highlighted in red (Figure 6B). For further details, all the information from the woman's prior contacts can also be accessed in the profile overview.

During a contact, the health worker can access the landing page (Figure 6C), which groups data entry forms based on the major clinical workflows that were identified during the design phase: Quick Check, Profile, Symptoms & Follow Up, Physical Exam, Tests, and Counselling & Treatment. Within these "containers," all ANC recommendations have a related question to record whether the health worker has performed the associated task. WHO recommendations that are not carried out are placed on a pending list of tasks, and those that are adequately fulfilled prompt a message with positive reinforcement. Other highlighted features include the following:

- Alerts to remind the health worker of a recommended action (eg, "An ultrasound is recommended for all women before 24-weeks gestation or even after if deemed necessary, to identify the number of fetuses, fetal presentation, or placenta location"), to provide positive reinforcement (eg, "Woman is fully immunized against tetanus!"), or to flag a risk (eg, "Pre-eclampsia risk counseling: the use of aspirin after 12 weeks gestation is recommended as well as calcium if low dietary intake area. Please also provide counseling")
- A task list of summarized actions to allow the health worker to identify potentially missed opportunities at the end of the contact, or to be reminded of pending actions (eg, test results that need to be recorded)
- Sparklines depicting trends in certain data elements (eg, weight, blood pressure, symphysis fundal height) (Figure 6D)
- Additional informative materials for health workers regarding nutrition counseling

**Figure 6.** Screenshots of the World Health Organization Digital Antenatal Care (WHO digital ANC) module. A: List of patients; B: Individual patient record summary; C: Home screen; D: Patient contact summary.

In addition, the MVP of the module also contains an interface for the manager at the health facility to set population levels (such as HIV prevalence) and site infrastructure parameters (such as the availability of ultrasound machines). For communication with the pregnant women, the MVP allows for the sending of SMS text messages (if the pregnant woman consents), and in a future version, there would be a complete interface sharing information as well as a virtual “pregnant woman card.” Finally, the MVP seeks to increase the use of data for accountability to drive quality service provision through the automated aggregation of key indicators and to increase the availability of dashboards for use by different stakeholders such as program managers.

### Test Cases

In order to assess the module’s components, 2 researchers (SMH and RS) elaborated 67 clinical test cases. The cases were designed to encompass the largest number of possible scenarios, testing all clinical algorithms. An online database was created using Google Forms, incorporating variables from the data dictionary. The team tested these cases to check the decision-support logic in the module and worked with the software developer to correct any issues discovered.

### Structured Documentation

Throughout the WHO digital ANC module’s development, the team meticulously documented the process for its creation. Firstly, during the definition of the MVP, targeted user personas were defined (PHC workers) and user stories were created (role-play of a typical ANC contact). Secondly, the aforementioned business processes, workflows, and contact schedule set the parameters for the module’s content (Figures 1 and 2). Next, the data dictionary aided in creating the core

data elements needed for the ANC service provision (Multimedia Appendix 1). The data elements linked together through the algorithms (based on the decision trees) and were also elaborated further in decision-support tables (Figure 7). Finally, the module provides a link between an individual’s data elements to the components (numerators and denominators), which constitute established ANC indicators to simplify the data aggregation process.

Beyond making the WHO digital ANC module available as a digital decision-support and client-record tool within OpenSRP, WHO is also making the structured documentation publicly available as digital accelerator kits [28]. This structured documentation is independent of the OpenSRP software and intended to accompany the WHO digital ANC module to assist countries in understanding the underlying data elements and algorithms to facilitate the customization of the ANC module to their context. Additionally, countries that may already have digital systems in place will be able to use the structured documentation (eg, the data dictionary and decision tables) to ensure that the content is aligned with the WHO guidelines, or at least to have a starting point from which they can design the digital system if they choose to use a separate software platform.

These different components of the structured documentation were derived from standardized methodologies in health informatics, most notably, business process mapping notation (BPMN) for the workflows, development of the data dictionary (which is itself a derivative of the XLS form standard), and decision model notation (DMN) for the decision logic. The formulation of the kits’ components was documented by the team, and the process of releasing structured documentation for digital systems is also being replicated across other health domains (eg, family planning, HIV).

## Discussion

There is a growing recognition of the multitude of software applications targeted at health workers [29,30]; however, the WHO digital ANC module reflects a systematic effort to ensure that the latest WHO clinical guidelines are available in digital form for routine use. As such, the distinguishing factor of the WHO digital ANC module is not necessarily the digital functionalities but rather the availability of the 2016 WHO ANC guideline content encoded in a format that countries can readily adapt and incorporate into service delivery [3].

Challenges in translating clinical guideline content to digital systems include potential misinterpretations that may result from not having the precise logic and data elements within the

guideline itself [3,31]. Furthermore, software development companies building digital decision support tools are often required to start from scratch in translating guideline content to digital workflows. With the creation of the WHO digital ANC module and accompanying structured documentation, the challenges associated with misinterpretation of the guideline content or unnecessary replication in distilling the recommendations are thus minimized. In settings where there are no digital systems for routine ANC in place, countries can leverage the WHO digital ANC module as an out-of-the-box generic digital system that can then be easily adapted to their local contexts instead of starting from scratch. Alternatively, in settings where electronic medical records and other digital systems already exist, the structured documentation in the WHO's forthcoming digital accelerator kits can be used to

inform the content within the digital system. Additionally, the ANC digital accelerator kit (upon which the module is based) aims to simplify and standardize individual-level and aggregate data collection, a key component to tracking guideline implementation at national and global levels.

The development of the WHO digital ANC module also resonates with an established approach developed by Boxawala et al [3] to manage the translation of narrative guideline recommendations to digital decision support tools. This framework consists of 4 sequential knowledge layers: the unstructured narrative recommendation as written in the guideline (Layer 1); a semi-structured derivative of the guideline recommendation in the form of decision trees, flowcharts, and data logic (Layer 2); a computable form of the recommendation represented in software code (Layer 3); and an executable digital decision-support tool that can be used directly by health workers (Layer 4) [3]. In our application of this framework, the WHO ANC recommendations represent Layer 1, the structured documentation of the digital accelerator kit corresponds to Layer 2, and the ANC module consists of Layer 3. Currently, Layer 4 is under development and seeks to translate the ANC recommendations into a computable and coded format that can be directly ingested by a digital decision-support system. This includes Fast Healthcare Interoperability Resources (FHIR), which will be embedded into the ANC module. This will facilitate the export of data in a standardized way for analysis by CQL and other methods optimized for FHIR, increasing interoperability.

Following the completion of the module, the team conducted user testing of the module with nurses and midwives in Indonesia and physicians in Brazil. These professionals were not part of the previous stages of the module's creation. A standardized protocol was developed to train health workers to use the module and elicit feedback from these health workers through focus group discussions and in-depth interviews. From these experiences, feedback was compiled, and the team made changes where deemed necessary prior to the generic version 1.0's release. The WHO digital ANC module (version 1.0) and underlying standardized documentation will be released for

global use to support countries and health care providers to adapt and adopt the WHO ANC recommendations.

We believe that this first version of the WHO digital ANC module is robust; however, future efforts are currently underway to support its implementation in various countries. As part of this process, the team is developing training materials (videos, handbooks, presentations, etc) for health workers at primary health centers. Additionally, a framework and indicators for monitoring, evaluating, and supervising the module's implementation and its impact on health worker performance will be created [32-34]. It is expected that the WHO digital ANC module will support the implementation of evidence-based practices and provide information for monitoring and surveillance; however, further evidence is needed to understand how the ANC module impacts the implementation of the WHO recommendations. The WHO is developing an implementation research study to assess whether the use of the module improves the fidelity to WHO ANC recommendations in various countries.

Ultimately, prescriptive and rigid recommendations are not appropriate or optimal, and over time, the WHO has moved toward context-specific recommendations and has developed tools that allow for the design of health care services based on local settings [35]. However, at the same time, doing so has also changed the complexity of interpreting and implementing recommendations. Digital tools have the potential to facilitate and accelerate the implementation of such guidelines on the ground. The WHO digital ANC module is a pioneering effort to create a roadmap for that process, which will inevitably be needed for policies across other health domains. The adaptive processes required for the implementation of the WHO ANC recommendations were enhanced at each step in the development of the WHO digital ANC module. This is a novel approach to facilitating the adoption and adaptation of guidelines through digital systems at the health delivery service level. The WHO will release the module for countries' adaptation and use. Further, the module's implementation will inform the WHO's ongoing efforts to create a pathway to adaptive and integrated (Smart) Guidelines in Digital Systems to improve health system quality, coverage, and accountability.

## Abstract

**Background:** Antimicrobial resistance is an important global health issue. In Germany, the national agenda supports various interventions to convert habits of antibiotic use. In the CHANGE-3 (Converting Habits of Antibiotic Use for Respiratory Tract Infections in German Primary Care) study, digital tools were applied for information delivery: tablet computers in primary care practices, e-learning platforms for medical professionals, and a public website to promote awareness and health literacy among primary care physicians, their teams, and their patients.

**Objective:** This study is embedded in the process evaluation of the CHANGE-3 study. The aim of this study was to evaluate the acceptance and uptake of digital devices for the delivery of health-related information to enhance awareness and change habits of antibiotic use in primary care in Germany.

**Methods:** This study used a convergent-parallel mixed-methods design. Audio-recorded semistructured telephone interviews were conducted with physicians, nonphysician health professionals, and patients in the CHANGE-3 program. Pseudonymized verbatim transcripts were coded using thematic analysis. In-depth analysis was performed based on the inductive category of information provision via digital information tools. Identified themes were related to the main postulates of Diffusion of Innovations theory (DIT) to provide an explanatory frame. In addition, data generated through a structured survey with physicians and nonphysician health professionals in the program were analyzed descriptively and integrated with the qualitative data to explore the complementarity of the findings.

**Results:** Findings regarding the acceptance and uptake of digital devices were related to three postulates of DIT: innovation characteristics, communication channels, and unanticipated consequences. Participants considered the provided digital educative solutions to be supportive for promoting health literacy regarding conversion of habits of antibiotic use. However, health care professionals found it challenging to integrate these solutions into existing routines in primary care and to align them with their professional values. Low technology affinity was a major barrier to the use of digital information in primary care. Patients welcomed the general idea of introducing health-related information in digital formats; however, they expressed concerns about device-related hygiene and the appropriateness of the digital tools for older patients.

**Conclusions:** Patients and medical professionals in German primary care are reluctant to use digital devices for information and education. Using a Diffusion of Innovations approach can support assessment of existing barriers and provide information about setting-specific preconditions that are necessary for future tailoring of implementation strategies.

**KEYWORDS**

antimicrobial resistance; educative digital solutions; health literacy; diffusion of innovations

## Introduction

### Background

Inappropriate use and prescribing of antibiotics are among the key contributing factors to antimicrobial resistance, which remains an important global health issue. Even after decades of scientific research and a range of improvement programs on the rational use of antibiotics, substantial room for improvement remains in promoting awareness and inducing necessary changes. In recent years, health services research worldwide has focused on interventions aimed at promoting the rational use of antibiotics, usually by providing information and education to health care workers, patients, and the public [1]. Thus, an evidence base has been established regarding the effects of educational interventions targeted at physicians that use internet-based training [2], reflection on habits and behaviors and peer exchange of information [3], changes in provider-patient communication toward participatory decision making [4,5], and involvement of the complete practice team to optimize organizational processes and to ease stress and strain on individuals [6]. Previous studies showed significant effects on decreasing rehospitalization rates and increasing patient empowerment by providing health literacy via tablet computers [7-9]. A recent review concluded that educating patients through smartphone or tablet apps improves treatment adherence and clinical outcomes and has positive effects on health care economics [10]. These studies were conducted in inpatient care settings and primarily aimed to deliver information to patients with postoperative conditions; meanwhile, factors that influence the acceptance and uptake of digital information delivery for promoting awareness and health literacy regarding the rational use of antibiotics in primary care remain less well researched.

In Germany, the national agenda has reinforced policies to restrain the prescription of antibiotics [11]. As in many other countries, approximately 90% of antibiotics are prescribed in ambulatory care, mainly by general practitioners (GPs) [12] and most commonly during 41% of consultations for acute respiratory tract infections (ARTIs), of which only 52% were in accordance with guideline recommendations [13]. In this context, the CHANGE-3 study (Converting Habits of Antibiotic

Use for Respiratory Tract Infections in German Primary Care, 2017-2020) applied a set of educative intervention components, of which several were delivered in digital formats: tablet computers in primary care practices, e-learning platforms for medical professionals, and a public website to promote awareness and health literacy among primary care physicians, their teams, and their patients (see [Multimedia Appendix 1](#) for screenshots). A process evaluation carried out alongside the trial investigated the uptake and diffusion of these interventions, which were novel to the targeted physicians and practices. [Figures 1](#) and [2](#) show examples of the topics covered on the study-specific website.

The diffusion of many innovations starts slowly and then accelerates before slowing again [14]. Diffusion of Innovations theory (DIT) describes the process through which innovations diffuse and become adopted through social networks in populations [14,15]. DIT can support research and program development in assessing and understanding processes that lead to the desired translation of new ideas and technologies into widespread practice [16]. This classic middle-range theory offers concepts and approaches that can explain receptivity of health care practices and policies by individuals and organizations [17]. At the same time, the diffusion approach may help connect “research-based innovations with their potential users in a knowledge-utilization process [14].”

To evaluate the uptake and acceptance of implemented digital information delivery solutions used in the CHANGE-3 study by physicians, care teams, and patients in primary care in Germany, this study integrated an approach based on DIT that addresses three major diffusion postulates: (1) specific characteristics of innovations influence their diffusion (Relative advantage, Complexity, Compatibility, Trialability, Observability), (2) communication channels and key individuals embedded in social networks play an important role, and (3) consequences of the uptake of innovations can be unanticipated. The study primarily focused on the digital information delivery components, as these comprise a new approach to promote awareness and health literacy in primary care in Germany with regard to converting habits of antibiotic use for ARTI.

**Figure 1.** Screenshot of the study-specific website in German (“Fewer antibiotics...more health literacy”).

**Figure 2.** Screenshot of the study-specific website in German (“Fewer antibiotics...more hygiene”).

## Objectives

The aim of this mixed-methods study was to assess the acceptance and uptake of digital interventions for education and information delivery to patients, physicians, and care teams with regard to converting habits of antibiotic use for noncomplicated ARTIs in primary care.

## Methods

### Study Design

This study is part of the process evaluation of the CHANGE-3 study, which was embedded in a two-armed cluster-randomized controlled trial with 57 practices randomized into each group (N=114). Randomization for the trial was stratified by rate of antibiotics prescriptions for ARTIs at baseline per practice and was performed by the Institute of Medical Biometrics and Informatics at the University Hospital Heidelberg [18]. Within the process evaluation and for this study, a mix of quantitative and qualitative methods was used in a convergent-parallel design [19–21] to gain insights into the working mechanisms of the intervention program, which aimed to convert habits of antibiotic use and strengthen health literacy competencies. Complementary interview guides and survey questionnaires were developed and used. Mixed-methods research combines qualitative and quantitative research elements with the aim of expanding and strengthening the conclusion and validity of a study [22]. By applying this design, a broad thematic spectrum could be analyzed to assess and understand factors relevant to the acceptance of digital information delivery with regard to converting habits of antibiotic use in primary care in Germany. The intervention components focused in this study comprised tablet devices with educational contents for patients, an e-learning platform for medical professionals which offered a communication skills training, and the study-specific website on rational usage of antibiotics for both groups (see [Multimedia Appendix 1](#)). The content provided via the tablet presented guideline-based educational videos and information and was adapted from the study-specific website [18,23] and from a similar application developed for a different study [24].

### Context

The comprehensive implementation program composed for the CHANGE-3 study (ISRCTN 15061174) was based on published research and experience in quality improvement programs [25,26], and it was tested in primary care settings. The overall aim of the CHANGE-3 study was to sustainably hinder the progress of antimicrobial resistance by promoting the conversion of antibiotic use habits and to increase health literacy in practice teams, patients, and the general public. To achieve this, a regional public campaign with multimedia approaches was used to encourage the general public's engagement with rational antibiotic use and their active participation in a participatory decision-making process. In addition, an educational practice team intervention targeted internal process optimization in practices using educational intervention components, including digital information devices, individual feedback on prescribing habits, and outreach visits. The process evaluation conducted alongside the implementation program was embedded in the cluster-randomized trial, and we were particularly interested in

documenting the uptake of interventions and understanding the mechanisms and impacts of the intervention components. The study was approved by the Ethics Committee of the University of Heidelberg (reference number S-349/2018). Participants in the process evaluation all gave written informed consent. Confidentiality and anonymity were ensured throughout the study. The planned outcome evaluation, which is not part of the process evaluation, will provide information about effects of the interventions on the prescribing of antibiotics for patients with respiratory symptoms. As the CHANGE-3 study only recently concluded, analyses referring to the outcome evaluation have not yet been completed.

### Survey

After the start of the intervention, all GPs (n=132) and a sample of nonphysician health professionals (n=208), comparable to medical assistants (MAs) in the United States [27], were invited to engage in a survey (T1) in May 2019. The participation of the MAs was restricted to a maximum of 2 per practice with the intention to limit imbalance in the sample and to ensure that the reimbursement budget would not be overdrawn. To be eligible for inclusion, the GPs and MAs were required to be participants in the intervention or control group in the CHANGE-3 study and to have mastered the German language. Based on constructs of the Theoretical Domains Framework (TDF) [28], a study-specific questionnaire was developed and used. It included tailored items to facilitate investigation and understanding of the mechanisms and impact of the intervention components as well as the contextual factors. No patients were invited to participate in this survey, as it focused on the practice teams' perspectives on the applied intervention components. The questionnaire also included items referring to socio-demographic aspects and characteristics of the work environment. Email reminders were sent out after 4 weeks to increase the response rate. In March 2020, all participants who had returned T1 questionnaires were invited to participate in the follow-up survey (T2). No reminder was sent out.

### Interviews

Open-ended, semistructured, guide-based telephone interviews with the GPs and MAs participating in the CHANGE-3 study and a sample of their patients were conducted to explore their perspectives on the applied intervention components in general and the digital information delivery in particular. The interprofessional team of researchers (Health Services Research, Public Health, General Practice) developed study-specific interview guides for the three groups of interviewees (see [Multimedia Appendices 2–4](#) for translated versions). Interview guides were based on constructs of the TDF [28], a literature review, and predefined research questions. All recruits were required to be at least 18 years of age, legally fully competent, and in fluent command of German. The potential recruits considered were GPs and MAs who were participating in the CHANGE-3 intervention group and were working in a primary care practice in the German federal state of Baden-Wuerttemberg or Mecklenburg–Western Pomerania. Invitations to participate in an interview were sent out via the aQua Institute, Goettingen, Germany. Patients who sought treatment for an ARTI during the intervention period at one of the intervention or control

group practices were also eligible to participate in an interview. Using an opt-in approach, selected participating practices could support and initiate patient recruitment by addressing eligible patients. Support material was provided to care teams in these practices and facilitated a structured patient recruitment process.

All interested parties meeting the inclusion criteria received printed material as well as a telephone call from the research team at the Department of General Practice and Health Services Research, University Hospital Heidelberg, Germany, to provide further information. Participants were required to return a signed letter of intent to be included in the process evaluation and participate in the interview. In addition, the interviewees completed a one-time sociodemographic survey. All interviewees and care teams who supported patient recruitment received a small reimbursement fee. The first interview in each group served as a pilot. After that, minor adjustments were included where considered appropriate by the research team. No targeted sample size was set for the interviews, and data were collected until saturation of information was reached.

### Data Collection and Analysis

All T1 and T2 survey questionnaires returned to the Department of General Practice and Health Services Research at the University Hospital Heidelberg by June 2019 and April 20, 2020, respectively, were registered and pseudonymized by an experienced study nurse (T1) and the research team (T2). Support staff recorded all questionnaire data electronically in SPSS version 25 (IBM Corporation). Data were checked for plausibility by two study team members (RPD and LK), and typos were corrected where applicable. Subsequently, the data were analyzed descriptively in SPSS by the same two researchers. For this study, survey data referencing digital information delivery and sociodemographic characteristics were extracted from sets of items of both survey questionnaires (T1, T2) and included for analysis (see [Multimedia Appendices 5](#) and [6](#) for the translated questionnaire items). Survey data were interpreted within the frame of applicable DIT postulates.

Applying a purposive strategy with regard to equal distribution of sex and region, all GPs and MAs in the intervention group were invited to participate in an interview. A sample of 39 interview participants was recruited by the CHANGE-3 study team at the Department of General Practice and Health Services Research, University Hospital Heidelberg, between November 2018 and April 2019. This strategy facilitated identification of individuals who were especially experienced with regard to the phenomenon of interest and supported a detailed understanding

of key themes and relations to specific behaviors and roles [29]. All interviews were conducted via telephone by two members of the research team at the Department of General Practice and Health Services Research, University Hospital Heidelberg. Both researchers had profound experience in qualitative interviewing. All interviews were audio-recorded, pseudonymized, and transcribed verbatim. Data were managed with MAXQDA 2018.2 qualitative data management software (Verbi Software). The qualitative data were first thematically analyzed in a framework analysis based on constructs of the TDF and then combined with an inductive de novo approach according to concepts emerging from the data. To provide an explanatory model, and because most statements appeared to relate to social processes affecting diffusion, the identified key themes were subsequently categorized in accordance with three mirrored DIT postulates: (1) innovation characteristics, (2) communication channels, and (3) unanticipated consequences. All qualitative data generated from the interviews with the GPs, MAs, and patients, the field notes, and the sociodemographic survey were included for analysis. Quantitative and qualitative data were first analyzed separately and then brought together to complement each other.

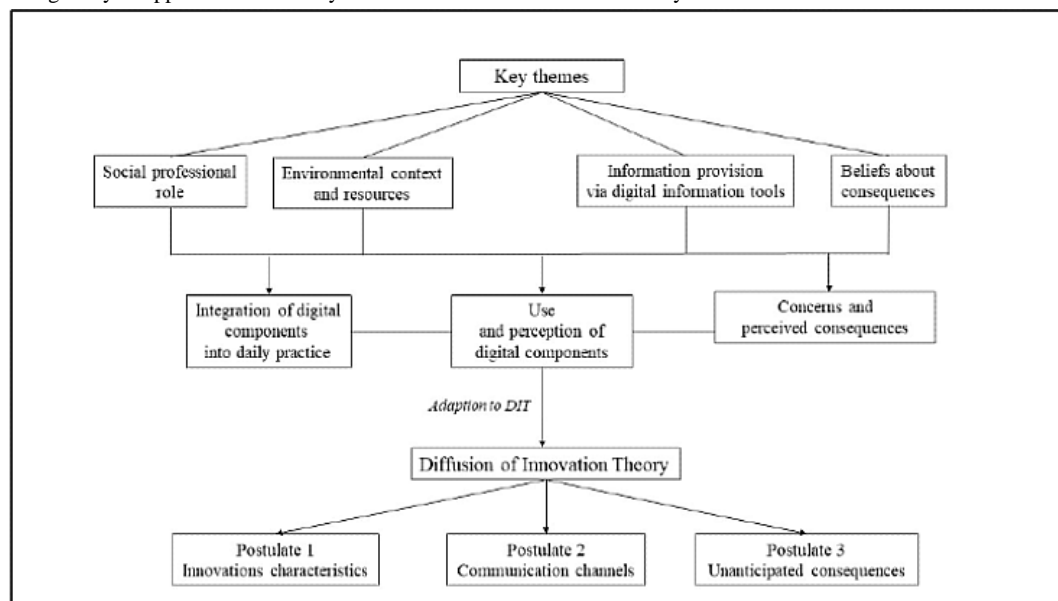

## Results

### Principal Findings

Findings derived from both quantitative and qualitative data are presented with a focus on digital information provision via the intervention components “tablet,” “e-learning platform,” and “website” and are categorized in accordance with selected postulates derived from DIT [13,14]. The postulates relate not only to relevant contextual factors expected to be identified from the survey data but also to perceptions regarding the professional role, beliefs about the consequences of the innovation, and emotions, as derived from the qualitative data.

The theorizing analytical approach of the analysis is shown in [Figure 3](#).

Key themes derived from the TDF provided the framework for the survey questionnaires and interview guides. Relevant contextual factors were identified from the survey data and qualitative data. During the qualitative analysis, the inductive domain “information provision via digital information tools” was added. All data were categorized according to the key themes and subsequently mirrored in the three DIT postulates where applicable to facilitate an explanatory framework for the findings.

**Figure 3.** Theorizing analysis approach of the study. DIT: Diffusion of Innovations theory.

### Sociodemographic Characteristics

A total of 80 GPs and 105 MAs returned the T1 questionnaire (N=185), and 63 GPs and 64 MAs returned the T2 questionnaire (N=127). In the intervention group, the mean age of the GPs was 53.2 years (SD 9.13) in T1 and 54.0 years in T2 (SD 9.70); in the control group, the mean age was 52.7 years (SD 9.6) in T1 and 56.5 years in T2 (SD 8.6). The mean age of the MAs was 40.9 years (SD 11.75) in both T1 and T2 in the intervention group; in the control group, the mean age was 42.0 years (SD 12.1) in T1 and 40.7 years in T2 (SD 11.4). The majority of the participating GPs in T1 were male (24/41, 59.5%, in the

intervention group and 25/39, 64%, in the control group), and the MAs were almost exclusively female (50/50, 100%, in the intervention group and 54/55, 98% in the control group). For T1, 28/41 (68%) of the GPs in the intervention group and 34/39 (82%) in the control group were reported to have implemented changes in their practice routines in the last two years. Additionally, 15/41 (37%) of GPs in the intervention group and 19/39 (49%) in the control group stated that they had participated in previous antibiotics studies. [Table 1](#) describes the characteristics of the participants in the intervention group and control group.

**Table 1.** Sociodemographic characteristics of the survey participants (T1) in this study (N=185).

Characteristic	GPs <sup>a</sup> (n=80)		MAs <sup>b</sup> (n=105)	
	Intervention group (n=41)	Control group (n=39)	Intervention group (n=50)	Control group (n=55)
Age, mean (SD)	53.2 (9.13)	52.7 (9.6)	40.9 (11.75)	42.0 (12.1)
Female sex, n (%)	17 (42.0)	14 (36.0)	50 (100.0)	54 (98.0)
Experience (years), mean (SD)	24.7 (9.6)	23.3 (9.2)	16.5 (11)	17.2 (11.2)
Implemented changes in the last 2 years, n (%)	28 (68)	34 (82)	34 (75)	38 (70)
Participated in another project to improve antibiotic prescribing, n (%)	15 (37)	19 (49)	14 (28)	32 (62)

<sup>a</sup>GPs: general practitioners.

<sup>b</sup>MAs: medical assistants.

[Table 2](#) describes the sociodemographic characteristics of the interview participants (N=39). The mean age of the GPs was 53 years (SD 8.29), with a mean of 24 years of expertise (SD 8.2). Of the 16 interviewed physicians, 13 (81%) had a background in general practice, 2 (13%) had a background in internal medicine, and 1 (6%) was still undergoing specialty training. All the MAs were female (7/7, 100%). The mean age of the MAs was 48 years (SD 11.8), with a mean of 22 years of

expertise (SD 11.8). The average years of employment in the GP practice in which they currently worked was 16.7 (SD 6.1). The mean size of the practice teams was 3 colleagues, GPs excluded. The mean age of the interviewed patients was 36 years (SD 12.2). On average, patients had been consulting their GP for eight years (SD 8). Of the 16 patients, 9 (56%) had ten years of school education.

**Table 2.** Sociodemographic characteristics of the interview participants in this study (N=39).

Characteristic	GPs <sup>a</sup> (n=16)	MAs <sup>b</sup> (n=7)	Patients (n=16)
Age, mean (SD)	53 (8.29)	48 (11.8)	36 (12.2)
Female sex, n (%)	9 (56)	7 (100)	10 (62.5)
Years of expertise, mean (SD)	24 (8.2)	22 (11.8)	N/A <sup>c</sup>

Years of consulting this GP, mean (SD)	N/A	N/A	8 (8)

<sup>a</sup>GPs: general practitioners.<sup>b</sup>MAs: medical assistants.<sup>c</sup>N/A: not applicable.

## Integration and Uptake of Digital Components Into Daily Practice

### Survey Data

In the intervention group, T1 survey questionnaires were completed and returned by 41 GPs and 50 MAs. In the control group, 39 GPs and 55 MAs returned completed questionnaires. In total, 80/132 (60.6%) of GPs and 105/208 (50.5%) of MAs responded.

The uptake of the digital interventions was mixed and was overall limited. In the intervention group, 33/41 GPs (81%) and 36/50 MAs (72%) reported that they had not used the e-learning platform. Of the GPs who had used it, 7/41 (17%) felt motivated to prescribe antibiotics according to clinical guidelines. It was found that 9/41 GPs (22%) and 16/50 MAs (32%) found the tablet to be a helpful device in addressing patients' expectations; meanwhile, 20/41 GPs (49%) and 19/50 MAs (38%) reported that they did not use the supplied tablets at all. When the tablets were offered to patients, 5/41 GPs (12%) and 13/50 MAs (26%) received the impression that patients actually used them and

browsed the provided information. Of the 41 GPs, the study-specific website motivated 15 (37%) to engage in guideline-oriented antibiotic prescribing, helped 19 (46%) address patient expectations, and supported 16 (39%) in their therapy decisions. Some GPs also reported that using the website influenced therapy decisions (12/41, 29%) and led to a reduction in prescriptions (11/41, 27%).

The T2 survey questionnaires were returned by 32 GPs and 32 MAs in the intervention group and by 31 GPs and 32 MAs in the control group. In total, 63/80 (79%) of eligible GPs and 64/105 (61%) of eligible MAs responded. With regard to the e-learning platform, 10/32 GPs (31%) and 2/32 MAs (6%) reported using it. The website was visited by 14/32 GPs (44%) and 13/32 MAs (41%). Tablet devices were used by 15/32 GPs (47%) and 20/32 MAs (63%). Regarding the uptake of the devices, the T2 data confirm the T1 findings.

**Table 3** provides information on the uptake of the three digital components as derived from the survey data. **Table 4** and **Table 5** provide information about the participants' subjective assessment of the intervention components.

**Table 3.** Uptake of digital components in the intervention group of the study, n (%).

### Interview Data

In the qualitative study conducted as part of the process evaluation of the CHANGE-3 study, a total of 39 telephone-based interviews were carried out with GPs (n=16), MAs (n=7) and patients (n=16). The average interview duration was 22.1 minutes (SD 6.21). Selected quotes supporting key statements are provided below with indications of the participant group and transcript position. Additional quotes are provided in Appendix 7.

### Uptake of Digital Components in Daily Practice

During the analysis of the interview data and the identified key themes, reluctance toward integrating the tablet intervention component into daily practice became apparent. In relation to DIT Postulate 1, “innovation characteristics,” the following section links this reluctance to use tablet devices with the five innovation characteristics from DIT.

The GPs raised concerns regarding the *compatibility* of their professional values with the digital devices. Of the 16 GPs interviewed, 6 (38%) articulated a conscious decision not to use the digital information tools. They saw their medical practice as a place of tranquility, where patients have the opportunity to calm down during times when they are constantly flooded with information. Moreover, 4/16 GPs (25%) raised additional concerns regarding the usage of the tablets, as they perceived themselves as the prior channel of information for patients and strongly saw themselves in the role of an adviser. They assumed that even younger patients would prefer advice from human beings, which may reflect an unclear *relative advantage* of the tablets. The MAs shared these opinions; however, they also addressed aspects referring to the quality of generally available information that is obtainable via digital sources. The patients suggested that using a television screen could be more appropriate for waiting areas. A subjectively perceived want of *observability* appeared to also foster reluctance toward using the devices. Referring to the required comprehension skills, one GP raised *complexity* concerns of potentially excluding older patients by using tablets; this GP mentioned that with the aim of equal treatment, tablets should not be used regularly for information delivery in primary care until a complete generation change has been accomplished. *Trialability* considerations did not seem to be relevant. In summary, the GPs expressed that the tablets did not play a major role in their approach to patient-centered information delivery.

*I think people already are getting bombarded enough with this stuff. I don't want that in the practice here. We actually also have a ban on mobile phones here. So, of course you can play around on your mobile phone, but you must not talk on the phone [...] I believe that this is also quite good for the patients if they come to rest for a few minutes in the waiting area. In this respect, I don't see a place for it in my practice now. [GP 14, #64]*

*And I also don't want my older patients in particular to have the impression that “This is something that I can't go along with anymore[...].” [GP 09, #21]*

*In my opinion, we already have enough gadgets like computer, tablets and so forth where patients can inform themselves, and some of them show up here with preconceived opinions about their conditions and how to treat them. You have to be a little careful there. [MA 03, #46]*

*I believe, it rather makes sense to offer a TV or something bigger where information is permanently running, because otherwise, just one person at a time is able to use it [tablet], which does not make a lot of sense then, or a constantly changing display of information everybody can follow would make more sense. A tablet doesn't change much, I guess. [Patient 02, #32]*

### Use and Perception of Digital Intervention Components

Although the provision of the digital information tools was communicated to all participating GPs and MAs, their recollection of this was limited. The following section reflects statements from interviewed GPs and MAs who were aware of the presence of the digital information tools. We also include hypothetical statements from participants who did not encounter the intervention components. All these statements provide insight into the beliefs of the study participants about the appraisal of digital devices and the dissemination of information about these devices.

Awareness of the provided e-learning module was limited. Only 2 of the 16 interviewed GPs (13%) described in-depth use of the provided e-learning platform and considered it to be helpful in counselling situations. The communicative elements were seen to be helpful in dealing with patients' potentially unwarranted expectations. Only one GP categorized the illustrated situations as unrealistic; however, they still considered

them to be helpful to highlight specific situations. The MAs did not describe using the e-learning module at all.

*Yes, very staged scene, but to make it clear to you, I thought it was good. [GP 06, #42]*

*Ah yes, so you just say, let's say, not affront the patient somehow and so you just indirectly say that people who have certain expectations or who want to think an antibiotic now would just lead faster to their goal to get well again, so these communication-related aspects were very helpful. [GP 02, #18]*

The website was visited by only a few of the interviewees. Time constraints and a lack of awareness of the existence of the website were mentioned as the main reasons for not using it, pointing to potentially insufficient introduction and communication. However, the design of the website was described as visually appealing, yet overloaded with information. All the participants considered an educational website providing clear and relevant health-related information to be an asset; however, they assumed that age-related preferences were in place.

*Yes, I am aware of it, but I did not visit it [website] yet. [MA 01, #78]*

*No, somehow that [website] went right past me. [GP 18, #54]*

*You could click on different topics, short and concise, attractively constructed, but I would have arranged it in a little less cluttered way, less information then. Yes, but overall it is attractively interesting, you readily want to engage with it. Well, "Oh, what's this," have a brief look. [GP 09, #9]*

Patients who had not yet had the opportunity to use the tablets were asked how they would envision provision of health-related information to patients in general practices. Of the 16 patients, 7 (44%) named tablet applications as potential information tools and demonstrated an open-minded attitude toward the digital provision of health-related information. Four of the 16 patients (25%) did not share their opinion, and 6 (38%) demonstrated a somewhat hesitant attitude toward digital devices. One patient saw the opportunity to use the tablet as a tool to prospectively retrieve information about the recommended usage of antibiotics. Regarding a potential lack of knowledge, this would provide the opportunity to avoid uncomfortable situations during consultation with the GP, potentially shorten the consultation, and allow more time to address unclear aspects and remaining questions. In contrast to this, another patient stated having no interest in health information provided by a tablet solution when having a cold and feeling sick. Furthermore, 5/16 patients (31%) considered televisions in waiting areas of medical practices to be a suitable alternative information tool. The website was considered to be an option for younger adults, and suggestions were made as to where such a site could be referenced.

*I am not sure. I mean, when I'm sick, I am really sick and when I'm sitting there, I personally have no interest in reading information on tablets. [Patient 17, #77-78]*

*By the help of information leaflet, right. It has to be printed on them so people can find the website. That's a possibility that spontaneously popped into my head. [Patient 12, #73]*

In addition, another patient pointed out the difficulty of staying in line with the received information if a GP acts contrary to the recommendations. When in doubt about the treatment, standing up against a physician and refusing an antibiotics prescription was considered to be difficult, especially in situations where no laboratory results were available. In this scenario, to be on the reputed "safe side," the patient would prefer to go along with the GP's decision.

*Because you go to the doctor and when he says: "Ah, well antibiotics are necessary," then you say: "Yes, well, then I will take them." So, I just have to come back to the ENT especially, because he hasn't taken a smear or anything else, for example, he just determined that: Chronic sinuses: antibiotics. And yes, it didn't do anything either. [Patient 03, #42]*

GPs and MAs noticed implications for their daily routines, which they attributed to participating in the study in general and to using the digital information devices in particular. Of the 7 MAs, 4 (57%) saw an impact of using the tablets on their daily routines. The main influence was seen in communication with patients. With the help of the devices, the MAs felt it was easier to convey the importance of antibiotics-free treatment to patients. Additionally, they saw the opportunity for patients to inform themselves prospectively, which was considered to lead to a decline in the number of necessary consultations. Additionally, the MAs described a broad range of assumptions and beliefs about the tablets' influences on their own knowledge gain. This extended from the feeling of "no influence at all" to the feeling of having "increased confidence" regarding the usage of antibiotics. GPs saw changes in their communicative interactions with patients and considered their participation in the CHANGE-3 study to have led to notably more forthright debates about the relevance of antibiotics. They reported that they had started to address patients' perceptions regarding the prescription of antibiotics more directly. Patients only hypothetically contemplated the potential effects of the digital provision of health-related information in primary care practices.

*Well, you actually ask the patients more often, right? "Do you expect an antibiotic?", you also say right away "viruses are not antibiotics accessible!", you discuss that simply more offensively, right? You also assume somehow that it is clear, but to most people it is not clear at all, perhaps one is too much in one's own world and perception, right? - you simply integrate this more obviously in the conversation. [GP 01, #22]*

*So, I think definitely better than before. I think you can always learn something and I definitely feel confident and literate [enough] in this topic to be able to also give the best possible advice to the patients. [MA 05, #34]*

## Concerns and Perceived Consequences

Unanticipated concerns and consequences which had not been considered beforehand emerged from the data and appeared to have a major impact on the participants' reluctance to use digital information tools. To begin with, the influencing factors were organizational in nature and addressed daily routines in general practices; hygiene issues were mentioned as a major factor that obstructed the use of tablets. GPs as well as patients articulated concerns about using tablets in a public waiting area with regard to keeping them clean and disinfected. While patients' concerns referred to the potential risk of infection, the GPs also contemplated the proper provision of disinfection wipes next to the devices. A noticeably low technology affinity led to reduced use of the tablets, the e-learning module, and the study-specific website. The e-learning platform provided video-based situations to all GPs in the intervention group to illustrate potential difficulties in provider-patient communication and in addressing patients' expectations; however, it was only used by a small number of participants. The GPs and MAs did not extensively familiarize themselves with the study-specific website. Thus, it was referred to only on occasion, and patients were not systematically made aware of it.

*Yes, I would ask myself: "How many people touched it before me?" I wouldn't touch that honestly. Well, and I don't know how often [...] it might get disinfected once a day, but if there are five people alone with a flu virus somehow and then it's not the same strain, yes, well [...] well, I do not support it. [Patient 11, #54]*

*So, on the one hand I find it problematic, also because everyone is tapping on it and also from the hygienic aspect I should actually put disinfectant wipes next to it [...] [GP 09, #21]*

Another unanticipated aspect was the perception of intensified time constraints in the usage of tablets. The MAs felt pressured to find time to incorporate the tablets into their daily routines. For them, the intervention component represented an additional task for which they felt responsible. The GPs and MAs both contemplated whether the amount of time a patient spends in the waiting area was sufficient for proper knowledge transfer. From their perspective, the value of tablets as an information tool did not justify investing the scarce resource of time into efforts to brief patients about the proper usage of the devices.

*Well, that would tie up far too much time at the front desk, if a MA first has to explain what to do with the tablet, then she has to collect a deposit for it and then return it, disinfect it, that would tie up far too much MA working time, so we didn't use it. [GP 04, #22]*  
*[...] at our place, patients often don't have much time in the waiting area to deal with it [tablet] because they don't sit [and wait] that long [...] [MA 07, #30]*

One further unexpected organizational aspect stemmed from a general concern of the GPs and MAs about the potential theft of the tablets. One MA recalled a moment when even a painting had been stolen from a wall in their practice. Under such circumstances, a tablet, as an object of higher value, was not considered to be the right information tool to distribute to

patients in a medical practice. As a consequence, due to hygiene issues, a perception of intensified time constraints, and concerns about potential theft, the tablets were rarely used as intended or were not offered to patients at all.

*Yes, and something has been stolen before, somehow a painting even from the wall, and we just didn't want to induce this stress with this tablet now, [...] we had this conversation in the practice [...] [MA 01, #22]*

## Discussion

### Overview

The findings of this study in German primary care provide insights into the uptake of digital devices, medical professionals' beliefs about digital educational interventions, and how these may have collided with the professionals' understanding of their professional roles. The implementation met with challenges and hesitation, with the main barriers being perceived incompatibility with existing routines, low technology affinity, and concerns regarding the complexity of digital tools.

Active use of digital devices for health-related purposes appears to be more common in other high-income countries in Europe, such as Denmark and the Netherlands, where web-based platforms for patient education and e-learning for GPs have been established. Based on research evidence and prior experiences, the tablet application, the e-learning platform, and the website were implemented to strengthen health literacy, encourage guideline fidelity, and provide a subsequent change in antibiotic use habits for ARTI in German primary care. Prior studies used tablet computers to specifically disseminate health literacy in adults [30-32], for self-management programs for chronic diseases [33], diagnostics [34,35], interventions for parents and children [36-40], coping strategies after diverse surgeries [8,41], or as tracking functions for aims of weight reduction [42] and general fitness [43,44]. However, the findings of this study demonstrate a variety of challenges and a reluctance toward using digital information tools in German primary care practices for both patients and health professionals. This may be due to incompatibility of the digital devices with practice routines, patient expectations, and the perceptions of GPs and MAs about their medical practice and professional values. The GPs emphasized that they wanted to create a safe harbor for patients in a complex technological world, and they still saw themselves as the primary source of valid information for patients. As this attitude may stem from professional self-conception and may even be intensified by the age factor, future implementation programs should take these factors into account. MAs attempted to incorporate the digital information provision but considered it to be of little importance. Thus, not all study participants came into contact with the digital intervention components, which may also be explained by the choice of communication channels used in the public campaign and the practice team intervention for the distribution of the innovation. Patients considered the provision of health-related information via a trustworthy website to be a good option for younger patients and named options for creating awareness of such a website. They also saw waiting area televisions, which were not offered in the participating practices, as a better

alternative to tablet devices. Adopters and nonadopters of the innovations voiced concerns about the applicability and adequacy of the digital components. In the next section, the findings will be discussed in relation to the selected DIT postulates to provide potential explanations for the findings.

### Postulate 1: Innovation Characteristics

Participants in this study found it challenging to implement the use of tablets into their organizational routines in primary care. The perceived lack of compatibility of this new intervention component with existing routines as well as the simple and convenient option to withdraw them appeared to be a major factor contributing to the absence of success. More importantly, a limited technology affinity and willingness to use digital solutions in the practice setting remained a major barrier. A qualitative study by Lyles et al [45] investigated tablets as a waiting room tool, where they were used as visit planners that focused on specific patient needs and were perceived as a “safe place” by patients to bring up sensitive topics. This supports our findings regarding the opportunity to avoid uncomfortable situations with GPs during consultations. Therefore, to disperse compatibility concerns, it may be beneficial to highlight the potential of tablet devices to maintain and support the desired “safe harbor” for patients.

Complexity concerns were also raised regarding the confrontation of older patients with modern technical devices. This is in line with the findings of a mixed-methods study by Patel et al [46] in which interviewed health care providers raised concerns about confronting older people with health literacy devices based on digital platforms. They surveyed 84 patients in a community health center waiting area in Massachusetts and identified a high level of interest in tablet-based health literacy solutions. Likewise, Stribling and Richardson [47] used tablets to provide educative health-related information in clinical waiting areas and surveyed patients afterward regarding their satisfaction with this method of digital information delivery. On average, the patients were satisfied with the usability and the educative input via the devices. However, in our study, complexity concerns for older people were primarily mentioned by health care providers or younger patients, not by the older people themselves. Future research should investigate perceptions of older patients more closely to evaluate if digital solutions are a reasonable intervention to strengthen their health literacy competencies.

The general possibility to observe the trialability effects of the new intervention [14] was not postulated sufficiently. It was assumed that the GPs would recognize the potential influence of the intervention on the health literacy competencies of patients. However, in light of known time constraints in primary care, it can be assumed that the GPs did not extensively evaluate the potential effects on patient health literacy and were not sufficiently aware of the inherent relative advantages. This leads to the assumption that there was no clear understanding of how the digital solutions could have been integrated into daily care routines and of the type of added value that could be expected. Instead, perceptions about innovation characteristics were more dominant, leading to a preference for more familiar and traditional solutions. Prior studies also used multimedia

approaches to provide information in a digitally enhanced manner and offered printed information, videos, or individualized risk assessments [31,32]. In contrast to our findings, those studies showed significant effects of the use of tablets as educational devices for patients. It can be assumed that in the absence of significant impediments, broader adoption and use of the technology-mediated information delivery approaches could have been possible.

### Postulate 2: Communication Channels

The value of a new innovation must be defined and communicated. With Postulate 2, DIT suggests promoting new interventions with the help of personal approaches and the use of gatekeepers and opinion leaders. Rogers [14] stated that people make decisions based not only on rational considerations, but even more on their personal beliefs. Thus, in the primary care setting, it could have been more effective to demonstrate the value of the digital information tools using peer support instead of providing informative material that was based on rational facts alone. Also, peer patient coaching efforts could have been considered, as a lack of knowledge about antibiotic resistance may affect patients' ability to understand the importance of the topic. Klingenberg et al [48] identified that less than 60% of patients in German primary care practices were aware of the possibility of being infected by resistant bacteria or the fact that antibiotics have no effects on viruses. To sufficiently transport knowledge and demonstrate the effectiveness and value of digital devices in achieving this transport, a more personal information delivery approach appears to be a relevant choice. However, with the exception of the offered outreach visits, such approaches remained largely unconsidered in the CHANGE-3 study, and gatekeepers were of no relevance.

### Postulate 3: Unanticipated Outcomes

The analysis of the qualitative data facilitated the identification of a number of unanticipated outcomes. Time constraints, insecurities, unclear procedures, hygienical aspects, and maintenance responsibilities were identified as barriers to sustainable application of the tablets in daily care. Reduced technology affinity greatly influenced the will and ability to use the digital information devices, the e-learning module, and the study-specific website. The e-learning platform was provided to all GPs in the intervention group. It consisted of video-based situations illustrating potential communicative difficulties between GPs and patients. The main focus was on addressing patients' expectations, especially if they wished to receive antibiotic-based treatment without indication. Although this situation is often claimed to occur frequently, the e-learning module was only used by a small number of participants.

Schreiweis et al [49] conducted a systematic review in which they aimed to identify barriers to and facilitators of the implementation of e-health devices. The main barriers were found to be concerns about theft, absence of motivation, added workload, and general issues in adopting eHealth devices into organizational routines. Facilitators were found in the ease of use, staff motivation, involvement of all stakeholders, and the availability of resources. The findings in our study seem to match these results.

The reduction of antibiotic resistance is a goal that is preventive in nature. Noncompliant usage or prescription of antibiotics appears to have no directly perceived influence on individuals. Thus, this subjectively perceived lack of observability can lead to slower adoption of innovations. The effects of a desired behavior change become visibly lagged in time, which increases the difficulty of achieving satisfactory adoption of new intervention components with preventive characteristics. Therefore, the relative advantage of preventive innovations must be prioritized in communication [16]. Under such circumstances, it is even more important to point out the relevance of new and, here, digital intervention components, as awareness and responsibility help ensure a desired rate of implementation [50]. However, although the adoption of digital information devices was slow in this study, our findings show that the GPs and MAs noticed changes in communication and interaction with patients, and they attributed these changes to participation in the study and the use of its components.

Rogers [14] defined five adopter categories (innovators, early adopters, early majority, late majority, and laggards) that describe types of individuals and their willingness to adopt innovations. The criterion for building these categories was the degree of innovativeness at which an individual feels ready to implement an innovation into their professional routine. For sufficient contrast, a closer look at the characteristics of innovators and laggards is worthwhile. While innovators are defined by a more encouraged attitude toward change, laggards are driven by traditional values and suspicion. Laggards and late majority adopters require the removal of uncertainties about new ideas to decrease their skepticism and help them feel safe to adopt those ideas. According to the findings of this study, MAs and GPs who considered unanticipated consequences and compatibility concerns may have been driven by uncertainties or tradition and, thus, can potentially be categorized as laggards. According to Rogers, uncertainties should be addressed by individualized messages and involvement of opinion leaders. Because innovators are crucial to reach a critical mass and to accelerate the adoption of new ideas, it may also be a purposive approach to identify innovators and early adopters beforehand and let them act as role models in their social network of peers [14]. However, opinion leaders were not involved or identified in this study, and early adopters were not used to accelerate the adoption of the digital information devices.

This mixed-methods study aimed to assess the acceptance and impact of educative digital information delivery to patients, physicians, and care teams. The intention was to promote and facilitate a conversion of habits of antibiotic use for noncomplicated acute respiratory tract infections in German primary care. However, identified barriers impeded a broader use of digital solutions, thus pointing to a need to tailor and strengthen future implementation strategies in the field. This can minimize potential perceptions of burden on care teams and enable increased use, as potential barriers would be identified prior to implementation.

## Strengths and Limitations

The purposive sample of interview participants facilitated a detailed exploration and understanding of the central themes and underlying perceptions of the three participant groups. Structural variance in the qualitative data was ensured through age, gender, and years of working experience. Qualitative interviews are an important research tool to enable and foster understanding of perspectives of targeted groups. Telephone interviews can be seen as a valuable method of collecting information on sensitive topics [51]. All participants felt comfortable with the chosen method, as it accommodated their busy schedules. No participant opted for a face-to-face interview. Rapport was built without effort and was supported by frequent vocalized acknowledgments during the interviews. The participant-centered approach enabled consideration of verbal prompts, follow-up questions, and note-taking without distracting or influencing the interviewees. Applying this method resulted in rich data. Notably, DIT was developed before internet and digitalization efforts gained momentum in daily life and work, providing countless options for rapid dissemination of innovations. This may indicate a need to reassess the current applicability of DIT. However, applying DIT provided a useful explanatory frame for the hesitant integration of digital educational devices. Analysis of all data was guided by adequate methodological strategies aiming to minimize research bias and reduce the risk of losing relevant content. Typicality of the observations was shown by providing simple counts where their support of the findings can be expected. This also addresses potential issues of anecdotalism and exoticism. Reporting of the qualitative findings followed the recommendations of the COREQ (COConsolidated criteria for REporting Qualitative research) checklist [52].

Some limitations must be reported. Some members of the study population participated in a similar study that ran almost concurrently. This may have contributed to a stronger awareness of the topic but also to a clouded perception that impeded stronger engagement with the digital solutions, which were used by only a small number of participants. Social desirability of answers in the data cannot be excluded, although it can be considered to be less probable in light of the presented findings. Health literacy interventions have a preventive purpose, which may reduce fidelity rates. All presented findings must be interpreted with caution in terms of their representativeness.

## Conclusion

Patients and medical professionals in primary care can be reluctant to use digital devices for information and education that aim to strengthen the rational use of antibiotics in ARTIs. To encourage a higher rate of intervention fidelity, future studies should consider identified barriers and facilitators in a detailed manner, and more tailored interventions should be developed accordingly. Interventions that are in line with professionals' perceptions will be crucial for success.

## Acknowledgments

The authors would like to thank all participating interview partners of this study and the aQua Institute, which gave overall support to conducting the CHANGE-3 study and the recruitment of the participating physicians and medical assistants. We also thank the staff at the Department of General Practice and Health Services Research at the University Hospital, Heidelberg, who were involved in transcribing the qualitative data and digitalizing the survey data.

## Abstract

**Background:** Transition-aged youth are particularly vulnerable to mental health problems, yet they are one of the least likely demographic groups to seek help.

**Objective:** The aim of this study is to explore the influences on and patterns in help-seeking for mental health concerns among transition-aged youth who attend postsecondary schools in Canada.

**Methods:** A qualitative research design was used, involving 12 semistructured focus groups with transition-aged youth (17-29 years) who attended postsecondary schools in Canada. A thematic analysis was conducted to code the transcripts and develop themes.

**Results:** Four main themes and subthemes regarding the process and experience of help-seeking were generated: (1) the influence of formal service providers (accessibility and experiences), (2) the influence of social factors (system navigation and stigma), (3) the influence of health literacy (symptom recognition, acting on symptoms, digital tools and the internet, and mental health awareness campaigns), and (4) the influence of low-intensity sources of support, namely, self-help.

**Conclusions:** Transition-aged youth seek help for mental health problems in different ways. Despite efforts to improve access to mental health services, transition-aged youth continue to face barriers to accessing these services, especially formal sources of support. The factors identified in this study that either hinder or facilitate help-seeking have pragmatic implications for developing help-seeking interventions and delivering mental health services for this population. In addition to other facilitators, family physicians are an important resource in the help-seeking process. Furthermore, digital help-seeking tools have unique characteristics that may make them an important source of support for transition-aged youth.

## Introduction

### Help-Seeking Behaviors of Transition-Aged Youth

The transition between adolescence and adulthood can be a particularly challenging time. Unique factors during this period, such as high levels of stress and anxiety, being introduced to alcohol and other drugs, and navigating new experiences and responsibilities, can make transition-aged youth vulnerable to mental health problems, which include substance use concerns [1]. Yet, they are one of the least likely demographic groups to seek help [2,3].

There is no universal definition of transition-aged youth. In the mental health literature, the age range spans anywhere between 14 and 29 years: some studies place it at 14-21 years, whereas others indicate 16-29 years [4]. For this paper, we adopted a broad definition of transition-aged youth of 17-29 years.

### Barriers to Help-Seeking

For this population, the process of seeking help for mental health concerns within the current social and health care system is arduous [5-7]. Barriers at the systemic, sociocultural, and personal levels can prevent or delay help-seeking among transition-aged youth [8,9]. A survey conducted in the United Kingdom found that 35% of youth with mental health concerns did not try to find help because of barriers such as poor access to care, perceived stigma, difficulty expressing concerns, and challenges navigating help-seeking processes or because they preferred to be self-reliant [10]. System-wide fragmentation makes it difficult to access appropriate services, information, and advice. These barriers have serious consequences, including self-medication and social, academic, and vocational difficulties [11]. They are compounded by other barriers such as long wait lists, stigma, high cost, lack of anonymity, and poor mental health literacy [12]. The result is often a failure to receive adequate mental health treatment [11-14]. The many barriers to help-seeking that transition-aged youth face need to be addressed to better serve the mental health needs of this population [8,9].

Eisenberg et al [15] identified 2 types of stigma associated with mental illness: perceived public stigma, which is defined as negative attitudes held by others, and self-stigma, which is defined as negative attitudes toward oneself. These 2 types of stigma interact and play a significant role in hindering help-seeking behaviors in transition-aged youth. Culture is another factor. Lack of cultural competence and sensitivity in mental health services, as well as the stigma attached to mental illness in many cultures, may make youths reluctant to seek help [15,16]. Together, these stigmas influence self-reliant behaviors, and transition-aged youths often prefer to cope with mental health problems on their own [1,2,16,17].

The nature of mental health problems can also be a barrier to seeking help. As these problems may have symptoms that are not easily recognized and often have a gradual onset, they might not be identified as issues that require medical attention; rather, the decision to consult a health care provider is influenced more by a voluntary help-seeking process [13]. Symptom recognition can be a factor in determining when to seek help.

### Facilitators to Help-Seeking

Although barriers to help-seeking for transition-aged youth have been well established in the literature, little is known about what facilitates help-seeking in this population [12,18]. Facilitators who have been identified include people having positive past experiences with formal and informal help-seeking as well as encouragement from others to connect with mental health services [12,19].

### Conceptual Help-Seeking Frameworks

In this paper, we use the conceptual framework by Rickwood and Thomas [13], which suggests that help-seeking is an adaptive coping process used to obtain external support to address a mental health concern. Within this framework, formal help is diverse and comes in the form of professional advice, support, and treatment delivered by professionals whose role it is to provide mental health care [13]. Semiformal help is offered by service providers who do not have a specified role in mental health care, such as teachers, coaches, and some community workers [13]. The third type of help, informal sources of support, such as friends and family, is also outlined in the framework and has been found to be important in encouraging youths to seek help [2,13,17,20,21]. Health Canada found that 27% of youth (aged 15-24 years) with mental, emotional, or substance use problems consulted informal sources compared with only 12% who consulted formal health professionals [20]. Self-help resources are a fourth type of support that includes sources such as self-help books and unguided website use. The framework also invites researchers to identify the stage within the process of help-seeking, the time frame, the type of help sought, and the type of mental health concern. Using a consistent framework to examine help-seeking is thought to increase the transferability of findings across studies and to better inform policy and practice decisions [13].

Confidentiality, trust, and positive relationships are important factors that encourage youths to pursue help from both formal and informal support groups [12]. Emotional competence (the ability to identify, describe, and manage emotions) can also predict help-seeking [17,22]. A survey of 300 undergraduate students found that those with low emotional competence were less willing to seek professional help and less likely to have positive experiences with mental health professionals [22]. More research is required to understand what factors promote help-seeking in transition-aged youth [8,9,23].

## Study Purpose

This study is part of a larger study that aims to evaluate and optimize a web-based and mobile health intervention called Thought Spot [24]. This crowdsourced digital platform enables transition-aged youth in postsecondary settings to look for and access mental health and wellness services. The app is a student-led project that prioritizes inclusion through steering committees, working groups, and focus groups. Thought Spot invites students to share their knowledge about services, discover wellness options on the web and in their geographical area, and post and read service reviews [24-26]. Although efforts have been made to improve access to mental health care for transition-aged youth, evidence suggests that barriers to care still exist [8]. The objective of this part of the larger study is to explore influences on and patterns in the help-seeking behaviors of transition-aged youth.

## Methods

### Setting and Participants

As part of the Thought Spot study [24], this paper reports the qualitative investigation of help-seeking behaviors that were generated through focus groups conducted throughout the study. A total of 17 focus groups were conducted on various topics as part of a participatory design research process to optimize the Thought Spot app. A subset of 12 focus groups that addressed help-seeking were examined for this paper. Participants were recruited using convenience sampling through web and offline methods that included posters, postsecondary school recruitment presentations, word of mouth, and social media posts (Facebook, Twitter, Instagram, and Slack). English-speaking youth aged 17 years or older who were enrolled in full- or part-time studies at a Canadian university or college were eligible to participate.

### Data Collection Procedures

Recruitment for this study took place over 3 years (July 2016-August 2018). Participants were enrolled on a first-come, first-served basis, with up to 10 participants per focus group. Priority was given to individuals who had not yet participated in the study. However, if there were fewer than 10 participants in a group, participants who had already attended another group were permitted to participate again if they requested to do so in response to study recruitment advertisements for subsequent groups. Participants were allowed to engage in more than one focus group, as each focus group was structured with different activities and modified help-seeking questions (Multimedia Appendix 1) [26]. In addition, we attempted to build engagement and capacity in the participatory design research process by having students participate and contribute more than once. Contributions of repeat participants were therefore expected to vary from group to group.

All participants signed informed consent forms and filled out a demographic form when they arrived for each focus group. A unique identifier was created based on participant demographics. Those who participated in multiple focus groups filled out a new demographic form for each group to avoid breaking confidentiality about having attended a previous group. Repeat participants were expected to use the same unique

identifier each time. Participants received Can \$40 (US \$31) and bus tokens as remuneration.

A semistructured interview guide (Multimedia Appendix 1) was developed for the overall study, with questions focusing on seeking help and health information.

Interviews were conducted in English and audio-recorded. Nine master's-level practicum students co-designed and facilitated the focus groups with the study team. There were 3 practicum student facilitators per group—1 acting as a note-taker, 1 as a flipchart assistant, and 1 as the main facilitator. These students included the authors (BL, CS, JS, JZ, and NV) and 4 students listed in the Acknowledgments section of this paper (AK, PD, SS, and VT). A staff research coordinator (AA or GF) and research analyst (EH) also attended the focus groups to provide general oversight and guide facilitation. Choosing to use practicum students to co-design and facilitate the groups reflected the decision to have transition-aged youth co-design the broader project. The focus group questions were broad and allowed participants to describe and discuss their experiences in as little or as much detail as they wanted.

### Data Analysis

Data collection continued until researchers determined that information saturation had been reached, as outlined in the published protocol [24]. Audio-recordings were transcribed verbatim, and data were entered into NVivo 12 (QSR International Pty Ltd) software after anonymizing and quality-checking transcripts for accuracy. Data were then coded using the 6 phases of thematic analysis by Braun and Clarke [27]. Phase 1 began with 1 researcher (JZ) reviewing the data and noting ideas as preliminary codes. In phase 2, 2 researchers (JZ and CS) generated initial codes based on all the transcripts and organized data relevant to each code. These codes included attributes of resources, types of service delivery, recommendations for future services, facilitators to use, barriers to use, outcomes of help-seeking, and help-seeking processes. In phase 3, 2 researchers (JZ and CS) organized data into potential themes based on the researchers' understanding of the data and in relation to any categories that may apply from the conceptual framework by Rickwood and Thomas on help-seeking [13]. The themes were reviewed with a wider research team for input and feedback around grouping and conceptualizing the codes into themes. Updates to the themes included further refinements of the types of facilitators (eg, internal or external) and barriers to help-seeking (eg, concern with health care providers, costs, lack of social support, stigma, system navigation, time). The themes were then reviewed in phase 4 by 1 researcher (CS) to ensure that they worked in relation to the coded extracts, and the researcher also defined the final themes. The themes were reviewed and verified by the second researcher (JZ) in phase 5. Phase 6 involved finalizing the selection of quotes for analysis (CS) and relating the analysis back to the research question and then reviewing and confirming the analysis (JZ). The study received Research Ethics Board approval by the ethics boards at the Centre for Addiction and Mental Health, University of Toronto, Ryerson University, and George Brown College.

## Results

### Demographics

Participants were male and female aged 17 to 29 years who attended postsecondary schools in Canada. A total of 110 requests were received from students to attend the 12 focus groups examined for this paper (some students requested taking part in more than 1 focus group). Of these requests, 24 did not result in focus group attendance for various reasons. In 13 requests, participants signed up for a group but then canceled their subscription, 5 (39%) were ineligible, 3 (23%) were not available on the dates of the groups, 2 (15%) could not

participate as the groups were full, and 1 (8%) did not respond after initial contact. The remaining requests resulted in 86 focus group attendees and 69 unique participants, based on our attendance data. A total of 10 participants attended more than 1 focus group, 2 attended 4 focus groups, 3 attended 3 focus groups, and 5 attended 2 focus groups. There was an average of 7 participants per focus group (range 4-9).

We were unable to remove 4 misidentified duplicate demographic surveys from our data. Therefore, although there were only 69 unique participants in the focus groups, we report the demographics of 73 respondents in [Tables 1](#) and [2](#). The demographics of the focus group participants are listed in [Table 1](#).

**Table 1.** The demographics of the focus group participants (N=73).

Demographics	Values, n (%)
<b>Gender</b>	
Male	20 (27)
Female	53 (73)
Nonbinary	0 (0)
<b>Age (years)</b>	
17-21	27 (37)
22-24	32 (44)
25-29	14 (19)
<b>Highest level of education achieved</b>	
Some university but no university degree	27 (37)
College diploma	6 (8)
Bachelor's degree	23 (31)
Some graduate school but no graduate degree	6 (8)
Master's degree	4 (5)
Other education or no response	7 (10)
<b>Ethnicity<sup>a</sup></b>	
Aboriginal (eg, First Nations, Métis, Inuit); Arab or Middle-Eastern; and Black (eg, origins include Canadian, American, Caribbean, African)	7 (9)
East and Southeast Asian (eg, Vietnamese, Cambodian, Korean)	4 (5)
Chinese	19 (24)
South Asian (eg, East Indian, Sri Lankan)	18 (23)
White or European	27 (34)
Don't know; other group	4 (5)
<b>Experience with mental health and substance use problems</b>	
Yes	38 (52)
No	26 (36)
Don't know or no response	9 (12)

<sup>a</sup>Some respondents answered in more than one category.

**Table 2.** Self-reported types of mental health or substance use problems (N=73).

Mental health problem <sup>a</sup>	Total, n (%)
Anxiety	19 (26)
Mood disorder (eg, depression, bipolar)	17 (23)
Comorbidity	16 (22)
Has a family member or friend with mental health or substance use problems	7 (10)
Borderline personality disorder, eating disorder, psychosis, posttraumatic stress disorder, and suicidal ideation	8 (11)

<sup>a</sup>Participants were able to indicate more than one answer.

All participants were identified as either male or female on the demographic form. *Trans* and *other* were also listed as gender options; however, no participants chose either of them. A subset (39/73, 53%) of participants elaborated on the types of mental health concerns they had (Table 2). To protect confidentiality and anonymity, if there were less than 4 responses for any of the categories in the demographics form, the responses were combined with other categories for the same question that also had less than 4 responses (Tables 1 and 2). This approach resulted in combined responses for some ethnicity categories and some types of mental health concerns.

Four main themes related to help-seeking were generated through transcript analysis and coding: formal services and providers influence help-seeking, social factors influence help-seeking, health literacy influences help-seeking, and self-help–low-intensity sources of support influence help-seeking. These themes and subthemes are listed in Multimedia Appendix 2.

### Formal Services and Providers Influence Help-Seeking

Formal sources of support are service providers with a specific professional role in delivering mental health (including addiction) care, such as family physicians, psychiatrists, and psychologists [12,13]. Participants discussed 2 main influences on seeking help from formal service providers: accessibility and empathy and trust.

#### Accessibility of Formal Service Providers

The ability of participants to access a formal service provider when they needed one was a common topic among the participants. Several participants reported contacting multiple formal service providers while help-seeking. They had difficulty accessing this type of support for various reasons. Participants often expressed concern about the instrumental costs (money and time) of seeking help from formal service providers. They also indicated that it was important during initial contact for service providers to create an empathetic and trusting environment. Establishing this connection made young people more willing to share their mental health concerns during subsequent encounters and seek treatment, services, or pathways to support in the future.

#### Wait Times Affect Access to Formal Services

Long wait times to be seen by formal service providers frustrated many participants and influenced their help-seeking behavior. One participant stated:

*The wait times for getting any support are ridiculous no matter where you go. Oh, a year, two years, six months. I'm already in crisis right now and I want it right now or like a week from now, not a year from now.* [Focus Group 1]

Participants were also discouraged by the reality of having to consult multiple service providers to address specific aspects of their mental health concerns, a fragmentation that precludes holistic support and increases wait times. One student told us:

*Everywhere you go...they want to only help you with one issue, it's just not helpful.* [Focus Group 1]

When the desired treatment or support was not available in a timely way, participants sought alternative types of assistance, such as crisis services. One participant spoke about a friend:

*If they were going through a crisis but they were waiting for the next appointment...they would always just go to the emergency department.* [Focus Group 7]

#### Financial Burdens Affect Access to Formal Services

Participants often described the financial burden associated with formal service providers (eg, psychologists, psychotherapists, counselors) in the community as a barrier to accessing help and pursuing optimal mental health. Some participants noted that although mental health services at postsecondary schools were generally more affordable than services in the community, these services sometimes make referrals to specialists in the community for students with serious mental health problems. Participants identified private psychotherapy as being inaccessible as it is expensive. They perceived pharmacological treatments to be more affordable. Accessibility was also limited by some health plans in Canada that did not cover participants' preferred treatments. One student told us:

*You often have to pay. And if you have no money or minimal money, there are not a lot of places that do scaling or they don't inform you that they do scaling. So, if you want to see a social worker or a psychologist or psychiatrist, it's often you need to pay \$150 an hour.* [Focus Group 3]

#### Ease of Access Affects Access to Formal Services

The ease of access supported participants' help-seeking efforts. Factors that increased access included convenient locations and times, anonymity and confidentiality, affordability, appointment booking, clearly displayed eligibility criteria, and short wait times. One participant stated:

*I felt too anxious to really talk about things, so it really helped that they had an email address and I didn't have to call in to make appointments, I could just schedule them over email.* [Focus Group 7]

Services and resources that provided a variety of options simplified the help-seeking process. Participants spoke highly of services that offered various entry points, multiple services, and several ways to learn about mental health. Some participants described their frustration with receiving siloed treatment for comorbid conditions and liked having services colocated in one place. One participant told us:

*Agencies are becoming hubs now, so most places have everything on-site, so people don't have to travel everywhere to get what they need.* [Focus Group 5]

Many participants identified family physicians as an important initial contact in the help-seeking process. Physicians helped them to navigate the mental health system and gave them information about other services or provided referrals to them. Family physicians typically made referrals to specialized mental health services. One student told us:

*I think the easiest way is probably to go through a doctor or some sort of professional.* [Focus Group 3]

### Experiences With Formal Service Providers: Empathy and Trust

Participants discussed both positive and negative experiences with formal service providers that influenced their help-seeking behaviors. Negative experiences with health care providers and fear of similar experiences in the future deterred help-seeking. Many participants described a lack of empathy or understanding from health care professionals or had heard about others' bad experiences, which made them hesitant to connect with these service providers. For several participants, the lack of connection made it difficult to talk about their problems. A student told us:

*I don't feel like I can trust another doctor. . . [They tell you] "It's temporary. It will pass. It's part of your life. You went through a crisis. It will go away. Don't worry about it." Or "I don't believe you. Maybe come in a week and you'll feel different." That type of stuff. There's a lot of, oh, oh. And if you do have mental illness, oh, maybe [you're] lying. Maybe [you] actually don't know what [you're] talking about. So there's that sometimes as well.* [Focus Group 1]

Negative past encounters decreased motivation to pursue help. Participants who had tried many times without success to access mental health support were skeptical about getting the help they needed or wanted. Some also lacked confidence in their current health care provider's abilities or were dissatisfied with their care. Participants described feeling hopeless in these situations and being unable to seek help elsewhere because of long wait times or high costs. One student mentioned:

*It's hard to start over because if you lose the person you have, you're going to have to start all over in the line. They're not going to just give you someone else. You're going to have to accept whatever you've got, and good luck trying to find someone else, because*

*it took six months to a year to find whoever you got in the first place.* [Focus Group 1]

Participants also mentioned the importance of receiving feedback from peers before taking action. They wanted to hear about the experiences of others with a particular support before they invested their own time and resources. One participant said:

*It kind of motivates you ... If someone else did this and found it helpful, I'm going to do the same thing as well.* [Focus Group 3]

### Social Factors Influence Help-Seeking

Social factors influenced help-seeking in both positive and negative ways. Participants discussed how informal supports (eg, friends, partners, parents) and semiformal supports (eg, teachers, work supervisors, academic supervisors, youth workers, coaches) could either facilitate or hinder help-seeking. Moreover, social stigma made it difficult for participants to speak about their mental health concerns and needs in their social networks.

### Social Support Affects System Navigation

Social support networks were critical during help-seeking. Participants felt empowered when they received social support or encouragement or when they saw someone else succeed in getting help. One student mentioned:

*I find a lot of times when someone describes an experience that they've had, I find that much more trustworthy than just looking at the idealized version of what it's supposed to be.* [Focus Group 3]

Participants identified different chosen social support networks, and how useful they found these different support networks also varied. Some participants felt that they had limited support from friends or family. Some attributed this lack of support to attending school far from home. Others mentioned that social isolation was connected to experiencing more severe symptoms of mental illness. Both situations hindered help-seeking. Complying with treatment was particularly difficult for participants who did not have family support. One participant told us:

*Sometimes...you ask for help and your family says we're not going to help you with that...You're prescribed medication and...your parents won't give you the money you need to buy them. But then your counselors are also like, "Well, you can't not take the medication."* [Focus Group 7]

Other participants had friends or family who were able to recognize and respond constructively to their mental health problems and facilitated the help-seeking process on their behalf. One participant said:

*So, normally in high school...at least in my experience, if you're struggling with mental health issues, your parents will kind of handle it. Like, your parents will make your doctor's appointments and find referrals and find you a psychologist or a psychiatrist. And by [post-secondary school], you have cycled through the system enough times that*

*you're fairly familiar and you know what to seek out. However, I know a lot of people who started university and, in their first year, developed some mental health issues. A lot of friends of mine would ask me, because they knew that I had experience with that, and they just feel lost.* [Focus Group 8]

For some, informal social supports were the first step to finding help. These people helped participants navigate the process and shared their own experiences. A student told us:

*We went online, but we found the online help to not be very specific or applicable and [we] had to take it one step further and consult either a friend or somebody who has been through it to get more of the personal touch.* [Focus Group 7]

Semiformal supports who do not have a specified role in mental health care (eg, coaches, residence fellows, professors) also helped participants navigate the system and checked in with them to see whether they had followed through on their intended action. One student told us:

*I've seen profs facilitate with counselors, making sure that the student is able to find someone or know where to go. . . If you tell someone and they're able to help you through the process and just support you through it, then makes it a lot easier.* [Focus Group 1]

### Stigma Affects Help-Seeking

Stigma was reported as a deterrent to seeking help from formal and informal supports. Not all participants had social networks that offered support around seeking help for mental health concerns. One participant mentioned:

*Within my group of friends. . . we don't talk about mental health that much, if at all.* [Focus Group 3]

Participants discussed the stigma of mental health problems and their fear of discrimination if they disclosed their mental health concerns. Internalized stigma, feelings of shame and embarrassment, and being in denial about their situation were common experiences. One participant said:

*I think sometimes seeking help can also be like a sign of weakness and that kind of stops you from going to seek help. Like, you feel like you should be able to deal with these things by yourself.* [Focus Group 9]

Participants were often afraid of being judged by friends, peers, and family. One student told us:

*Being involved in a group of friends that actually make fun of mental health problems, you can't even talk about it.* [Focus Group 7]

Another student said:

*Before, I had to go through my parent's insurance plans and they would know what I was taking all the time and it would make me feel uncomfortable and judged.* [Focus Group 7]

Participants also feared discrimination by their professors and peers and the potential consequences of disclosure for their career or academic ambitions. One participant said:

*I'm not sure if telling my personal or health issue to my prof will actually. . . what if I need a recommendation letter from this person later? Will this color their opinion of me and my work abilities?* [Focus Group 1]

One participant described how the stigma attached to pharmacological treatment made a friend hesitant to seek help:

*It's not just the side effects that he was worried about. He was also worried about the stigma associated with having to take medications for his depression.* [Focus Group 1]

Participants who were trained to be mental health service providers (eg, social workers, medical students, residents) also spoke about the unique stigma associated with help-seeking as a mental health care provider. One student in social work told us:

*I'm in social work. You're supposed to be able to help people. You're not supposed to be the sick one too... You're not supposed to be your clients... even though maybe those that need the help are those that are providing the help as well. And it's sometimes fearful for those that are providers just because they are told that they're not supposed to [seek help from formal health service providers] . . . because then they won't want to hire you.* [Focus Group 3]

As a result of these concerns, many participants wanted to keep their mental health problems private and seek help on their own. One participant said:

*I think it's still taboo to talk about getting help for mental health or addictions. There's more access now, but I think. . . people don't like asking for help.* [Focus Group 1]

Although societal and internalized stigma made some participants reluctant to seek support from their social networks, several participants spoke about the importance of finding people they could relate to. One student told us about a friend's experience:

*After she was diagnosed and everything, she told one friend about it and from there it just started a chain reaction, and one by one, everybody started saying. . . "Oh, we have that problem too, but we were too scared to tell anybody about it because it's such a taboo with our parents."* [Focus Group 1]

### Health Literacy Influences Help-Seeking

Participants discussed factors related to health literacy that could influence help-seeking. Mental health literacy is an awareness and maintenance of one's own mental health needs, becoming knowledgeable about formal diagnoses, treatments, and the effect of stigma, and being able to effectively seek help when needed [28]. In this study, steps toward health literacy by participants included recognizing symptoms, acting on symptoms, learning about mental health through web-based sources or awareness campaigns, and finding out what services are available. Participants used multiple entry points to learn

about mental health problems and the types of services they could access.

### **Health Literacy Affects Symptom Recognition**

Participants described difficulty in identifying mental health concerns and attaining and maintaining positive mental health. They noted that they needed first to be self-aware and recognize that their psychological state was out of the ordinary before they would access services. One participant said:

*I think a big thing was. . .self-awareness and this realization that maybe. . .this is not how you should be feeling every single day. That's like a very big turning point where you realize that. . .it's not normal to feel this way every day and you shouldn't have to feel this way every day. [Focus Group 3]*

Lacking this insight or not understanding how to find help, which includes getting a diagnosis, made it difficult to search for appropriate services. One participant told us:

*The very first step is to get a diagnosis. However, it's very difficult for people to take that step. Like, I genuinely do not know what services or programs are available for people who are just kind of experiencing symptoms but don't have a diagnosis. . .because. . .a lot of places. . .only provide these programs and services for people who already have a proper diagnosis. [Focus Group 8]*

Several participants also explained that youths might not know what types of assistance are available and need help to find appropriate resources or support. One participant said:

*Yes, it's hard to define what mental health help actually is. And so people tend to [run] in circles, avoid conversation around it because they don't really know how to describe what it is. [Focus Group 2]*

Some participants described not always being able to articulate their mental health history and symptoms, which made it difficult to solicit support from their networks. One participant said:

*I feel like maybe sometimes you're sitting at the doctor's office and you're probably experiencing some. . .mental health problems that you also want to talk about, [but] you don't know how to talk about it, and then time's up and the doctor needs to move on to the next patient, and then it kind of falls through the cracks. [Focus Group 1]*

### **Symptom Recognition Does Not Always Lead to Help-Seeking**

Although recognizing symptoms was the first step in seeking help, self-awareness did not always lead to action. Some participants described being aware of their distress but downplaying it or not knowing when to seek help. One participant told us:

*I find I always do this thing where I end up looking at someone that's worse off and I'm like, I can probably handle it or I can probably deal with it. [Focus Group 9]*

Another participant said:

*Participants also described lacking the motivation to pursue help, because of the symptoms of their mental health problem and "feeling so hopeless that you don't even want to seek [help]." [Focus Group 2]*

Participants who recognized that something was wrong described weighing the pros and cons of getting help. Some participants eventually accessed services as certain stressors made them feel that their situation had evolved into something more serious and they could no longer avoid getting help. One participant said:

*I'll never be feeling fine and thinking, "Oh, I should probably worry about my mental health right now." It's usually when I'm already at that low point, where I'm just desperately seeking mental health services. [Focus Group 7]*

### **Health Literacy Is Affected by Digital Health Tools and the Internet**

Accessing digital health resources on the web increased participants' mental health literacy. Participants often sought information through web-based media to validate their feelings and identify what kind of help was available for their particular concerns. One student told us:

*I'd go on [website]. . .it's not a diagnosis, but it can help you seek out one. I found that what I got was essentially what the doctor told me. [Focus Group 8]*

Using mental health resources effectively required being able to match information or services to identified needs and then feeling comfortable and confident reaching out to these supports. Participants often described web-based resources as an important entry point to help-seeking. One student said:

*I feel like the internet can be a good stepping stone. It's not really somewhere that you find conclusive answers, but it's a good starting point. [Focus Group 7]*

Participants often described using the internet and social networking websites or mobile apps (Facebook, Instagram, and YouTube) to look for support and mental health information. One participant said:

*There's a lot of Facebook group communities that sometimes are available. Not really services, but, like, groups of people that are like, "Yeah, I have the same problems." [Focus Group 8]*

Participants spoke about learning from the experiences of others. One participant said:

*I've also seen different videos, where a lot of YouTubers that I used to watch or I sort of watch, they've also gone through mental health issues. So a lot of them post about their experiences...Seeing someone open up about an experience and maybe you can relate, then it really takes off a lot of stress. [Focus Group 9]*

However, web-based information about mental health could be confusing, so participants sometimes reached their own conclusions. One student told us:

*A lot of different mental illnesses have the same symptoms... You end up self-diagnosing yourself with a bunch of different illnesses, which you might not have all or any of them.* [Focus Group 9]

Participants who sought support or resources on the web also described the information as ambiguous and the amount of information as overwhelming. One student said:

*It definitely looks like there's a lot of resources out there for a variety of needs and lots of stress[ors] people might be feeling, but... first being able to find and decide upon which one you actually want to pursue takes a lot of time. Then, when you actually try to access it, it seems really difficult and daunting.* [Focus Group 9]

Despite the issues that participants highlighted about using web-based resources, digital media was a popular source of help-seeking.

### **Health Literacy Is Affected by Mental Health Campaigns**

Participants reported that mental health campaigns improved their mental health literacy. Social marketing and other mental health campaigns increased motivation to seek help. Participants described feeling empowered by hearing other people's stories about finding support. One student told us:

*Bell Let's Talk Day comes around, and [people] start posting all over Facebook... being like, "I started out on this and got more comfortable with it, and now I'm better and I want to help other people get better."* [Focus Group 7]

Other participants recalled learning about support through promotional events, guest speakers, emails, posters, and pamphlets in high school. One student said:

*We had a social worker in high school that would come to all of the classrooms, so you were getting to see a social worker regardless.* [Focus Group 4]

Some participants recalled learning about mental health services before they personally experienced mental health symptoms. They became aware of these services through information sessions, word of mouth, emails, posters in university common rooms, pamphlets at community centers or health offices, advertisements on websites, or in-course syllabi offering advice or support for mental health and wellness. Many participants mentioned a phone helpline that was advertised on cereal boxes. Knowing about mental health resources before they were even needed supported navigation by providing a good starting point. One student told us:

*Even before I had to use the service, I was aware of what it was. Even before I had an inkling that I would ever need to call, I just knew what it was.* [Focus Group 4]

### **Self-Help: Low-Intensity Sources of Support Influence Help-Seeking**

Participants reported trying to take care of their mental health concerns on their own and discussed the importance of resources that enable self-management. They described self-help and wellness activities for managing mental health concerns as generally low-cost, self-guided, and immediately available. Participants who were not comfortable accessing crisis or formal services found self-help particularly useful.

Participants often experimented with making small changes in their lives through self-help apps that do not involve live support (eg, e-learning, web searching, computer-mediated therapy, mindfulness sessions). One student said:

*On YouTube... it's not actually going to see someone for cognitive behavioral therapy, but there's resources online of learning some of the techniques that they use and maybe they can implement, even if they don't actually go seek help [formally].* [Focus Group 4]

Another student mentioned:

*They had these online Instagram things where every day of the week it was a day of self-care.* [Focus Group 2]

Participants also accessed various digital mental health resources, such as Headspace [29], Meditation Studio App [30], 7 Cups [31], Buddify [32], and Virtual Hope Box [33]. Participants used these apps to manage their mental health every day, track patterns in their mood, or chat anonymously with people about their mental health concerns. One participant said:

*People who are in situations that don't have a lot of time – students, mature students, parents, etcetera – use online stuff like 7 Cups.* [Focus Group 5]

Unlike participants with more urgent mental health care needs, those who had only mild or moderate symptoms felt that crisis-based services were not a good fit for their needs, although they seemed to be the most readily available and accessible. One participant said:

*When I think of a hotline, I think of like an emergency or dire situation. It's not something that comes as a first resource for me.* [Focus Group 9]

Instead, participants with less urgent concerns tried to meet their needs through other accessible and affordable support for overall health and wellness (eg, fitness, meditation and mindfulness, journaling, nature walks, playing music, listening to music, playing with pets). One participant told us:

*[I do] hobbies that require a lot of concentration. If you play a musical instrument, you're forced to focus on the instrument and the music, and then your mind just completely forgets what it was stressed about at the time, so it kind of takes your mind off that, and when you come back to that situation, you kind of see things in a new perspective.* [Focus Group 3]

Other wellness resources were also common. Some participants temporarily distracted themselves from stress and unpleasant tasks with *guilty pleasures*, such as watching YouTube or

Netflix, or playing video games to clear their minds. However, they recognized that these activities provided only a temporary reprieve. One participant explained that Netflix sometimes reduced productivity as it was easy to spend a lot of time on it and neglect important tasks. One student said:

*Netflix is a common thing now. I think everyone watches a lot of TV. . . But, if you're obsessive, like watching massive amounts of TV, then it can really make things worse by procrastination of everything.*

[Focus Group 3]

Although participants identified many low-intensity sources of support, they recognized that some activities that youths use to cope with difficult feelings or situations may not be healthy. One participant said:

*Professionals, they're not really going to recommend going out for drinks, but sometimes going out for drinks just helps you deal with it.* [Focus Group 8]

Other participants pursued wellness by accessing low- or no-cost community- or school-based mental health resources. Alternatives to crisis services or professional support are listed in [Multimedia Appendix 3](#).

## Discussion

### Principal Findings

Despite the high prevalence of mental health problems that develop in adolescence and early adulthood, many young people still do not seek help [10,34-36]. This study identified many of the barriers to and facilitators of help-seeking that previous research has found, such as accessibility of sources of support, experiences, system navigation, stigma, symptom recognition, and behavioral intention. It also offers new insights for developing strategies and services to meet the mental health needs of transition-aged youth by discussing the role of digital resources in the help-seeking pathway and the types of self-help resources that young people look for during this process. We found that help-seeking differs significantly among transition-aged youth in terms of the types and forms of support they prefer. Many use a combination of support, which can be categorized into formal, informal, and self-help support, using the conceptual framework by Rickwood and Thomas [13]. Our study contributes to the existing literature by identifying a range of self-help options beyond websites that were accessed by youth. We added a new category for digital self-help apps that offer peer support, therapeutic techniques, or other forms of self-help ([Multimedia Appendix 3](#)) because they represent a fairly recent distinctive self-help category not included in previous classifications. Identifying these types of support and categorizing them according to a conceptual framework is an area for ongoing development within the help-seeking literature, in which most types of assistance are not adequately described or classified [13].

### Frequent Use of Low-Intensity Services During Help-Seeking

Our study suggests the frequent use of low-intensity services, such as the web or mobile apps, among transition-aged youth.

These digital services were noted as particularly helpful because of their ease of access. Our findings support other research that identifies web-based mental health resources as a primary source of support for transition-aged youth [13]. Many participants in our study reported using educational websites about therapeutic techniques, peer-to-peer active listening services, interactive self-help mobile apps, and social media (eg, Facebook, Instagram, Yik Yak). Recreational activities, accessed through websites such as Groupon and Meetup were also mentioned as ways to support mental health and overall wellness. The range of digital self-help apps that the youth in our study accessed are listed in [Multimedia Appendix 3](#). Our findings add to the current literature by suggesting that popular digital mental health and wellness apps may be unique access points for reaching young help-seekers. Improving and expanding these resources should become a priority, particularly where traditional offline mental health services are difficult to access [37]. More research is needed to determine the effectiveness of these emerging types of support.

### Web-Based Health Information May Hinder Help-Seeking

Self-directed efforts to increase health literacy also influenced the help-seeking process. Digital health solutions and the internet can facilitate access to information about mental health problems and services and increase mental health literacy. However, participants in our study cautioned that web-based self-help resources can also be counterproductive if users are unable to decide which resources match their needs. We reiterate other researchers' cautions that the web can cause information overload and increase the potential for harm (such as incorrect self-diagnoses) when help-seekers lack the skills and experience to evaluate the information they find on the web [12,38,39]. New coordinated public health initiatives should focus on teaching transition-aged youth how to evaluate the quality and credibility of web-based health information.

Although seeking help on the web was common, it was not always helpful, and the credibility of sources was sometimes uncertain. Youth also accessed emotional support on the web where they could anonymously engage with a community of peers who offered support by sharing points of view and helped them decide what help to pursue. Web-based help-seekers read testimonials and web-based reviews about what to expect from each service provider.

### Social Marketing Campaigns and Educational Outreach May Catalyze the Help-Seeking Process

In addition to actively pursuing help, transition-aged youth are also learning about mental health supports through social marketing campaigns and educational outreach. Research has found that youth who are exposed to social marketing or educational outreach around mental health are more likely to reach out for help and get treatment [40,41]. Our research adds to these findings, suggesting that early educational intervention has long-term positive effects on help-seeking in young people. More research is needed to determine the most effective way to encourage transition-aged youth to seek help for mental health problems.

## Instrumental Barriers to Help-Seeking

The findings of our study are also consistent with research that shows that general mental health care is largely inaccessible because of instrumental barriers that include distance, cost, and wait lists [42,43]. Although on-campus services at postsecondary schools in Canada can mitigate some of these barriers, for example, they are usually supported by tuition and ancillary fees or are covered by student insurance, these services also often have long wait times. Additionally, walk-in appointments and drop-in sessions are not always offered. Despite the advantages of campus-based services, our findings suggest that barriers remain for transition-aged youth who seek services on and off campus.

The extensive wait times reported in the literature were echoed in our findings. Only about 8.6% of agencies in Canada do not have a wait list for child and adolescent programs or services. However, timely access to treatment is critical because long wait times not only prolong psychological and physiological discomfort but can also increase attrition rates, reduce motivation to seek help, and decrease expectations and positive treatment outcomes [44,45]. Barriers to accessing care are compounded by other barriers, such as service fragmentation, poor health literacy, low motivation to change, and lack of social supports. Together, these barriers lead to underused or inappropriate services, poor follow-up rates, decreased service quality, and high health care costs.

## Mental Health Service Providers Influence Help-Seeking

Previous experiences with formal service providers were either deterrents or facilitators to help-seeking, particularly given the challenges of navigating the fragmented mental health care system. Past help-seeking experiences that were empathetic and instilled trust encouraged future help-seeking. Similarly, negative, stigmatizing experiences discouraged help-seeking. Our findings contribute to existing evidence that positive experiences with formal health providers, which focus on building a trusting relationship, are important to youth [12].

Family physicians are increasingly being recognized for their role in the mental health help-seeking process by supporting transitions between youth and adulthood [46], providing treatment [47], and making referrals to specialists [17]. Transition-aged youth in our study primarily viewed family physicians as gatekeepers for referrals to mental health specialists. Other studies have also found family physicians to be the first point of contact and to be responsible for making referrals, despite facing numerous barriers themselves (eg, lack of time, knowledge, resources, training) [47-50]. Our findings reiterate the unique role of family physicians in help-seeking and point to the need to train and support family physicians in guiding young patients through system navigation and treatment. Significant benefits could result from developing supports for family physicians to manage and diagnose young people with mental health concerns by offering timely access and continuity of care.

## Help-Seeking for Mental Health Providers in Training

Transition-aged youth in our study who were undergoing training to become formal mental health service providers, such as social workers or physicians, described a unique barrier to help-seeking in the form of stigma. As future professionals whose responsibility is to help others, they feared that disclosing their own mental health problems would damage their reputation and career prospects. However, mental health problems among health care professionals are well-documented and include depression, anxiety, substance abuse, and suicide risk [51-55]. Other research suggests that emotional distress during training (eg, medical residency) can persist into professional practice and lead to burnout [56]. To our knowledge, no research has been conducted on the help-seeking behaviors of this population; however, our findings underscore the importance of offering formal mental health supports tailored to the needs of mental health care providers in training and point to the need for further research in this area.

## Limitations

The qualitative approach of this study enriches our understanding and insights into the mental health help-seeking behaviors of transition-aged youth; however, the findings may not be generalizable beyond the Greater Toronto Area, where the study took place. Help-seeking behaviors likely differ across postsecondary and cultural contexts, particularly at postsecondary schools that do not have access to on-campus support services. In this study, it was not possible to determine the effects of location, sex, gender, or culture on help-seeking behavior. Our findings are useful for health care providers who are creating digital mental health programs and services to improve access to care. Using focus groups provided an opportunity for participants to express their personal experiences while navigating the help-seeking process. However, a limitation of focus groups is the potential toward normative discourse, especially in the context of mental health where people may not be comfortable talking about certain issues in a group setting. Another limitation was that certain groups were underrepresented in this study: depression and anxiety were the mental health problems reported by the vast majority of participants, and most participants were female. Youths with serious mental health problems (eg, psychotic disorders) and transition-aged males are known to be less likely to access any sort of health care or to participate in research [57]. These groups may be better engaged in their help-seeking behaviors through other channels, such as technology, health clinics, schools, and social media [58].

Multiple focus group attendance by participants who requested it was another possible limitation in this study (10 participants attended more than 1 group) as it has the potential to amplify some themes in relation to others. The rationale for agreeing to these requests was to increase participants' overall, sustained engagement with the participatory design research process throughout the study. As described in the Methods section, because of the differences between focus group topics, the contribution of participants was expected to be different from group to group. Another limitation related to repeat participants, who filled out a demographics form each time they attended a

focus group, was that we were unable to remove 4 misidentified duplicate demographic surveys from our data. This resulted in reporting on demographics for 73 participants, although only 69 unique participants were involved.

## Conclusions

Transition-aged youth are influenced by various barriers and facilitators when they seek information and support for mental health problems. Future investments should focus on reducing barriers associated with accessibility, system navigation, stigma, and symptom recognition. This study also identified digital health tools, the internet, and low-intensity sources of support

as important parameters in the help-seeking process. Family physicians were found to be important gatekeepers to other mental health services. Digital and web-based technologies and the additional supports or features they offer may also be powerful tools for promoting help-seeking. Young people who are trained to become mental health care providers may experience a unique barrier to help-seeking in the form of stigma, an area that warrants future research. There is also a need for research on the effectiveness and unique features of low-intensity supports in seeking help for mental health problems.

## Acknowledgments

The authors wish to thank all the study participants, the Thought Spot Student Group (a student research advisory committee), research team members, research coordinator Genevieve Ferguson, and the 4 practicum students who co-designed and facilitated groups: Amandeep Kaur, Paulysha De Gannes, Vivetha Thambinathan, and Shehab Sennah. This project was approved and funded by the Canadian Institute for Health Research. The authors are also grateful for the collaboration and support of the University of Toronto, Ryerson University, and George Brown College during this research.

## Abstract

**Background:** Engagement emerges as a predictor for the effectiveness of digital health interventions. However, a shared understanding of engagement is missing. Therefore, a new scale has been developed that proposes a clear definition and creates a tool to measure it. The TWente Engagement with Ehealth Technologies Scale (TWEETS) is based on a systematic review and interviews with engaged health app users. It defines engagement as a combination of behavior, cognition, and affect.

**Objective:** This paper aims to evaluate the psychometric properties of the TWEETS. In addition, a comparison is made with the experiential part of the Digital Behavior Change Intervention Engagement Scale (DBCI-ES-Ex), a scale that showed some issues in previous psychometric analyses.

**Methods:** In this study, 288 participants were asked to use any step counter app on their smartphones for 2 weeks. They completed online questionnaires at 4 time points: T0=baseline, T1=after 1 day, T2=1 week, and T3=2 weeks. At T0, demographics and personality (conscientiousness and intellect/imagination) were assessed; at T1-T3, engagement, involvement, enjoyment, subjective usage, and perceived behavior change were included as measures that are theoretically related to our definition of engagement. Analyses focused on internal consistency, reliability, and the convergent, divergent, and predictive validity of both engagement scales. Convergent validity was assessed by correlating the engagement scales with involvement, enjoyment, and subjective usage; divergent validity was assessed by correlating the engagement scales with personality; and predictive validity was assessed by regression analyses using engagement to predict perceived behavior change at later time points.

**Results:** The Cronbach alpha values of the TWEETS were .86, .86, and .87 on T1, T2, and T3, respectively. Exploratory factor analyses indicated that a 1-factor structure best fits the data. The TWEETS is moderately to strongly correlated with involvement and enjoyment (theoretically related to cognitive and affective engagement, respectively;  $P<.001$ ). Correlations between the TWEETS and frequency of use were nonsignificant or small, and differences between adherers and nonadherers on the TWEETS were significant ( $P<.001$ ). Correlations between personality and the TWEETS were nonsignificant. The TWEETS at T1 was predictive of perceived behavior change at T3, with an explained variance of 16%. The psychometric properties of the TWEETS and the DBCI-ES-Ex seemed comparable in some aspects (eg, internal consistency), and in other aspects, the TWEETS seemed somewhat superior (divergent and predictive validity).

**Conclusions:** The TWEETS performs quite well as an engagement measure with high internal consistency, reasonable test-retest reliability and convergent validity, good divergent validity, and reasonable predictive validity. As the psychometric quality of a scale is a reflection of how closely a scale matches the conceptualization of a concept, this paper is also an attempt to conceptualize and define engagement as a unique concept, providing a first step toward an acceptable standard of defining and measuring engagement.

## Introduction

In eHealth, the use of technology to support health and wellbeing (a well-documented issue) is nonadherence. Especially within digital health interventions (DHIs), users often do not use the offered technology the way that the developers of the technology intended, which is referred to as nonadherence [1,2]. Examples are participants not completing all lessons within a mental health intervention, not using a step counter app on a daily basis, or not using all functions within a diabetes management system. Developers and researchers often assume that there is a dose-response relationship: for people who use a technology more and who adhere to the technology, the positive effects are greater. There is some evidence to support this assumption [3], but many DHIs do not show this relationship [4]. It has been argued that this has to do with the way adherence is conceptualized and measured (eg, with just the number of logins) [4,5]. However, more importantly, it has also been posited that the reasons why people use a technology might be more important in predicting effectiveness than the frequency or duration of use. Research shows that when people use DHIs because they feel involved or are able to identify themselves with the intervention, these DHIs are more likely to be effective for these people [6,7].

When looking at the reasons behind DHI use, the concept of engagement often emerges as a predictor for effectiveness [8-10]. In a broad sense, engagement is often seen as how involved or occupied someone is with something, and as something that is related to a positive outcome, such as effectiveness. For example, in health care, patient engagement has been shown to be related to better health outcomes [11], and in organizations, work engagement is related to better performance [12]. In relation to DHIs, engagement has also been posited as related to better outcomes in terms of more effective interventions [9,13,14].

It is important to note the conceptual difference between adherence and engagement. Adherence only says something about the objective usage of a DHI and indicates whether or not a participant uses the DHI as was intended by the developers [5]. In some, but not all, conceptualizations of engagement, the usage of a DHI is part of engagement [8]. Moreover, in all conceptualizations of engagement, it encompasses other aspects as well, which refer more to the reasons behind using a DHI. This implies that a participant might be engaged but not adherent. For example, someone believes that using an app is very helpful to reach one's goals (highly engaged) but feels that using the app once a week rather than the intended usage of once a day already helps to reach those goals (nonadherent). A participant may also be adherent but not engaged when, for example, using an app as intended because a researcher or therapist has asked them to, rather than due to a feeling that the app is personally beneficial. While the conceptual differences between engagement and adherence might be understood, within

the context of DHIs, a shared understanding and definition of engagement is missing.

In order to gain more insight into how engagement can be defined and conceptualized within the context of DHIs, a recent review looked at the definitions and components of engagement in various domains such as students, health, and digital engagement [8]. This review concluded that engagement contains emotional, behavioral, and cognitive components. Until now, this is not fully reflected in the definitions for DHI engagement, where in many cases, engagement is defined as only a behavioral component (for example, only as the usage of a DHI). This problem of a very narrow definition of engagement that does not encompass the full breadth of the concept is acknowledged by others. For example, a review on engagement in DHIs concluded that engagement should be characterized as the extent of usage and a subjective experience characterized by attention, interest, and affect [9]. However, that review also found that the majority of articles included only viewed engagement in behavioral terms, that is, as usage. Yet the definition chosen in that review also does not seem to fully encompass the emotional, behavioral, and cognitive components of engagement. The field of engagement to DHIs still needs a "clear, tailored, and domain-specific definition of the construct, which captures the associated emotional, behavioral, and cognitive components present within the given context" [8].

In order to gain insight into the content of these components, we interviewed self-proclaimed engaged users of health apps to study what they view as being engaged [13,15]. Behavioral engagement seemed to focus more on having a routine in using the technology and making it a part of daily life than about the frequency of using it. In this case, the quality of the behavior (being a routine and costing little effort) was more important than the frequency of the behavior (usage), which also shows the difference between adherence and engagement. Cognitive engagement with a DHI was found to be prominently related to the goals of the users. People have to think that the technology is useful for them and that it increases their ability to achieve their own goals. This is related to the importance of personal relevance for engagement, as stated in earlier studies on DHIs [6,7,16], and is also similar to the "attention and interest" part of the definition of engagement of Perski et al [9]. Lastly, the study found that affective engagement played a role for every participant but was less salient in most cases. Interestingly, affect was not only focused on feelings towards the technology itself but also on achieving goals, differing from the concept of user engagement [17]. Furthermore, although most participants mentioned positive affect when achieving goals, negative affect also seemed to play a role. Participants experienced frustration when not achieving their goals, and for some, this may enhance their motivation to go on. Finally, identity seemed to play a role in affective engagement: users need to be able to identify in some way with the technology and what it stands for.

A recent systematic review has identified various ways to assess (a form of) engagement to DHIs, such as using qualitative methods, self-report scales, ecological momentary assessments, and system usage data [14]. However, most of these methods assess only a specific form or component of engagement. The study posited that self-report scales might be the most accessible way to gain a more nuanced view of engagement in larger samples, especially when attempting to include the subjective experience. However, most existing self-report scales are created for measuring user engagement with technologies such as e-commerce websites or video games [14]. In these contexts, the goals of users are different than in DHIs. Engagement with DHIs seems to be needed at 2 levels: engagement with the technology itself, and engagement with the health behavior the technology aims to improve [10]. This is in contrast to, for example, user engagement with a shopping website, which involves only engagement with the technology and not with another offline behavior. This makes these existing scales less applicable to eHealth technologies such as DHIs. Another issue with many existing user-engagement scales is that they often include attributes that predict engagement but are not, in itself, part of engagement; this applies, for example, to aesthetic appeal or usability, which raises validity concerns [14].

Within the aforementioned systematic review paper on measuring engagement, 2 scales specifically targeted at engagement with eHealth technologies such as DHIs were identified [14]. The first scale, the eHealth engagement scale, showed adequate internal reliability and predictive validity on, amongst other things, retention of information and intentions to change [18]. However, conceptually, this scale seems to be more focused on engagement with health-related information than acting on that information, and thus on behavior change, as is our focus [9,13,14]. Moreover, this scale is an example of a scale that includes attributes that might predict engagement but are not part of the engagement itself. For example, the scale includes an assessment of the credibility of the technology, which may be a predictor of engagement but is not something that is seen as part of engagement itself. The second scale, the Digital Behavior Change Intervention Engagement Scale (DBCI-ES), was developed based on a broader definition of engagement, including both behavior and a subjective experience that might encompass cognitive and affective components of engagement. However, 2 validation studies showed that the psychometric properties of this scale are somewhat problematic [19,20]. The main issues seem to lie in the combination of the subjective and objective engagement measure, and in the discriminant and criterion validity. The experiential part of the scale (DBCI-ES-Ex) did show predictive validity, but this was not assessed on outcomes (such as changed drinking behavior) but on subsequent login. If engagement is seen as important for effectiveness, even more so than usage and adherence, then it should predict outcomes and not usage.

Based on our previous work on defining the concept of engagement, we developed another scale: the TWEnt Engagement with Ehealth and Technologies Scale (TWEETS) [15]. This scale was developed based on the interview study with engaged health app users that was discussed earlier [13], and on the systematic review of the concept of engagement in

different domains [8]. The scale employs a definition of engagement that incorporates behavior, cognition, and affect, as is common in other fields of research where engagement is used [8,21]. In the TWEETS, engaged behavior includes the existence of a routine in which individuals use the technology, low effort required to use the technology, and technology usage that is not fixed but may fluctuate to fit with the needs of the current moment. Cognitive engagement is related to the technology being able to support and motivate people in reaching their goals, such as the goal of improving one's wellbeing. Moreover, it entails that engaged users are willing to spend mental effort in using a DHI because it helps them achieve their goals, and they are intrinsically motivated. Affective engagement is related to emotions that people feel when seeing their progress in the DHI, or a lack thereof, and related to emotions such as enjoyment felt when using the technology itself. Lastly, it entails identity: engaged users seem to identify themselves in some way with the technology or with the goal of the technology.

In order for this new scale to be of use, its internal consistency and reliability should be examined. Moreover, assessment is needed for whether the scale measures a unique concept and is sufficiently different from other concepts such as involvement and adherence. As engagement is a relatively new concept without an existing gold-standard assessment, there is no criterion to relate it to, contrary to how the validation of the DBCI-ES was set up [19,20]. In that study, usage was seen as a criterion; however, since engagement is more than just usage [9,10,14,15], we feel that this does not do justice to the full concept of engagement. At the same time, there are concepts that, while different, are related and should correlate with a measure of engagement, and there are concepts that should reflect something different than engagement, and therefore should not be correlated. Specifically, engagement is conceptually related to concepts like involvement (how meaningful a product is for an individual) and enjoyment (the action or state of deriving gratification from an object) [7,22,23]. Therefore, it is expected that engagement correlates with these aspects, but that this correlation is moderate.

Another question that bears discussion is whether engagement is, and should be, related to the usage of a system. Based on the conceptualization of engagement as employed in the TWEETS, it is expected that engagement is not strongly related to the number of times individuals use a DHI. This is similar to what was found in the psychometric evaluation of the DBCI-ES [20]. Furthermore, engagement should reflect a more goal-oriented or intrinsically motivating reason for using a DHI, instead of, for example, using something because you are inclined to do so due to your personality [9,13]. Therefore, engagement should not be correlated to personality traits as conscientiousness and intellect/imagination. Lastly, it is important to assess whether the measure of engagement predicts future outcomes such as behavior change and clinical measures, as it is theorized that engagement influences outcomes and not the mere usage of a system.

The current study was carried out in the context of students using step counter apps. The main goal is to evaluate the psychometric properties of the TWEETS (internal consistency

and reliability; and convergent, divergent, and predictive validity). As a secondary exploratory objective, the psychometric properties of the TWEETS were compared to those of the experiential part of the DBCI-ES (DBCI-ES-Ex). We chose not to include the behavioral subscale due to the finding that this behavioral subscale may not be a valid indicator of (behavioral) engagement [20].

## Methods

### Design

For this study, participants were asked to use any step counter app on their smartphones for 2 weeks. Because the study aims at exploring the psychometric properties of the TWEETS and not, for example, how engaging a specific DHI is, the focus on students and a step counter app was deemed feasible and appropriate. Furthermore, we aimed at studying the TWEETS in an ecologically valid way and, therefore, opted to use existing step counter apps instead of, for example, a dedicated research app. Participants were asked to fill out an online questionnaire at 4 time points: T0=baseline, T1=after 1 day, T2=1 week, and T3=2 weeks. This study was approved by the ethical committee of the University of Twente (application number 18881).

At T0, demographics (gender, age, nationality, and employment status) and personality were assessed; at the other 3 time points, aspects related to the use of the step counter app were measured (engagement, involvement, enjoyment, usage, and perceived behavior change). This allowed us to perform the analyses needed to assess the internal consistency and reliability, and the convergent, divergent, and predictive validity of the engagement scales. Convergent validity refers to the degree to which measures of constructs that theoretically *should* be related, *are* related. To assess convergent validity, we chose to correlate the engagement scales to measures that are deemed to be related to behavioral, cognitive, and affective engagement. For behavioral engagement, we decided to use frequency of use and adherence as theoretically related concepts, as these are often posited as part of, or related to, engagement [9,14]. For cognitive engagement, involvement was chosen as the theoretically related concept, as involvement captures the personal relevance of an object (in this case, a DHI), which is often seen as an important part of engagement [6,7,9,16]. For affective engagement, enjoyment was chosen as the theoretically related concept because affective engagement is often seen as a reflection on how much users enjoy using the DHI [22,24].

Divergent validity refers to whether concepts that should theoretically not be related are not related. As engagement should reflect the position of an individual toward a DHI (and not a general trait or an individual), we chose to use personality traits as the concepts for divergent validity. Specifically, the personality traits of conscientiousness and intellect/imagination were used because they might reflect a somewhat similar disposition as engagement but are still theoretically unrelated. Conscientiousness, or being diligent, might lead participants to take the task of using the DHI very seriously and to, therefore, possibly use a DHI more [25]. However, this is a different reason for using a DHI and should thus not be related to engagement. Intellect/imagination—a person's preference for imaginative,

artistic, and intellectual activities [26]—could also lead to participants using a DHI more, as many DHIs also involve some degree of intellectual activity. However, as a personality trait, it should, theoretically, not be related to engagement with a specific DHI.

Predictive validity refers to the extent to which a score on a scale (in this case, engagement) predicts a score on a criterion measure in the future. As it is theorized that engagement influences outcomes like behavior change and clinical measures, we used the effectiveness of the DHI as this criterion measure.

### Participants

Participants were eligible for the study if they were willing to use a step counter app on their smartphones for 2 weeks. Recruitment took place via the participant pool of the University of Twente, where students receive credit for participating in research, and through the personal networks of the researchers. A total of 313 participants completed the baseline survey from December 2019 to April 2019; of the 313 participants, 288 filled out T1, 279 filled out T2, and 269 filled out T3. The 288 participants who filled out the TWEETS at least once (at T1, T2, or T3) were included in this study. Few data were missing of the included participants: T0 of all participants was complete; at T1, the number of participants that completed each measure ranged from 285 and 286 on the different measures (for example, 285 participants filled out the adherence measure while 286 filled out the TWEETS measure); at T2, the number of participants ranged from 270 and 274; and at T3, participants ranged from 259 and 265. Of the 288 included participants, most were female (228/288, 79%) and students (253/288, 88%). Most participants were German (202/288, 70%); 16% (46/288) were Dutch and 5% (14/288) were South African. In total, participants of 19 different nationalities were included. The mean age of participants was 22 (SD 7.1; range 18-70) years.

### Procedure

After participants signed up for the study and gave informed consent, they filled out the online T0 questionnaire with demographic information. After completing this questionnaire, they were asked to choose a step counter app to use for the following 2 weeks. While some apps were suggested (such as pre-installed step counter apps), participants were allowed to use any app that they preferred or already used. They were asked to open the app at least once a day, but it was suggested that it might be helpful to use the app more often, for example, during the day to check whether or not they were on track to reach their goal and then again at the end of the day to see how they did. Furthermore, participants were informed that they would receive 3 online follow-up surveys: after the first day, after a week, and after 2 weeks. It was explained that these surveys would cover their experience with using the step counter app. To gain credits for their education, participants had to complete all surveys.

### Materials

The following describes the different constructs—engagement, personality, involvement, enjoyment, usage, and perceived behavior change—that were measured in the questionnaires.

## Engagement

Engagement was assessed with the newly developed TWente Engagement with Ehealth Technologies Scale (TWEETS; [Table 1](#)) [15]. The TWEETS consists of 9 items on a 5-point Likert scale (strongly disagree=0, disagree=1, neutral=2, agree=3, strongly agree=4). Of the 9 items, 3 are aimed at assessing behavioral engagement, 3 on cognitive engagement, and 3 on affective engagement. The full scale is presented in [Table 1](#).

**Table 1.** The Twente Engagement with Ehealth Technologies Scale (TWEETS).

Item	Thinking about using [the technology] the last week, I feel that:	Construct
1	[this technology] is part of my daily routine	Behavior
2	[this technology] is easy to use <sup>a</sup>	Behavior
3	I'm able to use [this technology] as often as needed (to achieve my goals)	Behavior
4	[this technology] makes it easier for me to work on [my goal]	Cognition
5	[this technology] motivates me to [reach my goal]	Cognition
6	[this technology] helps me to get more insight into [my behavior relating to the goal]	Cognition
7	I enjoy using [this technology]	Affect
8	I enjoy seeing the progress I make in [this technology]	Affect
9	[This technology] fits me as a person	Affect

<sup>a</sup>Based on the outcomes of this study, this item was later changed to “[this technology] takes me little effort to use.”

As a second measure of engagement, the experiential subscale of the DBCI-ES (DBCI-ES-Ex) was used, consisting of 8 items on a 7-point answering scale with anchored end and middle points: not at all=1, moderately=3, extremely=7 [20]. The items were set up in the following manner: “Please answer the following questions with regard to your most recent use of the step counter app. How strongly did you experience the following?” The items were (1) Interest, (2) Intrigue, (3) Focus, (4) Inattention, (5) Distraction, (6) Enjoyment, (7) Annoyance, and (8) Pleasure, with items 4, 5, and 7 reverse-scored. In this study, Cronbach alpha values were .72, .80, and .84 on T1, T2, and T3, respectively.

## Personality

The personality of participants was assessed with the Mini-International Personality Item Pool (Mini-IPIP), a 20-item short form of the 50-item International Personality Item Pool–5-Factor Model measure [27]. For this study, the subscales on conscientiousness and intellect/imagination were used (both consisting of 10 items with a 7-point answering scale), which have been shown to have good psychometric properties [26]. In this study, personality was assessed at T0. The Cronbach alpha value was .78 for conscientiousness and .77 for intellect/imagination.

## Involvement

Involvement was assessed using the short version of the Personal Involvement Inventory (10 items, mean score 1-7; a higher score means more involvement), which has been shown to have good psychometric properties [23]. In this study, Cronbach alpha values were .90, .93, and .94 at T1, T2, and T3, respectively.

The scale was adapted for each time point: after one day of usage, items were posed as expectations (for example, “*I think using this app can become part of my daily routine*”); after 1 and 2 weeks, items were posed as looking back at using the app. Furthermore, the scale allows for adaption to the studied technology by adding the technology, the goal, and the behavior relating to the goal. For the current study, this was implemented as “this app” and “increasing the number of steps I take each day.”

## Enjoyment

Enjoyment was assessed using the enjoyment subscale of the Intrinsic Motivation Inventory (IMI, 7 items, mean score 1-7; a higher mean score means more enjoyment), which has been shown to have good psychometric properties [28]. The Cronbach alpha values in this study were .87, .91, and .92 at T1, T2, and T3, respectively.

## Usage

As participants were allowed to use any step counter app for reasons of feasibility and ecological validity, it was not possible to gather objective usage data. Therefore, subjective usage was assessed by asking participants whether or not they opened the app at least once a day, as was advised (*yes*=adherent; *no*=nonadherent), and how often they opened the app on a regular day that they opened it (frequency). In this case, the frequency of use and adherence are largely independent of each other because the frequency relates to a regular day when they adhered (ie, opened the app at least once). Only when a user did not use the app on any given day would the user be both nonadherent and have a use frequency of 0.

## Perceived Behavior Change

At T2 and T3, as an indication for the effectiveness of the app, we assessed whether the participants perceived behavior change due to using the step counter app. This was assessed using 1 item (“Do you feel that you have changed your behavior because of using the step counter app?”), with 3 answer options (“yes,” “maybe,” and “no”).

## Data Analyses

Analyses were performed using SPSS Statistics (version 25; IBM Corp). Analyses were conducted with the data of the

participants who completed the measures that were used in each specific analysis. Due to the limited amount of missing data, no imputation of missing values was required. Engagement measured by the TWEETS and by the DBCI-ES-Ex violated the assumption of normality at all time points by being left-skewed. However, due to the relatively large sample size and the robustness of analyses such as Pearson correlations and analyses of variance (ANOVAs), parametric tests were used [29-31]. Furthermore, we performed exploratory nonparametric analyses on our data to see whether the results from these analyses would lead to different conclusions. This was not the case, and therefore, we report only the parametric analyses in this paper.

Internal consistency of the TWEETS and the DBCI-ES-Ex was assessed using the Cronbach alpha value of each scale at T1, T2, and T3. A value of .7 was seen as the absolute minimum, while .8-.9 was seen as good internal consistency [32,33]. Exploratory factor analysis for the TWEETS was performed using SPSS' Maximum Likelihood (ML) method with oblique rotation (SPSS' direct oblimin) for all time points separately [34]. The Scree test (by examining the scree plots) combined with an assessment of eigenvalues was used to determine the number of factors [34]. Test-retest reliability for the TWEETS and DBCI-ES-Ex were assessed by examining Pearson correlations between the TWEETS scores on T1, T2, and T3, and by examining Pearson correlations of the DCBI-E scores on T1, T2, and T3. Although no standards exist for a minimum acceptable value for a test-retest reliability estimate [35], a correlation coefficient does provide information on the stability or variation of a scale over time. Convergent validity was assessed by calculating Pearson correlations between the TWEETS, DBCI-ES-Ex, involvement, enjoyment, and use frequency at T1, T2, and T3. Moreover, differences in the TWEETS and DBCI-ES-Ex between participants that adhered and did not adhere to the app were calculated using a one-way ANOVA. Divergent validity was assessed by calculating

Pearson correlations between the TWEETS and personality (conscientiousness and intellect/imagination) and between the DBCI-ES-Ex and personality (conscientiousness and intellect/imagination). Lastly, predictive validity was assessed by separate linear regression analyses using TWEETS and separate linear regression analyses using DBCI-ES-Ex on T1 to predict perceived behavior change at T2 and T3, and TWEETS and DBCI-ES-Ex at T2 to predict perceived behavior change at T3.

## Results

### Internal Consistency and Reliability

Table 2 shows the mean values of the scores on the TWEETS and the DBCI-ES-Ex at the various time points. The Cronbach alpha values of the TWEETS were .86, .86, and 0.87 on T1, T2, and T3, respectively, indicating good internal consistency. Exploratory factor analyses of the TWEETS indicated that a 1-factor structure best fits the data and explained 41.4% of the variance, based on observed data on T1. Data from T2 and T3 also indicated a 1-factor structure with similarly explained variance at T2 (42.2%) and somewhat less explained variance at T3 (30.1%). Of the 9 items, 8 items loaded strongly ( $> 0.5$ ) on the 1 factor. The other item ("this technology is easy to use") loaded 0.35 - 0.39 on the factor on the different time points. This is still seen as acceptable to retain an item in a scale, as it is above the minimum threshold of 0.32 [30]. Furthermore, the Cronbach alpha values with this item removed showed minimal differences in internal consistency (.86, .87, and .88 on T1, T2, and T3, respectively). Pearson correlations of the TWEETS at different time points were all significant ( $P < .001$ ), with values of 0.58 (T1-T2), 0.61 (T1-T3), and 0.74 (T2-T3), showing moderate test-retest reliability. Pearson correlations of the DBCI-ES-Ex at different time points were all significant ( $P < .001$ ), with values of 0.70 (T1-T2), 0.67 (T1-T3), and 0.78 (T2-T3), showing relative stability over time.

**Table 2.** Descriptive statistics for the TWente Engagement with Ehealth Technologies Scale (TWEETS) and the experiential subscale of the Digital Behavior Change Intervention Engagement Scale (DBCI-ES-Ex) at different time points.

Scale	Time point 1, n; mean (SD)	Time point 2, n; mean (SD)	Time point 3, n; mean (SD)
TWEETS	286; 2.85 (0.63)	274; 2.65 (0.65)	259; 2.65 (0.65)
DBCI-ES-Ex	286; 4.64 (0.74)	273; 4.50 (0.86)	266; 4.49 (0.90)

### Convergent Validity

Pearson correlations between the TWEETS, DBCI-ES-Ex, involvement, enjoyment, and use frequency at the different time points are shown in Table 3. The 2 engagement scales showed moderate to strong correlations with each other. Both the TWEETS and DBCI-ES-Ex showed significant moderate to

strong correlations with involvement and enjoyment, which become stronger at later time points. The DBCI-ES-Ex scale consistently showed stronger correlations than the TWEETS with both involvement and enjoyment, with particularly strong correlations with enjoyment. Both scales show no or weak correlations with reported use frequency.

**Table 3.** Pearson correlations between the TWente Engagement with Ehealth Technologies Scale (TWEETS), the experiential subscale of the Digital Behavior Change Intervention Engagement Scale (DBCI-ES-Ex), involvement, enjoyment, and use frequency.

Scale & time point	Involvement	Enjoyment	Use frequency	DBCI-ES-Ex
<b>TWEETS</b>				
T1	0.57 <sup>a</sup>	0.60 <sup>a</sup>	0.08	0.57 <sup>a</sup>
T2	0.61 <sup>a</sup>	0.70 <sup>a</sup>	0.24 <sup>a</sup>	0.73 <sup>a</sup>
T3	0.67 <sup>a</sup>	0.77 <sup>a</sup>	0.04	0.80 <sup>a</sup>
<b>DBCI-ES-Ex</b>				
T1	0.54 <sup>a</sup>	0.69 <sup>a</sup>	0.02	N/A <sup>b</sup>
T2	0.63 <sup>a</sup>	0.81 <sup>a</sup>	0.26 <sup>a</sup>	N/A <sup>b</sup>
T3	0.70 <sup>a</sup>	0.82 <sup>a</sup>	0.03	N/A <sup>b</sup>

<sup>a</sup>Significant with  $P<.001$ .<sup>b</sup>N/A: not applicable.

Lastly, mean scores on the TWEETS between participants that adhered to the app (using it at least once a day) and those that did not adhere significantly differed at all time points ( $P<.001$ ), with adherers scoring higher than nonadherers (Figure 1). The

same was true for the DBCI-ES-Ex scale, with  $P=.028$  at T1 and  $P<.001$  at T2 and T3. However, the number of nonadherers was low, especially at T1 (T1: 2/285; T2: 36/270; T3: 46/262).

**Figure 1.** Engagement scores of adherers and nonadherers at the different time points. DBCI-ES-Ex: the experiential subscale of the Digital Behavior Change Intervention Engagement Scale; T: time point; TWEETS: TWente Engagement with Ehealth Technologies Scale.

### Divergent Validity

Pearson correlations between conscientiousness and the TWEETS at the different time points were nonsignificant. The same was true for intellect/imagination. For the DBCI-ES-Ex, the Pearson correlation with conscientiousness at T1 was weak but significant (0.17,  $P<.01$ ). Pearson correlations at the other time points and with intellect/imagination were nonsignificant.

### Predictive Validity

Results of the linear regression analyses using the TWEETS and DBCI-ES-Ex to predict perceived behavior change are shown in Table 4. These results show that both the TWEETS and DBCI-ES-Ex demonstrate predictive validity. As can be expected, the shorter the time between the measurement of engagement and the measurement of perceived behavior change, the more predictive engagement is, with engagement at T2 explaining around 24% of the variance of perceived behavior

change at T3, and engagement at T1 explaining 12-14% of the variance of perceived behavior change at T2. However, engagement measured at T1 was also predictive of perceived

behavior change at T3, with an explained variance of 16% when using the TWEETS and 9% using the DBCI-ES-Ex.

**Table 4.** Regression analyses with the TWente Engagement with Ehealth Technologies Scale (TWEETS) and the experiential subscale of the Digital Behavior Change Intervention Engagement Scale (DBCI-ES-Ex) to predict perceived behavior change.

Scale & time point	Perceived behavior change T2			Perceived behavior change T3		
	Beta	R <sup>2</sup>	F <sup>a</sup>	Beta	R <sup>2</sup>	F <sup>a</sup>
TWEETS T1	-.38	0.144	45.34	-.40	0.163	51.36
TWEETS T2	N/A <sup>b</sup>	N/A <sup>b</sup>	N/A <sup>b</sup>	-.49	0.242	84.04
DBCI-ES-Ex T1	-.35	0.120	35.84	-.30	0.087	25.70

<sup>a</sup> $P < .001$

<sup>b</sup>N/A: not applicable.

## Discussion

### Principal Findings

This study set out to evaluate the psychometric properties of the new TWEETS. A secondary exploratory objective was to compare these psychometric properties to those of the experiential subscale of the DBCI-ES.

For the TWEETS, internal consistency was high, indicating that the different items of the scale all measure the same construct. In line with this, exploratory factor analyses showed the scale consists of 1 factor; we did not find the 3-factor structure that we expected, resulting from the behavioral, cognitive, and affective engagement components and their respective items in the scale. An explanation could be that engagement as a concept comprises only 1 component and not the proposed 3 components. However, because of the theoretical background of the concept, we would be hesitant to accept this explanation without further research. A more likely explanation might be that there is a theoretical overlap between the component; for example, enjoying seeing the progress that you make through an app (affective engagement) might also influence the extent to which you feel that the app motivates you to reach your goals (cognitive engagement). Also, behavioral engagement might be more of a consequence of cognitive and affective engagement (for example, because people feel that the technology helps them achieve their goals and is fun, they might establish a routine of using it), rather than being on the same level as these components. However, an explanation might also lie in the small number of items in the scale; 5 or more strong loading items per factor are seen as desirable [34], which indicates that we should have at least 15 items that would be retained in the scale, indicating an even higher number of a priori items. However, data showed that the 1-factor structure that was observed in the data was solid, with 8 items loading strongly and the last one above the minimum to retain an item in a factor [34]. Future research could explore whether the components can be measured as separate constructs, for example, by adding more items and examining whether this is desirable, as it would also increase the length of the scale and, therefore, its participant burden. Another option may be to retain the TWEETS as a short-form

engagement measure and develop separate measures for the components to be able to investigate more detailed patterns of engagement when in-depth analyses are needed, for example, to explore whether different people have, or different technologies induce, a different distribution of engagement over the components. What the 1-factor structure of the TWEETS does show is that the different components of engagement are indeed related and measure the same construct. This strengthens the assumption that engagement is a combination of behavior, cognition, and affect, and more than just usage behavior.

Test-retest reliability analyses showed moderate positive correlations between the first and later time points, and a strong positive correlation between the later time points. Although this may be interpreted as low test-retest reliability when looking at this first time point, this might not be surprising, as engagement after 1 day of usage might be initial engagement, which may be different from longer-term engagement. This is also reflected in different models on the process of engagement in which engagement may vary over time [8,17]. It seems reasonable to expect engagement to change after getting more acquainted with the app, and when actually trying to use the app for a longer period in daily life. As integrating technology in daily life is often one of the largest struggles in eHealth and specifically DHIs [36], being able to do so or not might be an obvious reason for a change in engagement. Taking these factors into account, it may be even more remarkable to see that participants' initial engagement, based on only 1 day of using a DHI, is still as related to engagement at a later stage. Additionally, this change in the level of engagement over time might also explain the somewhat differing findings on convergent and divergent validity of the engagement scales at different time points. As is seen in other studies, different aspects might be more important and more related to engagement in the different stages of the process of engagement [17].

Related to this, the TWEETS showed predictive validity: engagement at an earlier time point was able to predict perceived behavior change at a later time. Even the engagement measure after the first day of using a technology showed this capability, which opens up many interesting possibilities [13]; when we are able to assess early on in an intervention whether or not we

expect it is going to be effective for an individual, we may be able to direct more support to those for whom it might not be effective. This can be, for example, in the form of personalized feedback or the suggestion of using a different intervention.

Analyses of divergent validity showed that the TWEETS was not correlated with personality factors. This strengthens the assumption that engagement is a separate construct and that this is reflected in this new scale. Analyses of convergent validity showed that the TWEETS is moderately to strongly correlated with involvement (which is seen as theoretically related to cognitive engagement) and enjoyment (which is seen as theoretically related to affective engagement) [24]. The strength of the correlations indicate that the concepts are related but should be viewed as separate. For behavioral engagement, we choose to relate the TWEETS to adherence and frequency of use, as these are aspects that are often seen as related to engagement [9,14,24], or even used to assess criterion validity [19]. Correlations between the engagement measure and frequency of use were nonsignificant or small, while differences between adherers and nonadherers on engagement were significant but small. This might indicate that engagement is related to usage, but much less so than is often assumed, again strengthening the multiple component definition of engagement. However, it should be noted that our usage measure was subjective, which sheds some doubt on the robustness of this measure. This could provide an alternative explanation of the weak correlation between frequency of use and engagement. Future research could investigate whether objectively measured frequency of use should be seen as a measure of convergent validity or whether it could be more appropriate to see it as a measure to assess divergent validity.

The exploratory comparison of the psychometric properties of both engagement scales—the TWEETS and the DBCI-ES-Ex—revealed that both scales show similar properties. As could be expected, the scales are significantly correlated to each other. Interestingly, this correlation is moderate at the first time point but strong at the last time point. This might indicate that they vary on how much they take the first impression that a DHI makes into account. A few notable differences between both scales are that the DBCI-ES-Ex shows quite a strong correlation to enjoyment, a bit stronger than the TWEETS, and that DBCI-ES-Ex did not fully reflect divergent validity. This might indicate that the DBCI-ES-Ex captures engagement not as a unique concept but more like enjoyment. Additionally, the TWEETS shows more predictive validity between the first and the last time point compared to the DBCI-ES-Ex. Overall, the TWEETS seems to reflect engagement better as a multifaceted and unique concept that has predictive value for the outcomes of an intervention.

## Limitations

This study has a few limitations that need to be discussed. First, the study was done mostly with students who received credits for participating in the study and thus for using the step counter app, which might have influenced their usage and engagement. However, as we were interested in the relationships between engagement and other measures, and not the level of engagement or usage, we feel that studying this target group was an

appropriate first step. Furthermore, we needed data on a broad spectrum of engagement, including low engagement. Therefore, including a target group that might not be completely intrinsically motivated to use a DHI was seen as appropriate. Future research should focus on measuring engagement in different populations and settings, for example, with lower educated participants or within the context of regular (mental) health care. It would be interesting to see whether different populations show different styles of engagement, such as whether lower educated participants might be more often affectively engaged, and whether this impacts the factor analysis of the scale.

Second, we used self-reported usage data and our variable for predictive validation was perceived behavior change and not actual behavior change. It would have been preferable to use objective usage data and actual behavior change data, but this was deemed infeasible for this exploratory study because participants could use any step counter app for reasons of ecological validity and feasibility. Therefore, it was not possible to objectively collect the usage data of all these different apps or the number of steps participants took every day. Also, to be able to measure actual behavior change in the average number of steps per day, a larger data collection period would have been necessary, which was beyond the scope of this study. However, as this was an exploratory study that provides a first step towards establishing whether the TWEETS is a useful measure of engagement in DHIs, this approach was deemed appropriate. Based on the promising findings of this study that engagement was able to predict perceived behavior change, the next step is to validate this finding in future studies using engagement to predict actual behavior change and other intervention outcomes. Also, the direction of change was not explicitly stated in the question. However, at multiple points in the study, it was stated that the goal of the app was to increase the number of steps taken per day. Moreover, participants could indicate in what way they changed their behavior. All participants that filled out that question indicated that they took more steps per day and not less steps. Therefore, we feel that the impact of not explicitly stating the direction of change was negligible.

A final limitation is that 1 item of the scale performed a bit less well than the others, although still above the minimum threshold to retain an item in a scale: the item “*this technology is easy to use*” should be revised in a way that better reflects the behavioral component of engagement and is less related to usability, which can be seen as a predictor of engagement. A different way to state the item that better reflects the quality of engagement behavior from our definition could be “*this technology takes me little effort to use.*” Nonetheless, the scale performed quite well on most criteria, indicating the potential of this new instrument.

## Conclusion

Overall, the TWEETS seemed to perform quite well as a 1-factor engagement measure: the scale showed high internal consistency, reasonable test-retest reliability and convergent validity, good divergent validity, and reasonable predictive validity. These properties seem comparable to—and, on some aspects, somewhat superior to—those of the experiential

subscale of the DBCI-ES. Further research is needed to replicate these findings in other target groups and eHealth technologies; however, the TWEETS seems to be a valuable addition to the toolbox of eHealth researchers, allowing them, amongst others, to be able to better investigate the relationship between engagement and effectiveness.

Lastly, the psychometric quality of a scale is, of course, a reflection of how closely a scale matches the conceptualization

of the concept. Therefore, this paper can also be seen as an attempt to conceptualize and define engagement as a unique concept, different from, for example, adherence and user experience. We have argued for a definition of engagement that entails behavioral, cognitive, and affective components and, through the analyses in the paper, have provided arguments in favor of this definition. This paper provides a first step toward an acceptable standard of defining and measuring engagement.

## Abstract

**Background:** User dropout is a widespread concern in the delivery and evaluation of digital (ie, web and mobile apps) health interventions. Researchers have yet to fully realize the potential of the large amount of data generated by these technology-based programs. Of particular interest is the ability to predict who will drop out of an intervention. This may be possible through the analysis of user journey data—self-reported as well as system-generated data—produced by the path (or journey) an individual takes to navigate through a digital health intervention.

**Objective:** The purpose of this study is to provide a step-by-step process for the analysis of user journey data and eventually to predict dropout in the context of digital health interventions. The process is applied to data from an internet-based intervention for insomnia as a way to illustrate its use. The completion of the program is contingent upon completing 7 sequential cores, which include an initial tutorial core. Dropout is defined as not completing the seventh core.

**Methods:** Steps of user journey analysis, including data transformation, feature engineering, and statistical model analysis and evaluation, are presented. Dropouts were predicted based on data from 151 participants from a fully automated web-based program (Sleep Healthy Using the Internet) that delivers cognitive behavioral therapy for insomnia. Logistic regression with L1 and L2 regularization, support vector machines, and boosted decision trees were used and evaluated based on their predictive performance. Relevant features from the data are reported that predict user dropout.

**Results:** Accuracy of predicting dropout (area under the curve [AUC] values) varied depending on the program core and the machine learning technique. After model evaluation, boosted decision trees achieved AUC values ranging between 0.6 and 0.9. Additional handcrafted features, including time to complete certain steps of the intervention, time to get out of bed, and days since the last interaction with the system, contributed to the prediction performance.

**Conclusions:** The results support the feasibility and potential of analyzing user journey data to predict dropout. Theory-driven handcrafted features increased the prediction performance. The ability to predict dropout at an individual level could be used to enhance decision making for researchers and clinicians as well as inform dynamic intervention regimens.

dropout; digital health; machine learning

## Introduction

The efficacy of digital (ie, internet, web, and mobile) behavioral interventions to improve a range of health-related outcomes has been well documented [1-3]. However, adherence to these interventions is a significant issue [4]. Intervention dropout, defined as a participant prematurely discontinuing a program, from internet-based treatments for psychological disorders typically varies between 30% and 50% [4-6]. However, the reason for such high dropout rates is still unclear [5], whereas longer treatment duration and user engagement appear to be associated with improved treatment outcomes and greater effectiveness of the digital intervention [7-10]. Furthermore, in a research setting, high dropout rates and, consequently, low exposure to digital content might affect the reported effects of a digital intervention and the validity of the results [11,12]. Although researchers have highlighted the need for a science of user attrition [13], there have been few advances in predicting dropout through advanced quantitative approaches in eHealth interventions [14]. In particular, previous work has identified hypothetical factors influencing attrition in eHealth programs, such as ease of leaving the intervention, unrealistic expectations on behalf of users, usability and interface issues, and amount of workload required to benefit from an intervention [13]. Such factors are likely to impact how a user ultimately engages with a program and could provide indicators for predictive factors but do little to advance predictive modeling of dropout when not applied in data-driven studies. Research suggests that an increased completion of modules in digital therapeutics increases treatment outcomes [15]. Identifying those patients that are likely to drop out of treatment and addressing the related issues can, thus, improve treatment outcomes and can be the basis of the development of micro interventions that target these high-risk participants to reengage them to complete the program [16]. Thus, predicting dropout on a participant level supports the decision making of experts in the target field and consequently leads to more personalized treatment strategies. In addition, inferential results can increase insight into the causes of attrition by revealing data-driven indicators. Participant-specific factors can help to identify individuals who benefit more from digital therapies compared with individuals for whom face-to-face treatment might be a better approach. To evaluate the possibility of predicting dropout in digital interventions and to shed light on some indicators of dropout, the aim of this study is to propose a process for user journey analysis to predict dropout from a digital intervention.

A wealth of data can be collected through the use of digital interventions. They often feature content that is administered over time as users complete tasks or components of the intervention, typically over several weeks or months [17-20]. Digital interventions also track and log different types of user interactions (eg, frequency of log-ins). These data provide a nuanced understanding of the usage behavior of participants over the course of an intervention [21]. Combined with

self-reported data, passively collected user data could be captured and used to provide deeper insight into how likely users are to drop out of an intervention on an individual level and lead to increased prediction performance.

A user journey is a sequence of interactions as an individual uses a digital intervention (ie, the path an individual takes to navigate through a program). Although user journeys are well known and established in the field of web-based marketing, to the best of our knowledge, its direct application to digital health interventions has not yet been examined. Web-based marketers leverage user journeys to collect information about an individual's behavior [22], often referred to as clickstream data analysis [23,24]. This increases the understanding of users' behavior by recognizing patterns in their sequence of actions. Thus, user journey analysis can reveal insight into an individual's behavior by enabling an analysis of data (eg, Ecological Momentary Assessment [EMA] or log data) that is not frequently used in the eHealth sphere [25].

There are several possible reasons why analysis of user journeys has not achieved prominence in digital health interventions. One obstacle lies in the analysis of large amounts of raw data. Analysis of user journeys often requires transformation of raw data, feature engineering, and the application of machine learning techniques, which can be a burdensome process [26] and is not a typical skill set of eHealth behavior researchers. Although user journeys have been used to predict different psychological factors such as mood, stress levels, or treatment outcomes and costs [25,27-31], to our knowledge, no work has provided steps to be taken to analyze raw user journey data and, at the same time, predict user dropout from a digital health intervention.

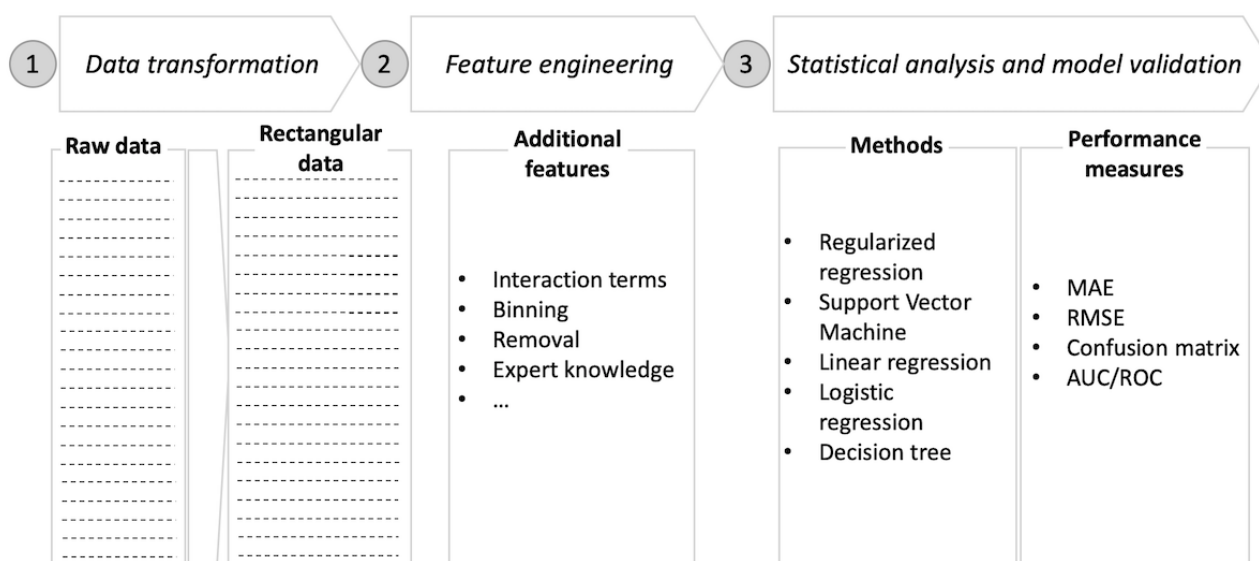

The overarching goal of this study is to establish and provide a step-by-step process that describes how to leverage user journeys to predict various behaviors (eg, dropout). This process involves several steps, including creating the basic data structure for handling user journeys, creating features that can add additional information to the existing raw data, and ultimately providing a framework for the statistical analysis. A technical implementation (R package) [32,33] of this process is provided for the research community. To demonstrate the application and potential utility of this process, we use it to predict user dropout in a randomized controlled trial of a fully automated cognitive behavior therapy intervention for insomnia (Sleep Healthy Using the Internet [SHUTi]) [34].

## Methods

### User Journey Process

The overarching steps of the user journey process are outlined in Figure 1. This process applies machine learning algorithms, specifically supervised learning, which is used when both input (eg, log-ins and mood symptoms) and output data (eg, dropout status) exist in the data set [35].

**Figure 1.** Process of analysis. AUC: area under the curve; MAE mean absolute error; ROC: receiver operating characteristics; RMSE: root mean square error.

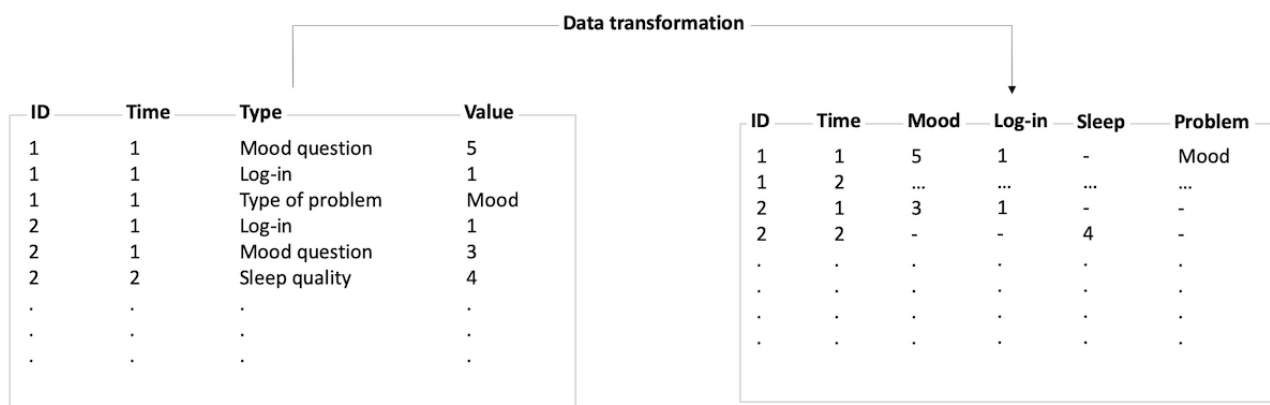

It is important for researchers to clearly define the outcome variable of interest. As dependent variables can take on different measurement scales (eg, discrete or continuous), defining the target variable has consequences for the choice of statistical models. When predicting discrete outcomes (ie, consisting of at least two discrete categories or labels), classification is often the appropriate approach. However, when predicting continuous outcome variables, the learning task is regression.

### Step One: Data Transformation

The first step in analyzing user journey data is to transform the raw data into a wide format, as can be seen in Figure 2. Thus, the transformed data are structured such that each row corresponds to a unique observation in *Time* for a particular user (*ID*).

**Figure 2.** Example of data transformation in the context of digital health interventions.

When transforming the raw data, it is important to specify the time window defining the time interval for which individual touch points are aggregated. The choice of the time window depends on the density of the observations in the raw data. For example, if a raw data set is composed of a few touch points over the course of a day, choosing a time window on a scale of days avoids sparseness of the transformed data matrix. In contrast, when predicting purchases in web-based marketing, for example, a large number of observations exist for each user on short timescales. Here, choosing a small window (eg, an hour) could be beneficial, as the resulting matrix will not be sparse and information loss is minimal. In an internet-based intervention, however, it is not unusual for self-reported data to be collected as little as once a day, with a user logging into the system only a few times a day. In this case, it would not

make sense to choose an hour-long window because the resulting matrix would be very sparse. Thus, choosing a time window on a scale of days would be a better choice.

If multiple observations of the same type occur within a time window, one must decide how to aggregate these values. For some variables, such as diary entries, taking an average may be desirable; for other variables, such as log-ins, the sum is a more appropriate aggregation. The provided technical framework supports the data transformation procedure. In addition, missing values often exist in the data. There are various procedures that can handle missing values. One might remove all rows that include missing values; however, this can lead to a reduction in observations. Other possibilities include imputation procedures such as using aggregated values of these features or

developing statistical models that predict the missing values based on other features. For more information on missing values, we refer to the study by Batista and Monard [36].

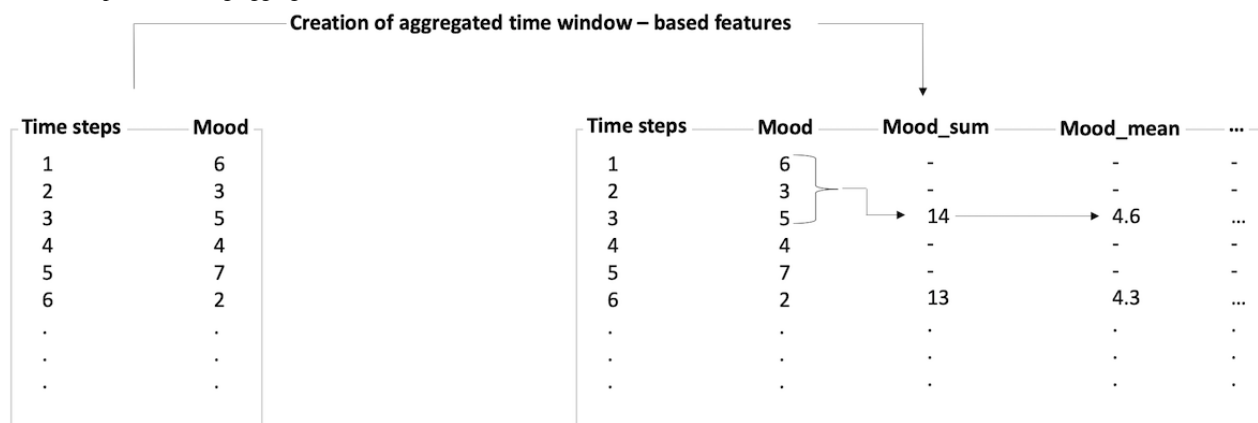

### Step Two: Feature Engineering

Feature engineering can be described as the process of including additional variables into the data with the intention of achieving increased predictive performance. As statistical learning relies heavily on the input data, this step is important for improving the accuracy of prediction [37]. There are 2 approaches to feature engineering: handcrafted or automated. Handcrafted feature engineering is a challenging task and requires human effort and domain knowledge. Therefore, it is appropriate for researchers with expertise in the domain that is represented by the data (eg, sleep) to be highly involved in the process [38-40]. A clear understanding of the problem to be solved is necessary to derive meaningful features [40]. Handcrafted feature engineering often involves a trial and error phase to experiment with different features [37]. Automated feature engineering involves the generation of candidate features that are evaluated based on their predictive performance. Tools exist for the application of automated feature engineering in different domains, such as natural language processing or machine vision [38,41,42].

Interaction terms, that is, the product of 2 original features, can lead to additional knowledge about their relationships and increased predictive accuracy. The provided technical framework supports generating them. In case of a large number of original features, however, including interaction terms results in many additional features.

In addition, time window-based aggregation methods can be beneficial in terms of predictive performance in the context of digital health interventions [31]. Here, based on a user-specified time window  $w$ , various types of aggregations are performed on the original features. Figure 3 represents the process of this task through the exemplification of self-reported EMA data. The *Mood* level is reported by an individual at different points in time (*Time steps*). For the creation of the aggregated features, a time window of  $w=3$  is specified in this example. Various statistical measures, such as the sum (*Mood\_sum*), mean (*Mood\_mean*), minimum, maximum, and SD (not shown in figure), are calculated for 3 consecutive measurements of the mood level ( $w=3$ ) and included as additional features in the data set. It should be noted that the creation of features can limit one's ability to reproduce study results if the feature engineering process is not well documented or if the data set changes over time. For the case study in this paper, we created various theory-driven features based on expert knowledge, which will be introduced in *Feature Engineering*.

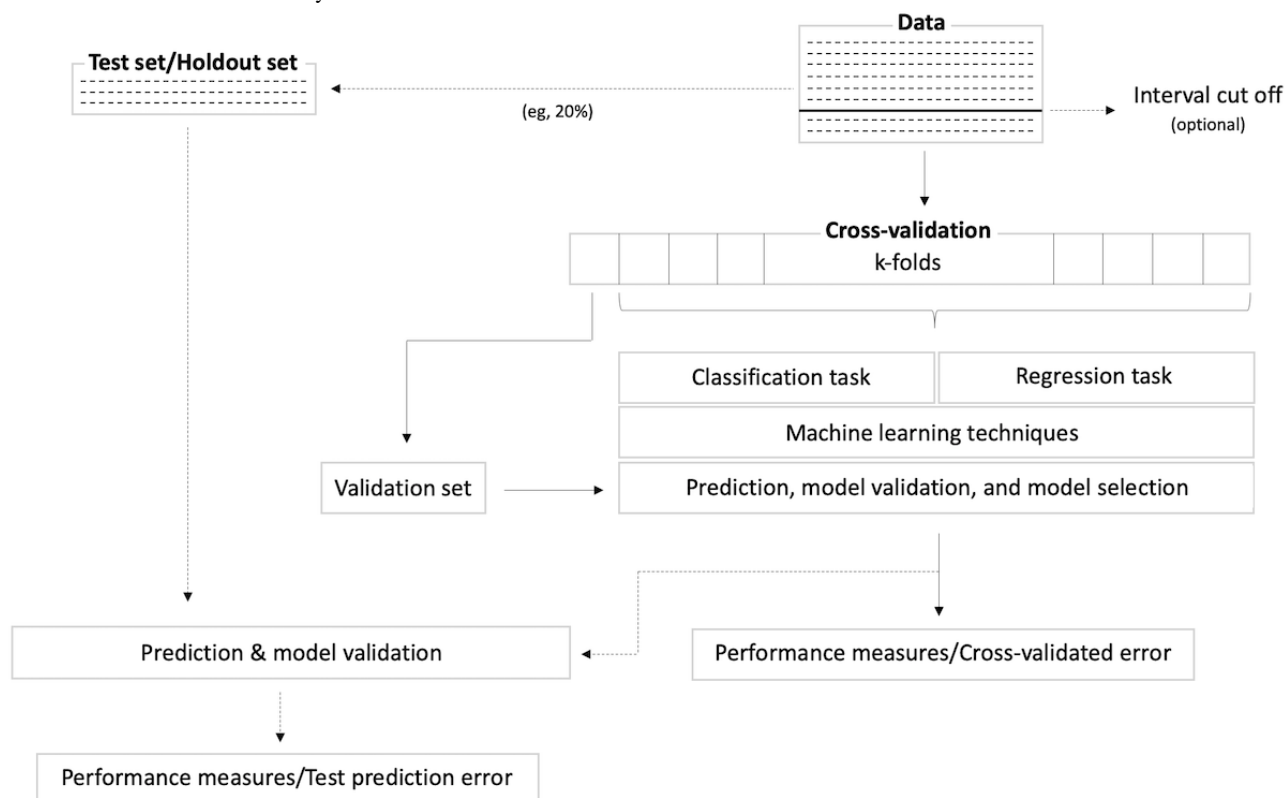

**Figure 3.** Example of creating aggregated time window-based features for  $w=3$ .

### Step Three: Statistical Analysis and Model Validation

The next step in analyzing user journey data is the application of machine learning techniques to predict the outcome variable. Figure 4 depicts this procedure. First, the data set can be split into a training set for fitting the data and learning patterns and

a test (or holdout) set. This test set is usually created if sufficient data are available. It is subsequently used to test the final model performance of the selected algorithm. It is difficult, however, to quantify *sufficient data* as it depends strongly on the field of research, applied models, and structure of the data.

**Figure 4.** Procedure of statistical analysis.

Depending on the task to be analyzed, the data can be further split based on particular points in time. If the aim of the analysis, for example, is the prediction of the outcome of an intervention, it might be useful to evaluate at what point in time the predictive accuracy is at its peak. The longer the time window, the higher the predictive accuracy can be assumed because more data are available. Thus, using time windows and basing the amount of usable data on these windows (*interval cut off*) can be useful in evaluating the feasibility of prediction.

There are a large number of machine learning techniques that can be applied to user journey data; some models can be applied to both learning tasks (classification or regression), such as support vector machines or decision trees, whereas others fit better for a specific task (ie, logistic regression for classification). Researchers may wish to compare their predictive performance to justify the model selection. Cross-validation is often applied to gauge the predictive performance of a specified model. Here, the data are divided into  $k$  chunks, where  $k-1$  chunks are used for training the machine learning techniques and the remaining data chunk is used for predicting the target variable. This procedure is repeated  $k$  times until each chunk has been used as a validation set. Ultimately, the model with the best performance is selected for the specified learning task. If a holdout set is maintained, the specified model is then trained based on all data. The target variable in the holdout set is then predicted and evaluated, which leads to the test prediction error.

Model validation checks the ability of a particular model to either fit the data or predict the outcome variable [43]. Eventually, the one with the best performance is selected. Nonvalidation can lead to inaccurate predictions and, thus, overconfidence in the developed model [44]. Model validation

should generally be executed on the validation set for each iteration of the cross-validation procedure (cross-validated prediction error) to select the best model and, subsequently, on an independent test set that was set aside earlier (test prediction error). In some cases, especially when sufficient data are not available, no independent test set is put aside and only the cross-validated error is reported, which can lead to an optimistic estimation of the error [44].

Deciding on the method of model validation also depends on the learning task. For regression, criteria such as the root mean square error or mean absolute error are often appropriate. For the classification task, confusion matrices and receiver operating characteristic (ROC) graphs are often used as performance indicators. More information about these validation procedures and their application can be found elsewhere [45].

In the provided technical framework, logistic regression, linear regression, support vector machines, boosted decision trees, and regularization techniques are implemented. As overfitting can occur when utilizing a large number of features [37] and some types of statistical procedures (eg, linear regression) cannot be applied when the number of features is greater than the number of observations, alternative techniques such as regularization and feature selection may need to be used [46]. A thorough review of these techniques is outside the scope of this paper, and readers are strongly encouraged to learn more about each of these techniques and how they pertain to their data and aims.

### Case Study

To illustrate the user journey analysis process, data were extracted from a trial of a web-based program (SHUTi) [47].

SHUTi is a fully automated web-delivered program that is tailored to individual users [47] and informed by the model for internet interventions [17]. SHUTi is based on the primary principles of face-to-face cognitive behavioral therapy for insomnia (CBT-I), including sleep restriction, stimulus control, cognitive restructuring, sleep hygiene, and relapse prevention. SHUTi contains 7 *cores* that are dispensed over time, the first core being a tutorial on how to use the program, with new cores becoming available 7 days after completion of a previous core. This format was meant to mirror traditional CBT-I delivery procedures using a weekly session format. SHUTi has been found to be more efficacious than web-based patient education in changing primary sleep outcomes (insomnia severity, sleep onset latency [SOL], and wake after sleep onset [WASO]), with the majority of SHUTi users achieving insomnia remission status 1 year later [48]. A mobile app version of SHUTi, Somryst, with equivalent content and mechanisms of action was recently cleared by Food and Drug Administration as the first prescription digital therapeutic for treating patients with chronic insomnia. Thus, the efficacy of SHUTi is well established. However, similar to other digital interventions, predicting user dropout is an important yet unaddressed issue. Thus, the primary aim of this case study is to demonstrate the feasibility of predicting user dropout from data generated by a digital health intervention.

The sample for this study was drawn from a trial consisting of 303 participants (218/303, 71.9% female) aged between 21 and 65 years (mean 43.3 years, SD 11.6). They were 83.8% (254/303) White, 6.9% (21/303) Black, 4.0% (12/303) Asian, and 5.3% (16/303) *other*. Participants were randomly assigned (using a random number generator) to receive SHUTi or web-based patient education (control condition). The study was approved by the local university's institutional review board, and the project was registered on clinicaltrials.gov

(NCT01438697). Inclusionary and exclusionary criteria as well as outcomes are reported in detail elsewhere [48].

Data from 151 participants who were assigned to SHUTi were used in this study. Both self-reported and system-generated types of data are available. Participants completed a battery of self-report measures at baseline and post intervention. A list and detailed description of the measures have been published previously [48]. Sleep diaries were also collected throughout the intervention period, along with information about bedtime, length of sleep onset, number and duration of awakenings, perceived sleep quality, and rising time. Data were collected prospectively for 10 days (during a 2-week period) at each of the 4 assessment periods (pre- and postintervention and 6- and 12-month follow-ups). Sleep diary questions mirrored those from the consensus sleep diary [49]. Values for SOL and WASO were averaged across the 10 days of diary collection at each assessment period. The system-generated data included individual log-ins and automated emails sent by the system as well as trigger events logged in the system. All data were used to predict user dropout, defined as not completing all 7 SHUTi cores (core 0 through core 6). Thus, users were classified as having dropped out or not. As noted elsewhere [48], 60.3% (91/151) participants completed all 7 cores in the SHUTi program.

## Results

The primary aim was to predict whether users prematurely dropped out of SHUTi (dropped out by core 6/completed core 6). Therefore, the learning problem is a binary classification (drop out/did not drop out). To verify the point at which the machine learning techniques were capable of predicting dropout, separate analyses were executed after the completion of each core (Figure 5) and only included data up to the core in question. The number of participants included in each analysis was 146, 141, 133, 116, 102, and 101 for cores 0 to 5, respectively.

**Figure 5.** Setup of analysis for dropout prediction.

## Data Transformation

As a first step, the raw data were transformed into a rectangular data matrix (wide format), which led to 981 basic features. Basic features are those features that were already included in the raw data. As an example, see column *Type* in Figure 2. In addition, 25 handcrafted and theory-driven features that were derived from the raw data were implemented. These features are introduced in the next section *Feature Engineering*. In total, 1006 features were used for the analyses. Whenever the same question (ie, in the case of diary data) was administered multiple

times a day, the mean of the reported values was chosen for numeric data and the mode for categorical data. To reduce the sparseness of the resulting data matrix, reported values for questionnaires such as the Insomnia Severity Index were repeated for each participant until the next occurrence of the questionnaire (this questionnaire was administered before each core). To address the issue of missing data, features were deleted based on the quantity of missing data. To evaluate how the deletion affects the predictive performance of the models, features were deleted that contained more than 5%, 10%, 15%, and 20% of missing values. This procedure reduced the number

of features tremendously. In addition, categorical variables that had only one level or category were removed. Less data are available for the analysis at time point core 0 compared with time point core 5. Thus, the number of features for each level of missing data was 83, 263, 299, and 401 features.

As the aim of this study was to predict dropout at core 6, each participant only had exactly one outcome value—they could either complete core 6 or not. Users that dropped out between cores 1 to 5 would be classified as having dropped out at core 6. Therefore, the user journey data must be aggregated for each

user. For most of the variables, the mean and mode were used as the aggregation method. However, for some variables, such as log-in information or number of days since the last contact, the sum is more appropriate. Table 1 illustrates the different aggregation procedures and the corresponding features. Features that are not listed were aggregated by mean and mode. The rest of the missing data were imputed using the median for numeric variables and mode for categorical features. In addition, an imputation based on the k-nearest neighbor (KNN) algorithm was applied (k=5). Both approaches were used to reveal which of them led to a better prediction performance.

**Table 1.** Aggregation of theory-determined features.

Feature aggregation method	Handcrafted features	Existing clinically important features
Sum: The sum of all observations of a specific feature for an individual	<ul style="list-style-type: none"> <li>Days since the last contact (any interaction)</li> <li>If sleeping duration is decreasing from core to core</li> <li>If sleep window duration is 5 or 8 hours</li> </ul>	<ul style="list-style-type: none"> <li>If the participant had an alcoholic drink that day</li> <li>If the participant took a nap</li> <li>If the system recorded a triggered event that day</li> <li>If the participant logged in that day</li> <li>If the system sent an email that day</li> </ul>
Last: The last observation of a specific feature for an individual	<ul style="list-style-type: none"> <li>Difference between preferred arising time in core 2 and core 3</li> <li>If preferred arising time is greater than 8 AM in core 2</li> <li>Average time in days to complete a core among all cores that have been available</li> <li>Time needed in days to complete a core in days (6 features for core 0-5)</li> </ul>	<ul style="list-style-type: none"> <li>If the participant finished homework in core 2</li> <li>Number of days where no diaries have been completed in the period of analysis</li> <li>Precipitating factor includes <i>major life event</i> or <i>health/psychological</i></li> </ul>
Mean: Mean of the observations of a specific feature for an individual	<ul style="list-style-type: none"> <li>Difference between awake and arise time</li> <li>Difference between preferred arise time and actual arise time (AM/PM)</li> <li>Difference between preferred arise time and actual arise time (minutes)</li> <li>Difference between preferred bedtime and actual bedtime</li> </ul>	<ul style="list-style-type: none"> <li>Naptime in minutes</li> </ul>

## Feature Engineering

A total of 25 theory-driven features were implemented for this case study. Some of these features, shown in Table 1, were handcrafted and some were already existing in the data set. Specifically, the handcrafted features were computed from the raw data and were deemed useful for model prediction. Few of these features are study-specific (eg, *if the participant finished homework in core 2*), whereas others could be used in any type of digital intervention (eg, *if the participant logged in*). As the number of features generated from the study data was already large, none of the generic feature generation methods were used. These 25 features were not deleted based on the missing value ratio (mentioned above) because there was a clinical or theory-driven rationale that they would influence prediction performance.

## Statistical Analysis and Model Validation

For the learning task, a set of machine learning techniques was used to select the model with the best prediction performance.

Specifically, support vector machines, boosted decision trees, and logistic regression with L1 and L2 regularization were applied. The optimal parameters were determined using a grid-based search and cross-validation. In addition, stratified 10-fold cross-validation was used for each analysis. To choose an appropriate statistical model, a heat map was created to illustrate the average area under the curve (AUC) across all core analyses for each model, imputation procedure, and threshold for percentage of missing values (Figure 6). As can be seen, the method of imputing the missing values did not have a strong influence on the performance of the applied statistical model. Increasing the percentage threshold negatively influenced L1 regularization and the support vector machine, whereas L2 regularization and boosted decision trees seemed not to be influenced tremendously. The best average AUC value (0.719) was achieved by applying boosted decision trees, deleting each feature that contained more than 15% of missing values, and imputing the rest of the missing values by KNN.

**Figure 6.** Heat map of average area under the curve values across core analyses for each model, imputation procedure, and threshold for percentage of missing values. AUC: area under the curve; KNN: k-nearest neighbor; LASSO: least absolute shrinkage and selection operator; SVM: support vector machine.

Figure 7 illustrates the ROC curves for each core analysis using the specified parameters. With the exception of core 4, the AUC values increased with each analysis. For each core, the predictions were better than random, indicated by AUC values above 0.5. Generally, the AUC values ranged between 0.6 and 0.9. Importantly, the prediction of dropout appears feasible early

in the intervention period (ie, core 1 and core 2). In addition, the area under the precision-recall curve (PRAUC) was computed. Across all core analyses, a PRAUC of 0.48 was observed, whereas chance had an average of 0.24. Thus, the model performs better than chance.

**Figure 7.** Receiver operating characteristic for each core analysis based on boosted decision trees (15% missing value deletion, k-nearest neighbor imputation). AUC: area under the curve; FPR: false-positive rate; TPR: true-positive rate.

Boosted decision trees were used to identify important features. Here, SHapley Additive exPlanation (SHAP) values were used [50]. SHAP values are a relatively new concept in the field of machine learning and essentially represent the importance of each feature and their contribution to the prediction by comparing the prediction of the model with and without a specified feature value depending on the order of their

introduction to the model. In addition to the importance of each feature, SHAP values quantify how features contribute to the prediction of the model.

Figures 8-13 include the 5 most important features according to the boosted decision trees for each core analysis. In each graph, the x-axis represents the values for each feature and the y-axis represents the SHAP values (ie, the effect each feature

has on predicting the completion of core 6 of the intervention). In the core 0 analysis, for example, finishing core 0 within 3 days (x-axis) has a positive influence on dropout, as can be seen on the y-axis above zero. However, taking more time to

complete core 0 (where x-axis is greater than 3) influences dropout prediction negatively as the graph approaches values under zero.

**Figure 8.** Five most important features for each core analysis according to boosted decision trees (15% deletion of missing values, and k-nearest neighbor imputation). The x-axis represents the values for each feature, and the y-axis represents the SHAP values. SHAP: SHapley Additive exPlanation; SOL: sleep onset latency; WASO: wake after sleep onset.

**Figure 9.** Five most important features for each core analysis according to boosted decision trees (15% deletion of missing values, KNN imputation, and Core 1 analysis). SHAP: SHapley Additive exPlanation; WASO: wake after sleep onset.

**Figure 10.** Five most important features for each core analysis according to boosted decision trees (15% deletion of missing values, KNN imputation, and Core 2 analysis). SHAP: SHapley Additive exPlanation.

**Figure 11.** Five most important features for each core analysis according to boosted decision trees (15% deletion of missing values, KNN imputation, and Core 3 analysis). SHAP: SHapley Additive exPlanation.

**Figure 12.** Five most important features for each core analysis according to boosted decision trees (15% deletion of missing values, KNN imputation, and Core 4 analysis). SHAP: SHapley Additive exPlanation.

**Figure 13.** Five most important features for each core analysis according to boosted decision trees (15% deletion of missing values, KNN imputation, and Core 5 analysis). SHAP: SHapley Additive exPlanation.

In general, 7 out of the strongest 22 features were handcrafted and theory driven. Table 2 summarizes all the features. Taking more time to complete the cores appeared to influence dropout. The time to complete core 0 predicted whether a participant eventually dropped out (core 0 and core 1 analysis). In addition, usual arise time and the time needed to get out of bed (from awake to arise) affected the prediction of dropout early on in the intervention. Participants who got up earlier than 4:30 AM and later than 6:45 AM, and participants who needed less than 9 min or more than 66 min to get up, negatively influenced the

prediction of completing core 6 of the intervention (x-axis of the feature usual arise time and time to get up for core 0). Furthermore, a greater WASO also appeared to influence the prediction of dropout status. These variables could, therefore, be an early indicator of dropout in this particular intervention.

In addition, if triggers were logged on for more than 18 days or participants received emails for more than 30 days, dropping out was more likely (core 3 analysis). Furthermore, if there was no interaction between the system and the participants for more than 67 days, the individuals were more likely to drop out.

**Table 2.** Summary of the unique top 5 most important features across analyses.

Predictors		Analysis at each point in time					
Feature	Description	Core 0	Core 1	Core 2	Core 3	Core 4	Core 5
Core 0 completion date—intervention start date <sup>a</sup>	Time to complete core 0 in days	+ <sup>b</sup>	+	N/A <sup>c</sup>	N/A	N/A	N/A
Arise time—awake time <sup>a</sup>	Difference between time of awakening and getting out of bed in minutes (time to get up)	+	N/A	N/A	N/A	N/A	N/A

## Discussion

### Principal Findings

Considering the increasing use of digital health interventions and the tremendous amount of data gathered in such interventions, a variety of methods can be used for the analysis of various data types and structures. In this study, a process for the analysis of user journey data in this context was proposed, and a step-by-step guide and technical framework for the analysis as an R package was provided. Challenges of data analysis based on user journeys, such as data transformation, feature engineering, and statistical model application and evaluation, were discussed. The analysis of user journeys can be a powerful tool for the prediction of various factors on an individual participant level. Here, it has been applied to real-world data to predict dropout from an internet-based intervention.

The application of the proposed process and evaluation of statistical models indicated the feasibility of dropout prediction by using this process. AUC values ranged between 0.6 and 0.9 for the selected machine learning algorithm (boosted decision trees). Most importantly, it was shown that the prediction of user dropout was possible early in the intervention, which could be helpful to clinicians and policy makers as treatment decisions are made and adjusted. In addition, this study indicated the importance of expert knowledge and subsequent implementation of handcrafted features. Not all existing statistical models necessarily require handcrafted features because automated feature engineering can already provide crucial insight; however, handcrafted features can increase prediction performance and lead to increased interpretability. In this study, handcrafted features appeared to be among the most important features according to the boosted decision trees, perhaps given the more nuanced understanding necessary for treating insomnia. It is important to keep in mind, though, that the analysis presented here was meant as a demonstration of the power of this approach. A much larger data set is needed to draw more firm and generalizable conclusions.

With this caveat, a number of interesting results emerged related to features and impact on dropout prediction. For example, as participants took longer to complete earlier steps of the intervention, they were less likely to complete the final step of the intervention. Thus, a discussion about how users can be motivated to complete early steps in the intervention may be very beneficial. In addition, the findings suggest that the time participants get out of bed in the morning and how much time they actually needed to get up might be an important factor for completing the sleep intervention. Participants who get out of bed between 4:30 AM and 6:45 AM and do not need more than 66 min to get out of bed were more likely to complete the final step of the intervention. In addition, trigger events might only have a positive effect in the short term, as the appearance of triggers more often than 18 days appeared to increase the likelihood of dropping out. However, it could be possible that this finding only accounts for participants who would not have completed the final step of the intervention. Assuming this, these participants were, therefore, not influenced by trigger

events. It is also important to emphasize that these results are based on a bottom-up, data-driven learning approach. Therefore, it is up to researchers to interpret the results and cross-validate them in other samples. Predictions in this context based on user journey data and the resulting knowledge about factors that influence these predictions, especially on an individual level, could lead to the implementation of strategies that seek to improve the utilization and efficacy of digital health interventions.

### Limitations

There are a number of limitations of this study that should be considered when interpreting the results. One limitation is the relatively limited number of participants included in the analysis and the large feature space. The predictive performance of the applied models is satisfactory, especially early on in the intervention. The process and models described in this study are technically feasible, although the reliability of the ensuing results may be impacted by limitations to sample size. Owing to the limited number of participants, the results of this study should be replicated in a larger sample. Furthermore, the amount of missing values impacts the analyses and can lead to bias. Obtaining more complete data can further increase the interpretability and predictive accuracy of the models. In addition to time window-based features and time-dependent variables, the demonstrated steps and this study in general do not include time-dependent feature engineering, such as the relation between features and observations across time. Researchers should examine the data set they are planning to analyze to determine whether time-dynamic features could be used in their projects. Another limitation is the fact that the data are heterogeneous at an individual participant level; thus, the application of models that consider heterogeneous parameters might provide deeper and more individualized information about the participants. However, considering the number of participants in the data, heterogeneous models have not yet been investigated. The results are, nevertheless, promising and can lead to increased knowledge about users and how dropout from digital health interventions is affected by various factors. Studies using larger data sets are necessary to improve model performance and confirm findings.

### Conclusions

This study proposes a step-by-step process for the analysis of user journey data in the context of digital health interventions and provides a technical framework. Furthermore, the proposed framework was applied to data from an internet-based intervention for insomnia to predict dropout of participants. These participants needed to complete 7 cores to finish the program. Importantly, our process was able to predict user dropout at each core better than chance. The predictive performance also varied by core; although the AUC was approximately 0.6 for cores 0 and 1, it was noticeably higher for the latter cores. This indicates that the user journey process can be used to predict dropout early in the intervention and prediction accuracy increases over the course of the intervention. This may allow researchers to preemptively address dropout before it occurs by providing support to users that may be struggling to engage. Among the machine learning techniques

we evaluated, boosted decision trees provided the greatest accuracy while deleting features that contained more than 15% missing values. In addition, a varying set of features was revealed that contributed to the prediction performance of dropout in this context. Replicating the results of this study in

a larger sample is needed to further validate the process outlined in this paper. Researchers may also wish to develop methods that predict the likelihood of user dropout over the duration of an intervention, which could enable researchers to devote resources to those at the highest risk of dropping out.

## Acknowledgments

This study was supported by grant R01 MH86758 from the National Institute of Mental Health. The funding source had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication. The authors thank Christina Frederick, BS, for her help with the study administration tasks. The authors specially thank Gabe D Heath, BA, and Steve P Johnson, BA, developers of the SHUTi intervention, for extracting and making all the data readily available for analysis.

## Conflicts of Interest

FT and LR report having a financial and/or business interest in BeHealth Solutions and Pear Therapeutics, 2 companies that develop and disseminate digital therapeutics, including by licensing the therapeutic developed, based in part, on early versions of the software utilized in research reported in the enclosed paper. These companies had no role in preparing this manuscript. LR is also a consultant to Mahana Therapeutics, a separate digital therapeutic company not affiliated with this research. Some of the research in this paper was conducted while FT was a faculty member at the University of Virginia. At that time for FT, and ongoing for LR, the terms of these arrangements have been reviewed and approved by the University of Virginia in accordance with its policies.

## Abstract

**Background:** Social anxiety disorder (SAD) is characterized by excessive fear of negative evaluation and humiliation in social interactions and situations. Virtual reality (VR) treatment is a promising intervention option for SAD.

**Objective:** The purpose of this study was to create a participatory and interactive VR intervention for SAD. Treatment progress, including the severity of symptoms and the cognitive and emotional aspects of SAD, was analyzed to evaluate the effectiveness of the intervention.

**Methods:** In total, 32 individuals with SAD and 34 healthy control participants were enrolled in the study through advertisements for online bulletin boards at universities. A VR intervention was designed consisting of three stages (introduction, core, and finishing) and three difficulty levels (easy, medium, and hard) that could be selected by the participants. The core stage was the exposure intervention in which participants engaged in social situations. The effectiveness of treatment was assessed through Beck Anxiety inventory (BAI), State - Trait Anxiety Inventory (STAI), Internalized Shame Scale (ISS), Post-Event Rumination Scale (PERS), Social Phobia Scale (SPS), Social Interaction Anxiety Scale (SIAS), Brief-Fear of Negative Evaluation Scale (BFNE), and Liebowitz Social Anxiety Scale (LSAS).

**Results:** In the SAD group, scores on the BAI ( $F=4.616$ ,  $P=.009$ ), STAI-Trait ( $F=4.670$ ,  $P=.004$ ), ISS ( $F=6.924$ ,  $P=.001$ ), PERS-negative ( $F=1.008$ ,  $P<.001$ ), SPS ( $F=8.456$ ,  $P<.001$ ), BFNE ( $F=6.117$ ,  $P=.004$ ), KSAD ( $F=13.259$ ,  $P<.001$ ), and LSAS ( $F=4.103$ ,  $P=.009$ ) significantly improved over the treatment process. Compared with the healthy control group before treatment, the SAD group showed significantly higher scores on all scales ( $P<.001$ ), and these significant differences persisted even after treatment ( $P<.001$ ). In the comparison between the VR treatment responder and nonresponder subgroups, there was no significant difference across the course of the VR session.

**Conclusions:** These findings indicated that a participatory and interactive VR intervention had a significant effect on alleviation of the clinical symptoms of SAD, confirming the usefulness of VR for the treatment of SAD. VR treatment is expected to be one of various beneficial therapeutic approaches in the future.

## KEYWORDS

anxiety; social anxiety disorder; virtual reality; intervention; effectiveness; questionnaires

## Introduction

Social anxiety disorder (SAD) is characterized by excessive fear of negative evaluation and humiliation in social interactions (eg, meeting unfamiliar people) and situations (eg, being observed while eating or drinking, and performing in front of others) [1]. Individuals with SAD avoid expressing opinions, talking to people, and forming friendships with colleagues. People with high social anxiety tend to negatively interpret ambiguous social information [2]. Therefore, individuals with SAD show negative interpersonal behavior, including conflict and emotional avoidance. This weakens interpersonal relationships and ultimately leads to social isolation [3]. In particular, SAD can impair work, research, and social life [4,5], as well as reduce well-being [6].

Contemporary theories of SAD emphasize the role of cognitive processes in maintenance of the disorder [7]. Individuals with SAD feel fear and anxiety about being embarrassed in social situations. Cognitive aspects of social anxiety include recalling past experiences of failure and having postevent negative ruminations, both of which exacerbate anxiety by negatively predicting future social events [8]. In addition, individuals with SAD are very sensitive to negative evaluation and social rejection [1]. People with internalized shame are likely to experience anxiety in interpersonal relationships, as this is based on awareness of negative evaluations from others [9].

Cognitive behavior therapy (CBT) is an effective treatment that targets the characteristics of SAD. CBT supposes that when people who experience social anxiety are exposed to socially threatening situations, negative thoughts are automatically evoked, triggering unstable behaviors, emotions, and physical reactions [10,11]. CBT helps identify the unhealthy core beliefs and rigid personal rules that contribute to social anxiety, and then provides various skills and strategies to test and weaken unhealthy attitudes, and to develop and strengthen alternatives. However, people with social anxiety symptoms have high barriers to seeking help from experts due to fear of the stigma surrounding mental health [12]. Additionally, patients with SAD are often not treated as the cost of treatment is high, and it is difficult to access information about professional treatments and services available to individuals. Moreover, the waiting time for treatment is long and the treatment barrier is high due to limited access to specialized services [13]. Therefore, the accessibility of CBT via mobile and desktop computers has been increasing [14], and the scope of treatment through virtual reality (VR) has been expanding recently [15].

VR creates a virtual environment that is blocked from the outside, providing the feeling of being in a new life-sized, computer-generated environment in which one can be immersed. Stereo audio, hand controllers, and eye trackers can be used to create a much more immersive experience. Safety, cost effectiveness, and convenience are advantages to using VR in psychiatric settings. VR can provide exposure treatment to individuals in a safer way than actual exposure, allowing for a quick response and change of stimulus factors if patients experience difficulty. It also reduces the time and costs involved in real exposure treatment [15].

Research has demonstrated the effectiveness of VR for several psychiatric conditions such as anxiety disorder, eating disorder, posttraumatic stress disorder, fear of misconduct, and arachnophobia [16]. VR therapy has an advantage of alleviating the burden of exposure treatment as it is difficult to configure specific, appropriate in vivo exposure conditions for people with SAD [17]. The effectiveness of the therapy can be enhanced through participatory VR because the patients can participate directly with the controllers.

In recent VR treatment research, an environment such as a virtual street, bus, or cafe was created. The results of the research demonstrated less anxiety and paranoia about social encounters in everyday life. In addition, patients reported social interaction anxiety, reduced depressive symptoms, and improved quality of life after VR treatment [18]. In a VR treatment study that presented scenarios such as speaking in front of an audience in a conference room, interviewing, self-introduction, and talking with relatives in an apartment, this intervention was effective in alleviating symptoms of social anxiety [19]. Interactive and participatory VR therapies have the advantage of providing high-immersion situations for participants. The incorporation of interactive virtual scenarios into VR therapy might more adequately target the idiosyncratic fears of participants with SAD.

The purpose of this study was to create a participatory and interactive VR intervention for the treatment of SAD and to evaluate the effectiveness of the intervention as the treatment progressed. Most VR treatments offer a variety of scenarios to individuals with SAD, but each scenario has limitations in that they are not tailored to the patient. In this study, the VR intervention consisted of scenarios in which the participant makes a presentation and the response of others varied according to the level of difficulty. This scenario allows for the provision of patient-specific VR treatment, and is configured to be more immersive and participatory. The VR scenarios were created

considering patients with SAD as the target audience. The intervention was assessed in young adults with SAD, specifically comparing the characteristic features of SAD from baseline to after several intervention sessions.

## Methods

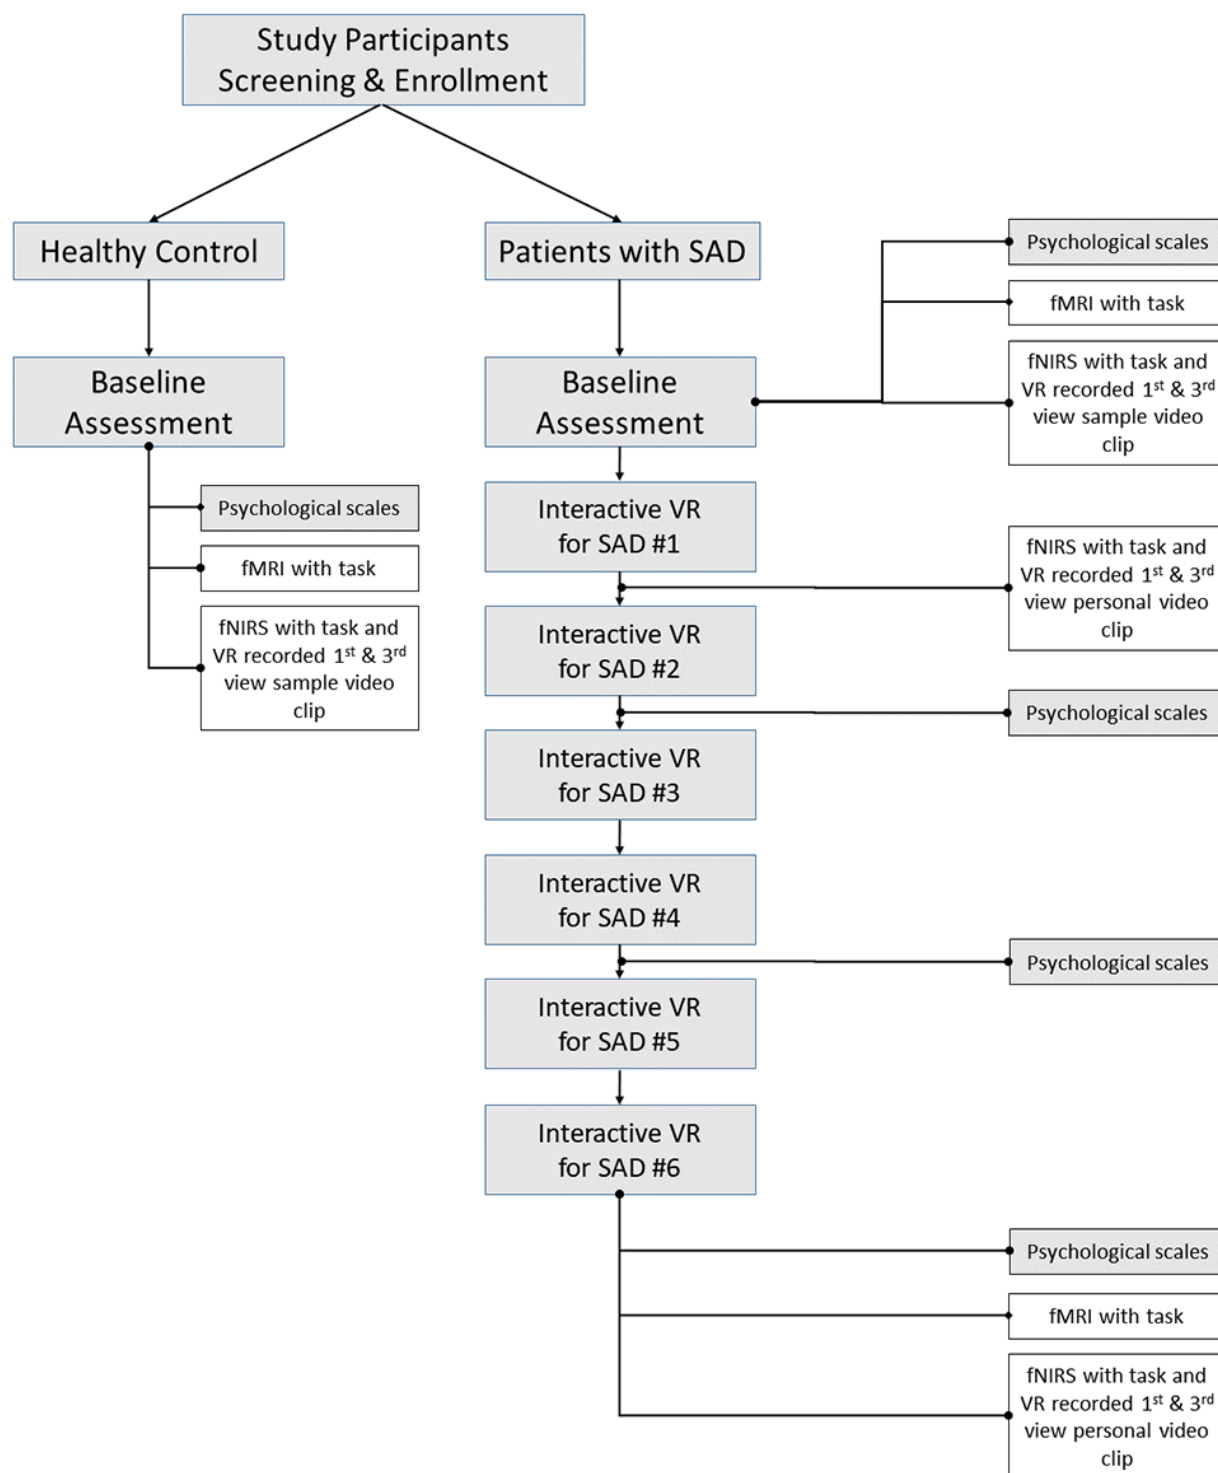

### Participants

We recruited individuals for the SAD and healthy control groups through advertisements for online bulletin boards at universities. The inclusion criteria for the SAD group were as follows: (1) Korean-speaking men or women between the ages of 19 and 31 years, (2) met the Diagnostic and Statistical Manual of Mental Disorders-IV criteria for SAD assessed by Mini-International Neuropsychiatric Interview [20], (3) individuals who were psychotropic medication-naïve without a psychiatric comorbidity (excluding depressive disorder and panic disorder), (4) not currently receiving psychotherapy, (5) no current medical or neurological diagnoses, (6) no history of psychotic symptoms vulnerable to a VR experience, and (7) not vulnerable to visual stimuli such as epilepsy. Exclusion criteria were as follows: (1) previous history of intellectual disability or organic brain damage, (2) experienced psychotic symptoms vulnerable to VR experiences, (3) vulnerable to visual stimuli such as epilepsy, and (4) unsuitable for participation in magnetic resonance imaging research. Healthy control participants had

no other neurological or psychiatric diagnoses. To determine whether the intervention had a clear, positive effect on individuals with SAD, only participants who had a score of 82 or higher on the Korean Social Avoidance and Distress Scale (KSAD) were enrolled [21]. The KSAD is a measure of the degree of experiencing anxiety in social situations and the tendency to avoid, and consists of 28 items assessed on a 5-point scale. Potential participants completed the KSAD online before enrollment. After the enrollment of participants who had a score of 82 or higher on the KSAD, we were able to collect data from a more homogeneous group of individuals with SAD who clearly had social anxiety.

A total of 40 patients with SAD and 34 healthy participants were enrolled in the study. Of these, 8 patients with SAD and 1 healthy control participant dropped out for personal reasons (eg, time constraints). Thus, a total of 32 patients with SAD and 33 healthy control participants completed this study. This study was part of a larger project that was conducted to evaluate the effects of interactive and participatory VR solutions using psychological scales, functional near-infrared spectroscopy, functional magnetic resonance imaging, and several physiological signals. An overview of the entire study is presented in Figure 1, and among these, only the psychological scale results were analyzed for this study to reduce distraction and clarify the subject. Other results will be presented in subsequent articles.

**Figure 1.** Overview of research flow chart for the entire project of participatory and interactive virtual reality (VR) treatment in patients with social anxiety disorder (SAD). This study reports the results of the analyzed data from the psychological scales. The content in the unshaded boxes represents different studies that will be presented in other papers. fMRI: functional magnetic resonance imaging; fNIRS: functional near-infrared spectroscopy.

The study was approved by the Korea University Anam Hospital Institutional Review Board and was conducted in accordance with the Declaration of Helsinki. All participants provided informed written consent after explanation of the study procedures.

## Participatory and Interactive VR Intervention for SAD

### Composition and Content of the VR Intervention

The participatory and interactive VR intervention for the control of social anxiety symptoms consisted of three stages (introduction, core, and finishing stages) and was divided into three levels (easy, medium, and hard) according to the difficulty of the core stage content. The VIVE (HTC Corporation, Taiwan)

VR headset was used for the intervention, and the heart rate, skin tension, and eye movement of the participant during the VR experience were measured.

In the introduction stage, participants were invited to select their own avatar and learn how to use the VR interface. To help participants adapt to VR and calm their mind, they partook in a meditation-based warm-up session. The core stage was the exposure intervention in which participants engaged in social situations. The situation was to enter a room where they were going to meet several other college students who were to introduce themselves to each other. In the virtual situation, 7 to 8 nonplaying characters appeared and introduced themselves (Figure 2). Once they finished their introductions, the participant

with SAD pressed the record button on the screen to introduce themselves. The nonplaying characters in the scenario listened to the participant's introduction, and the level of difficulty (easy, medium, and hard) was determined according to the nonplaying characters' attitude and degree of reaction to the participant. As the level of difficulty increased, the attitudes of the nonplaying characters who listened to the participant's introduction changed, in that they became more distracted and made small talk among themselves. At the hard level, one of the nonplaying characters challenged the participant when they were introducing himself/herself by saying, "Please introduce yourself properly." The finishing stage presented general cognitive and behavioral safety guidelines for SAD in both voice and text form in VR [22].

**Figure 2.** Screenshots of participatory and interactive virtual reality (VR) treatment in patients with social anxiety disorder, shown from the first- and third-person views [22].

First-person view

Third-person view

### Number of VR Sessions and Procedure

The VR intervention was designed for participants to perform a total of 6 sessions. Participants were allowed to perform 2 sessions in a row in a single visit, and the first session was started at an easy level. During the second session, participants could select and proceed to their desired level. It was explained that participants could stop at any time during the VR experience. Researchers were present throughout the VR experience to deal with any unexpected situations.

Participants completed a battery of assessments to evaluate the psychological state before and after the therapeutic VR sessions. Participants answered the self-reported psychological scales four times: at baseline (before the VR experience), after the second VR session, after the fourth session, and after termination (ie, after the sixth session).

### Assessments

#### Beck Anxiety Inventory

The Beck Anxiety Inventory (BAI) [23] measures the occurrence and severity of anxiety symptoms. The BAI consists of 21 items and each answer is scored on a scale of 0 (not at all) to 3 (severely). Higher total scores indicate more severe anxiety symptoms. We used the Korean version of the BAI (K-BAI) [24].

### State-Trait Anxiety Inventory

The State-Trait Anxiety Inventory (STAI) [25] was designed to measure state and trait anxiety in research and clinical practice. State anxiety is defined as a transient, momentary emotional status that results from situational stress, whereas trait anxiety represents a predisposition to react with anxiety in stressful situations [25]. The STAI consists of two subscales for measuring the intensity of anxiety as an emotional state (20 items) and individual differences in anxiety proneness as a personality trait (20 items). Each answer is scored on a scale of 1 (not at all) to 4 (almost always/very much so). We used a Korean version of the STAI (K-STAI) [26].

### Social Phobia Scale

The Social Phobia Scale (SPS) [27] was designed to measure the level of anxiety and fear in various social performance situations. The SPS consists of 20 items and each answer is scored on a scale of 0 (not at all) to 4 (extremely). We used the Korean version of the SPS (K-SPS) [28].

### Social Interaction Anxiety Scale

The Social Interaction Anxiety Scale (SIAS) [27] was designed to measure fear of social interaction situations such as meeting and talking with other people. Each question is presented in the form of a self-describing statement that describes cognitive, emotional, and behavioral responses in various social interaction situations. We used the Korean-Social Interaction Anxiety Scale

(K-SIAS) [28,29]. The K-SIAS consists of 20 items and each answer is scored on a scale of 0 (not at all) to 4 (extremely).

### **Brief-Fear of Negative Evaluation Scale**

The Brief-Fear of Negative Evaluation Scale (BFNE) measures the fear of being negatively evaluated by other people. The original, longer scale was developed by Watson and Friend [30], while the short-form version selected only items that had a correlation of 0.50 or more with the overall score. The Korean version (K-BFNE) developed by Lee and Choi [21] was used in this study. The K-BFNE consists of 12 items and each answer is scored on a scale of 1 (strongly disagree) to 5 (strongly agree).

### **Internalized Shame Scale**

The Internalized Shame Scale (ISS) [31] assesses shame proneness and internalized shame. The ISS has 30 items that consist of two basic scales for shame (24 items) and self-esteem (6 items). Shame-related questions evaluate the extent of shame that becomes magnified and internalized. We used the Korean version of the ISS (K-ISS) [32]. A factor analysis of the K-ISS identified a 4-factor structure: inadequacy (10 items), emptiness (5 items), self-punishment (5 items), and fear of mistakes (4 items).

### **Post-Event Rumination Scale**

The Post-Event Rumination Scale (PERS) [33,34] was designed to measure the frequency of postevent ruminations in social situations. The PERS comprises two scales including negative rumination (15 items) and positive rumination (9 items). Each answer is scored on a scale of 0 (never) to 4 (very often); higher scores indicate more frequent rumination. We used the Korean version of the PERS (K-PERS) [35].

### **Liebowitz Social Anxiety Scale**

The Liebowitz Social Anxiety Scale (LSAS) [36] assesses the degree of anxiety and avoidance in several typical social and performance situations. The LSAS consists of 24 items, which are answered for the degree of fear or anxiety (0, none to 3, severe) and avoidance (0, never to 3, usually). Higher total

scores indicate more severe social anxiety symptoms. We used the Korean version of the LSAS (K-LSAS) [37].

### **Statistical Analysis**

To examine the difference in categorical and continuous variables between the 2 groups (SAD and healthy control groups), we used the  $\chi^2$  test and the independent  $t$  test, respectively. To compare differences in the scores on the psychological scales between the SAD group and healthy control group at baseline and after termination,  $t$  tests were conducted. Repeated-measures analysis of variance (ANOVA) was conducted to investigate changes in the scores of the psychological scales in participants with SAD over the course of the VR intervention. All statistical analyses were performed using SPSS software version 24.0 (IBM Corp, Armonk, NY, USA). The significance level was set at  $P<.05$  (two-tailed).

## **Results**

Demographic information showed that the mean age of the SAD ( $n=32$ ) and healthy control ( $n=33$ ) participants was 23.12 (SD 3.12) and 23.55 (SD 3.38) years, respectively, with no significant difference ( $P=.60$ ). There was also no significant intergroup difference in gender distribution ( $P=.16$ ), with 11 males (34%) and 21 females (66%) in the SAD group, and 17 males (52%) and 16 females (49%) in the healthy control group. The mean education duration of the SAD group was 14.59 years (SD 1.37) and that of the healthy control group was 14.94 years (SD 1.77), which was not significantly different ( $P=.38$ ).

The psychological scales related to SAD were classified into several categories: general anxiety symptoms (BAI, STAI), SAD symptoms (SPS, SIAS, BFNE, KSAD, and LSAS), shame (ISS), and rumination (PERS). The comparison of scores on the psychological scales between the healthy control and SAD groups at baseline is shown in Table 1. For each scale, scores were significantly higher in the SAD group compared with those of the healthy control group (all  $P<.001$ ).

**Table 1.** Comparison of psychological states between the social anxiety disorder (SAD) and healthy control (HC) groups at baseline.

Measures	SAD group (n=32), mean (SD)	HC group (n=33), mean (SD)	<i>t</i>	df	<i>P</i> value
BAI <sup>a</sup>	15.03 (10.46)	3.39 (3.89)	6.16	63	<.001

## Changes in Social Anxiety

Repeated-measures ANOVA was conducted to assess changes in scores from baseline on the psychological scales in the participants with SAD after 2, 4, and 6 VR sessions. As shown in [Table 2](#), general anxiety symptoms as measured by the BAI and STAI-T significantly improved after treatment, whereas the STAI-S did not improve significantly. SPS, SIAS, KSAD,

BFNE, and LSAS, which are measures to evaluate the symptoms of SAD, all showed significant improvement after VR. The ISS showed significant improvement on the overall scale, and on the emptiness, self-punishment, and fear of mistakes subscales. There was no significant difference in inadequacy. Negative rumination, which is a subscale of the PERS, showed a significant improvement after the VR treatment, but positive rumination did not ([Multimedia Appendix 1, Table 2](#)).

**Table 2.** Changes in psychological states of participants with social anxiety disorder.

Measures	Baseline, mean (SD)	Session 2, mean (SD)	Session 4, mean (SD)	Session 6, mean (SD)	F statistic (df)	P value
BAI <sup>a</sup>	15.03 (10.46)	11.97 (9.33)	12.94 (11.29)	9.94 (9.58)	4.616 (2.348)	.009

Fear of mistake	12.78 (2.24)	11.19 (2.42)	11.25 (3.20)	10.16 (3.05)	10.891 (2.662)	<.001
<b>PERS<sup>j</sup></b>						
Negative rumination	31.38 (10.88)	27.03 (10.97)	25.81 (10.78)	23.41 (11.10)	6.974 (2.730)	<.001
Positive rumination	15.06 (6.29)	13.13 (5.84)	14.47 (6.73)	13.56 (6.83)	1.008 (2.812)	.39

<sup>a</sup>BAI: Beck Anxiety Inventory.<sup>b</sup>STAI-S: State-Trait Anxiety Inventory–State.<sup>c</sup>STAI-T: State-Trait Anxiety Inventory–Trait.<sup>d</sup>SPS: Social Phobia Scale.<sup>e</sup>SIAS: Social Interaction Anxiety Scale.<sup>f</sup>BFNE: Brief-Fear of Negative Evaluation Scale.<sup>g</sup>KSAD: Korean Social Avoidance and Distress Scale.<sup>h</sup>LSAS: Liebowitz Social Anxiety Scale.<sup>i</sup>ISS: Internalized Shame Scale.<sup>j</sup>PERS: Post-Event Rumination Scale.

Posthoc analyses for pairwise comparisons between baseline to sessions 2, 4, and 6 were performed by the Bonferroni method. The scales of BAI ( $P=.003$ ), and overall ( $P=.01$ ), emptiness ( $P=.001$ ), and self-punishment ( $P=.001$ ) of the ISS showed significant differences between baseline and session 6. The scales of PERS ( $P=.01$ ), SPS ( $P=.005$ ), SIAS ( $P<.001$ ), BFNE ( $P=.01$ ), and KSAD ( $P<.001$ ) showed significant differences between baseline and session 4. The fear mistake subscale of the ISS ( $P=.005$ ) showed a significant difference between baseline and session 2 ([Multimedia Appendix 1](#)).

### Changes in Psychological States Between Responder and Nonresponder Subgroups After VR Treatment

In general, the response to treatment is defined as a reduction of 50% or more from the baseline psychological scale. We

conducted a repeated-measures ANOVA for comparative analysis by dividing the participants into subgroups: those with a 50% or more reduction of the BAI scale value compared to the baseline were defined as the treatment responder group, and those with a less than 50% reduction were classified as the nonresponder group.

As presented in [Table 3](#), all psychological scale values except for STAI-S, positive subscale of the PERS, and inappropriate subscale of the ISS showed significant changes across the VR treatment session in both subgroups. A significant session-by-group interaction was found for the BAI value; however, no session-by-group interaction was observed for the other psychological scales.

**Table 3.** Changes in psychological states between responder and nonresponder subgroups according to virtual reality treatment.<sup>a</sup>

Measures	Responders (n=14), mean (SD)	Nonresponders (n=18), mean (SD)	Main effect of session		Session-by-group interaction	
			<i>F</i> (df)	<i>P</i> value	<i>F</i> (df)	<i>P</i> value

### Comparison of SAD and Control Groups After VR Treatment

We analyzed whether the scores on the psychological scales differed in the SAD group compared with those of the healthy

control group after 6 VR treatment sessions. Results from independent *t* tests showed that even after completing the VR sessions, the SAD group continued to have significantly higher scores than the healthy control group on all psychological scales (Table 4).

**Table 4.** Comparison of psychological states between the social anxiety disorder (SAD) and healthy control (HC) groups after virtual reality treatment.

## Discussion

### Principal Findings

The aim of this study was to analyze the effectiveness of a newly developed participatory and interactive VR intervention for individuals with SAD. In particular, using psychological tests related to SAD, we evaluated whether the VR intervention was effective in improving various symptoms.

General anxiety symptoms, measured by the BAI and STAI-T, were significantly improved compared with those measured before treatment, whereas state anxiety (ie, STAI-S) was not. State anxiety increases the threat value assigned to a stimulus or situation, and trait anxiety gives rise to a tendency to constantly direct attention toward the source of threat [38]. Any trait that does not change easily over a lifetime is a distinguishing feature of a person's character, and

anxiety-related traits are among the most important risk factors of anxiety disorder [39].

The scales that directly assess the symptoms of SAD showed significant improvement compared with those measured before treatment. SAD can be divided into symptoms that appear in specific situations and general social interactions [27], which were assessed with the SPS and SIAS, both of which showed significant improvement after VR. Scores on the LSAS and KSAD were significantly reduced after treatment. However, the LSAS score increased after session 2, and then decreased in the subsequent two time points (session 4 and session 6). BAI scores decreased in session 2, and then increased in session 4 before decreasing again in session 6. Similarly, the STAI (both state and trait scales) showed a decrease from baseline to session 2, followed by an increase after session 4 and then a decrease after session 6. Although this is only a pattern, it could be speculated that the tendency of anxiety to increase during a VR session is probably due to exposure to a VR session at a stage

in the middle of the intervention process before finally showing a significant therapeutic effect. This is an important consideration, because increased anxiety during a VR session may lead to a problem of dropping out of treatment due to poor treatment adherence after the initial treatment session. Treatment compliance is important in CBT because it requires a certain period of treatment, and exposure techniques can exacerbate symptoms in some cases [40]. In general, VR treatment is considered to have higher compliance than conventional treatment [41], but it is necessary to pay attention to changes in compliance during the treatment sessions.

Cognitive and emotional components are known to be involved in the development of SAD [42]. Scores on the ISS, which is used to evaluate internalized shame, improved significantly as VR treatment progressed, including a significant decrease on almost every ISS subscale (ie, emptiness, self-punishment, and fear of mistakes). Shame is an emotional component related to social anxiety that is based on a negative evaluation of the awareness of others, suggesting a positive relationship between social anxiety and shame [43-45]. A key part of cognitive models of social anxiety is that individuals perceive a negative evaluation by others [7]. In this study, negative rumination significantly improved after treatment, whereas positive rumination was not significantly different. Past studies of rumination have shown a relationship between negative rumination and social anxiety, but the relationship between social anxiety and positive rumination has been inconsistent or was not significant [33,46]. The improvement of negative rumination suggests that this can affect the cognitive structure of SAD.

Posthoc analysis to compare baseline scores to each session time point showed that VR had a significant effect on the fear of mistake subscale of the ISS at the initial point of treatment (after session 2). In comparison, BAI and the overall, emptiness, and self-punishment subscales of the ISS changed significantly only at the end of treatment (after session 6), and PERS, SPS, SIAS, BFNE, and KSAD scales showed significant changes around the middle point of VR treatment (after session 4). We could speculate that the improvement patterns of psychological symptoms may differ across the process of the VR treatment sessions. Since prolonging or shortening the number of VR treatment sessions might affect the therapeutic outcome on each psychological state, future studies are needed to determine how and when psychological symptoms change according to the VR treatment process and to establish the optimal number for VR treatment sessions.

Although we found significant improvements in SAD symptoms after treatment, these symptoms were still significantly different compared with those of the control group. This result shows that the VR intervention had a significant effect in the SAD group, but that the participants with SAD still exhibited prominent symptoms after VR treatment sessions. This suggests that the treatment effect of VR alone might not be sufficient to draw out the treatment response or remission. A meta-analysis of VR treatment focused on anxiety disorders found a small effect size [47]. Therefore, it is necessary to consider changes in treatment methods such as the combination of various treatment techniques, including conventional psychiatric

treatment or more repeated VR trials, to achieve a sufficient therapeutic effect in the real world.

We did not find any significant session-by-group interaction in the majority of the psychological scales except for BAI between the two subgroups of responders and nonresponders (according to changes in the BAI scale). This result can be presumed to be due to the limitation of the methodology in which the SAD group was divided into responder and nonresponder groups according to a single psychological scale. It is challenging to determine a clear cutoff as to what scale or criteria to use for distinguishing responders. Moreover, since this study attempted to collect data from a more homogeneous sample of individuals with social anxiety symptoms ( $KSAD \geq 82$ ), subgroup differences might not be expected. We hope to be able to derive meaningful results through further studies by comparison between subgroups according to the degree of severity based on the scores of different psychological scales, or by a comparative study according to whether or not the individual is also under medication for anxiety.

The results of this study indicated improvements in almost all elements of social anxiety measured, including general anxiety, social anxiety symptoms, and cognitive and emotional aspects of social anxiety, in the SAD group after treatment. Previous studies related to VR treatment for social anxiety have also shown an improvement in symptoms [47-49]; however, this study demonstrated an effect not only on social anxiety symptoms but also on a wide range of related factors, including general anxiety symptoms and cognitive and emotional characteristics.

## Limitations and Strengths

Our results should be interpreted within the context of the study's limitations. First, this study did not have a sham or waitlist control group, which limits interpretation of the results. Second, this study employed self-rated scales that could be confounded by bias (eg, participant motivation). Nonetheless, a comprehensive evaluation related to social anxiety disorder was attempted in analyzing the effectiveness of treatment, including changes during treatment sessions. This study enrolled participants in the patient group who met strict diagnostic criteria and had not received any other treatments, including psychiatric drugs. Given these strengths, the therapeutic effect of a VR intervention could be evaluated more accurately.

## Conclusion

This study investigated the effectiveness of a newly developed participatory and interactive VR intervention in patients with SAD. The results show that a VR intervention can be an effective treatment for various dimensions of SAD. Technology-based treatment in psychiatry is more cost-effective, easier to handle, and more manageable for both the therapist and client. VR treatment is a promising tool in the field of psychiatry, which can simulate situations for patients with anxiety in a safe, controllable, and reproducible way [15,50,51]. Future research should focus on ensuring that the effectiveness of these immersive VR treatments persist after treatment, and that treatments are made more effective through different treatment combinations or changes in techniques.

## Acknowledgments

This work was supported by a National Research Foundation of Korea (NRF) grant funded by the Government of Korea (MSIT) (NRF-2020R1C1C1007463), and the ICT & Future Planning for Convergent Research in the Development Program for R&D Convergence over Science and Technology Liberal Arts (NRF-2017M3C1B6070978).

## Authors' Contributions

DJ, JWH, and CHC conceived and designed the study. HJK, SL, and CHC performed the statistical analyses. HJK, SL, DJ, JWH, and CHC wrote the first draft of the manuscript. DJ, JWH, HJK, SL, GK, CYC, SC, SML, and CHC participated in data collection. All authors edited all versions of the manuscript. All the authors were involved in the interpretation of the results, and read, commented, and approved the final version of the manuscript.

## Abstract

**Background:** Information provided in an interactive way is believed to be engaging because users can actively explore the information. Yet empirical findings often contradict this assumption. Consequently, there is still little known about whether and how interactivity affects communication outcomes such as recall.

**Objective:** The aim of this study was to investigate mechanisms through which interactivity affects recall of online health information. We tested whether and how cognitive involvement, perceived active control, and cognitive load mediate the effects of interactivity on recall. In addition, we examined need for cognition and health literacy as potential moderators of the mediation effects. Given the increasing popularity of dietary supplement use, our health website focused on this topic.

**Methods:** In an online between-subjects experiment (n=983), participants were randomly assigned to control condition (no interactive features), moderate interactivity (dropdown menus), and high interactivity (dropdown menus and responsive infographics). Two weeks before the experiment, background characteristics and moderating variables were measured. During website visit, data on users' online behavior were collected. Recall was measured postexposure.

**Results:** Participants recalled significantly less information in the moderate (mean 3.48 [SD 2.71]) and high (mean 3.52 [SD 2.64]) interactivity conditions compared with the control condition (mean 5.63 [SD 2.18]). In the mediation analysis, we found direct, negative effects of moderate ( $b=-2.25$ , 95% CI  $-2.59$  to  $-1.90$ ) and high ( $b=-2.16$ , 95% CI  $-2.51$  to  $-1.81$ ) levels of interactivity on recall as well. In the relationship between interactivity and recall, cognitive involvement had a partial negative mediation effect (moderate interactivity:  $b=-.20$ , 95% CI  $-0.31$  to  $-0.10$ ; high interactivity:  $b=-.21$ , 95% CI  $-0.33$  to  $-0.10$ ) and perceived active control had a partial positive mediation effect (moderate interactivity:  $b=.28$ , 95% CI  $0.18$  to  $0.40$ ; high interactivity:  $b=.27$ , 95% CI  $0.16$  to  $0.40$ ).

**Conclusions:** Interactivity decreased recall. In addition, through interactivity participants were less involved with the content of the information, yet they felt they had more control over the information. These effects were stronger in the high need for cognition and high health literate groups compared with their counterparts.

Interactivity; cognitive involvement; active control; cognitive load; recall; need for cognition; health literacy; online health information; information processing; dietary supplements

## Introduction

### Relevance and Aim

One of the unique features of internet-delivered health information is that it can be provided in an interactive way. Interactive features are thought to create more engagement and involvement with the information, as visitors can actively interact with the information [1]. However, clear guidelines are lacking on how interactivity could be used in health communication [2]. Moreover, previous research has resulted in inconclusive findings regarding how interactive features affect communication outcomes. Interactive features may enhance user enjoyment, positive attitudes, and desirable behavioral intentions but they do not necessarily improve cognitive elaboration or information recall [3]. The aim of this study is to investigate whether and how interactivity can be used for improving recall of online health information. Given the increasing popularity of dietary supplement use and the complexity of the behavior [4,5], our study focuses on this topic.

### Theoretical Background

#### *Conceptualization of Interactivity*

In interactivity research, three approaches are distinguished: structural, experiential, and message exchange. In the structural approach, interactivity is conceptualized in terms of the technical attributes of the medium [6]. Such technical attributes include on-screen interactive features such as menus that allow user-to-system or user-to-user interactions [7]. According to the experiential approach, interactivity is the user's subjective perception of the level of the medium's interactivity [8]. The message exchange approach regards interactivity as an ongoing communication process in which (semantic) meanings between two or more communicators are exchanged [9]. We conceptualize interactivity according to the structural approach, since in terms of causality a media stimulus that is manipulated precedes users' responses to that stimulus [6]. Yet the structural approach often has been criticized for focusing only on direct relations between a media stimulus and the dependent measures omitting the possibility of third variable effects [6]. Therefore, in the conceptual model of this study, four types of variables were included: interactivity (manipulated independent variable), possible mediators, possible moderators, and a dependent variable.

#### *Moderated Mediation Model of Interactivity Effects*

In our conceptual model, we will test whether cognitive involvement, perceived active control, and cognitive load mediate the relationship between interactivity and recall. In addition, we will look at whether the need for cognition and health literacy moderate the proposed mediation effects.

Dual process models, such as the elaboration likelihood model (ELM), propose that information elaborated via the central route is likely to produce greater and more permanent changes in communication outcomes [10]. Individuals tend to get (more) motivated to process the information systematically, which involves effortful thinking, if the information is perceived as personally relevant to them [10]. It is proposed that individuals generate (more) cognitive responses (ie, the number of

content-related thoughts generated during exposure to the stimuli) to the information content if they process the information systematically [11]. Interactive environments may stimulate cognitive responses since they enable nonlinear, cognitively flexible information use (cognitive flexibility theory) [12]. For instance, navigation through hypertext might be beneficial for knowledge since hypertexts mimic the associative network of human memory [13]. If individuals are afforded the possibility to adapt their information use to their own preferences and cognitive needs, they may get more involved and more motivated to process the information more deeply and elaborate better on the content [14,15]. Therefore, we propose that interactivity improves recall through higher levels of cognitive involvement.

Research has shown that individuals' perceptions about interactivity are closely related to communicational outcomes such as attitudes [16,17]. From the different dimensions of perceived interactivity distinguished by Liu and Shrum [18], the control dimension, which refers to the autonomy individuals have in controlling the information flow, has been most often associated with cognitive elements of information processing [19]. Active control is characterized by voluntary and instrumental actions through which users are able to customize the information flow [18]. This entails navigational choices based on the user's own goals and wills [18]. We assume that if users are afforded the possibility to make conscious choices about the information flow based on their needs, they might be more motivated to process the information. Therefore, we propose that interactivity may improve recall through higher levels of perceived active control.

Interactivity may challenge individuals' information processing capacities by putting an extra burden on users. Tremayne and Dunwoody [20] found evidence that when users visited a more (vs less) interactive website, much cognitive effort was spent in navigation and orientation which had a detrimental effect on recall. In interactive environments, individuals must complete different tasks performed concurrently (eg, reading, navigating). Every task generates a cognitive cost on the working memory in terms of cognitive load. Moreover, tasks may interfere with each other since they compete for the same limited cognitive resources [21,22]. Consequently, there are fewer capacities left for information processing (ie, encoding, storage, retrieval). Indeed, research has shown that individuals retain less information when performing more than one task at the same time because multitasking inhibits the transfer of information into the short- and long-term memory [23,24]. Therefore, we assume that cognitive load increases with higher levels of interactivity, which may lead to decreased levels of recall.

#### *Moderators: Need for Cognition and Health Literacy*

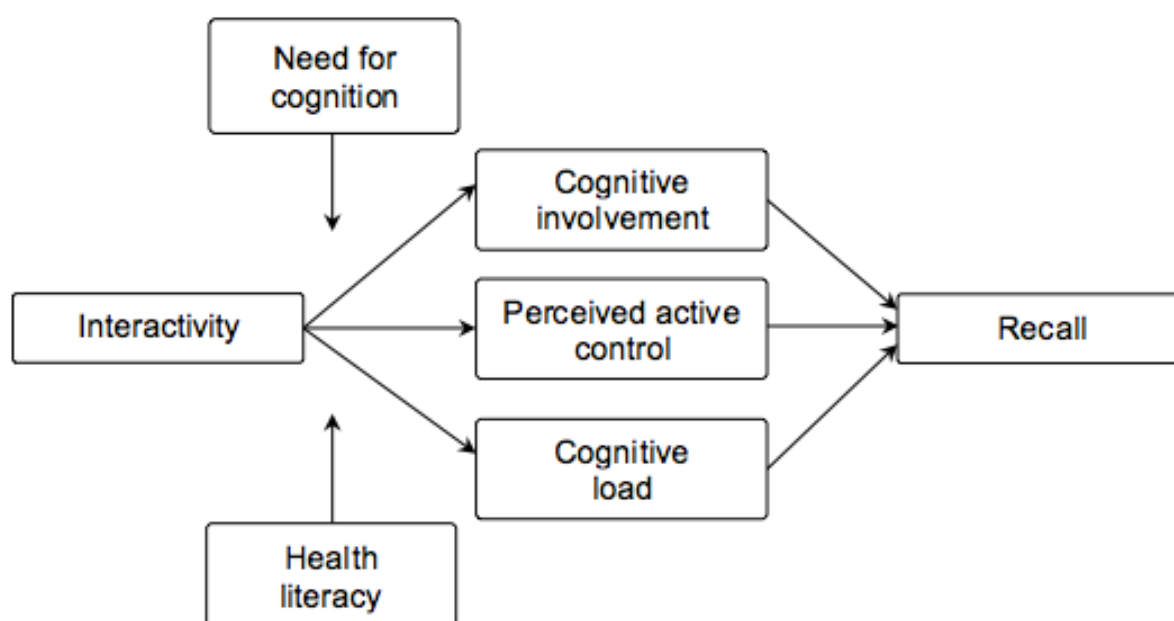

In addition to the mediation effects described above, we aim to explore whether individual difference variables moderate the proposed mechanisms. Information processing is influenced by individuals' ability and/or motivation to process information [10,22]. Need for cognition reflects the tendency to engage in and enjoy effortful cognitive endeavors [25,26]. It is considered a stable trait that may be influenced by situational factors such as interactivity [27]. Evidence suggests that interactivity

improves information processing, especially among low need for cognition individuals [28]. This may be related to the fact that individuals with low need for cognition prefer interactive websites more than their high need for cognition counterparts [29]. In situations with low personal relevance, individuals with low need for cognition are more attracted by peripheral cues which are attributes that are not inherent to the strength of arguments in the message [30]. In contrast, individuals with high need for cognition concentrate more on the real attributes of the information, such as the strength of arguments. Therefore, they rely less on the way information is presented [28]. However, high need for cognition individuals are more cognitively immersed when engaging in interactive websites than low need for cognition individuals [28,31]. According to the findings of Sicilia et al [28], in both low and high need for cognition individuals, the flow experience increases when they visit an interactive (vs noninteractive) website, but this increase is higher among individuals with high need for cognition.

Individuals may also differ in their ability and skills to understand and use health information. Health literacy entails

“the motivation, knowledge, and competencies to access, understand, appraise and apply health information in order to make judgments and take decisions...concerning health care, disease prevention, etc” [32]. In general, low health literate individuals engage less in health information seeking and have greater difficulties with reading and searching for health information on the internet [33,34]. Moreover, interactivity may challenge users with limited literacy skills since they have difficulties with recognizing graphic links (ie, pictures that function as hyperlinks), using navigational tools, and understanding graphics that respond to mouse movements [35]. In addition, sufficient levels of metacognitive skills are needed to make mindful navigational selections and build meaningful sequences of information, for instance, in a hypermedia environment [36]. However, it should be noted that research has shown that interactive features designed specifically for individuals with low health literacy (eg, low text difficulty) are beneficial for online health information processing [37]. We summarized our conceptual model in Figure 1.

**Figure 1.** Conceptual model of moderated mediation effects of interactivity.

In sum, we aim to answer the following research questions: through which mechanisms does interactivity affect recall of health information? Do these mechanisms differ according to individuals' level of need for cognition and health literacy?

## Methods

### Design

A between-subjects experiment with three levels of interactivity (no interactivity, moderate interactivity, high interactivity) was conducted to investigate the effects of interactivity on cognitive involvement, perceived active control, cognitive load, and recall. Two weeks prior to the experiment, background characteristics

and moderator variables were measured. During the experiment, pre- and postexposure measures were performed.

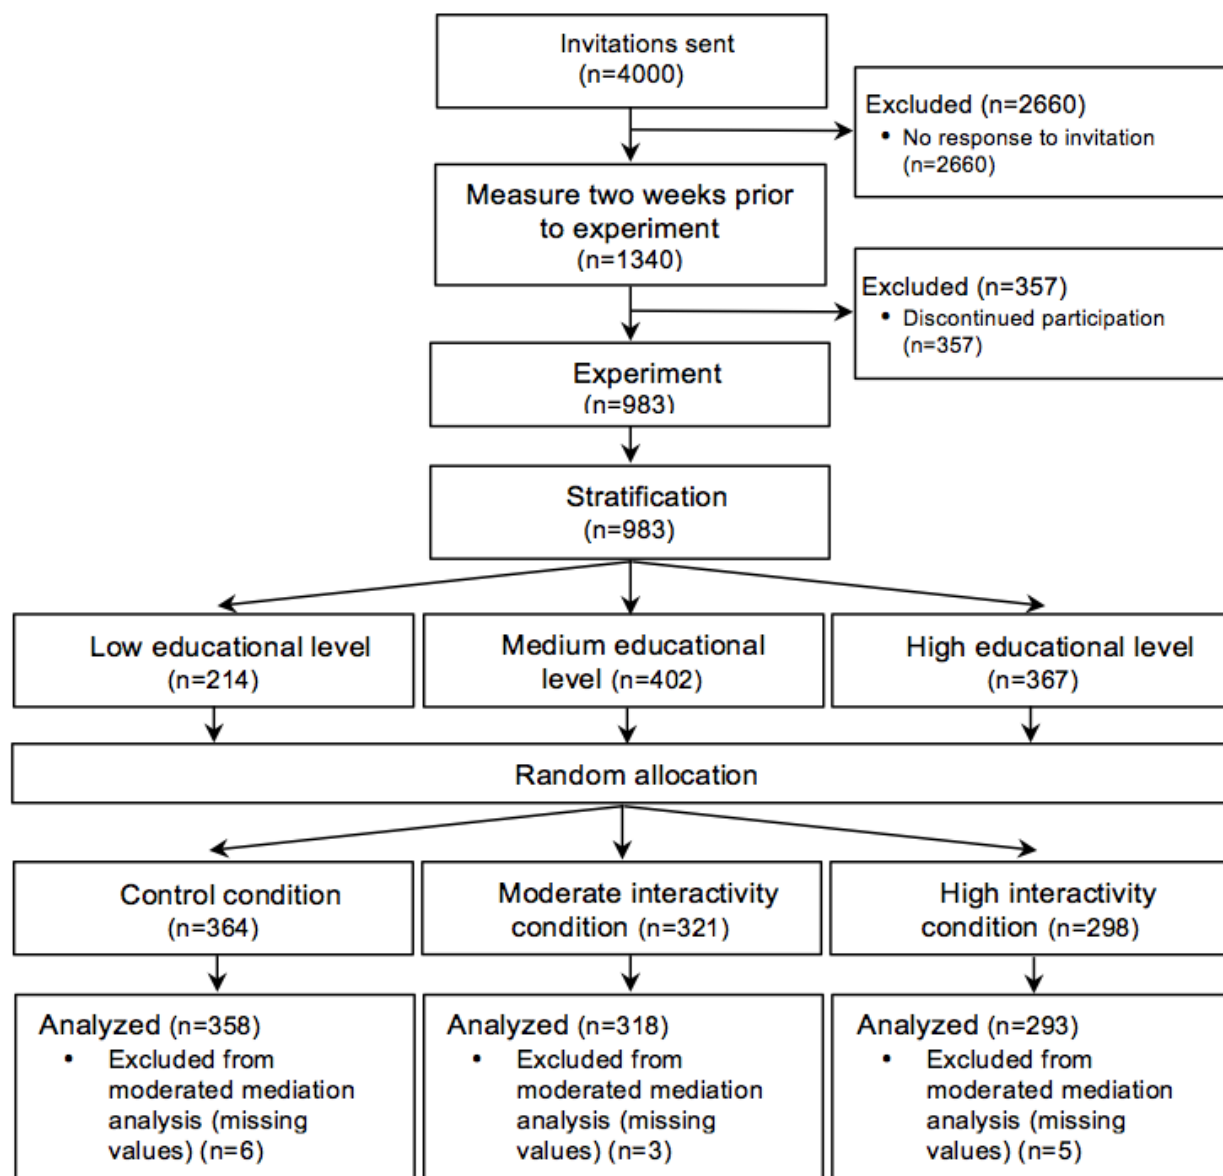

### Participants

A priori power analysis with G\*Power indicated that at least 776 participants were needed to detect small effects (ie,  $f^2=.02$ ) with an alpha level of .05, .90 statistical power, and 4 predictors. Participants were recruited from 26,000 active panel members of I&O Research, an ISO 26362–certified research bureau for access panels in market, opinion, and social research [38]. I&O Research recruits its panel members offline (eg, from municipal registers) and self-registration is not allowed in order to prevent selection biases such as the overrepresentation of frequent internet users [38]. A random sample consisting of 4000

individuals was drawn from the panel, of which 33.50% (1340/4000) responded to the invitation to participate in the first part of the study (see Figure 2). This response rate was comparable to the average response rate of this panel (ie, 35%) [38]. The final sample consisted of 983 (73.4%) individuals who participated in both parts of the study and completed the

pre- and postexposure questionnaires. Among these participants, 50 €10 gift cards for an internet warehouse were raffled. Due to technical issues, data of 15 respondents were lost in the preexposure measurement. Therefore, these participants were excluded from the moderated mediation analyses.

**Figure 2.** Flowchart of the stratification and random allocation procedure.

## Procedure

An invitation with the subject line “Consumer information on food and dietary supplements” was sent by email to participants on March 21, 2017. The email contained a short description of the study, an explanation of the procedure, and contact details of the researcher. Upon agreeing to participate in the study and giving informed consent, individuals were asked to complete a short questionnaire about health literacy, need for cognition, and educational level. Based on individuals’ educational level, the sample was divided into three strata: low, medium, and high educational level. On April 25, 2017, participants were invited to take part in the actual experiment. Prior to visiting the website, individuals completed a preexposure measurement

about their knowledge of the research topic and dietary supplement use. Then, within each stratum, participants were randomly assigned to one of the three versions of a website about vitamin B6 and dietary supplements. The random allocation was programmed by the website developer, Done Digital Kft. In order to make the browsing task similar to a real-life online health information search, participants had the freedom to decide what information and in which order they wanted to explore and no specific instructions or time limits were given. Participants were allowed to view the website only once. In order to prevent any preexposure to the stimulus material, the website was not publicly accessible. Once participants were finished browsing on the website, they were directed to the postmeasurement questionnaire.

## Ethical Approval

According to the decision of the Research Ethics Commission of Maastricht University Medical Centre and Maastricht University (decision number: METC 16-4-268), the Medical Research Involving Human Subjects Act does not apply to this study. At the time of the study, further ethical clearance was not required.

## Stimulus Material

In all three conditions, the information presented was identical and aimed to provide complete information about vitamin B6, its physiological effects, how it relates to food, and the risks and benefits of supplementation with vitamin B6. The goal was to offer information that is well balanced in terms of describing advantages and disadvantages of vitamin B6 and improves individuals' understanding of whether and to whom supplementation with vitamin B6 may be reasonable. The recommendations of the Ottawa Decision Support Tutorial were used [39].

In addition to the textual information, the website included four educative infographics that contained information about the Recommended Dietary Allowance of vitamin B6 by age category and gender, the vitamin B6 content of different food products, scientific evidence of possible health effects of vitamin B6, and safe and unsafe doses of vitamin B6 dietary

supplements. Further details about the content and structure of the website are presented in [Multimedia Appendix 1](#).

## Experimental Stimuli

Three versions of a website were developed sharing the same content, layout, and pictures but differing in terms of levels of interactivity. In our study, interactivity refers to the technical attributes of the medium [6]. In line with previous research that falls into the structural approach of interactivity [1,40], we manipulated levels of interactivity in terms of the amount of interactive tools available on the website interface (eg, menus) for accessing and interacting with the content of the website. Accordingly, in the control condition no interactive features were presented. Participants navigated by scrolling up or down on the webpage and the infographics did not respond to users' mouse movements. In the moderate interactivity condition, a dropdown menu consisting of nine submenus was the only interactive tool presented on the website. The infographics shown in the moderate interactivity condition were static. In the high interactivity condition, two types of interactive features were presented: a dropdown menu and responsive infographics. Three rounds of pilot tests were conducted before the websites were finalized. In [Figure 3](#), the differences in the navigation (scrolling vs dropdown menu) between the conditions are presented. In [Figure 4](#), the differences in the infographics (static vs responsive) between the conditions are presented.

**Figure 3.** Navigation in the control condition (left) and in the moderate and high interactivity condition (right).

**Figure 4.** Example of an infographic in the control and moderate interactivity condition (left) and the high interactivity condition (right).

## Measures

### Dependent Variable: Recall

The measure of recall was based on the construction integration model [41] that distinguishes between two levels of comprehension: the text base level (ie, literal recall of information) and the situation model level (ie, to make inferences to situations based on the information) comprehension. During two cycles of pretesting, 4 questions were developed to measure text base level comprehension and 2 questions to measure situation level comprehension; 3 of the 6 questions were in multiple-choice format in which only one answer option was correct. Three other questions were in multiple response format in which multiple answer options were correct. In both types of response options, the “I don’t know” option was also presented. Participants received 1 point for each correct answer, up to 9 points in total.

According to the principal component analysis, the 6 items loaded on one single underlying construct (eigen value: 2.866, 47.765% of variance explained). In addition, factor loadings were .582 or higher. All 6 items correlated significantly with each other, ranging from  $P=.25$  to  $P=.51$ .

### Mediating Variables

Participants’ cognitive involvement with the website content was measured with a thought listing task [11]. Individuals were asked to list thoughts about vitamin B6 that came to their mind during their website visit. Participants could list up to 12 thoughts in empty text boxes, each beginning with the statement: “Vitamin B6 is:...” Each field of text that was completed counted as a thought. The cognitive involvement measure was placed second in the postexposure questionnaire, after the 1-item manipulation check of interactivity. Compared with thought listing measures during exposure, obtaining responses after the stimulus can be accomplished without the interruption or

distraction from the stimulus [11]. In addition, loss or retention in poststimulus measures of cognitive involvement is negligible [11].

Perceived active control refers to users’ voluntary and instrumental actions that directly influence their website experience [8,18]. Liu’s [8] 4-item measurement of perceived active control was used.

Cognitive load was conceptualized as the perception of “the cognitive capacity that is actually allocated to accommodate the demands imposed by the task” [42]. It was measured with 4 items derived from the Subjective Workload Assessment Technique (mental effort subdimension) [43,44] and from the NASA Task Load Index (effort subdimension) [43,45].

### Moderating Variables

Need for cognition was measured with 7 items derived from the Dutch version of the 18-item Need for Cognition Scale (NCS) [46]. A limited number of items may be sufficient to measure need for cognition since evidence suggests that the full NCS measures a single underlying construct [26,47,48]. Therefore, the items with the highest factor loadings were chosen from the study of Hevey and colleagues [49].

Health literacy was measured using the Newest Vital Sign in Dutch (NVS-D), which was developed to measure an individual’s capacity to assess, understand, and use textual and numerical health information [50]. Consequently, this 6-item tool tests three types of skills that are important in finding and interpreting health information: math, locate-the-information (by reading and comprehending), and abstract reasoning (ie, making inferences from the information to specific situations) [51]. For each correct answer, respondents received 1 point, up to 6 points in total. Details of the measurement scales (number of items, example items, answer categories, mean scores, and Cronbach  $\alpha$ ) are presented in Table 1.

**Table 1.** Overview of number and examples of questions, answering categories, mean scores, and Cronbach

Variable	Number of questions	Example of questions/items, answer options	Mean (SD)	Median <sup>a</sup> (IQR)	Cronbach alpha
Recall <sup>b</sup>	6	“Some groups of individuals are at risk of developing vitamin B6 deficiency. Which groups are these?” “Someone is using high-dose vitamin B6 dietary supplements (100 milligram) for a long period of time. What kind of influence can this have on the health condition of this person?” Multiple choice or multiple response answer options	4.30 (2.71)	— <sup>c</sup>	.77
Cognitive involvement <sup>d</sup>	12	“During your website visit, certain thoughts about vitamin B6 may have come to your mind. Please write down your thoughts about vitamin B6 in the text boxes below.” Open-ended questions	—	3 (3)	—
Perceived active control	3	“While I was on the website, I could choose freely what I wanted to see.” Totally disagree (1) to totally agree (7)	3.98 (1.29)	—	.80
Cognitive load	4	“I had to think hard in order to understand the information on the website” Totally disagree (1) to totally agree (7)	4.05 (1.42)	—	.92
Health literacy <sup>e</sup>	6	“If you are allowed 60 grams of carbohydrates as a snack, how much ice cream could you have?” Open-ended questions	—	6 (1)	—
Need for cognition	7	“I really enjoy a task that involves coming up with new solutions to problems” Totally disagree (1) to totally agree (7)	4.94 (1.02)	—	.83

<sup>a</sup>For variables with non-normal distribution, the median and IQR are presented.

<sup>b</sup>Recall scores could range from 0 (no correct answers) to 9 (all answers are correct).

<sup>c</sup>Not applicable.

<sup>d</sup>Cognitive involvement scores could range from 0 (no thoughts) to 12 (12 thoughts).

<sup>e</sup>Health literacy scores could range from 0 (no correct answers) to 6 (all answers are correct).

## Manipulation Check Measure

The effectiveness of the manipulation was measured by asking respondents: “To what extent do you agree with the following statement: This website is interactive” with answer options ranging from 1 (totally disagree) to 7 (totally agree) [52].

## User Activity

During participants’ website visit, the following user activity indicators were measured: duration of website visit in seconds (mean 11,765.69 [SD 92,169.31], range 5-1,302,883), the extent of scrolling down on the website (control condition: mean 0.98 [SD 0.32]), total amount of clicks on the nine menus (moderate interactivity condition: mean 6.11 [SD 3.45]; high interactivity condition: mean 6.13 [SD 2.64]), and total amount of clicks on the four infographics (high interactivity condition: mean 11.05 [SD 9.09]). Due to personal browser settings such as a disabled JavaScript [53], user activity data of 524 participants out of the 983 participants were collected.

## Control Variables

Several variables were measured to control for their potential influence in the statistical analyses. The following demographic background characteristics were measured: gender, age, and highest educational level. The latter was measured with 7 responses: 1=primary education or less, 2=preparatory secondary vocational education (level 1) or equivalent, 3=secondary vocational education, 4=senior secondary vocational education

(level 2-4) or equivalent, 5=senior general secondary education, university preparation education, 6=bachelor’s level or equivalent, and 7=master’s level or above. The strata of low (1-3), middle (4 and 5), and high educational level (6 and 7) were based on these responses. In addition, meat consumption, diet, mode of life (eg, anthroposophic nutrition), dietary supplement use, and involvement with the topic vitamin B6 were measured. Involvement was measured with 3 items from Zaichkowsky’s [54] personal involvement inventory scale (eg, “The topic vitamin B6 is important to me,” 1=totally disagree to 7=totally agree).

## Statistical Analyses

Descriptive statistics were run to investigate sample characteristics. In order to check normal distribution of the variables, we looked at skewness and kurtosis and visually inspected the histogram and boxplot of each variable. We detected nonnormal distribution in three variables: health literacy (skewness: -1.67, kurtosis: 2.28), cognitive involvement (skewness: 1.48, kurtosis: 3.68), and time spent on website (skewness: 9.42, kurtosis: 101.41). To investigate the proposed mediations and examine whether differences exist between subgroups, the PROCESS macro for SPSS Statistics version 2.16.3 (IBM Corporation) was used [55]. PROCESS applies bootstrapping to estimate 95% bias-corrected confidence intervals for total and indirect effects. Bootstrap procedures are unaffected by violations of parametric assumptions and have

higher type I error control and power than the normal theory approach [55,56]. In PROCESS, 76 different conceptual diagrams are available. Model number 4 is programmed to test a simple mediation. In order to test mediations, model 4 (10,000 samples) was used with three mediators operating in parallel: cognitive involvement, perceived active control, and cognitive load. In the analyses, the independent variable interactivity was defined as multicategorical; consequently, it was automatically dummy coded by PROCESS (D1: moderate interactivity condition; D2: high interactivity condition; reference category: control condition). The percentage mediated effect was calculated for each significant indirect effect separately by dividing the corresponding unstandardized regression coefficient of the ab path (indirect effect) by the unstandardized regression coefficient of the c path (total effect) and multiplying it by 100. To examine differences between subgroups regarding the mediations (high vs low health literacy, high vs low need for cognition), model 4 (10,000 samples) was run for each group separately. Subgroups were created based on a mean split. This approach of testing moderated mediation effects was chosen for a technical reason. PROCESS v2 had limited features for dealing with multicategorical variables, which meant that it was

not possible to calculate an interaction term of a multicategorical and a numerical variable and put it in the model as a variable [57]. All analyses were conducted with adjustments for gender, age, educational level, dietary supplement use, involvement with the topic vitamin B6, being on a diet, following a certain rule of life (eg, anthroposophy), meat consumption, and duration of website visit. Analyses were conducted with SPSS version 23.

## Results

### Sample Characteristics

Slightly more female (530/983, 53.9%) than male (453/983, 46.1%) individuals participated in the study. Participants were on average aged 53.2 (SD 15.31) years, and most of them held either a medium (402/983, 40.9%) or high educational level (367/983, 37.3%; Table 2). More than half of the sample (524/983, 53.3%) had used dietary supplements in the last 12 months. Participants can be regarded as neutral toward the topic vitamin B6 since they were moderately involved (mean 3.42 [SD 1.54]).

**Table 2.** Sample characteristics (n=983).

Characteristic	Value
Gender (male), n (%)	453 (46.1)
Age in years, mean (SD)	53.20 (15.31)
<b>Educational level, n (%)</b>	
Low	214 (21.8)
Medium	402 (40.9)
High	367 (37.3)
Living according to a specific mode of life (yes), n (%)	92 (9.4)
Meat consumption (yes), n (%)	945 (96.1)
Being on a diet (yes), n (%)	201 (20.4)
Dietary supplement use in the last 12 months (yes), n (%)	524 (53.3)
Involvement with the topic vitamin B6 <sup>a</sup> , mean (SD)	3.42 (1.54)

<sup>a</sup>Involvement was measured on a 7-point Likert scale. The higher the score, the more involved participants were.

### Manipulation Check of Interactivity

The analysis of variance revealed significant differences between the three versions of the website regarding interactivity ( $F_{2,980}=24.99$ ,  $P<.001$ ,  $\eta^2=.05$ ). Post hoc Bonferroni tests indicated that all three versions differed significantly from each other. Participants rated the level of interactivity as low in the control condition (mean 3.31, SE .10, n=364), as moderate in the moderate interactivity condition (mean 3.89, SE .10, n=321), and as high in the high interactivity condition (mean 4.30, SE .10, n=298). Thus, the manipulation was successful.

### Descriptive Statistics of User Actions Within Conditions

Users spent the most time (minutes) browsing the website in the control condition (median 2.62 [IQR 1.54-3.96]), followed

by the moderate (median 0.8 [IQR 0.45-2.84]) and high interactivity condition (median 0.83 [IQR 0.43-3.23]). In the control condition, 78.7% (203/258) of participants scrolled all the way down the website and viewed all website content. In the moderate interactivity condition, 14.8% (21/142) of users clicked on all dropdown menus and viewed the complete content, whereas in the high interactivity condition only 8.9% (11/124) did so. Within the high interactivity condition, the proportion of participants who used all infographics was higher (36/124, 29.0%) than of those who used all dropdown menus (11/124, 8.9%). Descriptive statistics of user actions within conditions are presented in Table 3.

**Table 3.** Indicators of user activity per condition (n=524).

Variable	Control condition (n=258)	Moderate interactivity condition (n=142)	High interactivity condition (n=124)
Duration of website visit in minutes, mean (SD) [range]	366.19 (2146.69) [0.08-21714.72]	112.54 (1103.02) [0.08-13083.52]	78.05 (893.48) [0.10-11599.07]
Scrolled to end of browser window <sup>a</sup> , % (modus) [median]	78.7 (1) [1]	N/A <sup>b</sup>	N/A
Used all dropdown menus <sup>c</sup> , % (modus) [median]	N/A	14.8 (7) [6]	8.9 (7) [6]
Used all infographics <sup>d</sup> , % (modus) [median]	N/A	N/A	29.2 (4) [2]

<sup>a</sup>Scrolled scale ranges from 0 (no scroll down) to 1 (scrolled to end of window at least once).

<sup>b</sup>Not applicable.

<sup>c</sup>Dropdown menu use scale ranges from 0 (no clicks on menus) to 9 (all menus were used at least once).

<sup>d</sup>Infographic use scale ranges from 0 (none of the infographics were used) to 4 (all infographics were used at least once).

### Main Effect of Interactivity on Recall

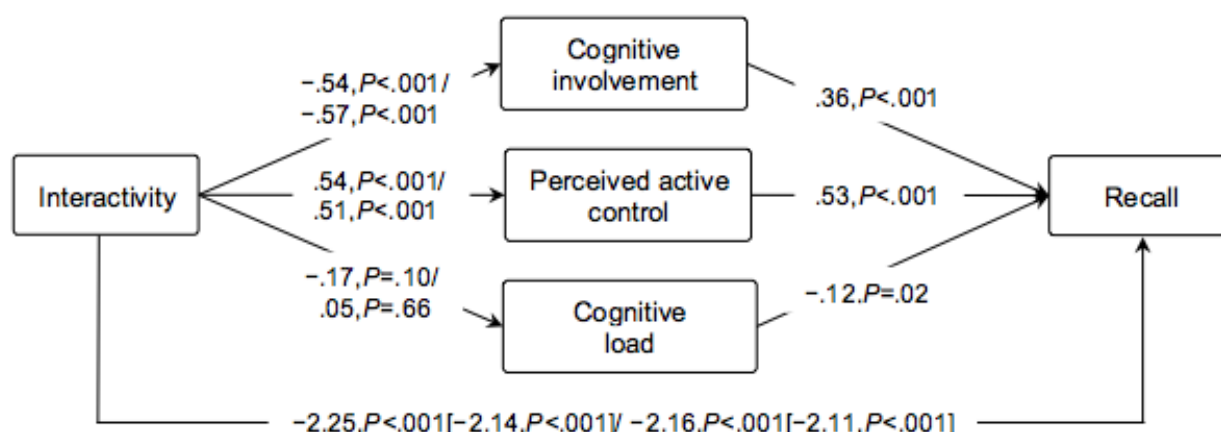

Analysis of variance showed that recall score differed significantly between the conditions ( $F_{2,980}=82.329$ ,  $P<.001$ ,  $\eta^2=.144$ ). According to the Bonferroni post hoc test, participants recalled significantly more information in the control condition (mean 5.63 [SD 2.18]) compared with the moderate (mean 3.48 [SD 2.71]) and high (mean 3.52 [SD 2.64]) interactivity conditions.

### Mediating Effect of Cognitive Involvement, Perceived Active Control, and Cognitive Load

Results showed that the effects of levels of interactivity were mediated by cognitive involvement (moderate interactivity:

$b=-.20$ , 95% CI  $-0.31$  to  $-0.10$ , 9% mediated effect; high interactivity:  $b=-.21$ , 95% CI  $-0.33$  to  $-0.10$ , 10% mediated effect) and perceived active control (moderate interactivity:  $b=.28$ , 95% CI  $0.18$  to  $0.40$ , 13% mediated effect; high interactivity:  $b=.27$ , 95% CI  $0.16$  to  $0.40$ , 13% mediated effect) but not by cognitive load (moderate interactivity:  $b=.02$ , 95% CI  $0$  to  $0.07$ ; high interactivity:  $b=-.01$ , 95% CI  $-0.04$  to  $0.02$ ). The mediations were partial as there was a remaining significant direct effect of interactivity on recall (moderate interactivity:  $b=-2.25$ , 95% CI  $-2.59$  to  $-1.90$ ; high interactivity:  $b=-2.16$ , 95% CI  $-2.51$  to  $-1.81$ ). Levels of interactivity and the three mediators explained 34% of the variance in recall ( $F_{14,953}=35.76$ ,  $P<.001$ ). The unstandardized path coefficients of the direct and total effects are presented in Figure 5.

**Figure 5.** Unstandardized path coefficients of the direct and total effects (in brackets) of moderate and high interactivity on the mediators and recall compared with the control condition (n=968).

### Conditional Indirect Effect of Interactivity on Recall According to Two Levels of Need for Cognition

The study sample was split into high (ie, score  $\geq 4.95$ , 519/968) versus low (ie, score  $\leq 4.94$ , 449/968) need for cognition using a mean split. Results showed that in individuals with low need for cognition exposed to the moderate interactivity condition, the effects of levels of interactivity were mediated by cognitive

involvement ( $b=-.18$ , 95% CI  $-0.36$  to  $-0.05$ , 8% mediated effect) and perceived active control ( $b=.14$ , 95% CI  $0.01$  to  $0.30$ , 6% mediated effect) but not by cognitive load ( $b=.12$ , 95% CI  $-0.03$  to  $0.08$ ). In low need for cognition individuals exposed to the high interactivity condition, none of the proposed mediations were significant.

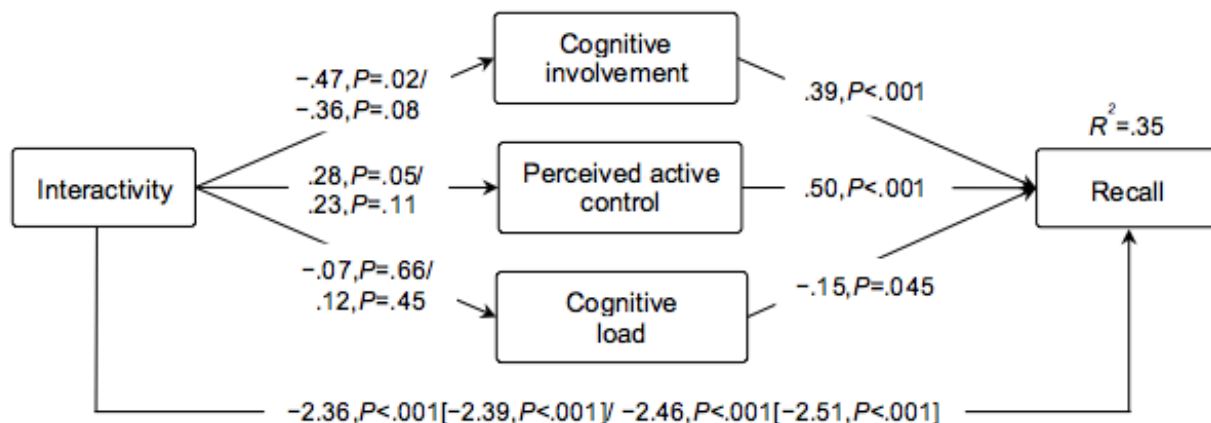

In individuals with high need for cognition, in the moderate interactive condition a significant mediation effect of cognitive

involvement ( $b=-.21$ , 95% CI  $-0.38$  to  $-0.08$ , 11% mediated effect) and active control ( $b=.43$ , 95% CI  $0.27$  to  $0.64$ , 22% mediated effect) was found. The mediation effects of cognitive involvement ( $b=-.28$ , 95% CI  $-0.46$  to  $-0.14$ , 16% mediated effect) and perceived active control ( $b=.43$ , 95% CI  $0.25$  to  $0.65$ , 4% mediated effect) were also significant in the high interactivity condition. Regardless of the condition, no mediation effect of cognitive load was found in high need for cognition individuals. As presented in Figure 6, levels of interactivity had a significant direct effect on recall.

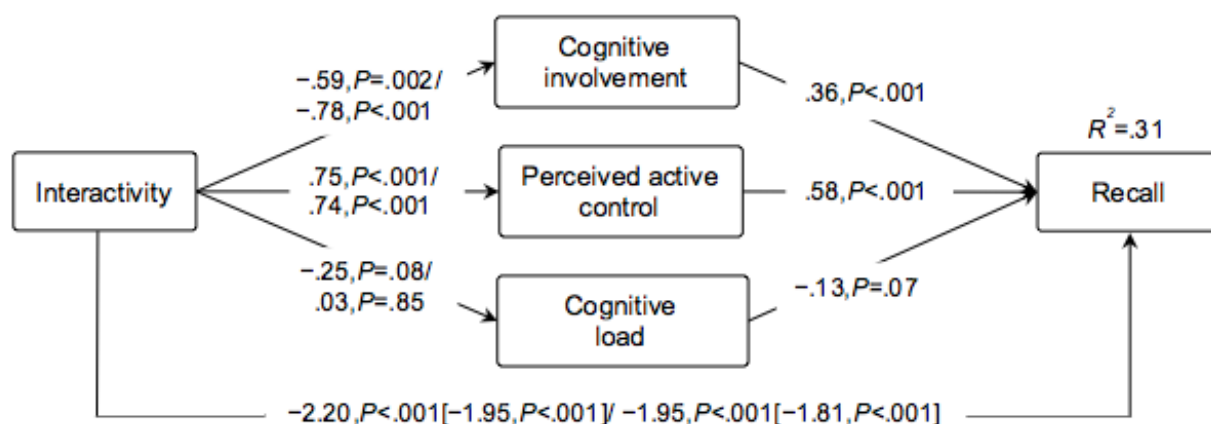

no mediation effects were found in low health literate individuals.

**Figure 6.** Unstandardized path coefficients of the direct and total effects (in brackets) of moderate and high interactivity on the mediators and recall compared with the control condition in the low ( $n=449$ ) and high ( $n=519$ ) need for cognition group.

### Low need for cognition group

### High need for cognition group

### Conditional Indirect Effect of Functional Interactivity on Recall According to Two Levels of Health Literacy

In order to test health literacy as a potential moderator of the mediation effects, individuals were categorized as having a low (ie, score  $\leq 5.14$ , 379/968) or high (ie, score  $\geq 5.15$ , 589/968) health literacy level using a mean split. Results showed that in low health literate individuals, interactivity effects on recall were mediated significantly only by cognitive involvement ( $b=-.18$ , 95% CI  $-0.37$  to  $-0.03$ , 7% mediated effect) in the moderate interactivity condition. When levels of interactivity were high,

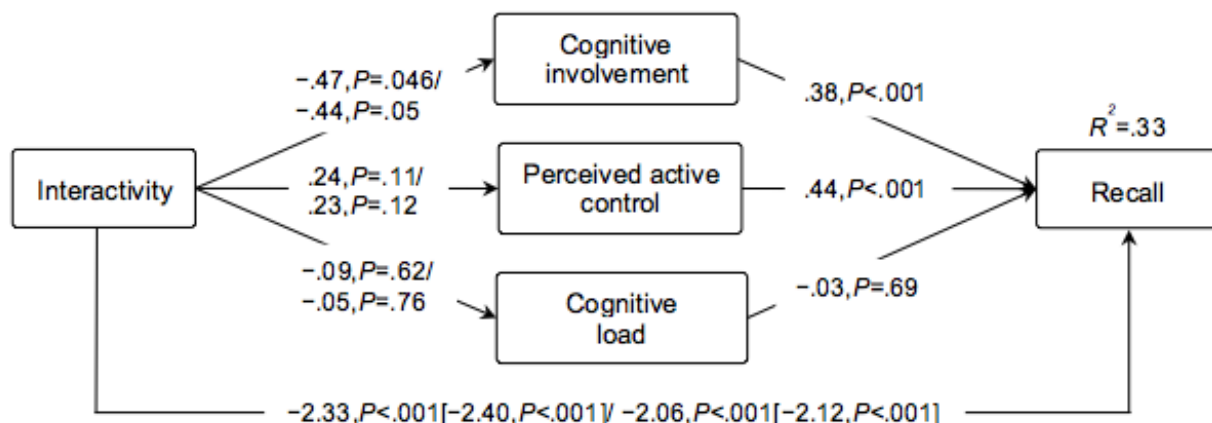

no mediation effects were found in low health literate individuals.

In high health literate individuals exposed to the moderate interactivity condition, interactivity effects were mediated by cognitive involvement ( $b=-.21$ , 95% CI  $-0.36$  to  $-0.09$ , 10% mediated effect) and perceived active control ( $b=.42$ , 95% CI  $0.28$  to  $0.60$ , 18% mediated effect). In the high interactivity condition, cognitive involvement ( $b=-.25$ , 95% CI  $-0.41$  to  $-0.12$ , 11% mediated effect) and perceived active control ( $b=.40$ , 95% CI  $0.22$  to  $0.61$ , 20% mediated effect) also partially mediated the effect. Direct and total effects are presented in Figure 7.

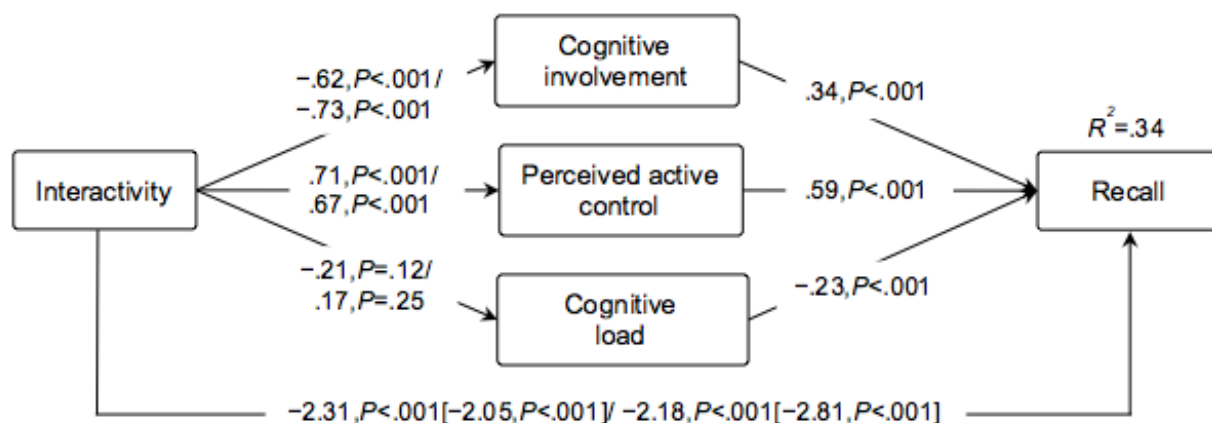

**Figure 7.** Unstandardized path coefficients of the direct and total effects (in brackets) of moderate and high interactivity on the mediators and recall compared with the control condition in the low (n=379) and high (n=589) health literacy group.

### Low health literacy group

### High health literacy group

## Discussion

### Principal Findings

Our study aimed to examine whether and how cognitive involvement, perceived active control, and cognitive load influenced the relationship between moderate and high levels of interactivity and recall. In addition, we looked at whether those pathways differed according to individuals' level of need for cognition and health literacy. Two out of the three mediation effects we tested were significant: a negative indirect effect of interactivity on recall was found through cognitive involvement and a positive indirect effect was found through active control. Cognitive load did not mediate the relation between interactivity and recall. In addition, the mediations found were partial since beside indirect effects, interactivity also had direct negative effects on recall. Participants in the moderate and high interactivity conditions remembered less information compared with the control condition.

With regard to cognitive involvement, we found a small, negative indirect effect that indicates that moderate and high levels of interactivity reduced recall through reduced cognitive involvement (ie, fewer thoughts generated). According to the

ELM, individuals' cognitive responses such as the number of thoughts generated increase if information processing follows the central route [58]. Our results may indicate that higher levels of interactivity hinder systematic information processing, resulting in less recall. This assumption is in line with previous research in which participants generated significantly fewer thoughts when exposed to interactive features (vs noninteractive features) [59]. A possible explanation for these findings might be that when individuals are exposed to interactive media that require different types of user actions (eg, reading, navigating), individuals may split their cognitive resources between the tasks. Since information processing capacities are already limited, this may lead to less conscious thinking about the message content [22,60]. Jeong and Hwang [61] found that media multitasking hindered systematic information processing resulting in reduced levels of attention, comprehension, and recall.

Our results showed that moderate and high levels of interactivity improved recall indirectly through enhanced perceptions of active control. In terms of dual process models, this may provide additional evidence that users tend to take the peripheral route of information processing when using interactive media. Sundar and Limperos [62] argue that new media offers several types

of technical affordances (eg, navigability) that may serve as cues (ie, snap judgments). For instance, the browsing heuristic refers to users' online information-seeking behavior in which they skim the site content and check out the menus or hyperlinks superficially [63]. Indeed, our data on user activity showed that participants did not make use of all interactive functions of the moderately and highly interactive websites. However, the magnitude of the mediation effect of perceived active control was comparable in both experimental conditions. As previously suggested, perceived active control may not be a function of the quantity but of the type of interactive features presented on a website [64].

Since we found no mediation effect of cognitive load, we suppose that moderate and high levels of interactivity are not more cognitively demanding in terms of information processing than static content (ie, control condition). Website complexity is a function of page length; amount of information presented; and number of pictures, hyperlinks, or other elements embedded in the website [65]. Our nonsignificant finding might be explained by the fact that we did not vary website content across conditions; we only varied the amount of interactive tools through which participants could interact with the website.

The direct, negative effect of interactivity on recall might be explained by user activity data revealing that both time spent on the website and amount of content visited were the highest in the control condition. This may imply that if users are provided with interactive features, their information search becomes more purposive, and the increased selectivity exposes them to less information, resulting in less recall.

It should be noted that in our study we examined the effects of cognitive involvement, perceived active control, and cognitive load in three separate pathways between interactivity and recall. However, these concepts should be examined in relation to each other as well. For instance, users' sense of high active control might be related to cognitive involvement. Active control entails autonomous user actions that might be driven by intrinsic interest, which is positively related to focused attention [31]. Therefore, future research should examine whether and how these concepts are related to each other.

### Differences in Mediation Effects With Regard to Need for Cognition and Health Literacy

The partial negative mediation effect of cognitive involvement and partial positive mediation effect of perceived active control

were of greater magnitude in individuals with high (vs low) need for cognition and in individuals with high (vs low) health literacy. While need for cognition and health literacy are generally associated with higher levels of elaboration and recall of (health) information [27,66,67], such associations were not found in research on interactive media [28,68], or negative associations were found [69]. Since literature suggests that interactive websites are preferred more by individuals with low need for cognition than their counterparts [29], we assume that interactivity distracts high need for cognition individuals from systematic information processing.

### Limitations

Our study had some limitations. First, we might have found less contrast between low and high health literacy groups since 87.2% of the sample (844/968) had adequate health literacy, according to the categorization of the newest vital sign [50,51]. Second, we did not measure recall of interactive and noninteractive website content separately. Accordingly, conclusions can be drawn only about individuals' overall recall of the website content. Third, this study was an online experiment that could be completed on participants' own device at home. Therefore, it is possible that not all participants paid full attention to the website as some outliers were found in the variable duration of website visit. However, analyses yielded comparable results when excluding those 66 outliers from the sample. Fifth, the topic of the study may seem very specific to some participants and appeal only to a selective group of individuals, namely those interested in nutrition and dietary supplements.

### Conclusions

Higher levels of interactivity decreased recall through reduced levels of cognitive involvement. At the same time, higher levels of interactivity increased recall through enhanced perceptions of active control. No significant mediation effects of cognitive load were found. In addition, the identified indirect effects were of greater magnitude in individuals with high (vs low) need for cognition and with high (vs low) health literacy. Beside the indirect effects, levels of interactivity decreased recall directly in all analyses.

### Acknowledgments

This research was supported by the Netherlands Food and Consumer Product Safety Authority. The authors would like to thank Done Digital Kft for website development and technical support.

### Authors' Contributions

The study was designed by PEM, SME, AO, and HdV. All authors participated in the development of the experimental stimulus and evaluated the results of the pilot tests. PEM conducted the statistical analyses, and results were interpreted with SME, AO, and HdV. PEM drafted the manuscript, and SME, AO, and HdV gave feedback on the manuscript. All authors approved the final version of the article.

## Abstract

**Background:** Owing to an increase in digital technologies in health care, recently leveraged by the COVID-19 pandemic, physicians are required to use these technologies appropriately and to be familiar with their implications on patient care, the health system, and society. Therefore, medical students should be confronted with digital health during their medical education. However, corresponding teaching formats and concepts are still largely lacking in the medical curricula.

**Objective:** This study aims to introduce digital health as a curricular module at a German medical school and to identify undergraduate medical competencies in digital health and their suitable teaching methods.

**Methods:** We developed a 3-week curricular module on digital health for third-year medical students at a large German medical school, taking place for the first time in January 2020. Semistructured interviews with 5 digital health experts were recorded, transcribed, and analyzed using an abductive approach. We obtained feedback from the participating students and lecturers of the module through a 17-item survey questionnaire.

**Results:** The module received overall positive feedback from both students and lecturers who expressed the need for further digital health education and stated that the field is very important for clinical care and is underrepresented in the current medical curriculum. We extracted a detailed overview of digital health competencies, skills, and knowledge to teach the students from the expert interviews. They also contained suggestions for teaching methods and statements supporting the urgency of the implementation of digital health education in the mandatory curriculum.

**Conclusions:** An elective class seems to be a suitable format for the timely introduction of digital health education. However, a longitudinal implementation in the mandatory curriculum should be the goal. Beyond training future physicians in digital skills and teaching them digital health's ethical, legal, and social implications, the experience-based development of a critical digital health mindset with openness to innovation and the ability to assess ever-changing health technologies through a broad

transdisciplinary approach to translate research into clinical routine seem more important. Therefore, the teaching of digital health should be as practice-based as possible and involve the educational cooperation of different institutions and academic disciplines.

## Introduction

### Background

With the progress in the introduction of digital solutions in patient care, such as electronic health records [1-3], artificial intelligence (AI) for decision support [4,5], telemedicine [6-8], or robotic surgery [9], the need for physicians and other health care professionals to get familiar with digital health is increasing. The recent COVID-19 pandemic has highlighted the advantages of remote care and puts pressure on health care professionals and infrastructure to adapt to a fast-developing, globalized world [10].

Although the introduction of new technologies in medicine is accompanied by public hope for better and more efficient patient care [11,12], experts agree that a new technology can only be as good as the physician using it [13]. Implementing digital health technologies into clinical settings remains a prolonged process [14], with one of the major barriers being the lack of health professionals' knowledge and awareness of the new technologies and the skills to use them [15].

Training physicians and nurses in the practical use of digital technologies at an early stage of their career is overdue to prepare them for their future challenges [3,13,16]. In this context, data literacy is considered a decisive skill for health care workers [17]. Digital literacy of students and young physicians, who are often referred to as the generation of digital natives, is discussed ambivalently in the literature. Although some authors postulate that growing up with digital services may lead to differentiated use in a professional context [18], other publications stress that the implication of the digital native stereotype would leave learners unsupported and technologies used in inappropriate ways, making further research in this area indispensable [19].

The relevance of implementing digital health education in medical curricula is evident [16]. Various pilot projects have been described in the literature, with differences in length and focus [20,21]. All of them reported a high level of satisfaction among students attending digital health-related courses, with expected positive influences on their skillset in later professional life [22].

According to a Europe-wide survey, medical students felt lacking digital literacy and demanded a wider implementation of digital health topics in their curricula [23,24]. Along with the need for education on ethics and technology specifics, a general introduction to the topic and the teaching of basic aspects of the field were asked for [23,24]. In 2019, the deans of 25 European medical universities agreed on the rapid implementation of digital health education in their respective

medical schools' curricula, focusing on interprofessional education, practical skills, and innovation [25]. To scale up the implementation of digital health in health care education, there is still a need to provide and exchange best practices of digital health in medical education. The ongoing public funding of digital health research projects has so far not been correlated with an increase in the number of corresponding courses in the medical curriculum [23]. The implementation of teaching initiatives for digital competencies should urgently be improved.

### Aim

We intended to deliver a proof of concept of teaching digital health at a medical school, describing the development, introduction, and evaluation of a 3-week elective module. We further aimed to identify undergraduate medical competencies in digital health and their suitable teaching methods.

## Methods

### Ethics Approval and Consent to Participate

Ethical approval for this study was granted by the ethics committee of the Charité—Universitätsmedizin Berlin (EA1/236/19). Participation in the study was voluntary. Before the study, all participants provided their consent.

### Study Setting

This mixed methods study took place at the medical school of a large German university hospital, the Charité—Universitätsmedizin Berlin, in the context of the development and deployment of a pioneer teaching module for digital health, which was realized in January 2020. At the time of the study, approximately 7500 students were enrolled at the medical school [26]. Although medical informatics was taught as an independent study program since 1972 in Heidelberg, Germany, and was mentioned in the Medical Licensure Act (*Approbationsordnung für Ärzte*) since 1989, medical informatics is only marginally taught in the German medical curriculum. The terms *digital* or *digital health* are still not mentioned in the Medical Licensure Act in Germany. By the end of the third year of the undergraduate modular medical track, students at the Charité have to choose an elective module from a variety of 3-week course programs covering different medical fields that are usually not covered by the mandatory curriculum. The modules are in direct competition for the students' interest and comprise 60 teaching hours (45 min each). Only the modules selected the most often by the students take place.

Over the course of 2 years, we developed a teaching module for digital health based on qualitative results of semistructured interviews with experts described below and by reviewing

similar existing projects. The module was designed to change over time, flexibly reacting to the feedback received and to new scientific findings. In multiple face-to-face meetings, calls, and emails with potentially interested parties, we identified 32 lecturers from 16 departments of our university hospital as well as from 6 academic and nonacademic partner organizations who were willing to participate.

The cooperation with the lecturers led to a high variety of digital health topics, such as lessons on law, ethics, and economics as well as on digital pharmacology or AI and big data in research. In addition to the theoretical teaching in seminars, our main focus was to provide hands-on experience with digital health technologies. Practice units on smart implants and wearables, symptom checker apps, telecardiology, mixed reality-assisted surgery, and video consultations were included with the help of experts and developers of the corresponding technologies. To enable the students to play the roles of different health system stakeholders, we encouraged them to compete in groups during a mini-hackathon. During the course of the whole module, each student group invented and eventually pitched a new product for a specific problem in health care. Further details and lessons can be found in the module timetable ([Multimedia Appendix 1](#)).

## Study Design

We chose a mixed methods approach consisting of an abductive, qualitative study based on semistructured interviews and a cross-sectional survey study using a web-based questionnaire. Qualitative data included the interview transcripts and results from the open-ended questions of the questionnaire. Items from the questionnaire with a five-point Likert-type scale as a response format were considered quantitative data.

## Data Collection

Between October and December 2019, DG conducted semistructured interviews with 5 experts in digital health and

medical education. Purposive sampling was deployed on the research team's professional external networks to select experts with complementary backgrounds in Europe.

We developed the interview guideline according to the research question ([Textbox 1](#)) and tested and adjusted the questions during pilot interviews within the research team. The interviews were conducted in English or German via phone calls and were recorded and transcribed verbatim by the interviewer (DG). Interview transcripts were reviewed by AP and LM. The median interview length was 31 min (range 27-50 min).

Furthermore, we collected feedback on the module and further digital health topics from the participating lecturers and via corresponding surveys. Survey items were generated through a literature review and informal research meetings ([Multimedia Appendix 2](#)). We grouped 17 items into 3 topics and chose a five-point Likert-type scale as an ordinal response format, with the options strongly agree (1), agree (2), neutral (3), disagree (4), and strongly disagree (5), and 4 open-ended questions. Respondents were also given space to comment on each topic. The 3 topics were (1) digital health at medical schools, (2) experience from the digital health module, and (3) feedback on the organization of the digital health module.

Pretests within the research team did not alter the questionnaire. Through pilot tests with associated research colleagues, clarity, relevance, and arrangement of the questionnaire items were improved.

The survey questionnaire was given to the participated students on the last day of the module as a paper version and slightly modified for participating lecturers of the module. For the latter, we sent an email invitation with multiple reminders to participate in the survey to all 32 lecturers. This web-based survey data were collected and managed using REDCap (Research Electronic Data Capture) tools hosted at Charité—Universitätsmedizin Berlin [27,28]. No incentive or compensation was given to the survey participants.

**Textbox 1.** Guideline questions for the semistructured interviews.

1. What is your relation to digital health and what are you currently dedicating to professionally?
2. How do you think will digitalization affect doctors' work in the future, and what are the biggest challenges?
3. What topics of digital health would you recommend to teach at German medical schools?
4. Which teaching methods would you imagine or consider to be the most effective for teaching digital health?
5. How can awareness for the challenges of digital health be maximized among medical students?
6. Based on your own experience, do you have further advice on what factors should be considered when teaching digital health?

## Data Analysis

We performed an abductive analysis of the interview transcripts and the results of the open-ended questions of the questionnaire from the lecturers and students to identify the predominant themes [26]. Predefined themes included teaching format and learning objectives. The theme consisted of multiple codes that were later defined as subthemes. The saturation of codes was achieved with a growing number of interviews to ensure covering the majority of the aspects connected to our research question. All coding was performed and reviewed by DG, AP,

and LM using MaxQDA qualitative data analysis software (MaxQDA 18.3.2; VERBI GmbH).

Descriptive data analysis of questionnaire items was conducted using Microsoft Excel 2020 (version 16.35).

## Results

### Overview

We constructed this mixed methods study based on 5 interviews with digital health experts and a questionnaire involving

lecturers and students. The sunburst diagram (Figure 1) visualizes the qualitative results, specifically the 4 themes in the inner ring with the most relevant subthemes in the middle ring that are specified in the outer ring.

**Figure 1.** This sunburst diagram represents the qualitative results. Within the 4 themes (inner ring), subthemes (middle ring) are assigned and specified (outer ring). ELSI: ethical, legal, and social implications.

The quantitative data were represented by the questionnaires, where the response rate was 91% (10/11) for the students and 100% (32/32) for the lecturers.

## Qualitative Results

### *Need for Digital Health*

#### **In the Health Care System**

According to the respondents, the positive effects of digital health on the health care system were clearly visible in areas such as communication, documentation, and patient empowerment. Digital health technologies would be already integrated into physicians' everyday lives and were

indispensable, as younger patients, in particular, would explicitly demand for them.

#### **In the Medical School Curriculum**

It was stated that the health care system of the future would be highly digitalized. It would, therefore, be necessary to prepare medical students accordingly as early as possible. Digital health would already be part of today's clinical practice, and concerns were expressed that a lack of knowledge in this field would lead to individual failure. Medical students would have to lose their initial reservations and become critical experts of digital health as much as their analog counterparts.

## ***Learning Objectives—Skills***

### **Digital Literacy**

Respondents emphasized that training with digital technologies from various perspectives, such as engineering, law, data protection, and ethics as well as statistical knowledge in the context of evidence-based medicine, should be part of the curriculum. The digital literacy acquired in this way would include an understanding of the meaningfulness and application areas of AI, robotics, big data, and telemedicine and thus help in one's own clinical work and in cooperation with other professional groups. Increasingly, patients would use digital services and apps, but convincing doctors to use them would remain to be a major challenge. As health apps are already being used in practice, their medical, legal, ethical, and economic implications should be a part of medical education and training.

Digital literacy would describe the sensitivity, confidence, and understanding with which physicians could apply new digital applications to promote health. Respondents pointed out that by gaining practical experiences with digital health, medical school graduates should be able to use a wide variety of digital health technologies. Interpersonal skills such as intuition and sensory experience in patient contact would gain importance, especially regarding diagnostics. Health care staff would have to be able to communicate in various novel ways (eg, apps, telemedicine). Therefore, expertise in a variety of communication methods with a special emphasis on remote care should be acquired in medical schools.

### **Innovation Capabilities and Entrepreneurial Skills**

Adapting to the constantly changing professional environment would require physicians to have their own inventive spirit and a lifelong willingness to progress and rethink. Physicians would be responsible for proactively shaping the transformation of medicine. This role could only be fulfilled by the corresponding conviction to be innovative. Innovation methods such as design thinking could be helpful to act visionary in this context.

Future medical school graduates should be trained to apply entrepreneurial skills in a digitalized and data-rich health care system to promote health care, according to the respondents. They should be able to think entrepreneurially and act innovatively, searching for new ways to sustainably integrate innovation into clinical workflows.

### **Transdisciplinary Cooperation and Open Access Mentality**

Problems could be approached and solved confidently in transdisciplinary cooperation. The respondents stated that this should also be taken into account in the teaching concept for digital medicine. Cooperation with other disciplines, such as computer science, nursing, administration, user experience design, industry, law, data protection, and ethics, should be trained at an early stage because mutual understanding of the roles would facilitate communication.

In our health care system, including medical schools, much more cooperation and sharing of knowledge is needed. E-learning should ideally be publicly available.

### **Patient-Centered Approach**

Physicians should be given the freedom to focus on patients rather than on technology. For this purpose, their focus should be on human interaction. For physicians, digital health would be about the ability to advise mature, proactive patients sensibly and to accompany them through the health care system appropriately through direct communication using digital health wherever appropriate.

### **Fearless of Change**

Lack of awareness and experience in using digital technologies would fuel reservations in health care workers, according to the respondents. Actors, especially in leading positions, would feel that their professional authority or seniority was being questioned. Trying out and getting to know new possibilities in a relaxed manner could reduce fears, even among older generations and up to executive levels, and lead to successful clinical implementation.

## ***Learning Objectives—Knowledge***

### **Data Literacy**

Clinical decisions were increasingly based on complex data. Identifying the relevant data and deriving good decisions from it would require a high degree of data competence from future physicians. Statistics would remain an important basis for scientific action in this context. It was stated that the responsible and sensible use of systems based on AI is an important medical skill and should become a compulsory learning objective for medical students.

### **Ethical, Legal, and Social Implications**

Medicine in its current form would be unethical according to the respondents. Digitalization and modern data science could improve this by analyzing patient data to make clinical care more based on objective evidence. Often, issues in digital health would lead to ethical questions, which should be discussed by experts and students using exemplary situations. Legal aspects, in particular regarding the regulation of medical practice and medical devices, should be taught by experts during the course of studies. The culture of societal change in the context of digitalization should be a central component of the curriculum.

### **Data Protection**

According to the interviewees, data protection, data security, and privacy were one of the greatest challenges for physicians in the course of digitalization, for example, in the case of mobile health apps. They should be taught transparently and according to clear guidelines by appropriate experts. As most patients care about the privacy of their health data, medical students should learn to ensure that their actions are in accordance with the correct data protection regulations.

### **Health Economics**

Basic economic knowledge and health economic aspects such as financing and resource optimization were missing in medical schools' curricula and should be taught specifically for digital health.

## Teaching Format

### Practical Experiences

The direct handling of new technologies would reduce fears and promote enthusiasm for digital technologies. *Learning by doing* would be the preferred form to learn about technical applications because it creates experiences, helps to shape interests, and ensures a *view beyond the end of one's own nose* (interview quote). The goal of teaching digital health would be its successful clinical implementation. Therefore, existing technologies should be included in the medical curriculum and demonstrated by experienced lecturers. Students should be trained practically involving direct contact with patients and technologies to handle unexpected new situations in relation to digital health and encouraged to be creative and culturally reflective by creating their own content, for example, in the course of a hackathon.

### Lectures

Short impulse lectures would be a useful teaching method, especially for large groups. Frontal lectures could be more effective for deepening a topic or as a supplement to practical training, especially if they do not last longer than 10 min.

### Open Discourse

An open-ended discourse on the values, visions, and competencies of medical students among themselves and with various stakeholders in digital health (patients, physicians, nurses, etc) would lead to a high degree of reflection and heightened awareness of the relevance of the topic. Thus, critics and enthusiasts would be simultaneously involved.

### Other Proposed Teaching Formats

Small group lessons in (carefully selected) groups of up to 10 students would ensure more enthusiasm for the course content, stated the respondents. Peer teaching would be very effective and bring individual experience into the curriculum. The creation of independent work is recommended as a teaching format. E-learning would be a suitable format, especially for theoretical content, and could be used in a scalable manner. In general, digital medicine teaching should be integrated longitudinally into the curriculum.

### Cooperation

#### Cross-Faculty

Digital health could be taught as a study component of various study programs, such as medicine, economics, or sociology.

According to respondents, transdisciplinary teaching was more attractive and stimulating. Interuniversity exchange would be profitable, and joint courses would be useful for students and lecturers.

### Cross-Institutional and Cross-Functional

In the teaching of digital health, lecturers, students, scientists, alumni, and experts from all participating study programs as well as external experts would be partners. It would also be advisable for the lecturers to consult with each other to ensure continuity and interlocking of the teaching content.

### Industry and Business

The respondents believe that integration of different actors from industry and business into the teaching of digital health at medical schools would help both students and companies to benefit and learn from each other.

## Quantitative Results

### Students' Evaluation

All participating students agreed that digital health should be part of the mandatory curriculum at medical schools (8 strongly agree and 2 agree) and taught early in their careers (8 strongly agree and 2 agree) and that competencies are more relevant than knowledge for medical graduates (5 strongly agree and 5 agree; [Figure 2](#)). Regarding whether medical students are digitally literate, the opinion was split. Most students strongly disagreed or disagreed that digital health is sufficiently represented at medical schools (5 strongly disagree, 4 disagree, and 1 agree). All students agreed that digital health would impact physicians' work over the next 5 years (9 strongly agree and 1 agree).

Regarding the experiences from this module, all students agreed that this module made them aware of medical skills that they were not aware of before (6 strongly agree and 4 agree), that the teaching format helped them in the study process (5 strongly agree, 2 agree, and 2 neutral), and that interdisciplinary teaching formats would be an enhancement to the module (5 strongly agree, 3 agree, and 2 neutral; [Figure 3](#)). All students agreed that the module motivated them to get more involved with digital health (9 strongly agree and 1 agree) and that they felt well prepared for their future clinical work (3 strongly agree and 6 agree). For most students, this module was the first time they encountered digital health at medical school (8 strongly agree, 1 agree, and 1 strongly disagree).

There was a strong overall satisfaction with the organizational aspects of the module ([Multimedia Appendix 3](#)).

**Figure 2.** Students' opinions regarding digital health at medical schools.**Figure 3.** Students' experience with the digital health module.

### Lecturers' Evaluation

The majority of the lecturers stated that digital health should be part of the mandatory curriculum at medical schools (24 strongly agree, 6 agree, and 2 disagree) and that medical students should be taught digital health early in their career (25 strongly agree, 4 agree, 1 neutral, and 1 disagree; [Figure 4](#)). Most lecturers responded that a competency-centered teaching

approach is more suitable than a knowledge-based approach (17 strongly agree, 9 agree, 3 neutral, and 3 disagree). Regarding digital literacy among medical students, opinions were split. The majority of lecturers disagreed that digital health would be sufficiently represented at medical schools (14 strongly disagree, 8 disagree, 5 neutral, 1 agree, and 3 strongly agree). All lecturers

agreed that digital health will impact physicians' work over the next 5 years (27 strongly agree and 5 agree).

Regarding experiences from this module, lecturers agreed that this module over 3 weeks is suitable for teaching new disciplines (21 strongly agree, 9 agree, and 2 neutral; [Figure 5](#)). The majority of lecturers agreed that they would be willing to teach digital health as a fixed part of the medical curriculum (19 strongly agree, 7 agree, 5 neutral, and 1 disagree) and that more interdisciplinary teaching would enhance this module (12 strongly agree, 9 agree, 9 neutral, 1 disagree, and 1 strongly

disagree). Lecturers stated that this module animated them to teach more about digital health (16 strongly agree, 12 agree, 3 neutral, and 1 disagree). Regarding whether lecturers made important experiences during this module as well as whether lecturers taught digital health for the first time, opinions were split.

Overall, there was a high satisfaction rate for module organization, although in some individual cases, room for improvement was seen concerning the organizational communication ([Multimedia Appendix 3](#)).

**Figure 4.** Lecturers' opinions regarding digital health at medical schools.

**Figure 5.** Lecturers' experience with teaching in the digital health module.

## Discussion

### Principal Findings

In this mixed methods study, we provide valuable evidence on digital health teaching at medical schools. Our findings indicate that teaching digital health in medical schools not only comprises the knowledge transfer of technological advancements in health care. However, equally important is to shape the mindset of future physicians, teaching them to be open toward innovation, willing to develop and share novel insights through a transdisciplinary and patient-centered approach, and to be able to overcome fears of adopting digital health technology in clinical routine. Our results show that practical experiences, for example, with clinically implemented technology, bedside teaching, or by own creations as hackathons, are fundamental and should only be complemented with short impulse lectures. Small groups and peer teaching support the learning process.

The vast majority of lecturers and students stated that digital health is not sufficiently represented at medical schools and should be part of the curriculum. Both lecturers and students felt encouraged to get more involved with digital health after participating in the module.

### Need for Digital Health

The digital transformation of our health care system can increase the quality, accessibility, and affordability of health services [29]. By implementing digital technology for health care provision, we can apply health services more efficiently and individually. Within the next 20 years, it is expected that 90% of all jobs in the United Kingdom's National Health Service would require digital skills [30]. With an increasing flood of information for medical staff, there are already data reporting staff to be overwhelmed by alarms and notifications [31].

Intelligent systems may filter these and other digital information, making them better usable for patient care, which is more urgent than ever in some medical disciplines [32]. Furthermore, many processes could be simplified through the implementation of telemedicine in health care, thereby optimizing patient care [33,34].

Some sources name a lack of health care professionals' awareness and knowledge as a main barrier to a successful digital transformation of health systems [30,35]. The European Medical Students' Association recently identified a significant gap between students' willingness to act in a digitalized health care environment and the knowledge and skills acquired in their curriculum [23,24,36]. Medical staff and medical students can be regarded as ready and willing to use digital health technology in their clinical routine. However, adequate and regular training in digital devices as well as a structured curriculum in digital health are still lacking in most institutions [37,38], whereas some associations recommend up to 40 hours of education on biomedical and health informatics for medical and nursing students during their studies [39]. Our findings show that the need for digital health and its teaching is increasing, which is acknowledged by students, lecturers, and experts. Therefore, mandatory modules on digital health, medical informatics, or medical technologies should be included in the curricula of medical schools.

### Digital Health in Medical Schools

Elective classes and programs on digital health slowly find their way into medical curricula. This process is driven by individual pilot projects rather than by validated and coordinated guidelines or national regulations [16,38,40-48]. Pilot projects, adapted to the individual curricular conditions of medical faculties, can be the first step toward realizing a longitudinal interdisciplinary

approach to implement digital health in the overall curriculum [13,16,49-51].

In 2013, the German Association for Medical Informatics, Biometry and Epidemiology developed national competency-based learning objectives titled *Medical Informatics Learning Objectives for Undergraduate Medical Education*, which are consistent with the recommendations of the International Medical Informatics Association [50]. The objectives are in line with our findings implicating that medical graduates should have a broad knowledge of data literacy; be trained to assess ethical, legal, and social implications (ELSIs) and privacy aspects of digital health; and estimate the health economic consequences of novel technologies. Here, specialist expertise in digitalization beyond medicine could be offered in a local interdisciplinary and interprofessional network of universities. Even impressions from politics and business should be included to convey a comprehensive picture. Finally, addressing a peer-to-peer teaching approach, the motivation and competencies of many medical students as digital natives may have a very high potential to be included in medical curricular teaching offerings.

The national and international exchange of *best practice* examples and networking will be helpful in this respect. At the same time, however, urgent efforts should be made to define standards for the teaching of digital skills in medical studies at national levels [39].

### Undergraduate Medical Competencies in Digital Health

The future-proof physician must be able to apply digital health in the clinical routine. Our results emphasize that physicians should be open toward innovation and transdisciplinary cooperation throughout their careers and include the ability to recognize entrepreneurial potentials. Brunner et al [38] classified the digital health capabilities expected of medical graduates into 4 domains: (1) *digital technologies, systems, and policies*, covering digital literacy and ELSI; (2) *clinical practice and applications*, including the ability to integrate digital health into clinical routine; (3) *data analysis and knowledge creation*, including the ability to apply basic data analytics to unstructured digital data sets; and (4) *system and technology implementation*, suggesting that medical professionals should participate in the development and implementation of digital health. The latter aspect is also stressed by our results and a recent publication that demands physicians with dual competencies in clinical and data science expertise [49]. A medical graduate should be able to use digital health technology, interpret its results, and explain those to the patients.

Another main finding of our study is that teaching digital health should be about teaching a mindset that allows flexibility and suitability for an unknown and rapidly evolving future of our health care sector, rather than teaching the use of individual technologies or the right approach only for specific situations. This mindset includes openness to change, curiosity, and collaboration across functions, roles, professions, institutions, and hierarchical gradients. It also requires the willingness to actively anticipate and form the future of health care through reflection and innovation. Eventually, a strong awareness of

changing patients' and health care workers' needs and for new ELSIs should result from this mindset. It may be acquired by confrontation with a broad variety of different digital health aspects in terms of patient treatment, medical technologies, and the structure of health systems, as we did in our module.

Our results emphasize that passive knowledge transfer in the form of lectures is outdated, although it is the most used teaching method in medical schools [52]. A focus on students' engagement (eg, own creation in hackathons, peer teaching) and linking knowledge transfer to practical experiences (eg, bedside teaching with available digital technology) is desirable and effective. Students should be given the opportunity to deepen their knowledge and skills in special fields (eg, clinical data science, design thinking) in extracurricular activities or in the form of an elective module [49]. The exchange with other disciplines in workshops or hackathons can be the seed for future health innovations and entrepreneurial ventures. They are promising methods for introducing the inventor mindset to future physicians and offer the possibility of teaching medical students together with students of more information technology (IT)-focused and data-focused subjects. A close collaboration with IT faculties, for example, through an MD and computer scientist tandem, should be anticipated.

### Limitations

This mixed methods study provided novel insights into undergraduate medical competencies in light of digital transformation in health care and the development and deployment of a digital health module at a German medical school. However, a number of limitations apply.

First, the results are based on a limited number of participants. As a descriptive approach, quantification or generalization of the results is not possible but may still provide important impulses for further research and development in the field. Second, due to the selection bias of students and lecturers, the results of the questionnaire might only reflect the opinion of digital health advocates and are not representative. Third, the described undergraduate competencies in digital health are an additional source of information; therefore, there is no guarantee of completeness.

### Conclusions

Digital health competencies are key competencies for future-proof physicians and should therefore be included in the core curriculum at medical schools. For a first curricular implementation and to gain early local experiences, elective modules such as ours are suitable and can provide important information for existing didactic strengths in teaching this topic. The exchange of best teaching practices and institutional collaborations will further leverage the reach of this intent.

Digital health education should focus on building and sharpening a critical and experience-based *digital health mindset*, rather than passively transferring knowledge of technology specifics. Active teaching methods such as practice units, discussions with experts, and hackathons should be used to teach a broad variety of subjects. Interprofessional learning and teaching with nonmedical disciplines is recommended to add to the diversity

of perspectives and to prepare for increasingly interprofessional patient care.

## Acknowledgments

The authors express our gratitude to the digital health experts who participated in the interviews. Furthermore, the authors thank all students and lecturers for their feedback on this module and for sharing their opinions about digital health, especially the lecturers who also dedicated their time and effort for planning and performing new lessons within the context of the described module. The authors acknowledge support from Hacking Health Berlin, the German Research Foundation (DG), and the Open Access Publication Funds of Charité—Universitätsmedizin Berlin.

## Authors' Contributions

DB had the idea of developing and conducting a digital health module at the Charité—Universitätsmedizin Berlin. The study was conceived by AP, DB, DG, and FB. DG conducted data acquisition. Qualitative and quantitative data were analyzed by AP and DG, supported by KB and LM. AP and DG wrote the manuscript, supported by KB and LM. DB supervised all parts of the study. All authors critically reviewed and approved the manuscript.

## Abstract

**Background:** Automatic text summarization (ATS) enables users to retrieve meaningful evidence from big data of biomedical repositories to make complex clinical decisions. Deep neural and recurrent networks outperform traditional machine-learning techniques in areas of natural language processing and computer vision; however, they are yet to be explored in the ATS domain, particularly for medical text summarization.

**Objective:** Traditional approaches in ATS for biomedical text suffer from fundamental issues such as an inability to capture clinical context, quality of evidence, and purpose-driven selection of passages for the summary. We aimed to circumvent these limitations through achieving precise, succinct, and coherent information extraction from credible published biomedical resources, and to construct a simplified summary containing the most informative content that can offer a review particular to clinical needs.

**Methods:** In our proposed approach, we introduce a novel framework, termed Biomed-Summarizer, that provides quality-aware Patient/Problem, Intervention, Comparison, and Outcome (PICO)-based intelligent and context-enabled summarization of biomedical text. Biomed-Summarizer integrates the prognosis quality recognition model with a clinical context–aware model to locate text sequences in the body of a biomedical article for use in the final summary. First, we developed a deep neural network binary classifier for quality recognition to acquire scientifically sound studies and filter out others. Second, we developed a bidirectional long-short term memory recurrent neural network as a clinical context–aware classifier, which was trained on semantically enriched features generated using a word-embedding tokenizer for identification of meaningful sentences representing PICO text sequences. Third, we calculated the similarity between query and PICO text sequences using Jaccard similarity with semantic enrichments, where the semantic enrichments are obtained using medical ontologies. Last, we generated a representative summary from the high-scoring PICO sequences aggregated by study type, publication credibility, and freshness score.

**Results:** Evaluation of the prognosis quality recognition model using a large dataset of biomedical literature related to intracranial aneurysm showed an accuracy of 95.41% (2562/2686) in terms of recognizing quality articles. The clinical context–aware multiclass classifier outperformed the traditional machine-learning algorithms, including support vector machine, gradient boosted tree, linear regression, K-nearest neighbor, and naïve Bayes, by achieving 93% (16127/17341) accuracy for classifying five categories: aim, population, intervention, results, and outcome. The semantic similarity algorithm achieved a significant Pearson correlation coefficient of 0.61 (0–1 scale) on a well-known BIOSSES dataset (with 100 pair sentences) after semantic enrichment, representing an improvement of 8.9% over baseline Jaccard similarity. Finally, we found a highly positive correlation among the evaluations performed by three domain experts concerning different metrics, suggesting that the automated summarization is satisfactory.

**Conclusions:** By employing the proposed method Biomed-Summarizer, high accuracy in ATS was achieved, enabling seamless curation of research evidence from the biomedical literature to use for clinical decision-making.

## KEYWORDS

biomedical informatics; automatic text summarization; deep neural network; word embedding; semantic similarity; brain aneurysm

## Introduction

### Background

Automatic text summarization (ATS) is a leading topic in the field of information retrieval research, particularly in the medical and biomedical domains, which offers an efficient solution to access the ever-growing amount of scientific and clinical literature by summarizing the source documents while maintaining their most informative contents [1]. The large quantity of biomedical data now accessible to clinicians makes it challenging to locate the correct data rapidly; thus, automatic summarization can provide highlights particular to clinical needs [2]. Moreover, achieving precise, succinct, and coherent information extraction from credible published biomedical resources to construct a simplified summarization plays an imperative role in clinical decision-making, educating patients, and medical education. At the same time, automating this process will provide better opportunities for users to obtain the most critical points of required clinical knowledge without having to delve into an enormous amount of text, saving hours of searching. It is highly desirable to accurately identify scientifically sound published studies and summarize selected studies against a given type (eg, intervention and prognosis) of clinical query.

The primary requirements in carrying out this task of extracting noteworthy information are the efficiency of the process, contextualization, and precision of retrieved contents. Efficiency pertains to reducing human involvement and achieving the required materials in a timely manner; contextualization refers to the user objective relevant to a clinical task; and precision of contents applies to the correct identification of needed contents from trustworthy resources. Owing to the massive increase in the biomedical research literature, finding relevant, scientifically sound, and fit-to-context information has become more and more challenging for precise automatic text classification and summarization. The field of text classification and ATS is well-explored [3-7]; however, minimal work has been done in a clinically fit-to-context summary of biomedical text [8,9]. Medical text summarization poses a unique set of challenges compared to summarization in other domains [10].

The main limitations of existing medical text summarization are as follows: (a) inability to capture the clinical context while ranking the sentences for the summary; (b) lack of consideration in checking the quality of the documents before performing summarization; (c) inability of identifying context and implicit information present in the biomedical text, which cannot explicitly match with the user query; (d) lack of purpose-driven ranking and selection of passage for the final summary; and (e) nonuse of a large training set for training deep neural network models. To overcome these limitations, this paper introduces a

novel framework called Biomed-Summarizer, which provides a quality-aware Patient/Problem, Intervention, Comparison, and Outcome (PICO)-based intelligent and context-enabled summarization of contents of biomedical literature to satisfy the requirements listed above. Unlike the use of traditional features using a bag of words (BoW) approach, in which the text is tokenized into multiple words and each word is given a number representing the frequency of its use [3], more powerful word-embedding techniques have recently been introduced, such as word2vec [11,12] and GloVe [13], to combat the issues of data sparseness and context-overlooking by generating a vector space, typically of several hundred dimensions [14]. The word2vec approach creates vectors at the sentence or document level by employing the sentence2vec or doc2vec model [15]. The Biomed-Summarizer framework uses the Keras tokenizer [16] to generate a contextually rich set of features with a compact number of dimensions to enable semantics-based matching for precise extraction, summarization of contents, and avoiding sparseness. These features are then used as input to our bidirectional long-short term memory (Bi-LSTM) [17] classification model to identify the PICO sequence. PICO was initially proposed for formatting a clinical question. Subsequently, researchers have used the PICO structure for information retrieval and sentence identification in the text of biomedical documents [18-21]. In deciding which sequences to include in the final summary, we considered a comprehensive criterion that provides information on the quality of the study to which that sequence belongs, the relevance of the sequence to the user query, study type, credibility of the publishing venue, and freshness in term of the date of publication.

In summary, the main contributions of this paper are as follows. First, we introduce a novel framework, termed Biomed-Summarizer, for extractive multidocument ATS of biomedical documents. The summary construction is based on PICO elements identified in each record. Additionally, we employ contextual and quality parameters for the selection of a subset of a PICO sequence of sentences to include in the final summary.

Second, for quality recognition, a highly optimized multilayer feed-forward neural network model, multilayer perceptron (MLP), is presented to acquire significantly accurate results. This model offers binary classification to identify the soundness of a study based on data (title and abstract) and metadata (article type, authors, and publishing venue and date) features.

Third, for PICO elements classification, we propose a Bi-LSTM recurrent neural network (RNN) model trained on the vector representation of the text, which significantly boosts the performance compared to conventional machine-learning models such as support vector machine (SVM), logistic regression, decision tree, and naïve Bayes. Unlike previous studies that

focused on the detection of PICO elements one-by-one by employing a separate binary classifier for each PICO element, the proposed approach is a multiclassifier model, which classifies PICO sequences simultaneously from any given biomedical study.

Fourth, to accurately extract the PICO sentences to be included in the final summary, we present a novel method of calculating the similarity between the query and medical text using the Jaccard coefficient after semantically enriching the text using medical ontologies.

Finally, we offer a publicly available dataset [22] comprising thousands of abstracts related to intracranial aneurysm (also known as cerebral or brain aneurysm) curated from the biomedical literature for PICO-based classification. Additionally, another open-source dataset [22] is presented for the quality recognition model.

We aimed to achieve these contributions through the precise, succinct, and coherent information extraction from credible published biomedical resources, and to construct a simplified summary containing the most informative contents that provide a review particular to clinical needs.

## Related Works

### *ATS in the Biomedical Domain*

Summarization techniques are generally divided into two categories: abstractive and extractive [2,4]. Abstractive summarization methods examine the text and generate a new summarized text as a representative of the original text. In contrast, extractive summarization methods recognize the important part of the text, extract that component, and generate the summary verbatim. Extractive summarization approaches are classified into different categories such as statistical-, topic-, graph-, discourse-, and machine learning-based approaches [5]. Single and multidocument summarization are the two principal categories concerning the number of documents, whereas generic and query-specific are the two main types of summaries [5]; however, another possible criterion can be used to classify these studies into item set-based mining, and classification and ranking. The item set-based mining approach extracts domain concepts in the representative sentences to generate a graph-based summary [1,23,24]. The classification and ranking-based approach first detects key sentences and ranks them according to their importance in the text to produce a plain textual summary. For such a task, some researchers have used statistical features such as term frequency, sentence position, and similarity with the title [25,26], whereas other methods incorporated semantic information extracted from external linguistic resources [26,27].

### *Identification of PICO Elements in Text*

Minimal work has been done in the area of PICO-based retrieval of contents from the biomedical literature. The existing studies are categorized based on three aspects: individual PICO element identification [9,18,28], sentence classification [21,29], and question and answer with summarization [9,30]. In a proceeding, the authors presented a process of a PICO corpus at the individual element level and sentence level [31]. A hybrid

approach of combining machine learning and rule-based methods was proposed for the identification of PICO sentences and individual elements in successive order [20]. Another study on PICO sentence extraction was carried out with a supervised distance supervision approach that capitalizes on a small labeled dataset to mitigate noise in distantly derived annotations [32]. The authors developed a naïve Bayes-based classifier and reported that it is not sufficient to rely only on the first sentence of each section, particularly when high recall is required [28]. Boudin et al [33] used multiple supervised classification algorithms to detect PICO elements at the sentence level by training data on structured medical abstracts for each PICO element. The results showed that the detection accuracy was better for the Patient/Problem compared to the Intervention and Outcome elements.

### *Quality of Biomedical Studies*

Several promising approaches have been explored [34-41] to retrieve high-quality (ie, scientifically sound) studies from the PubMed database. Among these, some methods such as PubMed Clinical Queries rely on Boolean-based strategies using Medical Subject Heading (MeSH) terms and keywords [39,40]. Clinical Queries are often considered as a reference point for assessing the effectiveness of approaches intended to retrieve scientifically sound studies from PubMed. Some methods have also used supervised machine-learning algorithms such as SVM, naïve Bayes, and decision tree to identify scientifically rigorous studies from PubMed [34,37,38,42]. These approaches mainly depend on bibliometric features, semantic features, and MeSH terms. The limitation of approaches that use MeSH terms is the availability, as MeSH terms are added to PubMed citations with an average time gap of 20 to 252 days after an article is published [40,43]. Very recently, a deep-learning approach was used for the task of detecting quality articles in PubMed [40,41]. Deep learning-based approaches have proven to improve accuracy over the existing approaches of machine-learning models, PubMed Clinical Queries search, and McMaster text word search in terms of precision. These approaches were trained on a treatment-related dataset.

### *Sentence Scoring and Ranking for Summarization*

Various methods have been proposed to choose what text should be included in the final summary [1,4-8,23,24,44]. The most common method is the frequency-based approach, in which a sentence with a word holding the highest frequency is given more importance [45]. Some studies have found similarities in a sentence with the title of the document [5]. If a sentence encompasses words in the title, the sentence is assigned a score value of 1; otherwise, a score value of 0 is assigned. Another approach commonly followed for the selection of sentences to include in the summary is the cue words technique, in which the cue words are provided by the user [4,6,44]. A score value of 1 is assigned to the sentence if it contains these cue words; otherwise, a score value of 0 is assigned. Sentence position and length are also considered for sentence inclusion in the summary. These techniques are used to score a sentence by linearly combining the individual scores of each method [44]. Based on the scoring, a certain number of sentences with high ranks are picked up to include in the final summary. Recently,

deep-learning approaches have been widely used in text summarization [3,46-49]. A neural network-based general framework was proposed for single-document summarization using a hierarchical document encoder and attention-based extractor [48]. For the sentence ranking task of multidocument summarization, a ranking framework was presented using a recursive neural network (R2N2) [49]. A query-focus summarization system called AttSum [46] was proposed that determines ranking based on *both* saliency and relevance in contrast to previous approaches of learning to rank based on *either* relevance or saliency.

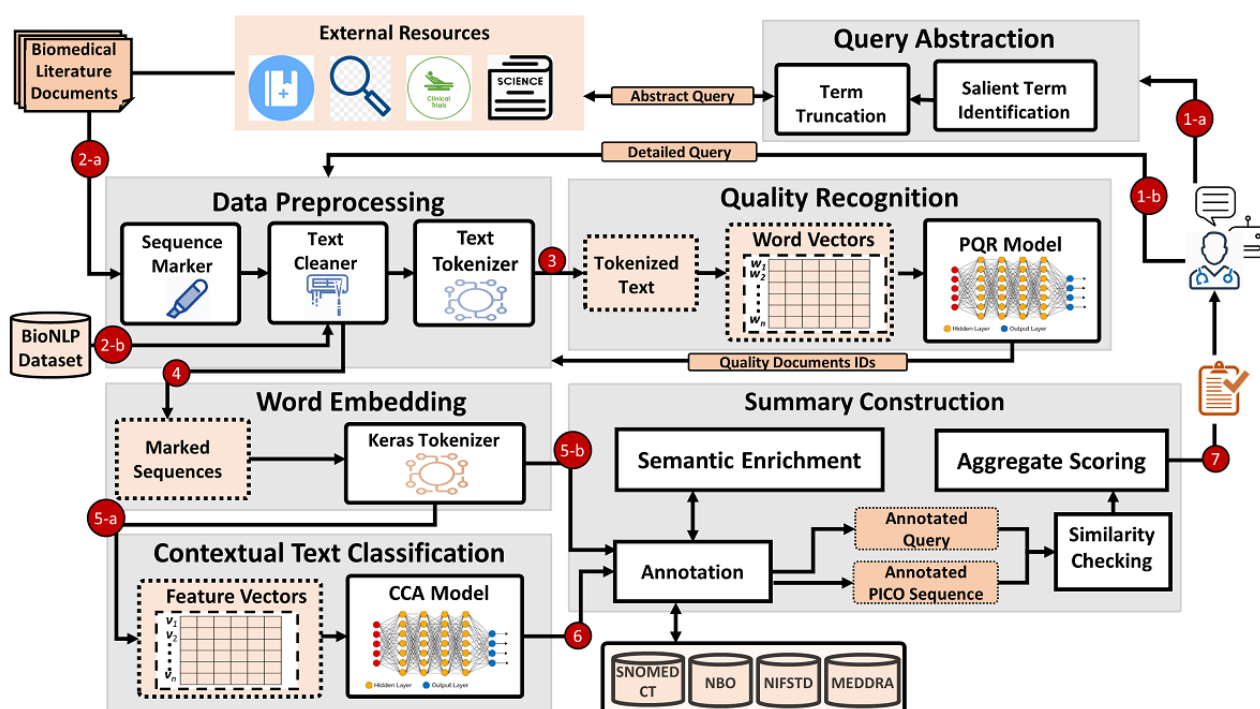

The prominent issues with existing approaches are as follows: (a) inability to capture the clinical context while ranking the sentences for creating summarization, (b) omitting the check on the quality of the documents used in the summary, (c) inability of identifying implicit information located in the body text of a study that is not explicitly matched with the user query, (d) lack of purpose-driven ranking and selection of passage for the final summary, and (e) unavailability of a large training set for training deep neural network models. Biomed-Summarizer circumvents all of these limitations.

## Methods

### Overall Design

Figure 1 shows the architecture of the proposed Biomed-Summarizer framework highlighting four main modules: data preprocessing, quality recognition, contextual text classification, and text summarization. The main tasks in data preprocessing are sequence marker, cleaning, tokenization, vector generation, and feature creation. The quality recognition module identifies the scientific soundness of a study using a feed-forward deep-learning binary classifier that is trained on biomedical data and metadata features. The contextual text classification classifies the PICO sequence of sentences in the selected quality documents using the Bi-LSTM model, an RNN trained on a large set of data acquired from BioNLP [21] and domain-specific Medline abstracts. Lastly, the summarization module generates a summary from the classified PICO sequences of multiple documents using a sequence scoring method consisting of semantic similarity (between a query and a text sequence extracted from a biomedical study), the publishing venue's credibility, and year of publication.

**Figure 1.** Proposed Biomed-Summarizer architecture with four major components: data preprocessing, quality recognition, context identification, and summary construction. PQR: prognosis quality recognition; CCA: clinical context-aware; PICO: Population/Problem, Intervention, Comparison, Outcome.

### Data Preprocessing

Biomed-Summarizer acquires data from two input sources: BioNLP dataset and PubMed. The BioNLP dataset is publicly available, whereas we retrieved the domain-specific abstracts from PubMed. The process used to parse raw abstracts retrieved from the PubMed and BioNLP is described below.

#### Sequence Marker

The task of sequence marker is to parse each raw abstract in the dataset to retrieve the headings based on the keywords listed in

the dictionary, as shown in Textbox 1. If a keyword is matched in the abstract, we extract the text (sequence of sentences) under that heading and mark it with the corresponding label. For instance, if a heading “objective” is found in an abstract, label “A” is assigned to the text. The dictionary is based on a previous study [21] with extension of a few more keywords (eg, Patient 1 and Patient 2). This process is repeated for all of the abstracts in the dataset of documents retrieved from PubMed.

**Textbox 1.** Master dictionary representing keywords that appear in headings in the structured abstracts of biomedical studies.

*dict = {'A': ['objective', 'background', 'background and objectives', 'context', 'background and purpose', 'purpose', 'importance', 'introduction', 'aim', 'rationale', 'goal', 'context', 'hypothesis'], 'P': ['population', 'participant', 'sample', 'subject', 'patient', 'patient 1', 'patient 2'], 'I': ['intervention', 'diagnosis'], 'O': ['outcome', 'measure', 'variable', 'assessment'], 'M': ['method', 'setting', 'design', 'material', 'procedure', 'process', 'methodology'], 'R': ['result', 'finding'], 'C': ['conclusion', 'implication', 'discussion', 'interpretation table']}*

We employed the following steps to prepare data for the clinical context-aware (CCA) classification model.

### Text Cleaning

The process of text cleaning removes special characters, punctuation, stop words, and URLs present in the text. For removing stop words, we used the Python NLTK library [50].

### Tokenization

This process splits the sentences retrieved after the text cleaning process into individual tokens. We used the Keras tokenizer [16] to create a list of tokens for each biomedical paragraph.

### Vector Generation

We considered a maximum of 50,000 words for each paragraph and generated a 250-dimension vector representation using Keras text [16] to sequence functionality. We made sure that each vector length is the same.

As a result of the above steps, we obtained a vector representation of each paragraph, which is then used for training and testing of the CCA classification model. An example of text sequences and corresponding class labels is shown in Table 1. It is important to mention that we do not require a process of sequence marking on BioNLP data because these sentences are premarked.

**Table 1.** Example sequence of sentences for an assigned category of Aim, Population, Methods, Interventions, Results, Conclusion, and Outcomes.

Sequence	Category
The aim of the present study was to evaluate whether the Anterior communicating artery (A com) aneurysms behave differently from the aneurysms located elsewhere with respect to size being a rupture risk. To this end, we examined the clinical data of ruptured A com aneurysms and analyzed other morphological parameters, including size parameter, providing adequate data for predicting rupture risk of the A com aneurysms.	Aim (A)
Between January 2010 and December 2015, a total of 130 consecutive patients at our institution with the A com aneurysms- 86 ruptured and 44 unruptured-were included in this study. The ruptured group included 43 females (50%) and 43 males (50%) with the mean age of 56 years (range, 34-83 years). The unruptured group included 23 females (52%) and 21 males (48%) with the mean age of 62 years (range, 28-80 years). All patients underwent either digital subtraction angiography or 3-dimensional computed tomography angiography. The exclusion criteria for this study were the patients with fusiform, traumatic, or mycotic aneurysm. There were preexisting known risk factors, such as hypertension in 73 patients, who required antihypertensive medication; other risk factors included diabetes mellitus (9 patients), coronary heart disease (9 patients), previous cerebral stroke (18 patients), and end-stage renal disease (3 patients) in the ruptured group. In the unruptured group, 38 patients had hypertension, 4 had diabetes mellitus, 5 had coronary heart disease, 10 had a previous cerebral stroke, and 2 had end-stage renal disease.	Population (P)
Four intracranial aneurysms cases were selected for this study. Using CT angiography images, the rapid prototyping process was completed using a polyjet technology machine. The size and morphology of the prototypes were compared to brain digital subtraction arteriography of the same patients.	Methods (M)
After patients underwent dural puncture in the sitting position at L3-L4 or L4-L5, 0.5% hyperbaric bupivacaine was injected over two minutes: group S7.5 received 1.5 mL, Group S5 received 1.0 mL, and group S4 received 0.8 mL. Interventions after sitting for 10 minutes, patients were positioned for surgery.	Intervention (I)
The ruptured group consisted of 9 very small (<2 mm), 38 small (2-4 mm), 32 medium (4-10 mm), and 7 large (>10 mm) aneurysms; the unruptured group consisted of 2 very small, 16 small, 25 medium, and one large aneurysms. There were 73 ruptured aneurysms with small necks and 13 with wide necks (neck size >4 mm), and 34 unruptured aneurysms with small necks and 10 with wide necks.	Results (R)
The method which we develop here could become surgical planning for intracranial aneurysm treatment in the clinical workflow.	Conclusion (C)
The prevailing view is that larger aneurysms have a greater risk of rupture. Predicting the risk of aneurysmal rupture, especially for aneurysms with a relatively small diameter, continues to be a topic of discourse. In fact, the majority of previous large-scale studies have used the maximum size of aneurysms as a predictor of aneurysm rupture.	Outcome (O)

### Quality Recognition Model

The proposed model, as shown in Figure 2, comprises multilayer feed-forwarded neural networks as a so-called MLP. The MLP is further optimized with an ensemble method using adaptive boosting (AdaBoost). The final AdaBoost-MLP, termed the prognosis quality recognition (PQR) model, was trained on a

dataset acquired automatically through PubMed searches based on the following two criteria: selecting the “Clinical Query prognosis” filter and choosing scope as “narrow.” To build and evaluate the model, we performed the steps involved in the preparation of a dataset for training the deep-learning models, followed by training and tuning the deep-learning models. Additionally, we compared the performance of the proposed

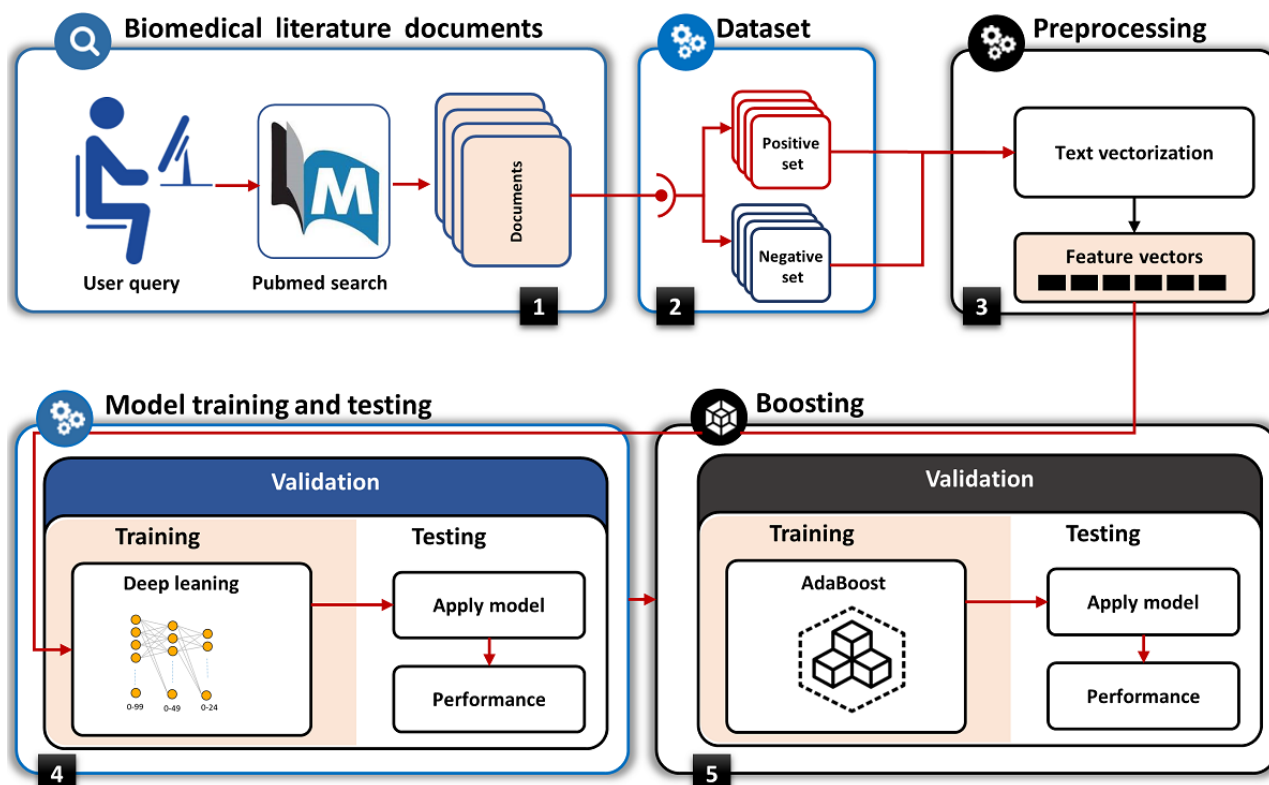

model with those of shallow machine-learning models in terms of precision and recall.

For training and testing the PQR model, we collected a dataset consisting of a total of 2686 Medline abstracts, 697 of which

were considered to be positive studies (ie, scientifically sound). To retrieve positive studies, we used the interface of Clinical Queries [33]. To retrieve negative studies (ie, not scientifically sound), we used the interface of PubMed and retrieved studies that were not included in the positive set.

**Figure 2.** Process steps of proposed prognosis quality recognition (PQR) model training and testing.

### Training and Tuning the Deep-Learning Model

The PQR model is trained using five textual features, including two data features (title and abstract) and three metadata features (article type, publishing journal, and authors). The data features were preprocessed through applying the steps described above. The model consists of 5 layers with 3 hidden layers of size 100, 50, and 25, respectively. The input layers take the BoW vectors generated from data features. The “Maxout” activation function was used with 10 epochs. The data were split into a 70:30 ratio for training and testing.

### Comparison with Shallow Machine-Learning Models

To identify the best performer on our dataset, we compared a set of machine-learning algorithms, including SVM, naïve Bayes, k-nearest neighbor, and decision tree. These algorithms were tested in other studies [35,39] for addressing similar problems.

### CCA Classification Model

The CCA classification model aims to develop a multiclass classifier that can accurately classify text from selected quality documents (given by the quality model) into one of the following 7 classes: Aim, Methods, Population, Intervention, Results, Outcome, and Conclusion. We then merged Methods and Population into a single category (P) and Outcome and Conclusion into a single category (O) because of their strong

correlation found in the text. Although our focus was to utilize PICO classes in the summarization task, we retained the other categories to enable additional non-PICO clinical applications such as summarization for medical education and deriving rules from clinical trials for developing the knowledge base of a clinical decision support system.

PICO is a well-known terminology in evidence-based medicine. Our proposed CCA classifier incorporates the Patient/Problem, Intervention, and Outcome PICO components in addition to two more classes, Aim and Results. PICO detection is a sequential sentence classification task rather than a single sentence problem; therefore, the sequence of sentences is jointly predicted. In this way, more complete context is captured from multiple sentences, which then improves the classification accuracy of predicting the current sentence. The steps followed to build and evaluate the model were: (a) preparation of a dataset for training the deep-learning model, (b) training and tuning the deep-learning model, and (c) comparison with traditional machine-learning models in terms of precision and recall.

### Model Building

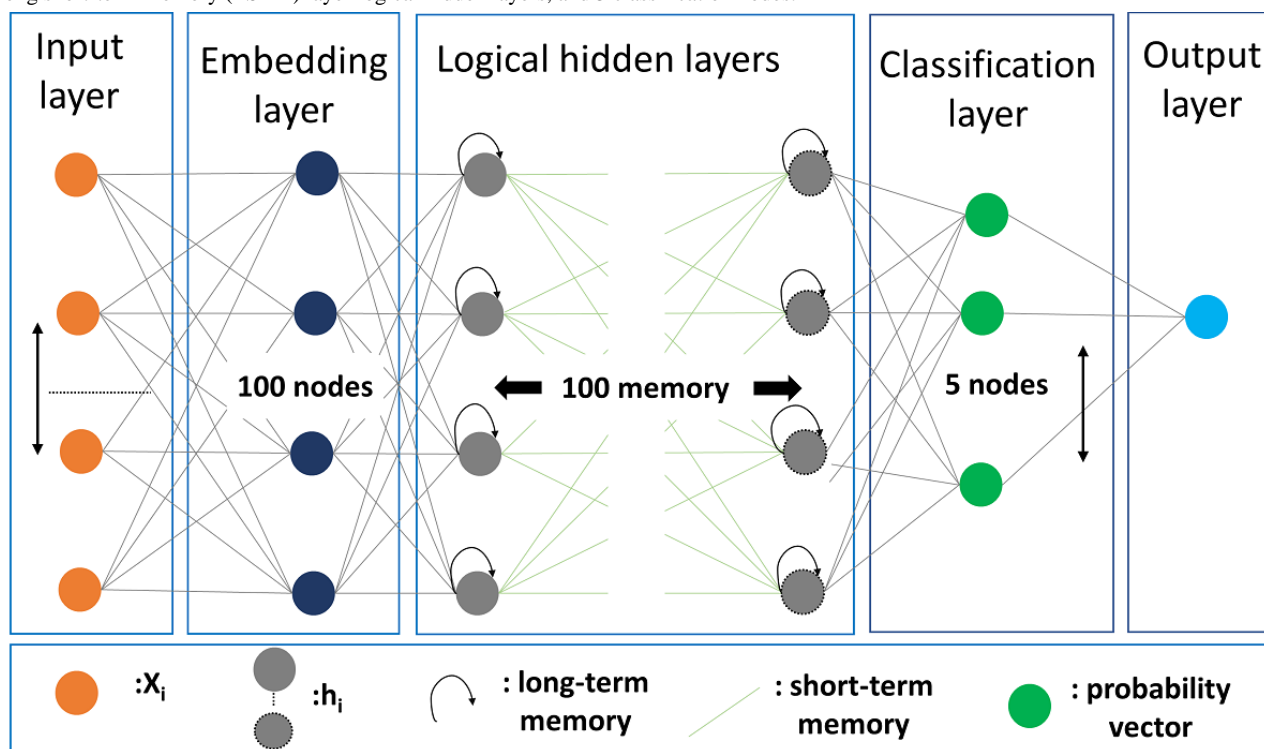

The neural network model is heavily used in text processing due to the ability to process arbitrary-length sequences. RNNs are immensely popular in multiclass text classification. To build and evaluate the classification model, we employed the Bi-LSTM model as a type of RNN. This model preserves the

long-term dependency of the text and is one of the most popular models in text classification.

As shown in Figure 3, the input layer consists of 250 dimensions showing the numeric features created using the Keras tokenizer, embedding layer, LSTM logical hidden layers, classification layer, and output layer. In brief, the trained CCA model has the following features: (1) an initial training dataset comprising 173,401 records, 90% (n=156,060) of which were used for training and 10% (n=17,341) of which were used for testing; (2) the first hidden layer is the embedding layer that uses

100-dimension vectors to represent each paragraph; (3) the next layer is the LSTM layer with 100 memory units, and the recurrent dropout rate was set to 0.2; (4) the next layer is the dense layer with 5 nodes, and we used the SoftMax activation function for multiclassification, and categorical\_crossentropy as a loss function; (5) the training dataset is further divided into two parts, 10% of which was used to validate the category and minimize the loss function, resulting in 140,454 records used for training and 15,606 used for validation; (6) the model was then trained across 5 epochs with a minibatch size of 64.

**Figure 3.** Clinical context-aware (CCA) classifier trained on 250-dimension feature vectors, 100 nodes at the embedding layer, 100 memory units of the long short-term memory (LSTM) layer logical hidden layers, and 5 classification nodes.

## ATS

For the ATS task, we developed a sentence-scoring mechanism based on a multifeatured matrix, consisting of 4 features (relevance, study type, venue credibility, and freshness), where each feature was learned with a specific method as explained in the following sections.

First, an individual score value is assigned to each feature, which is then aggregated in the final column as a final score using the formula in Equation 1:

$$\text{Aggregate Score} = \beta R_{score} + \gamma (ST_{rank} + VC_{score} + f_{score}) \quad (1)$$

where  $R_{score}$  is the relevance score,  $ST_{rank}$  is the study type rank,  $VC_{score}$  is the publishing venue credibility score,  $f_{score}$  is the freshness score, and  $\beta=70$  and  $\gamma=10$  are the scaling constants to keep the aggregate score in the range of 0 to 100.

## Relevance Score

For the relevance score, we developed a semantic similarity algorithm, Jaccard similarity with semantic enrichments (JS<sup>2</sup>E) as a 6-step algorithm that uses the BioPortal application

programming interface to access biomedical ontologies (SNOMED CT, MedDRA, NBO, NIFSTD) for obtaining semantic enrichment and the Jaccard similarity metric to find similarities between two texts.

In step 1, an individual sequence of text is obtained from the query, which is preprocessed to remove the special characters, separate characters, and different formatting tags. In step 2, the preprocessed text is annotated using BioPortal. In step 3, each token is enriched using “definition,” “synonyms,” and “prefLabel” relations from selected ontologies. In step 4, the annotations of text are retrieved using the “definition” relationship, along with the preprocessing (step 1) and annotation (step 2) procedures. In step 5, the annotated tokens received in step 2 are combined with the “synonyms” and “preflabel” obtained in step 3 and the annotated tokens received in step 4, and the data structure of metatokens is constructed. Finally, in step 6, the Jaccard similarity between the metatokens of the text sequence and the query is calculated using Equation 2:

$$R_{score} = S_m \cap Q_m / S_m \cup Q_m \quad (2)$$

where  $S_m$  are the metaset tokens of the text sequence in a document and  $Q_m$  are the metaset tokens of the query.

Study Type

The study type plays a vital role in proving a study’s usefulness for a user concerning a clinical task. For instance, if a surgeon wants to look for advances in successful surgical treatments, randomized control trials or a meta-analysis of randomized controlled trials will be the priority. The priority will change if the user is interested in prognosis-related studies. Study types can be used to grade evidence concerning quality and other elements [34,51,52]. To find the priority of different study types in the category of prognosis, we conducted a questionnaire-based survey among domain experts who were asked to assign a score value for each study type. An example of a filled-in questionnaire by a physician is provided in Multimedia Appendix 1.

The final rank value is then learned from the average value of rank values assigned by the domain experts, as shown in Equation 3.

where  $V_i$  represents the rank values assigned to a study type by each domain expert,  $n$  is the total number of domain experts that participated in the questionnaire, and  $\alpha=0.1$  is a scaling constant to keep the final score value in the range of 0 to 1.

Table 2. Assigned weights for research study year of publication.

Year of publication	Rank
Previous 1-5 years	1
Previous 6-10 years	2
Previous 11-15 years	3
Other	4

The final score was calculated according to Equation 5:

$F_{score}=\alpha(R_i\rightarrow R_f)$  (5),

where  $R_i$  is the initial value assigned to each year obtained from Table 2,  $R_f$  is the mapped score obtained through mappings {1→10, 2→9, 3→8, and 4→7}, and  $\alpha=0.1$  is a scaling constant to keep the final score value in the range of 0 to 1.

Text Selection for Summary

The aggregate score calculated using Equation 1 provides the final rank values for a text sequence. Two types of summary structures can be generated: (1) a PICO-based summary, in which we select the top  $k$  text sequences in each part of PICO out of a total  $n$  number of sentences to be included in the final summary as  $|n/k|$  sentences from the Patient/Population component,  $|n/k|$  sentences from the Intervention component,

Venue Credibility

The credibility of a study publishing venue, including journals, proceedings, and books, is also an important parameter; however, it is more of a subjective matter. Therefore, it is necessary to consult with the stakeholders of the service. For this study, we sought to obtain a list of valuable publishing venues. We involved resident doctors to rank various venues concerning their credibility. An example of a filled questionnaire by a physician is provided in Multimedia Appendix 1. The final credibility score was determined from the average value of rank values assigned by the domain experts, as shown in Equation 4:

where  $S_i$  is the initial rank assigned by the domain experts,  $S_f$  is the mapped score obtained through mappings {1→10, 2→9, 3→8, 4→7, 5→6, and 6→5}, and  $\alpha=0.1$  is a scaling constant to keep the final score value in the range of 0 to 1. We applied the majority vote method before using the mapping function.

Freshness

Freshness represents the date of publication of a study, which is useful to consider to keep up with the advancement in a domain. We included this attribute in summarization with a higher rank assigned to more recent studies, following the less current studies, as described in Table 2.

and  $|n/k|$  from the Outcome component; and (2) a non-PICO-based summary, where we select the top  $k$  text sequences without considering their classification.

Summary Presentation

Our proposed model of automatic summarization can generate a summary for a single document or multiple documents simultaneously. For summaries of a single document, the selected set of representative PICO sequences is arranged in a template of Population/Problem, Intervention, and Outcome, as shown in Textbox 2. The templates are displayed according to the number of documents retained after a quality check. For instance, if we have a set of 5 studies retrieved against a user query, our algorithm will generate 5 individual summaries presented in the order of the most recent document summary followed by the others.

Textbox 2. Example summary of a biomedical document represented with the Patient/Problem (P), Intervention (I), and Outcome (O) sequence.

P: One hundred and fifty patients ...duration at a frequency of at least once per week
I: After patients underwent dural puncture ... patients were positioned for surgery
O: Number of follow-up appointments attended ... occurrence of secondary ocular hypertension

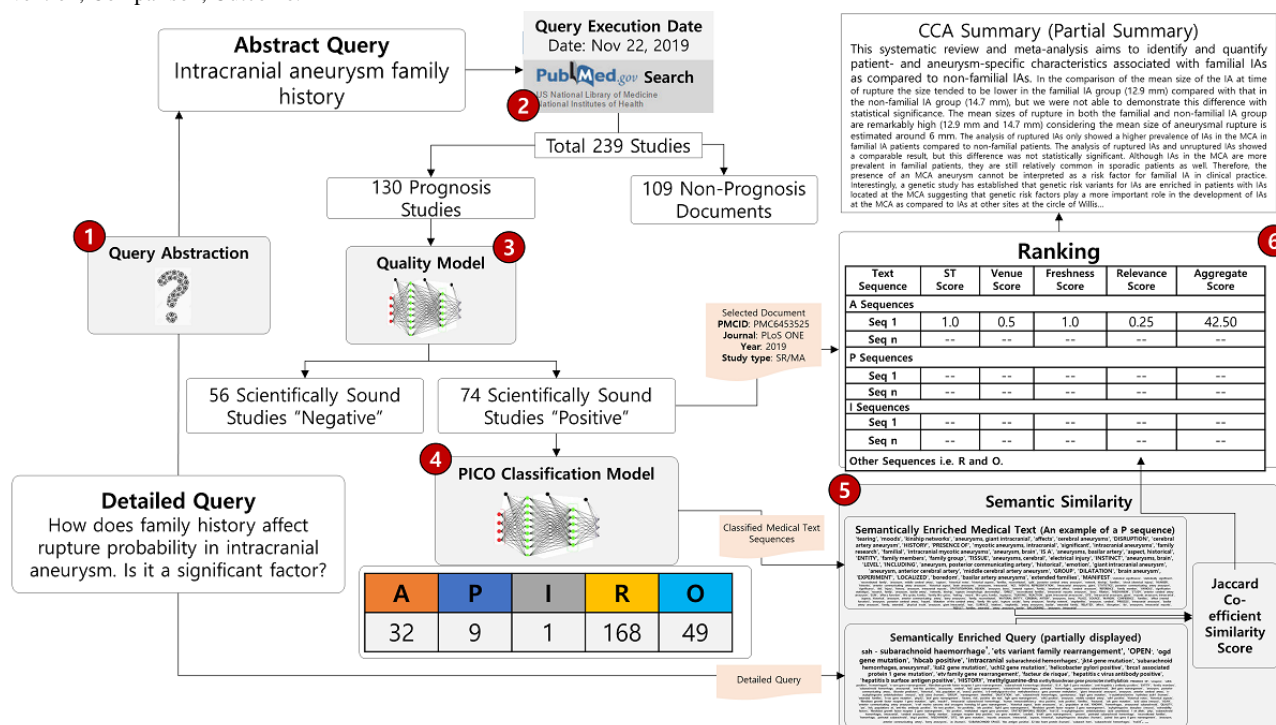

In the case of a multidocument summary, our algorithm first identifies PICO sequences in all documents, finds the score for each sequence, selects the highest-scoring sequence in each category, and concatenates all scored sequences to obtain a combined summary of each type. In this case, the sequences included in the summary may or may not belong to a single document; however, each sequence is linked to its corresponding documents for audit, transparency, and education.

### Example Case: Step-by-Step Scenario of Summary Generation

To clarify the steps of the proposed Biomed-Summarizer framework, we take the following example query: “How does family history affect rupture probability in intracranial aneurysms; is it a significant factor?” (Abstract Query-Intracranial aneurysm family history). As shown in Figure 4, the user query was first abstracted from a detailed user

query to increase the recall of retrieving studies. Second, the query was run on the PubMed search service, which returned a total of 239 studies, 130 of which were prognosis studies. Third, these studies were run through a quality model, “PQM,” which identified 74 studies as scientifically sound and the rest were filtered out. Fourth, the set of 74 studies was given to the PICO classification model in the form of text sequences, which were classified into five classes: Aim (32), Patients (9), Intervention (1), Results (168), and Outcome (49). Fifth, the PICO text sequences and the detailed query were passed through semantic similarity, in which the texts were first enriched semantically using medical ontologies, and the similarity score was calculated using the Jaccard coefficient. Sixth, the documents were ranked according to the accumulated score of four parameters: relevance score of the query and text, study type, venue’s credibility score, and freshness score. Finally, the required summary is created and presented to the user.

**Figure 4.** Step-by-step scenario of query execution, retrieval of documents, quality checking, clinical context-aware (CCA) classification, semantic similarity, ranking, and summary creation. A: Aim; P: Population/Patients/Problem; I: Intervention; R: Results; O: Outcome; PICO: Patient/Problem, Intervention, Comparison, Outcome.

## Results

### Dataset Preparation

To evaluate the performance of the proposed framework, we prepared two different datasets to test the proposed Biomed

Summarizer framework. One dataset was used for the development and testing of the PQR model (D1), whereas the other was used for the development and testing of the CCA model (D2). The preparation protocols of both datasets are outlined in Table 3. These datasets are available to the research community via a GitHub link [22].

**Table 3.** Dataset preparation protocols.

Preparation Protocol	PQR <sup>a</sup> dataset (D1)	CCA <sup>b</sup> dataset (D2)
Description	This dataset was created for the quality assessment of biomedical studies related to the prognosis of brain aneurysm.	This dataset was curated for the use of PICO <sup>c</sup> sequence classification. The final dataset was specific to the prognosis of brain aneurysm.
Purpose	To select only published documents that are scientifically rigorous for final summarization.	To identify a sentence or a group of sentences for discovering the clinical context in terms of population, intervention, and outcomes.
Methods	The manual preparation of the dataset is a cumbersome job, and thus AI <sup>d</sup> models were used. For development of an AI model, a massive set of annotated documents is needed. Annotation is a tedious job; therefore, PubMed Clinical Queries (narrow) as a surrogate were used to obtain scientifically rigorous studies.	N/A <sup>e</sup>
Data sources	PubMed Database (for positive studies, the “Narrow[filter]” parameter was enabled).	First, we collected a publicly available dataset, BioNLP 2018 [21], which was classified based on the PICO sequence in addition to “Method” and “Results” elements. To increase the dataset size, we added more sentences related to brain aneurysm created from Medline abstracts retrieved using the NCBI <sup>f</sup> PubMed service Biopython Entrez library [53].
Query	The term “(Prognosis/Narrow[filter]) AND (intracranial aneurysm)” was used as a query string.	The term “Intracranial aneurysm” (along with its synonyms “cerebral aneurysm” and “brain aneurysm”) were used as a query string.
Size	2686 documents, including 697 positive (ie, scientifically rigorous) records	A total of 173,000 PICO sequences (131,000 BioNLP+42,000 Brain Aneurysm) were included in the dataset.
Inclusion/exclusion	Only studies that were relevant and passed the criteria to be “Prognosis/Narrow[filter]” were included in the positive set. The other relevant studies not in the positive set were included in the negative set. All other studies were excluded from the final dataset.	Only structured abstracts identified with at least one of the PICO elements were considered to extract the text sequence.
Study types	RCTs <sup>g</sup> , systematic reviews, and meta-analysis of RCTs were given more importance.	RCTs, systematic reviews, and meta-analysis of RCTs were given more importance.

<sup>a</sup>PQR: prognosis quality recognition.

<sup>b</sup>CCA: clinical context–aware.

<sup>c</sup>PICO: Patient/Problem, Intervention, Comparison, Outcome.

<sup>d</sup>AI: artificial intelligence.

<sup>e</sup>N/A: not applicable.

<sup>f</sup>NCBI: National Center of Biotechnology Information.

<sup>g</sup>RCT: randomized controlled trial.

## Experimental Setup

To evaluate the CCA and PQR classification models, we performed experiments on a 64-bit Windows operating system with an Intel Core i5 CPU, 3.20-Hz processor with 8-GB memory using dataset D1 and D2, respectively. The experiment was performed using RapidMiner studio [54] to train and test the PQR models, whereas the python deep learning library Keras was used for the CCA classification model [55].

## PQR Model

The aim of this experiment was to quantify the comparative analysis of the proposed deep-learning model with other

machine-learning models. Using the default settings of RapidMiner, the SVM model followed the kernel type “dot,” kernel cache of 200, and complexity constant  $c$  of 0.0; the DT criterion was “gain\_ratio” with a maximum depth of 10; the  $k$  of the  $k$ -nearest neighbor was 5 with the mixed measure of “MixedEuclideanDistance.” The comparison of the performance of these models with that of a deep-learning model was assessed in terms of the F1-score, accuracy, and area under the curve (AUC) value, as shown in Table 4.

We tuned the hyperparameters of the MLP by varying the hidden layers, size of layers, activation function, and epochs, and obtained varied results as shown in Table 5.

**Table 4.** Comparative results of the deep-learning model with shallow machine-learning models.

Algorithm	F1-score	Accuracy	AUC <sup>a</sup>
Naïve Bayes	90.83	87.47	0.987
Decision tree	85.10	74.07	0.50
k-nearest neighbor	46.53	48.39	0.829
General linear model	89.34	82.38	0.904
Support vector machine	86.96	77.79	0.983
Deep learning (MLP <sup>b</sup> )	93.17	90.20	0.967

<sup>a</sup>AUC: area under the receiver operating characteristic curve.

<sup>b</sup>MLP: multilayer perceptron.

**Table 5.** Results of multilayer perceptron with varied hyperparameter settings.

Hidden layers (n)	Hidden layer size	BoW <sup>a</sup>	Activation	Epochs (n)	Recall	Precision	F1-score	Accuracy	AUC <sup>b</sup>
2	50, 50	No	Rectifier	10	90.28	96.25	93.17	90.2	0.967
3	100, 50, 25	No	Rectifier	10	93.47	96.71	95.06	92.8	0.969
3	100, 50, 25	No	Maxout	10	96.82	96.01	96.41	94.67	0.976
3	100, 50, 25	No	Maxout with Dropout	10	98.16	93.61	95.83	93.67	0.963
3	100, 50, 25	No	Tanh	10	90.62	97.65	94.00	91.44	0.978
3	100, 50, 25	Yes	Rectifier	10	93.47	98.24	95.80	93.92	0.999
3	100, 50, 25	Yes	Maxout	10	94.47	97.41	95.92	94.04	0.977
3	50, 50, 50	No	Rectifier	10	87.77	96.86	92.09	88.83	0.958
3	200, 100, 50	No	Rectifier	10	92.96	96.86	94.87	92.56	0.975
4	200, 100, 50, 25	No	Rectifier	10	93.63	96.05	94.82	92.43	0.973

<sup>a</sup>BoW: bag of words.

<sup>b</sup>AUC: area under the receiver operating characteristic curve.

As highlighted in [Table 5](#), the highest accuracy and F1-score were obtained with the setting of 3 hidden layers consisting of 100, 50, and 25 neurons, respectively. The activation function was set to Maxout, and the model was trained on 10 epochs. Finally, we boosted the performance of the selected model with

an ensemble approach using AdaBoost. The results of the optimized version of the proposed model are shown in [Table 6](#), demonstrating an F1-score of about 97% and an accuracy of 95.41% with an AUC of 0.999.

**Table 6.** Ensembling of deep-learning models.

Boosting Model	Recall	Precision	F1-score	Accuracy	AUC <sup>a</sup>
Ensemble voting (MLP <sup>b</sup> , DT <sup>c</sup> , NB <sup>d</sup> )	95.81	97.28	96.54	94.91	0.955
Proposed model (AdaBoost <sup>e</sup> -MLP)	97.99	95.9	96.93	95.41	0.999

<sup>a</sup>AUC: area under the receiver operating characteristic curve.

<sup>b</sup>MLP: multilayer perceptron.

<sup>c</sup>DT: decision tree.

<sup>d</sup>NB: naïve Bayes.

<sup>e</sup>AdaBoost: adaptive boosting.

## CCA Model

We experimented with the combination of dataset D1 described above. The classification model results are shown in [Table 7](#).

The individual decision class performance of the proposed model is reported in [Table 8](#). We found high F1-score values ( $\geq 80$ ) for classes with top support (Aim, Outcome, Results, Population) as compared to the scores of the minor classes, which indicated that the dataset size needed to be increased for each of these minor classes to obtain a higher F1-score.

**Table 7.** Comparative results of deep learning with traditional machine-learning models.

Model	Recall	Precision	F1-score	Accuracy
Logistic Regression	0.42	0.34	0.36	0.42
AdaBoost <sup>a</sup>	0.49	0.48	0.46	0.49
Gradient Boost	0.50	0.59	0.45	0.50
ANN <sup>b</sup>	0.29	0.08	0.13	0.29
kNN <sup>c</sup>	0.35	0.36	0.37	0.35
Proposed Bi-LSTM <sup>d</sup> model	0.93	0.94	0.94	0.93

<sup>a</sup>AdaBoost: adaptive boosting.

<sup>b</sup>ANN: artificial neural network.

<sup>c</sup>KNN: k-nearest neighbor.

<sup>d</sup>Bi-LSTM: bidirectional long-short term memory.

**Table 8.** Precision, recall, F1-score, and support for individual classes of the proposed deep-learning model.

Class	Precision	Recall	F1-score	Support
Aim	0.94	0.95	0.95	3133
Intervention	0.84	0.94	0.89	1238
Outcome	0.96	0.94	0.95	5036
Result	0.96	0.94	0.95	4852
Population	0.94	0.95	0.94	3082

### Proposed Semantic Similarity Algorithm (JS<sup>2</sup>E)

We measured the correlation strength based on the standard guideline of the Pearson correlation coefficient in the biomedical domain [20]. We evaluated different similarity approaches, including string similarity (Jaccard), term frequency (count vectorizer), and pretrained word embedding using GloVe, Google word2vec, and fastText. The results showed that semantic enrichment is crucial to find the similarity between the texts because it significantly increases the size of the token

set of texts by including synonyms, definitions, and preLabel from ontologies. We tested this method on a well-known biomedical dataset, BIOSSES [56], which contained 100 pairs of sentences manually annotated by the experts. As shown in Table 9, the Pearson correlation coefficient after semantic enrichment increased by 8.9% relative to that of the best-performing Jaccard similarity. Concerning the pretrained word-embedding model GloVe, word2vec (Google), and fastText (Facebook), the correlation improved by 41.8%, 60.5%, and 17.3%, respectively.

**Table 9.** Comparison of similarity approaches.

Methods	Pearson correlation coefficient (0.0-1.0)
Jaccard similarity	0.56
Cosine similarity (Count Vectorizer)	0.54
GloVe Embedding	0.43
Word2Vec (Google)	0.38
fastText (Facebook)	0.52
Jaccard Similarity after semantic enrichment (JS <sup>2</sup> E)	0.61

### Expert Evaluation of Candidate and Reference Summaries

The PICO-based summary obtained after classification and performing JS<sup>2</sup>E was then compared with the classical summary obtained using JS<sup>2</sup>E without classification. We considered the JS<sup>2</sup>E summary without classification as a baseline summary. Evaluation and comparison of two summaries were performed

by three independent evaluators and scored between 0 and 5 on the following three metrics: summary relevance to the inbound query (M1); Aim, Population, Intervention, Results, and Outcome classification representation in the summary (M2); and model summary better than the baseline summary (M3).

Table 10 shows the Pearson correlation coefficients of the scores of each evaluator (A, B, and C) concerning the average scores of the remaining two evaluators for each evaluation metric (M1,

M2, and M3). There was a strong association among the scores of each evaluator concerning each metric, suggesting that automated summarization performed best on all three parameters. The lowest correlation coefficient was 0.728, which is still considered to be high on the correlation scale.

The distribution of the scores by each of the evaluators concerning each metric is described in Table 11. The distribution suggests that there are sufficient instances for each of the scores in the evaluation dataset.

**Table 10.** Correlation matrix (Pearson correlation coefficients) of similarity approaches among evaluators for summaries according to the three metrics.

Metric	Evaluator A	Evaluator B	Evaluator C
M1 <sup>a</sup>	0.728	0.767	0.837
M2 <sup>b</sup>	0.826	0.924	0.841
M3 <sup>c</sup>	0.772	0.843	0.804

<sup>a</sup>M1: summary relevance to the inbound query.

<sup>b</sup>M2: aim, population, intervention, results, and outcome classification representation in the summary.

<sup>c</sup>M3: model summary better than the baseline summary.

**Table 11.** Frequency distribution of scores with respect to each metric by all evaluators.

Metric	Score	Frequency
M1 <sup>a</sup>	2	4
M1	3	10
M1	4	12
M1	5	4
M2 <sup>b</sup>	2	3
M2	3	10
M2	4	10
M2	5	7
M3 <sup>c</sup>	3	12
M3	4	16
M3	5	2

<sup>a</sup>M1: summary relevance to the inbound query.

<sup>b</sup>M2: aim, population, intervention, results, and outcome classification representation in the summary.

<sup>c</sup>M3: model summary better than the baseline summary.

## Discussion

### Principal Findings

The proposed Biomed-Summarizer framework generates extractive summaries for single and multiple documents with acceptable accuracy. The evaluation results signify that the proposed framework performs significantly better than existing approaches, which was also evident from the correlation matrix generated by comparing the candidate and reference summaries obtained for each defined parameter. The PQR model trained on a large dataset of biomedical literature of intracranial aneurysm showed an accuracy of 95.41% in terms of recognizing quality articles. The CCA multiclass classification model outperformed the traditional machine-learning algorithms and achieved 93% accuracy for classifying five categories: Aim, Population, Intervention, Results, and Outcome. The semantic similarity algorithm demonstrated a significant Pearson correlation coefficient of 0.61 (on a 0-1 scale) from a well-known BIOSSES dataset after semantic enrichment,

representing an improvement of 8.9% over the baseline Jaccard similarity score.

An accurate clinical summarization is expected to revolutionize the field of domain-specific knowledge graphs [57] and clinical decision support systems. For example, an individual PICO-extracted element from a biomedical text could be represented as a relationship in a knowledge graph, which could then be used for various clinical applications or could be directly supplied to clinical decision support systems for physicians to link to internal data-driven instances. The importance of linking external evidence (extracted from the biomedical literature) to internal evidence is important when the internal data are unable to capture all critical risk factors. One of our motivations was to extract the evidence from a PICO-based summarization of documents relevant to intracranial aneurysm (also known as cerebral or brain aneurysm). Since neither decision support systems nor knowledge graphs providing external evidence for complex neurological diseases such as intracranial aneurysm exist, there is a need to achieve automated summarization for

such conditions to enhance translational research and clinical decision making synergistically. The proposed automated summarization framework will be pivotal to develop a hybrid machine-learning and knowledge-based clinical decision support system, termed NeuroAssist [58], which aims to predict aneurysmal rupture (ie, subarachnoid hemorrhage). The other possible application areas of the proposed framework include automation of writing systematic reviews over a set of published clinical trials, extraction of evidence for evidence-based medicine, precision medicine, and development of clinical assistants/chatbots.

The current work in the biomedical domain is mainly focused on issues of concept- or sentence-based relevance without relating a concept or sentence to a clinical context. Although the sentence-based classification approach is well-regarded for ATS, relying on only the relevance of a sentence without capturing its clinical context and semantics may lead to a clinically undesirable summary. Some of the summarization work focuses on creating summaries from abstracts only, which may result in low recall due to missing an important sequence of text that exists only in the body of the document. In addition, in previous works, the dataset used for training and testing [29] contained only 1000 abstracts, which is not sufficient for a deep-learning model to be generalized. Recently, a new dataset was published in the BioNLP 2018 proceedings [21], but it does not consider the quality evaluation of the source documents used for extracting the text for summarization. Therefore, we curated a dataset comprising over tens of thousands of abstracts from Medline and combined it with the BioNLP dataset.

PICO-based ATS remains an unexplored area; however, work has been done on individual aspects such as PICO elements identification in the text [21,29,30], quality recognition of therapy-related biomedical studies [40,41], and sentence-based summarization without PICO and quality evaluation [3,32]. To the best of our knowledge, the proposed Biomed-Summarizer framework for biomedical ATS is the first of its kind to use a

quality recognition model, PICO-based classification using LSTM-based recurrent deep neural network model for key sentence identification trained on contextual vectors, and the JS<sup>2</sup>E algorithm for semantic matching of the user query and PICO text sequences.

The proposed approach offers a few potential benefits compared to existing methods. First, unlike traditional machine-learning approaches that depend on features that are well-structured and less noisy, deep learning deals well with an unstructured noisy text. Therefore, our deep-learning model can be reused for domains using data of the same nature. Additionally, the accuracy of the proposed deep-learning model is expected to increase further if the volume of the dataset is extended. Second, our approach considers the quality evaluation of the documents being used in summarization in addition to publishing venue credibility, which offers two-fold benefits: it enhances the confidence of physicians on the system-generated summary and has applicability in real clinical settings, and, because it filters out the documents with the lowest quality from the retrieval set, the computational time of summary creation is reduced with respect to checking the similarity of the text with the query. Third, our proposed model is based on the PICO structure, which provides additional semantics as compared to a non-PICO approach in terms of understanding the problem, interventions, and outcomes.

Traditional approaches are not cognizant of capturing the clinical context; therefore, the resultant summary includes sentences based on a high similarity score and sentence position, and is therefore less clinically effective. **Textbox 3** shows an example of a summary generated by the proposed method considering the clinical context; sequence 1 represents the aim of the study, sequence 2 represents the patient population included in the study, and sequence 3 represents the outcome of the study. In contrast, the conventional method selects the top three sequences based on high relevancy but misses the clinical context.

**Textbox 3.** Effectiveness of Biomed-Summarizer in terms of clinical significance.

#### Conventional Method

*Sequence 1: The prevailing view is that larger aneurysms have a greater risk of rupture. Predicting the risk of aneurysmal rupture, especially for aneurysms with a relatively small diameter...*

*Sequence 2: Alongside with the posterior communicating cerebral artery and middle cerebral artery of bifurcation, the anterior communicating cerebral artery (A com) is one ....*

*Sequence 3: The A com artery is known to be one of the common sites of aneurysm rupture. Given the diversity of geometry, the difference of the dominance of A1 arteries ....*

#### Proposed Method

*Sequence 1: The aim of the present study was to evaluate whether the A com aneurysms behave differently from the aneurysms located elsewhere with respect to size being a rupture risk ....*

*Sequence 2: Between January 2010 and December 2015, a total of 130 consecutive patients at our institution with the A com aneurysms-86 ruptured and 44 unruptured-were included in this study ....*

*Sequence 3: The prevailing view is that larger aneurysms have a greater risk of rupture. Predicting the risk of aneurysmal rupture, especially for aneurysms with a relatively small diameter....*

## Limitations and Future Directions

The training datasets could be reviewed for the noise generated during the creation of automated annotation to obtain even more accurate results in PQR and CCA models. The current summary is a textual summary that contains sentences in the original form as they are presented in the source documents without any further processing to extract statistical information for an easy catch up of the contents.

## Conclusion

Compared to traditional approaches, state-of-the-art deep neural network models can achieve high accuracy for an ATS task when trained on nonsparse semantically enriched features. Additionally, the automated pipeline for seeking research evidence can enable the seamless curation of voluminous biomedical literature to use in clinical decisions. By designing the proposed Biomed-Summarizer framework, we employed a

set of methods for information extraction from credible published biomedical resources to construct a simplified summary that is precise, relevant, and contextually suited to clinical needs. We designed the framework to provide openness for other researchers to use, extend, or even make use of a subpart of it and extend for designing their own systems and services. Alongside the framework, we created a specialized dataset containing PICO elements and a few other text sequences such as Aim, Method, and Result for researchers to use in their experiments in the domain of brain aneurysm. The PICO dataset was extended using a custom data-mining process by incorporating the rigorous text processing techniques on PubMed research documents. This method can be further used to create a PICO dataset in other related biomedical domains by obtaining related research papers from PubMed. The evaluation results signify that the proposed Biomed-Summarizer framework performs significantly better than existing approaches.

## Abstract

**Background:** Online physician rating websites commonly ask consumers to rate providers across multiple physician-based (eg, spending sufficient time, listening) and office-based (eg, appointment scheduling, friendliness) subdimensions of care in addition to overall satisfaction. However, it is unclear if consumers can differentiate between the various rated subdimensions of physicians. It is also unclear how each subdimension is related to overall satisfaction.

**Objective:** The objectives of our study were to determine the correlation of physician-based and office-based subdimensions of care and the association of each with overall satisfaction.

**Methods:** We sampled 212,933 providers from the Healthgrades website and calculated average provider metrics for overall satisfaction (likelihood to recommend doctor), physician-based subdimensions (trust in physician, ability to explain, ability to listen and answer questions, and spending adequate time), and office-based subdimensions (ease of scheduling, office environment, staff friendliness, and wait time). We used Spearman rank correlation to assess correlation between subdimension ratings. Factor analysis was used to identify potential latent factors predicting overall satisfaction. Univariate and multivariable linear regression were performed to assess the effect of physician and office-based factors on overall satisfaction.

**Results:** Physician-based metrics were highly correlated with each other ( $r=.95$  to  $.98$ ,  $P<.001$ ), as were office-based metrics ( $r=.84$  to  $.88$ ,  $P<.001$ ). Correlations between physician-based and office-based ratings were less robust ( $r=.79$  to  $.81$ ,  $P<.001$ ). Factor analysis identified two factors, clearly distinguishing between physician-based metrics (factor loading = 0.84 to 0.88) and office-based metrics (factor loading = 0.76 to 0.84). In multivariable linear regression analysis, the composite factor representing physician-based metrics (0.65, 95% CI 0.65 to 0.65) was more strongly associated with overall satisfaction than the factor representing office-based metrics (0.42, 95% CI 0.42 to 0.42). These factors eclipsed other demographic variables in predicting overall satisfaction.

**Conclusions:** Consumers do not differentiate between commonly assessed subdimensions of physician-based care or subdimensions of office-based care, but composite factors representing these broader categories are associated with overall satisfaction. These findings argue for a simpler ratings system based on two metrics: one addressing physician-based aspects of care and another addressing office-based aspects of care.

**KEYWORDS**

online ratings; Healthgrades; physician ratings

**Introduction**

Online physician ratings websites have become an increasingly influential source of information for health care consumers [1-3]. While rating websites provide transparency and a platform for patient feedback, there is little data supporting their validity and utility in identifying high-quality care [4-6]. Nevertheless, studies suggest that consumers believe these sites are important in choosing a physician [7]. A survey of 1000 surgical patients at Mayo Clinic found that 75% would choose a physician and 88% would avoid a physician based on ratings alone [8]. As testament to the growing acceptance and trust in consumer ratings, payers and institutions now list commercial consumer ratings as part of online provider listings, and a percentage of Medicare payments are redistributed to hospitals with higher quality metrics and better patient evaluations [9-11]. Of the top 20 hospitals in a recent US News & World Report ranking, 10 of them currently display ratings for their providers [12].

Most ratings websites prominently feature overall satisfaction scores on a 5-star Likert scale [13,14]. To improve clarity, some websites additionally ask consumers to rate physicians on specific subdimensions of care related to the physician's bedside manner (eg, level of trust in provider's decisions, how well the provider explains medical conditions, how well the provider listens and answers questions, spending sufficient time with patients) and office (eg, ease of scheduling, staff friendliness, total wait time, office environment) [15-17]. Although there is good face validity in asking consumers to rate physicians on these discrete, service-related aspects of care, there is a lack of data showing that patients actually distinguish between these subdimensions. Furthermore, the individual contribution of each subdimension to overall satisfaction is unknown.

In this study, we analyzed a large, heterogeneous sample of quantitative online reviews to determine if consumers are able to parse different components of the patient experience and identify physician and office characteristics that predict higher overall satisfaction scores. We hypothesized that all physician-related scores would be highly correlated, since patients are asked to rate subdimensions that are all related to bedside manner, while office-based scores may vary, as they measure distinct aspects of care that are unrelated.

**Methods****Data Source**

We sampled online consumer reviews for providers in the United States from the Healthgrades website using a method that has previously been described [18]. The dataset consisted of 2.7 million reviews for 830,308 providers up to March 31, 2017. These data were linked with demographic information from the US Centers for Medicare & Medicaid Services Physician Compare website using National Provider Identifier numbers: this information included medical specialty, region, gender, and year of graduation from medical school. In order to sample

physicians with an adequate number of reviews, we excluded physicians with 4 or fewer reviews ( $n=611,013$ ). We also excluded physicians who were missing information on their primary specialty ( $n=1813$ ) or who were identified as nursing or nonclinical specialty providers ( $n=4549$ ). Our final analytic sample comprised 212,933 physicians. The study was approved by the Cedars-Sinai IRB.

**Physician Rating Selection**

Average provider metrics across all reviews on a 5-star Likert scale were collected for overall satisfaction and subdimensions of perceived physician quality including level of trust in provider's decisions, how well the provider explains medical conditions, how well the provider listens and answers questions, and spending the appropriate amount of time with patients (see [Multimedia Appendix 1](#) for a screenshot of the homepage and a sample review). Office-based metrics were also collected across subdimensions of ease of scheduling urgent appointments, office environment, staff friendliness and courteousness, and total wait time.

**Statistical Analysis**

Physician demographics were described using median and interquartile range for continuous variables and counts with percentages for categorical variables.

Spearman rank correlation coefficient was used to assess the correlation between overall satisfaction, physician-based ratings subdimensions, and office-based ratings subdimensions. Additionally, a scatter plot matrix was used to visually depict the strength of association between pairings of overall satisfaction, physician-based, and office-based metrics.

To identify potential latent factors among our physician-based and office-based metrics, exploratory and confirmatory factor analysis was conducted [19]. Sampling adequacy was confirmed by the Kaiser-Meyer-Olkin statistic (0.93) to examine the appropriateness of the sample size for conducting exploratory factor analysis [20]. Sampling adequacy values between .80 to .90 are considered excellent, where values between .50 and .60 are considered marginal, and below .50 considered unacceptable [21]. The Bartlett test of sphericity was also conducted to test the null hypothesis of an identity matrix and the suitability for factor extraction ( $P<.001$ ) [22].

To determine the number of potential latent factors in our sample, we conducted the Horn parallel analysis [23]. Parallel analysis involves the generation of a random dataset with the same number of observations and variables. The eigenvalues and correlation matrix are computed from this dataset and compared with results of the eigenvalues from factor extraction. The point at which the eigenvalues from the random data exceed the values from factor extraction indicates that any further factors encompass primarily random noise. We identified the point at which the decrease in eigenvalues became negligible on the scree plot ([Figure 1](#)), which revealed a 2-factor solution. Factor extraction was conducted based on the orthogonal varimax rotation and extracted using the maximum likelihood.

Exploratory factor analysis was performed using a 1-, 2-, and 3-factor solution with the resulting cumulative variance explained of .840, .929, and .932, respectively.

Confirmatory factor analysis was further conducted to test 1-, 2-, and 3-factor models of overall patient satisfaction. The hypothesized latent factor structure is overall physician satisfaction measured by physician ratings subdomains. The confirmatory factor analysis model was fit using lavaan version 0.5-23 (Rosseel, 2012) and showed acceptable goodness of fit (Tucker-Lewis index 0.989, comparative fit index .993, root mean square error of approximation 0.087 [90% CI 0.086 to 0.088], goodness of fit index 0.975, adjusted goodness of fit index 0.945, and standardized root mean square residual 0.01) with all subdomains loading significantly on their hypothesized latent factors ( $P < .001$ ). Furthermore, discriminatory validity of the measures has been assessed using composite reliability and the average variance extracted for the 2-factor solution. Composite reliability among the physician satisfaction measures (0.99) and office staff satisfaction measures (0.95) both showed

high internal consistency [24]. The average variance extracted also showed a high amount of variance captured by the two factors solution for both physician satisfaction (0.97) and office staff satisfaction (0.87) [25]. In contrast, the fit of the 1-factor model provided a lower chi-square (262,257 vs 20,950), lower Akaike information criterion (219,065 vs 460,370), lower root mean square error of approximation (0.087 vs 0.297), and higher comparative fit index (0.993 vs 0.912) and goodness of fit index (0.975 vs 0.730) in comparison with the 2-factor model.

To assess the relative impact of physician-based and office-based metrics on overall satisfaction, univariate linear regression was performed [26]. Additionally, a multivariable linear regression model was performed regressing the saved factor scores extracted from exploratory factor analysis on overall satisfaction adjusting for all physician demographics.

All statistical analyses were performed using R version 3.5.1 (R Foundation for Statistical Computing) with 2-sided test and significance level of .05 [27].

**Figure 1.** Scree plot.

## Results

Physician characteristics are summarized in Table 1. The majority of our sample were medical specialists (128,678/212,933, 60.43%) from the southern United States (80,751/212,701, 37.96%) who graduated from medical school after 1985 (146,246/209,095, 69.94%). Median scores for overall satisfaction, physician-based metrics, and office-based metrics were universally high (range 4.1 to 4.3) and interquartile ranges for scores were narrow. The majority of wait times were within 10 to 15 minutes (113,51/212,921, 53.31%).

Physician-based metrics were highly correlated with each other ( $r = .95$  to  $.98$ ,  $P < .001$ ), as were office-based metrics ( $r = .84$  to  $.88$ ,  $P < .001$ ; Figure 2). Correlations between physician-based and office-based ratings were less robust ( $r = .79$  to  $.81$ ,  $P < .001$ ). Overall patient satisfaction correlated more strongly with physician-based metrics ( $r = .95$  to  $.97$ ,  $P < .001$ ) than office-based metrics ( $r = .82$  to  $.84$ ,  $P < .001$ ). Distributions of subdimension scores for providers with overall satisfaction scores of 5.0, 4.0, 3.0, and 2.0 were narrow, with interquartile range of subdimensions spanning a maximum of 0.4 points for physician-based subdimensions and 0.8 points for office-based subdimensions (Table 2).

**Figure 2.** Correlation matrix of physician-based and office-based subdimension ratings.**Table 2.** Distribution of subdimension scores for providers with overall satisfaction scores of 5.0, 4.0, 3.0, and 2.0.

Subdimension	5.0	4.0	3.0	2.0
<b>Physician-based, median (IQR)</b>				
Trust	5.0 (5.0-5.0)	4.1 (4.0-4.2)	3.2 (3.0-3.3)	2.3 (2.1-2.4)
Explains	5.0 (5.0-5.0)	4.1 (4.0-4.3)	3.2 (3.0-3.3)	2.2 (2.1-2.4)
Listens	5.0 (5.0-5.0)	4.1 (4.0-4.2)	3.2 (3.0-3.3)	2.2 (2.0-2.3)
Time spent	5.0 (5.0-5.0)	4.1 (4.0-4.3)	3.2 (3.0-3.4)	2.3 (2.0-2.4)
<b>Office-based, median (IQR)</b>				
Scheduling	4.8 (4.7-5.0)	4.1 (3.9-4.3)	3.4 (3.1-3.7)	2.7 (2.3-3.1)
Office cleanliness	4.9 (4.8-5.0)	4.3 (4.1-4.5)	3.7 (3.4-4.0)	3.0 (2.2-2.4)
Staff friendliness	4.9 (4.8-5.0)	4.1 (3.9-4.4)	3.5 (3.2-3.8)	2.8 (2.4-3.1)

Factor analysis was used to identify latent clusters of variables predicting overall patient satisfaction. One-, 2-, and 3-factor solutions were tested. Although a 1-factor solution explains the majority of the variance, the second factor explains an additional ~10% variance, where the third factor provides negligible information, which supports the results of the parallel analysis (Figure 1, Table 3). In the 2-factor model, two discrete clusters

of variables exceeded the a priori defined loading cutoff of  $\geq 0.70$  (Table 3). These clusters corresponded directly with physician-based metrics (factor 1 loading values 0.84 to 0.88) and office-based metrics (factor 2 loading values 0.76 to 0.84). Confirmatory factor analysis showed that the individual subdomains loaded successfully upon the a priori hypothesized latent factor structure (Table 4).

**Table 3.** Factor loadings from exploratory factor analysis.

Physician ratings subdimension	1-Factor solution	2-Factor solution		3-Factor solution		
	Factor 1	Factor 1	Factor 2	Factor 1	Factor 2	Factor 3
Level of trust in provider's decision	0.99	0.86	0.48	0.84	0.52	0.11
How well provider explains medical conditions	0.99	0.87	0.47	0.85	0.51	N/A <sup>a</sup>
How well provider listens and answers questions	0.99	0.88	0.46	0.86	0.50	N/A
Spends appropriate amount of time with patients	0.98	0.84	0.49	0.82	0.53	N/A

Proportion variance explained	0.84	0.53	0.40	0.49	0.44	0.00
Cumulative variance explained	0.84	0.53	0.93	0.49	0.93	0.93

<sup>a</sup>N/A: Not applicable.**Table 4.** Factor loadings from confirmatory factor analysis.

Latent factor and items	Loadings	P value
<b>Physician-based metrics</b>		
Level of trust in provider's decision	0.98	<.001
How well provider explains medical conditions	0.99	<.001
How well provider listens and answers questions	0.99	<.001
Spends appropriate amount of time with patients	0.98	<.001
<b>Office-based metrics</b>		
Ease of scheduling urgent appointments	0.92	<.001
Office environment, cleanliness, comfort, etc.	0.93	<.001
Staff friendliness and courteousness	0.95	<.001

In univariable linear regression analysis, all physician-based metrics and office-based metrics were associated with overall satisfaction (Table 5). The physician-based subdimensions most strongly associated with overall satisfaction were trust in physician and ability to explain, with overall satisfaction ratings increasing by 1.05 (95% CI 1.04 to 1.05) and 1.03 (95% CI 1.03 to 1.03) points for each point increase in subdimension score, respectively. The office-based subdimension most strongly associated with overall satisfaction was office cleanliness, with overall satisfaction ratings increasing by 1.09 (95% CI 1.09 to 1.1) for each point increase in office cleanliness score. Stepwise increases in office wait times were strongly associated with worsening overall satisfaction ratings; for example, compared with those with total wait time under 10 minutes, a wait time

of 31 to 45 minutes was associated with a decrease of –1.35 (95% CI –1.37 to –1.34) in overall satisfaction score. Since subdimension scores were highly correlated, latent factors identifying physician-based metrics and office-based metrics were used in multivariable analysis. In multivariable linear regression, physician-based metrics (0.65; 95% CI 0.65 to 0.65,  $P<.001$ ) were more strongly associated with overall satisfaction than office-based metrics (0.42; 95% CI 0.42 to 0.42,  $P<.001$ ), and the association of office wait times was strikingly diminished (Table 5).

While physician demographics such as practice region and years in practice were also associated with overall satisfaction score in univariable analysis, none were meaningfully associated with overall satisfaction in multivariable analysis (Table 5).

**Table 5.** Univariable and multivariable linear regression model predicting overall satisfaction.

Characteristics	Univariable		Multivariable	
	$\beta$ (95% CI)	<i>P</i> value	$\beta$ (95% CI)	<i>P</i> value

## Discussion

### Principal Findings

Online physician ratings have been steadily gaining popularity, with physicians rated a median of 7 times across commercially available websites [1,28]. More consumers are aware of these

ratings and are using them as the primary source of information to guide their health care decisions [7,29]. In addition, more physicians are now being rated across multiple platforms [2,3,30], yet despite the groundswell of interest and uptake of online ratings, very little data exist to support their validity and utility in assisting consumers choose better physicians [4,13,31-33]. In this analysis of a large sample of quantitative

online reviews, we found that physician-based subdimensions were very highly correlated with one another, demonstrating that consumers rarely differentiate between the commonly rated subdimensions of physician care. Office-based subdimensions of care were also found to be highly correlated with one another. However, there was more heterogeneity observed when comparing physician-based subdimensions with office-based subdimensions, suggesting that patients are better at parsing between the perceived quality of the physician versus their office staff. Factor analysis objectively supports this contention, clearly identifying two discrete factors predicting overall satisfaction, one clustered around physician-based care and one around office-based aspects of care. In multivariable regression analysis, the composite factors measuring physician- and office-based care far eclipsed other demographics in prediction of overall satisfaction in terms of magnitude. We believe this data suggests that physician ratings should be simplified to two simple metrics: one evaluating physician-based care and one evaluating office-based services.

The principal finding of our study is that commonly rated subdimensions of physician-based care are highly correlated with one another, which calls into question their utility over a single measure of satisfaction with the physician. Either the vast majority of physicians are consistently all good, average, or bad across all categories of care or consumers are unable to discriminate between the measured characteristics of their physicians. Since the former explanation does not seem likely, we favor the latter explanation. Kadry et al [34] also found a high correlation between various subdimensions of care across multiple rating websites in their analysis of 4999 total ratings and argued for a single rating for physician-based care. Indeed, based on our more comprehensive data analysis, a single measure of satisfaction with the physician and a single measure satisfaction with the office staff would suffice. Reducing the number of ratings could improve the understandability of these reviews and increase response rates [35,36].

An additional explanation for why the physician-based subdimension scores in our study may be highly correlated is the fact that they are measuring a similar construct: bedside manner. While the office-based subdimensions measure discrete, quantifiable characteristics such as office environment and ease of scheduling appointments, the physician-based subdimensions measure aspects of relationship building between doctor and patient [37,38]. It is difficult to conceive of a physician who would be superb at one aspect of relationship building (eg, listening and answering questions) and abysmal at another (eg, building trust). To our knowledge, none of the subcomponent scores of online ratings have undergone rigorous psychometric validation to determine if they are measuring distinct constructs. Although our study is not a psychometric assessment, it does suggest deficiency in discrimination between the subdimension scores by their overwhelming correlation with each other. As an extension of this line of thought, an alternative to reducing physician ratings to single measures of physician- and office-based care would be to identify components of care that patients can differentiate between using rigorous psychometric techniques.

While online ratings may be flawed, they are clearly an important source of direct consumer feedback, and we believe that these ratings have the potential to give physicians important quality improvement feedback [4,6,14,39,40]. While composite measures of physician- and office-based care were the predominant predictors of overall satisfaction in multivariable linear regression, there were some other notable characteristics that are worth mentioning. In univariate analysis, incremental increases in wait time predicted significantly worse ratings. On just a 5-point Likert scale, physicians with wait times over 45 minutes had an average of a 1.9-point lower rating compared with physicians with wait times under 10 minutes. Even physicians with wait times of just 10 to 15 minutes had nearly a half point decrease in ratings. As physician ratings do not fall under a normal distribution, these decreases can have a significant impact in the online perception of a physician when compared with his or her peers [18]. Interestingly, physician age and experience did not seem to affect their ratings with the exception of physicians who had graduated between 2005 and 2016. While surveys have shown that patients generally prefer physicians toward the middle of their career, this younger group actually had higher ratings despite less clinical experience. Gao et al [2] also had similar findings from another physician review website [41]. Younger physicians may have a better understanding of their online presence and focus more time identifying ways to improve their rating. Nonetheless, as mentioned above, physician-based metrics and office-based metrics far outstripped these demographic predictors of overall satisfaction in our multivariable model.

## Limitations

There are several limitations to our study. We aggregated data only from one website. However, this is the most frequented physician rating website with a large, heterogeneous mixture of physicians from across the United States [34]. Aggregation of data from multiple websites may be impractical given the large number of websites and various rating methods. In addition, these reviews naturally have an implicit selection bias and may not always be authentic. To minimize this bias, we only included physicians with more than the median number of reviews (4).

## Conclusions

In this analysis of the ratings of 212,933 providers, we found that consumers do not often differentiate between commonly assessed physician-based subdimensions of care. Physicians were most often scored in a monochrome fashion: scores all good, average, or bad. Office-based subdimensions of care were also highly correlated and were scored in a similarly monochrome fashion. In multivariable analysis, composite latent factors identifying physician-based metrics and office-based metrics were both independently associated with overall satisfaction scores, eclipsing all other physician demographic predictors in terms of magnitude. Based on this, we question the utility of commonly used subdimension scores and instead recommend a single measure of satisfaction for the physician and a single measure of satisfaction for the office staff. Alternatively, further research should be conducted to identify

qualities of physicians and office staff that consumers are well positioned to evaluate and are meaningful to patient experience.

## Abstract

**Background:** Metabolic disorders are established precursors to cardiovascular diseases, yet they can be readily prevented with sustained lifestyle modifications.

**Objective:** We assessed the effectiveness of a smartphone-based weight management app on metabolic parameters in adults at high-risk, yet without physician diagnosis nor pharmacological treatment for metabolic syndrome, in a community setting.

**Methods:** In this 3-arm parallel-group, single-blind, randomized controlled trial, we recruited participants aged 30 to 59 years with at least 2 conditions defined by the Third Report of the National Cholesterol Education Program expert panel (abdominal obesity, high blood pressure, high triglycerides, low high-density lipoprotein cholesterol, and high fasting glucose level). Participants were randomly assigned (1:1:1) by block randomization to either the nonuser group (control), the app-based diet and exercise self-logging group (app only), or the app-based self-logging and personalized coaching from professional dietitians and exercise coordinators group (app with personalized coaching). Assessments were performed at baseline, week 6, week 12, and week 24. The primary outcome was change in systolic blood pressure (between baseline and follow-up assessments). Secondary outcomes were changes in diastolic blood pressure, body weight, body fat mass, waist circumference, homeostatic model of assessment of insulin resistance, triglyceride level, and high-density lipoprotein cholesterol level between baseline and follow-up assessments. Analysis was performed using intention-to-treat.

**Results:** Between October 28, 2017 and May 28, 2018, 160 participants participated in the baseline screening examination. Participants (129/160, 80.6%) who satisfied the eligibility criteria were assigned to control (n=41), app only (n=45), or app with personalized coaching (n=43) group. In each group, systolic blood pressure showed decreasing trends from baseline (control: mean  $-10.95$ , SD  $2.09$  mmHg; app only: mean  $-7.29$ , SD  $1.83$  mmHg; app with personalized coaching: mean  $-7.19$ , SD  $1.66$  mmHg), yet without significant difference among the groups (app only:  $P=.19$ ; app with personalized coaching:  $P=.16$ ). Instead, those in the app with personalized coaching group had greater body weight reductions (control: mean  $-0.12$ , SD  $0.30$  kg; app only: mean  $-0.35$ , SD  $0.36$  kg,  $P=.67$ ; app with personalized coaching: mean  $-0.96$ , SD  $0.37$  kg;  $P=.08$ ), specifically by body fat mass reduction (control: mean  $-0.13$ , SD  $0.34$  kg; app only: mean  $-0.64$ , SD  $0.38$  kg,  $P=.22$ ; app with personalized coaching: mean  $-0.79$ , SD  $0.38$  kg;  $P=.08$ ).

**Conclusions:** Simultaneous diet and exercise self-logging and persistent lifestyle modification coaching were ineffective in lowering systolic blood pressure but effective in losing weight and reducing body fat mass. These results warrant future implementation studies of similar models of care on a broader scale in the context of primary prevention.

## KEYWORDS

metabolic health; health behavior; lifestyle modification; mobile health

## Introduction

Metabolic disorders are established precursors to cardiovascular disease [1]. Previous studies have demonstrated that even at subclinical stages, persons with elevated blood pressure, blood glucose level, cholesterol level, and adiposity are at significantly higher risk of adverse cardiometabolic outcomes [2]. Despite recent health care policy changes that have expanded healthy lifestyle advocacy initiatives, a considerable proportion do not achieve the guideline-recommended metabolic profile [3-5]. Therefore, timely and persistent management of metabolic abnormalities are crucial in preventing adverse health outcomes at an individual level and conserving substantial health care costs at a national level.

Alongside the advent of new medicines, technological innovations have aided in easing accessibility to and enriching the quality of health care. They have eliminated practical barriers, thereby allowing the distribution and improvement of health care via nonconventional routes at unprecedented speeds [6]. Several features include the transmission of medical records, social media forums for open discussion, web-based interactive education programs, higher precision diagnostics, real-time status tracking, digitalized clinics (ie, telemonitoring), and prescription dispensation [7,8].

In particular, the ubiquity of mobile phone technology has incentivized industries to create smartphone-based apps for health monitoring [9]. Previous trials [10,11] have evaluated the efficacy and effectiveness of such tools in the context of secondary prevention. For example, among patients receiving cardiac rehabilitation after hospitalization for myocardial infarction, daily text message reminders led to greater medication adherence and exercise capacity compared with patients receiving usual care [10]. The utility extends to general populations; a Finnish trial [11] demonstrated both short- and long-term weight loss among people who were overweight and who logged weight daily and received dietary management instructions over a period of 1 year. By collecting data in real time, these mobile-based apps enable researchers to assess multiple behaviors and to prompt change at low cost and with high ease.

Nonetheless, there are important limitations in the current literature. Previous studies [12-14] have primarily recruited clinic patients who were already using or were exceptionally motivated to use health management tools. Methodologically, many studies [7] estimated the effect of these mobile interventions based on per protocol analysis. It has been established that physical activity and diet affect blood pressure

level not only in hypertension patients but also in people with prehypertension or elevated blood pressure [15]. Recent blood pressure guidelines [15,16] emphasized early lifestyle modification for people whose blood pressure is above the normal range. However, the effects of smartphone-based apps in lowering blood pressure have not been properly assessed in people whose blood pressure is above the normal range in real-world settings.

In this context, the objective of the study was to evaluate the longitudinal effect of smartphone-based health care app on metabolic parameters in a sample of the general population with moderate metabolic abnormalities yet without clinical diagnosis nor pharmacological treatment. We hypothesized that the participants receiving both real-time personalized coaching and self-logging diet and physical activity would yield greater improvements in blood pressure and other metabolic parameters than those who were only self-logging or who did not use the app.

## Methods

### Study Design

The study was designed as a single-blind 3-arm parallel-design randomized controlled trial delivering a 6-month primary prevention program via mobile app to a population with moderate metabolic abnormalities with neither diagnosis nor treatment for metabolic disorders. The main objective was to evaluate the effectiveness of health management app on metabolic parameters over 3 follow-up examinations. Community-dwelling adults residing in Seoul and nearby capital regions were recruited. The study protocol was approved by the institutional review boards of Severance Hospital and Yonsei University Health System (4-2017-0666), and the protocol of the study is registered at ClinicalTrials.gov (NCT03300271).

### Participants

Candidate participants were identified based on objectively measured metabolic profiles from a previous Cardiovascular and Metabolic Diseases Etiology Research Center (CMERC) observational cohort study [17]. Briefly, the CMERC study [17] aimed to identify novel risk factors and to investigate the distribution and effects of known cardiovascular and metabolic diseases risk factors.

We recruited smartphone users aged 30-59 years with at least 2 metabolic abnormalities defined by the modified version of the Third Report of the National Cholesterol Education Program expert panel on detection, evaluation, and treatment of high blood cholesterol in adults [18] using the criteria for Asian

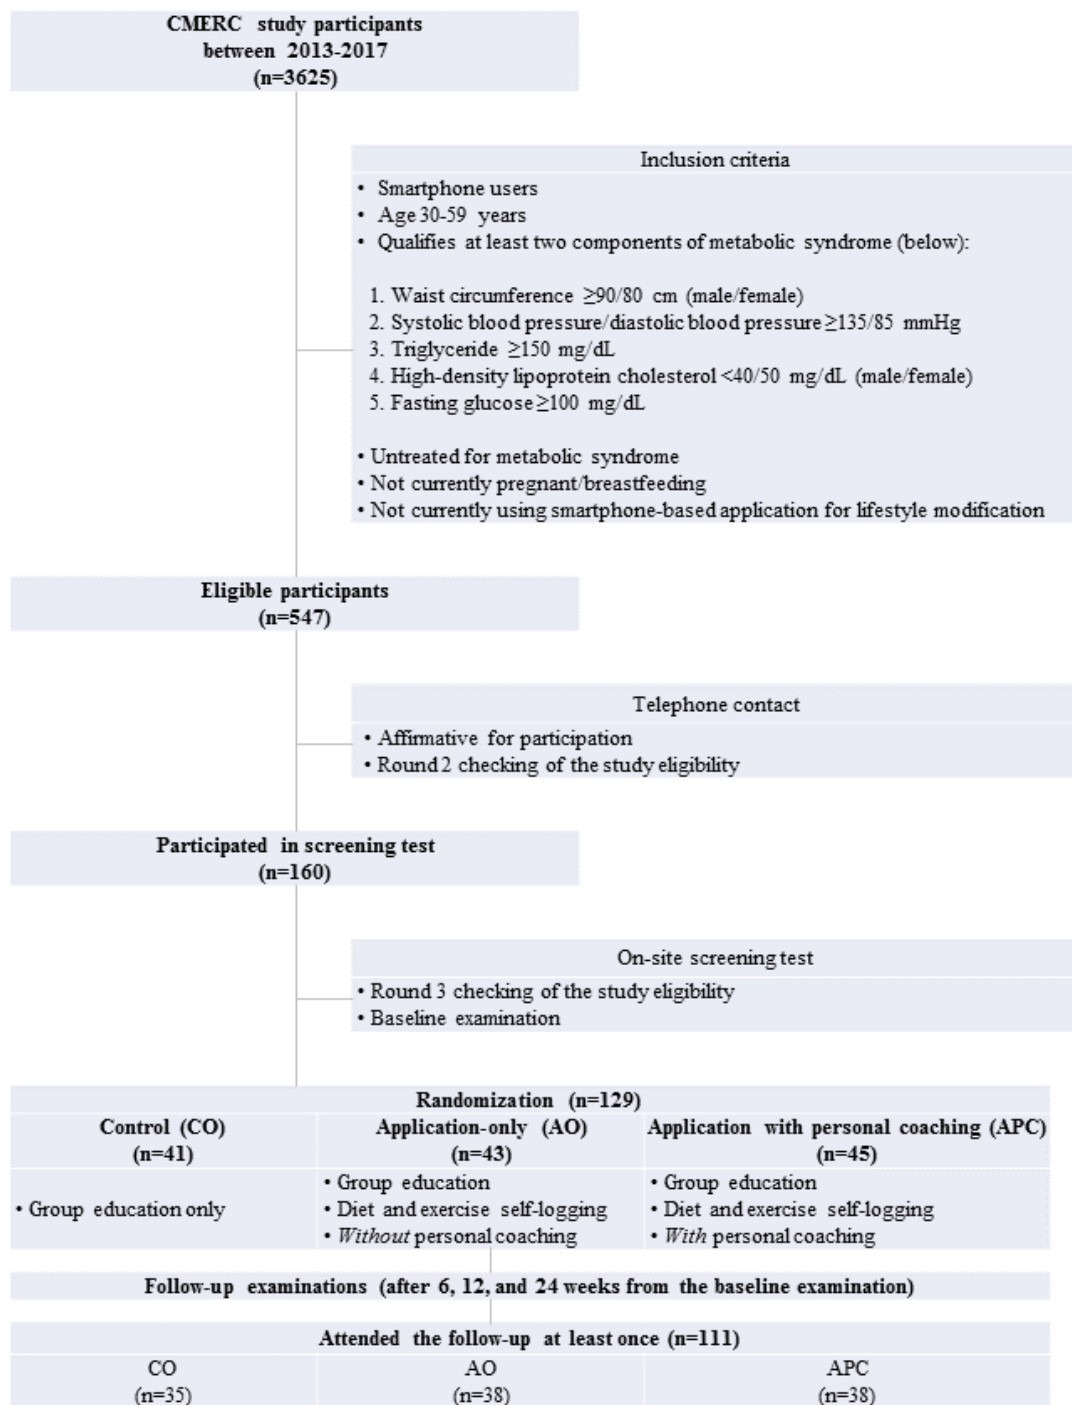

populations: waist circumference (male:  $\geq 90$  cm; female:  $\geq 80$  cm), blood pressure (systolic:  $\geq 135$  mmHg; diastolic:  $\geq 85$  mmHg), triglyceride  $\geq 150$  mg/dL, high-density lipoprotein (HDL) cholesterol (male:  $< 40$  mg/dL; female:  $< 50$  mg/dL), and fasting glucose level  $\geq 100$  mg/dL. Exclusion criteria included users of smartphone-based health care apps for lifestyle modification, individuals with a previous diagnosis of cardiovascular disease, malignant cancer, or metabolic syndrome, individuals who were taking antihypertensives, lipid-

or glucose-lowering drugs, and women who were pregnant or breastfeeding at the time of the study.

Among 3625 CMERC cohort participants [17], 546 people qualified. We contacted these individuals via telephone and mail for recruitment. Of the 160 (29.1%) who expressed affirmative for screening test, a total of 129 participants (23.6%) attended the baseline examination (Figure 1).

Participants were asked to give their written consent without knowledge of the intervention assignments.

**Figure 1.** Flow diagram of the study participants. CMERC: Cardiovascular and Metabolic Diseases Etiology Research Center.

## Randomization and Masking

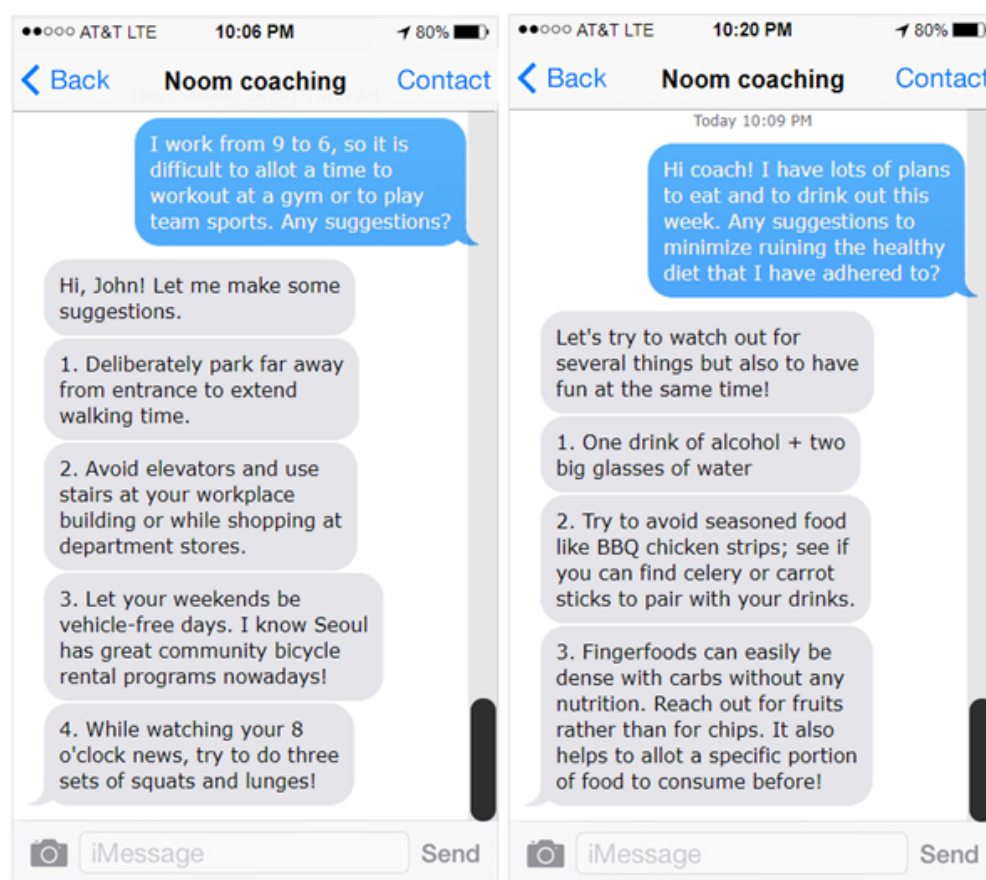

We randomly allocated participants into 1 of the 3 intervention arms via sex- and age-stratified block randomization. Specifically, we set the block size equal to 6 from sex (male or female) by age group in decile (30, 40, and 50) using R (version 3.4.4; R Foundation for Statistical Computing). We adopted a single-blind approach; thus, the effectiveness would be assessed by masked researchers unaware of the randomization results. The allocation concealment was achieved via individualized texting, which instructed all participants to adhere to their respective intervention, to avoid using other health management apps, and to refrain from sharing of their intervention instructions with each other for the entire study duration. To minimize crossover or contamination, we (1) retrospectively ensured no unallocated feature had been installed to the app only group from the app's user-specific metadata and (2) asked the participants whether they had engaged in other health-related trials, programs, or apps at every follow-up assessment.

## Procedures

At the baseline assessment, all participants received on-site education that entailed information on metabolic syndrome and preventive strategies, including validated exercise regimens and nutritious cooking recipes. Then, we randomly allocated

participants into 1 of the 3 intervention arms: the control group (control;  $n=41$ ) received only the aforementioned baseline education and was asked to refrain from concurrently engaging in any smartphone-based lifestyle modification app or programs; the app only (app only;  $n=45$ ) and the app with personalized coaching (app with personalized coaching;  $n=43$ ) groups also received the baseline education and were additionally asked to use a smartphone-based weight management app called Noom (Noom Inc). Specifically, Noom allows users to log details regarding daily food intake and physical activities. For instance, a user can record a specific menu item (ie, fastfood chain M's cheeseburger), consumed portion (ie, single serving, half of cheeseburger), and time of consumption (ie, breakfast, 8 AM). From Noom's nutrition metadata, the app readily calculates total calories and macronutrients consumed for each log entry. Likewise, a wide array of physical activities (ie, indoor treadmill walking) are available for selection from the predefined list. After entering the intensity (ie, pace) and duration (ie, 60 minutes) of physical activity, the app yields energy expenditure in kilocalories, accounting for the user's sex, age, height, and weight. As an additional feature, it delivers structured health-related curricula and personalized feedback from certified exercise regimen coordinators and clinical dieticians based on their reviews of the user's logs (Figure 2).

**Figure 2.** Example of personalized coaching.

The default frequency of personalized coaching was set to 3 times per week; however, the actual frequency varied depending

on the user's participation rate. Only the app with personalized coaching group received the personalized coaching. All users'

activation statuses were evaluated based on the number of weight, meal, and physical activity logs. Weekly, we defined each user as active if the user had recorded at least 1 aforementioned parameter.

The universal baseline examination included anthropometric measurements, blood tests, and face-to-face interviews on demographics, disease history, and health behavior. Then, participants received text messages notifying them of the study initiation. The app only and app with personalized coaching groups were given additional instructions regarding the Noom app installation procedures; each user received a unique identification code.

## Outcomes

The primary outcome was change in systolic blood pressure between the baseline and follow-up at 6, 12, and 24 weeks. The secondary outcomes were changes in diastolic blood pressure, body weight, body fat mass, waist circumference, homeostatic model of assessment of insulin resistance (HOMA-IR), and lipid profile (triglyceride and HDL cholesterol) between the baseline and follow-up at 6, 12, and 24 weeks.

Anthropometric measurements were performed with strict adherence to standardized protocols and using calibrated equipment. Blood pressure was consecutively measured using both single- and double-arm automated oscillometric devices (HEM-7080, Omron Health; WatchBP Office Central, Microlife) at a single sitting. The mean of second and third measurements were used for analysis. Participants underwent blood tests after overnight fasting for a minimum of 8 hours. Fasting plasma glucose and insulin levels were assessed using colorimetry method (ADVIA1800 Auto Analyzer, Siemens Medical Solutions). HOMA-IR was calculated as the product of fasting glucose and insulin levels divided by 405 in mg/dL. Weight was measured to the nearest 0.1 kg on a digital scale (DB-150, CAS). To minimize measurement variability, a zero-point adjustment was routinely conducted using weight blocks (20, 40, and 60 kg). Bioelectrical impedance analysis delineated body composition (BSM-330, INBODY). Waist circumference was measured to the nearest 0.1 cm using a plastic tape (SECA 201, SECA), while maintaining the level of the measuring tape.

Physical activity was assessed by the Korean version of the International Physical Activity Questionnaire [19]. Using validated alcohol consumption and cigarette smoking ratings, participants were divided into non-, previous-, and current categories for alcohol consumption and smoking.

## Statistical Analysis

The target sample size was 150 participants, chosen to provide precise estimates of the intended effect of mobile app usage. Specifically, the sample size calculation was conducted based on the expected difference in systolic blood pressure after 24 weeks across the 3 intervention arms [20]. We assumed a statistical power of 80% and a significance level of  $P < .05$ . Based on previous literature [20,21], we expected a mean systolic blood pressure difference of 6 mmHg with a standard deviation of 10 mmHg after 24 weeks. When considering 10% attrition

rate and 3-arm design, the study required a minimum recruitment of 150 participants.

We employed analysis of variance to assess differences in demographic and health-related behavior. Then, we compared the extent of changes in each metabolic parameter across participants randomly assigned to control versus app only and app with personalized coaching groups, separately, using an intention-to-treat approach; all participants who participated in at least 1 of the 3 follow-up assessment were included in the analysis. We used independent  $t$  tests to evaluate the primary and secondary outcomes at each time point. To account for repeated measurements over multiple follow-ups, we employed a linear mixed model to determine the effect of mobile health care apps on the prespecified outcomes. Specifically, the unstructured linear mixed model incorporates time and group $\times$ time interaction terms to assume no homogeneity across the 3 groups at the baseline. From the random intercept model, the estimated beta coefficient of the group $\times$ time interaction term was regarded as the effect of the app usage. The changes are presented as estimated beta coefficient ( $\beta$ ) and standard error (SE). All statistical tests were 2-sided and the statistical significance was set at a  $P < .05$ . All analyses were performed using R and SAS (version 9.4; SAS Institute Inc).

All data were collected, registered, and managed on ClinicalTrials.gov (NCT03300271). Data were deidentified and accessible only by designated researchers. All researchers strictly adhered to data security protocols. For unbiased data monitoring and trial safety overseeing, the research director delegated Dae Ryong Kang, a professor of biomedical data science at Yonsei University, Wonju College of Medicine, Wonju, Korea, who remained independent of the research execution.

## Results

### Participants

All participants were enrolled on October 28, 2017, and the last participant completed the week 24 follow-up on June 2, 2018. Of the 129 enrolled individuals, 41 (32%) were randomly assigned to the control group, 45 (35%) to the app only group, and 43 (33%) to the app with personalized coaching group (Figure 1). In the end, 111 participants attended at least 1 follow-up examination (week 6: 107; week 12: 100; week 24: 105), yielding a 14.0% attrition rate overall.

### Baseline Characteristics

Table 1 shows the general characteristics of the study participants at the baseline screening. Overall, the participants were similarly distributed in terms of age, metabolic parameters, and health behaviors across the 3 groups. At baseline, systolic blood pressure was comparable across the 3 groups (control: mean 131.8 mmHg; app only: mean 130.8 mmHg; app with personalized coaching: mean 133.3 mmHg). Such comparability across the groups ensured the baseline differences did not affect the changes in metabolic parameter over the study period.

**Table 1.** General characteristics of the study participants at the baseline screening.

Variables	Control (n=41)	App only (n=45)	App+personalized coaching (n=43)
Age (years), mean (SD)	49.5 (7.9)	49.2 (7.5)	48.9 (7.8)
<b>Sex, n (%)</b>			
Male	19 (46.3)	23 (51.1)	21 (48.8)
Female	22 (53.7)	22 (49.9)	22 (51.2)
Number of metabolic abnormalities, mean (SD)	2.9 (0.8)	2.9 (0.9)	2.8 (0.9)
Systolic blood pressure (mmHg), mean (SD)	131.8 (15.8)	130.8 (15.2)	133.3 (14.9)
Diastolic blood pressure (mmHg) , mean (SD)	87.4 (9.9)	86.6 (10.7)	89.0 (11.7)
Height (cm), mean (SD)	166.4 (8.8)	165.3 (10.4)	164.0 (8.9)
Weight (kg, mean (SD)	71.8 (13.2)	72.6 (12.4)	71.9 (11.6)
Body mass index (kg/m <sup>2</sup> ), mean (SD)	25.8 (2.8)	26.5 (3.2)	26.6 (2.9)
Waist circumference (cm) , mean (SD)	89.1 (8.2)	90.8 (8.2)	90.4 (7.0)
Percent body fat, mean (SD)	30.3 (6.8)	31.9 (7.1)	31.6 (5.7)
Fat mass (kg), mean (SD)	21.5 (5.2)	23.1 (6.4)	22.5 (4.5)
Skeletal muscle mass (kg) , mean (SD)	28.1 (7.1)	27.6 (6.2)	27.5 (6.1)
Total cholesterol (mg/dL), mean (SD)	212.9 (31.6)	197.4 (34.1)	205.1 (31.8)
Triglyceride (mg/dL), mean (SD)	212.9 (138.0)	176.6 (107.7)	169.2 (72.7)
HDL <sup>a</sup> cholesterol (mg/dL), mean (SD)	46.1 (8.4)	47.1 (11.2)	46.3 (10.5)
LDL <sup>b</sup> cholesterol (mg/dL), mean (SD)	139.1 (28.8)	127.5 (35.0)	137.1 (30.7)
Fasting blood glucose (mg/dL), mean (SD)	98.1 (13.8)	105.9 (39.4)	98.9 (19.0)
Insulin (mIU/mL), mean (SD)	11.4 (4.8)	11.5 (4.8)	11.8 (3.9)
Hemoglobin A <sub>1c</sub> (%), mean (SD)	5.9 (0.7)	6.1 (1.2)	5.8 (0.7)
HOMA-IR <sup>c</sup> , mean (SD)	2.8 (1.2)	3.0 (1.5)	2.9 (1.5)
Hypertension, mean (SD)	2 (4.9)	2 (4.4)	1 (2.3)
Diabetes, mean (SD)	0 (0.0)	0 (0.0)	0 (0.0)
Dyslipidemia, mean (SD)	3 (7.3)	1 (2.2)	1 (2.3)
<b>Smoking status, n (%)</b>			
Never	19 (46.3)	28 (62.2)	25 (58.1)

Alcohol consumption (g/day), mean (SD)	22.1 (38.8)	10.4 (15.5)	11.5 (18.1)
<b>MVPA<sup>d</sup> engagement, n (%)</b>			
Yes	2 (4.9)	8 (17.8)	9 (20.9)
No	39 (95.1)	37 (82.2)	34 (79.1)
Sedentary time (hours/day), mean (SD)	7.2 (2.7)	6.6 (2.8)	7.1 (3.9)

<sup>a</sup>HDL: high-density lipoprotein.<sup>b</sup>LDL: low-density lipoprotein.

<sup>c</sup>HOMA-IR: homeostatic model assessment of insulin resistance.

<sup>d</sup>MVPA: moderate-vigorous physical activity.

To ensure homogeneity between those who attended and those who did not attend follow-up at least once, we have compared the baseline characteristics as illustrated in [Multimedia Appendix 1](#). In regard to age, sex, anthropometry, and glycemic and lipid profiles, no statistically significant differences (age:  $P=.10$ ; sex:  $P=.09$ ; systolic blood pressure:  $P=.36$ ; diastolic blood pressure:  $P=.93$ ; BMI:  $P=.98$ ; total cholesterol:  $P=.95$ ; fasting glucose level:  $P=.25$ ) were detected between the 2 groups. The only notable difference was the proportion of current smokers; those who did not attend any follow-up examinations had a higher proportion of current smokers than those who attended at least once (44.4% versus 17.1%;  $P=.04$ ; [Multimedia Appendix 2](#)).

### Comparisons at Each Time Point

All 3 groups showed varying amounts of systolic blood pressure reduction overall. In reference to the baseline examination, the control and app only groups showed the most dramatic reduction at week 24 (control: mean  $-10.95$ , SD 11.98 mmHg; app only: mean  $-7.19$ , SD 9.98 mmHg), whereas the app with personalized

coaching group showed the most dramatic systolic blood pressure reduction at week 12 (mean  $-7.82$ , SD 11.98 mmHg). However, compared to the control group, neither the app only nor the app with personalized coaching group had significantly different systolic blood pressure change at any follow-up examination ([Figure 3](#)).

For secondary outcomes, participants in the app with personalized coaching group generally lost more body weight (mean  $-0.96$  kg versus  $-0.12$  kg; [Figure 4](#)), lost more body fat mass (mean  $-0.79$  kg versus  $0.13$  kg; [Figure 5](#)), and had smaller waist circumferences (mean  $-1.86$  cm versus  $-0.08$  cm; [Multimedia Appendix 2](#)) by the end of the study period. At week 24, diastolic blood pressure ( $P=.42$ ; [Multimedia Appendix 3](#)) and other glycemic (fasting glucose level:  $P=.99$ ; HOMA-IR:  $P=.63$ ; [Multimedia Appendix 4](#) and [Multimedia Appendix 5](#), respectively), and lipid indices (triglyceride level:  $P=.93$ ; HDL cholesterol level:  $P=.46$ ; [Multimedia Appendix 6](#) and [Multimedia Appendix 7](#), respectively) had not changed significantly.

**Figure 3.** Systolic blood pressure changes from the baseline across the 3 groups at each time point. AO: app-only; APC: app with personalized coaching; CO: control, SBP: systolic blood pressure.

**Figure 4.** Body weight changes from the baseline across the 3 groups at each time point. AO: app-only; APC: app with personalized coaching; CO: control, SBP: systolic blood pressure.

**Figure 5.** Body fat mass changes from the baseline across the 3 groups at each time point. AO: app-only; APC: app with personalized coaching; CO: control.

### Linear Mixed Model

Neither the app only (control versus app only at week 24:  $\beta=2.93$ , SE 2.42,  $P=.23$ ) nor the app and additional personalized feedback feature (control versus app with personalized coaching at week 24:  $\beta=3.18$ , SE 2.42,  $P=.19$ ) significantly contributed to systolic blood pressure reduction at any of the follow-up examinations (Multimedia Appendix 1). In regard to secondary outcomes, statistically significant effects were observed for body weight and body fat. Compared to the participants in the control group, those in the app with personalized coaching group lost more body weight at week 12 ( $\beta=-0.93$ , SE 0.43;  $P=.03$ ) and at week 24 ( $\beta=-0.87$ , SE 0.42;  $P=.04$ ). This translated to an average difference of 0.14 kg of body weight loss per month

between participants in the control group and participants in the app with personalized coaching group. In parallel, the app with personalized coaching group lost more body fat than the control group did at week 24 ( $\beta=-0.95$ , SE 0.46,  $P=.04$ ). This was equivalent to participants in the app with personalized coaching group losing an average of 0.19 kg more body fat per month than those in the control group. The app with personalized coaching group showed significant HOMA-IR level reductions at week 12 ( $\beta=-0.55$ , SE 0.27,  $P=.04$ ). However, separate examination by fasting glucose level did not show significance ( $P=.80$ ) and the HOMA-IR reductions diminished by week 24 ( $\beta=-0.22$ , SE 0.26,  $P=.40$ ). Otherwise, there were no significant effects of the app on diastolic blood pressure (app only:  $P=.83$ ; app with personalized coaching group:  $P=.47$ ), waist

circumference (app only:  $P=.32$ ; app with personalized coaching:  $P=.12$ ), triglyceride (app only:  $P=.70$ ; app with personalized coaching:  $P=.23$ ), HDL cholesterol (app only:  $P=.14$ ; app with personalized coaching:  $P=.91$ ), or fasting blood glucose level (app only:  $P=.38$ ; app with personalized coaching:  $P=.84$ ; [Multimedia Appendix 1](#)).

## Discussion

### Principal Findings

Mobile-based behavioral health interventions that permit real-time data collection and sharing are increasingly commonplace, enabling researchers to assess multiple health behaviors in various contexts. At the same time, they prompt users to be more self-aware and to modify their own health behavior. In this context, the goal behind this study was to assess the real-world effectiveness of a smartphone-based self-monitoring health management app in a community-dwelling population of individuals without diagnosis or treatment of metabolic disorders. App usage showed differential effects on metabolic parameters at different time points. Overall, the primary outcome of systolic blood pressure followed a decreasing trend from the baseline yet did not change notably between the 3 groups at any follow-up examinations. Instead, the simultaneous diet/exercise logging and lifestyle coaching yielded relatively greater body weight reduction, specifically via body fat mass reduction. These effects were attenuated yet sustained at 6 month.

Despite no significant systolic blood pressure improvement in this study, previous studies [12-14,22-24] have identified the utility of mobile apps in lowering blood pressure through self-monitoring and information delivery services. In several randomized controlled trials [12-14,22-24] conducted in obesity clinic settings, text messages or emails for antihypertensive medication adherence, tailored guidance on salt intake, smoking cessation, and physical activity interventions reported significant differences in blood pressure reduction compared to usual care. However, unlike our study in which community-dwelling individuals without overt metabolic syndrome participated, similar studies [7,21,25] have been primarily performed on patients based on completers' analysis rather than intention-to-treat. Considering varied levels of initiative for health management often used as a proxy for adherence and attrition, our results indicate that effectiveness of these self-care apps may considerably differ by study population and analytical methods.

Moreover, Liu and colleagues' [25] examination of internet-based counseling interventions among patients with elevated blood pressure indicated that e-counseling interventions significantly reduced daytime systolic blood pressure by 3.8 mmHg (95% CI  $-5.63$  to  $-2.06$ ), with greater reductions from more sustained interventions. Since our study relied on a single-occasion blood pressure measurement in the examination setting, the results may potentially be distorted by whitecoat or masked hypertension.

Furthermore, a significant limitation of accumulated evidence is that many studies [7] were conducted for durations less than

6 months. Given that hypertension is a chronic condition that requires long-term pharmacological treatment and lifestyle modification, prolonged observation should be allotted for more accurate assessment of intervention adherence and subsequent blood pressure changes.

In our study, body weight reduction, via body fat mass loss, was the most evident improvement from app usage, as indicated by similar trials [26,27]. Among overweight adults, daily transmitted personalized multimedia message services providing weight control materials have proven to induce greater weight loss ( $-1.97$  kg difference, 95% CI  $-0.34$  to  $-3.60$  kg) than the non-receiving group [26]. A systematic review [25] consistently identified the association between self-monitoring or online obesity treatment programs and body size reduction via targeted advice on reduced energy intake, increased physical activity, and social support. Often, the studies incorporated the use of structured regimen, regular self-monitoring, circumstantially appropriate feedback, prompt communication, and social support [27]. Abraham et al [28] classified such intervention content, including information-motivation-behavior skills model (ie, providing information about behavior-health link), social-cognitive theory (ie, prompting barrier identification, general encouragement), control therapy (ie, self-monitoring, interactive feedback), relapse prevention and behavior sustenance, and more. Although the extent and nature of the interventions varied across studies, these elements commonly found in mobile technology interventions, altogether, appear crucial in driving greater changes.

Our study results indicated that the 6-month usage of the mobile app did not substantially improve insulin sensitivity. Yet, an analogous meta-analysis [29] demonstrated that comprehensive lifestyle modification delivered through a mobile app lowered hemoglobin A<sub>1c</sub> level by an average of 0.5% over 6 months of follow-up. Interestingly, this decrease was not accompanied by concurrent improvements in other diabetes risk factors, such as blood pressure, cholesterol levels, or adiposity [29]. However, considering that hemoglobin A<sub>1c</sub> reflects long-term fluctuations of glycemic control (unlike fasting glucose level used in our study), Liang et al [29] raised concerns regarding insufficient follow-up period. Moreover, since these trials were conducted on persons diagnosed with diabetes of varying subtypes and adherence to antihyperglycemic treatments, it would have been challenging to isolate the effectiveness of the mobile app intervention from changes in treatment behavior. Therefore, the different representation of glycemic state and participant characteristics warrant caution in assuming or denying the attribution of these technology-based intervention to other nonspecific benefits.

Over the span of 6 months, our participants did not show significantly different changes in triglyceride and HDL cholesterol levels across the 3 groups. Yet, Park and Kim [30] showed that, among gynecology and family medicine outpatients, the use of web-based diet and exercise diaries and the specialists' weekly lifestyle modification recommendations improved total ( $-12.9$  mg/dL) and low-density lipoprotein ( $-11.3$  mg/dL) cholesterol levels after 12 weeks. Again, it is hard to extrapolate from clinic setting population in which individuals

may already be utilizing health management app prior to trial entrance or may be taking medications (ie, statins) that distort the true effects of the interventions.

The greatest novelty of our study lies in its evaluation of the mobile app's effectiveness via intention-to-treat approach in nonpatient population without the concern of confounding by pharmacological treatment. Considering that the general population consists of individuals with wide-ranging levels of digital literacy and utility, willingness for lifestyle modification, and physiological and socioeconomic backgrounds, our study portrays the effectiveness of mobile-based health management app in real-world setting. Furthermore, the assessor-blinding enabled true compliance assessment in the sample regardless of individual preference for or competency with the app, thereby evaluating the app's real-world potential. In addition, because we assessed the changes in metabolic parameters repeatedly over a considerable time horizon, our results reflect the long-term trajectory of the metabolic indices, empirically. Lastly, as a 3-arm parallel design with concurrent control, we were able to discriminate whether the self-logging of diet and exercise was sufficient to induce improvements in metabolic parameter or whether additional personalized coaching was the critical element in shaping healthy behavior.

Nonetheless, several limitations warrant cautious interpretation of our study findings. During the screening test, we faced an unexpectedly greater number of participants who did not satisfy the inclusion criteria, and thus, we were unable to reach the goal sample size. During the study period, because the participants had varying attendance to each of the follow-up examination, there may have been residual heterogeneity among participants who attended follow-up examinations none, once, twice, or all follow-up examinations. Yet, those lost to follow-up were demographically similar to those who participated in the study with the exception of current smoking status. If any effects were present, we expect such attrition to have an effect on the study results toward the null. Moreover, because the participants were

selected from an already-established cohort, higher self-efficacy and proficiency may have been present. Therefore, the results may not be entirely generalizable to the general population. However, the original cohort study was purely observational; thus, our findings still represent individuals typically seeking health management without referral to physician nor pharmacological treatment. Furthermore, similar literature has suggested that baseline self-efficacy appraisals may not be entirely pertinent to practical skills or opportunities to sustain life changes [15]. In this context, we expect comparable initiatives for lifestyle modification between our study and the general population. Lastly, considering that blood pressure, body size, glycemic index, and lipid indices are reflective of chronic states, our 6-month study period may have been insufficient to witness changes. Future studies with a larger sample size and a prolonged study period may better assess the effectiveness of lifestyle modification mobile apps on the long-term trajectory of metabolic indices.

## Conclusions

Among the community-dwelling adults with moderate metabolic abnormalities without diagnosis or treatment for disorders, we examined the effect of a smartphone-based app on changes in metabolic parameters. By the end of the 6-month study period, no changes to systolic blood pressure were significant for participants who utilized both diet/exercise logging and personalized coaching compared to logging-only or nonusing groups. Instead, the self-logging and lifestyle coaching yielded greater body weight reduction via body fat mass loss. The research investigating mobile health management interventions that confer accessible and cost-effective benefits remains in its infancy, especially in general populations. Future studies focusing on comparative effectiveness using alternative study designs and on populations of various health, socioeconomic, and cultural backgrounds are needed to integrate these apps in everyday lives and clinic practice.

## Acknowledgments

This study was supported by a grant from the Korean Health Technology R & D Project, Ministry of Health & Welfare, Korea (HI13C0715). The Ministry of Health & Welfare did not have any role in the writing of the manuscript nor in the decision to submit the manuscript for publication. The authors have not been paid to write this article by any pharmaceutical company or any other agency. The corresponding author had full access to all the data in the study and had final responsibility for the decision to submit for publication.

## Authors' Contributions

JHL, J-SS, HY, and HCK conceived and designed the trial. J-SS and HCK developed the education program. SMJC, JHL, J-SS, HY, YWJ, and HCK helped perform the study. SMJC, JHL, J-SS, HY, YWJ, and HCK acquired the data. SMJC, JHL, and HCK analyzed and interpreted the data. SMJC and JHL drafted the manuscripts. SMJC, JHL, and HCK critically revised the manuscript. SMJC and JHL performed the statistical analysis. J-SS and HCK supervised the study. All authors approved the final version of the manuscript.

## Conflicts of Interest

## Abstract

Although many people access publicly available digital behavioral and mental health interventions, most do not invest as much effort in these interventions as hoped or intended by intervention developers, and ongoing engagement is often low. Thus, the impact of such interventions is minimized by a misalignment between intervention design and user behavior. Digital micro interventions are highly focused interventions delivered in the context of a person's daily life with little burden on the individual. We propose that these interventions have the potential to disruptively expand the reach of beneficial therapeutics by lowering the bar for entry to an intervention and the effort needed for purposeful engagement. This paper provides a conceptualization of digital micro interventions, their component parts, and principles guiding their use as building blocks of a larger therapeutic process (ie, digital micro intervention care). The model represented provides a structure that could improve the design, delivery, and research on digital micro interventions and ultimately improve behavioral and mental health care and care delivery.

**KEYWORDS**

micro intervention; mental health; mhealth; eHealth; engagement; intervention; adherence; behavior change; behavioral health

## Introduction

Mental illnesses and substance use disorders constitute a major public health challenge, with large personal social and economic costs [1-3]. Evidence-based interventions exist; however, most people with mental or behavioral health issues receive no treatment, and for those who do receive care, the average duration of untreated illness is excessive [3-6]. This treatment gap is linked to psychological and social barriers, such as feelings of embarrassment, stigma, and shame [7], as well as structural barriers, such as pricing and inconvenient time or location of services [2,3,8-10].

Technology-enabled intervention delivery models have grown on the promise to increase access to care. Behavioral and mental health apps can often be accessed without requiring others to be aware of personal behavioral or mental health issues, without

physically attending appointments, and with considerably lower cost than that of face-to-face services. Self-help apps and programs, in particular, can often be accessed with no referral and be available 24/7. The reduction of barriers associated with traditional service access is important for improving access to care; however, it also brings some challenges. Those who make it to traditional services have often invested considerable effort to seek and engage with services and hence might often have high levels of motivation. For example, one study found that most outpatients surveyed prior to entering psychotherapy tended to believe they will be highly involved, invest large efforts, and make large changes in their life [11].

Models of care delivery that eliminate key barriers might reach an audience with very different characteristics, interests, and motivation than those reached by traditional services. Nowhere is this more evident than in the real-world usage of self-guided

digital behavioral and mental health interventions situated outside of traditional treatment settings. A recent study examined the real-world use of popular mental health apps and reported that after 15 days of use, the median percentage of daily active users (open rate) was 4.0%, with a median app retention rate of 3.9% [12]. These findings are congruent with researchers' own reports of poor real-world program use [13]. Subsequently, a recent systematic comparison of published reports and real-world usage of the same programs reported that users who participated in trials had four times higher eHealth program usage in comparison with real-world users of the same programs [14]. These findings imply that a high portion of those interested in digital behavioral and mental health interventions in the real world are not investing as much effort in these interventions as intended by intervention developers.

Many efforts have attempted to overcome this challenge, including efforts to address content packaging and personalization of treatment [15-17] and efforts to investigate the impact of intervention design features on engagement [18-21]. Another way of thinking, however, would be to accept that people might enter digital behavioral or mental health interventions with reduced levels of interest and motivation and to design interventions appropriate for such people. One potential modification to interventions would be to make interventions shorter and much more focused. These shorter and more focused interventions have been called "micro interventions" [22,23], which are highly focused interventions delivered in the context of a person's daily life in order to help them reach desired proximal targets. These small units of beneficial therapeutics can be delivered with little burden on the individual. Therefore, micro interventions have the potential to not only lower the bar for entry to an intervention but also the commitment and effort needed for purposeful engagement.

People commonly seek and receive micro interventions all the time. Receiving an answer to a question posted in a Facebook community about parenting could be viewed as a micro intervention. Playing an uplifting song may assist individuals with emotion regulation and could also be viewed as a micro intervention. Micro interventions are not unique to digital interventions, however, new technological affordances, such as the widespread penetration of smartphones [24,25] and the global increase in internet access [26,27], present opportunities to easily offer digital micro interventions in people's natural context. These digital micro interventions could substantially increase access to effective behavioral and mental health care by lowering the amount of effort required to reach beneficial gains.

Despite the accessibility of these affording technologies and the frequency of digital micro interventions being deployed daily, a conceptualization of digital micro interventions and how to effectively integrate them within larger therapeutic processes has not been offered. In this paper, we aim to address this gap. We begin by defining a digital micro intervention and its component parts. We then describe principles guiding the use of digital micro interventions as building blocks of a larger therapeutic process (ie, digital micro intervention care). We close by clarifying the differences between digital micro intervention care and a stepped-care approach. [Table 1](#) provides an explanatory overview of key terms described in the body of this work. Through this paper, we hope to help create a language and conceptualization that enables scholars to clarify the importance of specific digital micro interventions within larger processes and to support the creation of digital micro intervention care and the publication of studies around them.

**Table 1.** Key terms described within the paper.

Term	Definition	Example
<b>Digital micro intervention</b>	An intervention intended to achieve a highly focused objective using in-the-moment elements. These elements are not necessarily linked directly to the achievement of a larger clinical aim.	Guiding parents in several small steps to help them increase positive attention toward desired behaviors of their child.
Events	The elemental (smallest) components of digital micro interventions. Each event is an in-the-moment attempt for change or impact toward the overall target of the intervention.	An app-based gratitude exercise encouraging parents to focus on their child's positive attributes.
Decision rules	Guiding which events are deployed and when.	Including a short educational event before deploying a series of repeating in-the-moment gratitude exercises.
Proximal assessments	Assessing the impact of the event.	Short educational event might correspond to the proximal outcomes of increasing knowledge and motivation.
Overall micro intervention outcome	The target of the micro intervention which is not likely the same as the overall clinical goals.	Reaching parental sustainable positive attention toward the child (and not reduction in symptoms of the child's behavior problems).
<b>Digital micro intervention care</b>	Using digital micro interventions as building blocks of a larger therapeutic process aimed toward a target outcome.	Providing different digital micro interventions within a long process of helping parents develop emotional and social competences in their child.
Micro interventions	The building blocks of this model of care. See definition of micro intervention above.	See example for a digital micro intervention in the first row.
Conceptual model of the therapeutic process	Defines how digital micro interventions can address steps within the therapeutic process; utilized to identify the relevant digital micro interventions and the context in which they should be used.	Providing a rationale as to how emotional/social competences develop and what issues should be prioritized based on established concepts.
Therapeutic narrative as a linking bridge between interventions	A narrative presented to the user serving as a linking bridge enabling to move from one digital micro intervention to another in a way that consolidates the experience of the different interventions.	An automated prewritten text sent to parents that acknowledges their success in completing two past micro interventions; explains the rationale for the current intervention and in what ways this new intervention is meaningful.
Hub	Centralizes and links between the separate micro interventions; delivers micro interventions as well as the therapeutic narrative based on the conceptual model and an evaluation of user context/needs.	See the "One Hub to Enable Proper Digital Micro Intervention Care" section.

## Defining a Digital Micro Intervention and Its Component Parts

### Overview

Micro interventions differ from standard (ie, more extended) and brief interventions in their breadth, goals, and time frame. Standard and brief interventions are designed to achieve a broad clinical aim (eg, overcome depression and gain desired weight loss) by providing consumers with a complete package of elements [28-30]. Micro interventions, by comparison, are narrower in scope and intended to achieve a highly focused objective [22,23], using in-the-moment elements to promote emotional, cognitive, or behavioral change. These in-the-moment changes are not necessarily linked directly to the achievement of a larger clinical aim, although they may have implications or contributions to such an aim. For example, while a parent training program may aim to target reducing a child's disruptive behaviors as the overall goal (standard intervention), a digital micro intervention will target a much more focused aim such as guiding the parents in several small

steps to help them increase their positive attention toward desired behaviors of their child. Because these interventions are highly focused, in most cases, their time frame will be shorter than other interventions.

We propose that digital micro interventions are based on the following three core components: events (the individual outreaches to the target of the digital micro intervention), decision rules (guiding which events should be deployed and when), and assessments (determining the impact of the event and the intervention). In what follows, we will describe these components in detail.

### Events

Events are the elemental components of digital micro interventions. Each event is an in-the-moment attempt for change or impact toward the overall target of the intervention. A digital micro intervention may be based on one event [31,32] or multiple events [23,33]. Table 2 displays common goals of events along with associated definitions and examples. Events can be informational, such as providing didactic material in the

moment; interventional, such as attempting to spur some form of change or action in the moment like calm breathing; or supportive, such as providing some encouragement, understanding, or social support. The critical aspect is that the

end point for benefit tends to be near term. For example, an informational event should be something that can be taught quickly.

**Table 2.** Common goals of digital micro intervention events, descriptions, and related examples.

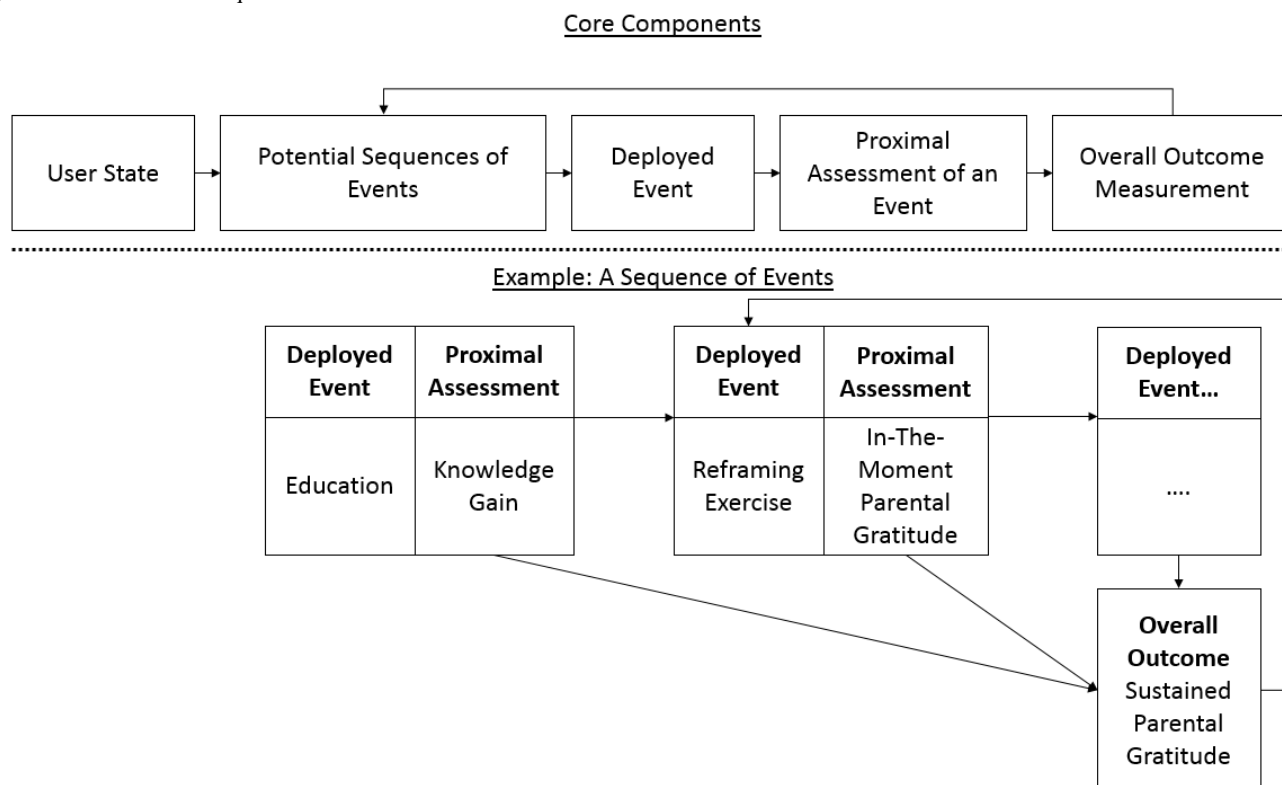

Goals/targets	Description	Example
Educational	Didactic material or psychoeducation intended to teach someone something in the moment.	A video teaching a parent how to discuss the importance of a certain behavior with a child. A timely text message motivating a person to conduct a physical activity.
Feedback	Providing information in the moment to reflect an individual's current state in a beneficial way.	Feedback about how one's current activity compares to activity at another time, such as you walked 15,000 steps today, which is 5000 more than average.
Change of perspective (eg, reframing)	Tunnel individual's focus or provoke thought processes intended to engage a person with a different perspective.	An app-based gratitude exercise encouraging an individual to focus on one's positive attributes, to increase in-the-moment satisfaction [22].
Trigger desired action	Reminder or incentive to get people to engage in a concrete action in the moment.	A notification from a wearable device suggesting that an individual stand [34].
Skill acquisition	Providing support in skill acquisition.	In-the-moment guidance on breathing exercise.
Load reduction of therapeutic-related activity	Enabling the manifestation of a beneficial activity through simplification.	In-the-moment report on calorie intake using a smartphone camera to capture a photo of food.
Symptom relief	Providing relief of negative symptoms.	An app helping a person to identify and perform competing activities to reduce in-the-moment desire for binge drinking.
Social/emotional support	Providing or indicating support from an actual or perceived other.	A text message indicating support or understanding.

## Decision Rules

Decision rules refer to specifications regarding which events should be deployed and when. They sequence and combine events in meaningful ways to create the micro intervention. When decision rules deploy events according to time-based, user-based, or environment-based information, the digital micro interventions can also be referred to as either ecological momentary interventions [35,36] or just-in-time adaptive interventions [37]. The sequence of events that follow from decision rules is closely tied to the intervention developer's understanding of the mechanistic underpinnings of how the micro intervention is perceived to operate (see Figure 1 for a suggested illustration). For example, if an intervention developer designs an intervention with the goal of achieving sustained parental gratitude, including a short educational event before a series of repeating in-the-moment exercises, the developer assumes that knowledge or understanding of the therapeutic rational is necessary prior to the interactive exercises.

This notion of a digital micro intervention as an effective sequence of events has conceptual overlap with the notion of evidence-based kernels of Embry and Bilgan [38]. In their

definition, kernels are influential elements, which constitute “fundamental units of behavior influence in the sense that deleting any component of a kernel would render it inert.” Similarly, the right combination of events is responsible for producing the digital micro intervention's outcome. As such, both the proximal assessments of events and the general outcome of the micro intervention can feed into decision rules to guide future events. Decision rules may also incorporate contextual elements, including a user's state, environmental variables, or previously identified user characteristics, to allow dynamic tailoring of the micro intervention's content [39,40]. For example, if parental gratitude is not sustained in individuals who do not achieve knowledge gain before a successful exercise event routine, it might mean that for individuals who fail in the first event (knowledge gain), there is no need to continue with the planned sequence. Alternatively, it might be that some individuals do not require a gain in knowledge prior to effective exercise events, and therefore, identifying them earlier based on their prior characteristics would enable to offer alternative paths within the same micro intervention. Indeed, contextual variables appear to be important predictors of the likelihood a person will respond to a prompt and engage with the intervention [41].

**Figure 1.** Illustration of a sequence of events based on decision rules.

## Assessments

Assessing a digital micro intervention's impact can be divided into assessing the overall outcome of the intervention and assessing the more proximal outcomes of deployed events. The overall outcome for digital micro interventions can be quite varied, although it is important to differentiate between the intervention outcome and the overall clinical goals, which are likely not the same. A digital micro intervention for individuals with serious mental illness, for example, might focus on medication adherence [42] in the hopes of reducing clinical symptoms. In this case, each event included within the intervention would focus on steps and proximal outcomes related to medication adherence. For example, supporting reasons for taking medication might correspond to the proximal outcome of increasing motivation, and providing tailored reminders for dosing periods or schedules might correspond to the proximal outcome of decreasing the cognitive effort needed to remember to initiate the desired activity. Assessing the overall benefit of this digital micro intervention, therefore, should focus not on how the intervention results in an overall clinical goal (eg, reduced symptoms of serious mental illness), but rather on how it impacts medication adherence. Importantly, if we examine the impact of events, we can explore how much each event contributes to the proximal outcome as well as the overall digital micro intervention goal.

Another aspect that relates to assessments is the user's engagement with the micro intervention. In digital micro interventions, user engagement can be documented continuously based on program usage and experience of engagement (ie, measuring the quality of attention, involvement, and immersion during program usage) [43-46]. These data could be key in

identifying not only those who properly engage with the intervention, but also those who disengage without getting all they need from it, in order to feed intervention decision rules to re-engage the users.

In this section, we have defined a digital micro intervention and presented its component parts. Subsequently, we address aspects that relate to the provision of digital micro intervention care. These aspects require us to take into consideration principles guiding the use of digital micro interventions as building blocks of a larger therapeutic process.

## Digital Micro Intervention Care: Digital Micro Interventions as Building Blocks of a Larger Therapeutic Process

### Overview

As described above, typically, individual micro interventions have relatively specific targets, rather than being full standalone treatments. Therefore, when developers think of a digital micro intervention within a larger therapeutic process, they have to determine what makes the intervention relevant or helpful, which additional digital micro interventions are expected or may be required over time, and how to integrate between the separate interventions within one therapeutic framework. In this section, we aim to address principles that support such a successful integration.

### A Conceptual Model to Guide Which Digital Micro Interventions are Required and in What Context

In order to identify the relevant digital micro interventions and the context in which they should be used, developers need a

conceptual model of the therapeutic process and how digital micro interventions can address steps within this process. As an illustration, consider the example of providing different digital micro interventions within a long process of helping parents develop emotional and social competences in their child. In order to identify the required interventions, it is first necessary to build a rationale as to how these competences develop and are maintained, and what issues should be prioritized. [Table 3](#) presents such an example. The table is based on social learning and behavioral theories [47,48], which build on concepts such

as the parenting pyramid offered in the Incredible Years program [49], and parental monitoring and prevention of child behavior problems [47]. According to the model portrayed in the table, there are levels of parenting behaviors (setting prioritization between basic and more advanced behaviors) and benefits for the child that occur when parents exercise these behaviors. The desired parenting behaviors are then used to identify the relevant digital micro interventions for each level (see examples in [Table 3](#)).

**Table 3.** An example for a model defining the capabilities parents are required to present in order to prevent behavior problems and promote social and emotional competence.

Priority level	Goal	Parent behavior	Examples for relevant digital micro interventions	Child gains
First level	Parental availability	Presence; attention; monitoring	Notifying the parents to put their smartphone away when doing activities with their child; triggering to leave the child a positive note on the kitchen table to increase presence during working days.	Attachment; self-esteem; cooperation
First level	Positive parenting practices	Positive involvement; positive modelling; conversations; play	Teaching how to play with a 4-year-old child through scenario-based learning.	Attachment; self-esteem; cooperation
Second level	Problem solving/prevention	Social coaching; proactive identification of relevant guidelines; consultations	Brief online video guidance on how to coach a 3-year-old child during play on using their mouth instead of their hands.	Social skills; meeting their potential; motivation; accountability
Third level	Dealing with acute negative symptoms	Neglecting unhelpful routines and parenting styles; embracing beneficial practices	Connecting the parent with a peer through an online community in order to find the right consequence for a child's misbehavior.	Back to normative developmental cycle; illness prevention

The prioritization portrayed in the levels also presents the context in which each intervention is mostly relevant. If a digital micro intervention care developer builds on this specific conceptualization, it would not make sense from their view to train parents to set clear limits before they are, for example, present in their children's life. As such, the incorporation of a model helps developers avoid designing and presenting people with a specific micro intervention that is not contextually relevant with the larger perspective in mind.

### Nurturing a Therapeutic Narrative to Link Between Independent Interventions

The literature suggests the importance of a clear therapeutic pathway and rationale to the user's therapeutic process and that relatability factors embedded within a digital intervention support a working alliance [50-53]. A theme can serve as a linking bridge enabling to move from one digital micro intervention to another in a way that consolidates between the different interventions. It is also essential because the right narrative would make the intervention more contextually relevant to the specific process the consumer is going through. For example, a parent who learned and conducted a gratitude exercise with the family around the dinner table may benefit if

it were connected to the theme of overcoming a child's noncompliance, when this digital micro intervention is part of the general aim of treating a child's disruptive behaviors. A different narrative may be in place for the same gratitude-invoking intervention, when the larger goal is different, for example, increasing parenting satisfaction among veterans with posttraumatic stress disorder [54,55]. Another simple example would be a digital micro intervention teaching individuals to change or reframe negative and unhelpful thoughts, which could be used for a broad range of clinical problems [56-58]. Naturally, the binding therapeutic narrative between different digital micro interventions would be different based on the targeted clinical problem.

Because the general process is the result of several digital micro interventions combined together, a therapeutic narrative may also have an important advantage as a moderator of the connection between each intervention and the sense of ownership and commitment toward the general process (see [Figure 2](#) for a suggested illustration). This sense of ownership and commitment may, in turn, lead to beneficial outcomes such as an increase in motivation to invest in subsequent digital micro interventions in the same domain.

**Figure 2.** Nurturing a therapeutic narrative as a moderator to the connection between a digital micro intervention and sense of ownership and commitment to the therapeutic process.

### One Hub to Enable Proper Digital Micro Intervention Care

The setting of multiple digital micro interventions within one therapeutic process requires a hub component in order to centralize and link between the separate interventions based on the principles discussed above. The hub is aimed at instilling a sense of accountability in the client [59] and at creating an integrated experience that relates to the therapeutic process, while taking an individual's history into account. The hub meets these aims by (1) recognizing an individual's state and context, (2) recommending interventions that are relevant, and (3) helping create and maintain the right narrative, meaning, and values that derive from each intervention and linking it to the larger therapeutic process.

The hub function could be performed by any entity that is set to meet these aims (a digital application, a human technology coach, a consumer who self-manages his or her state, or a psychotherapist). For example, in their study of the IntelliCare suite of apps aimed at treating depression and anxiety, Mohr and colleagues used a digital app as a hub that consolidated recommendations for the use of new apps [60]. Recommendations were based on a user's current usage data of different apps within the IntelliCare suite to identify apps that the person will most likely use and find useful. Eventually, 95% of participants downloaded five or more IntelliCare apps as part of their therapeutic process, demonstrating both the technical feasibility and acceptability of this approach [60]. In another study, health technology coaches met occasionally with patients diagnosed with schizophrenia and suggested different digital tools based on individuals' rehabilitation states and needs, and the impact of the tools they were using over time [61]. We could eventually see a new form of care, where a clinician (eg, a psychotherapist and psychiatrist) acts as a facilitator and meets with patients to suggest personalized digital micro interventions, including apps and online community support.

Figure 3 presents a visualization of the relationship between the core components of digital micro intervention care and aims to represent how the facilitator (digital app, health technology coach, clinician, etc) integrates different interventions to curate one whole therapeutic process. The key components are as follows:

(1) *The conceptual model*: Defines which digital micro interventions are required, the relevant therapeutic narratives that link between different interventions, and the need states that also determine the evaluation scheme.

(2) *Digital micro intervention planner/identifier*: Encompasses the process of identifying the relevant interventions that are currently available and planning new interventions. The required interventions are defined based on the targeted need states determined within the conceptual model (see Table 3 for an example).

(3) *Digital micro intervention suite*: Includes all the potential interventions that are available. Once a need state is identified, the relevant intervention will be offered to the individual.

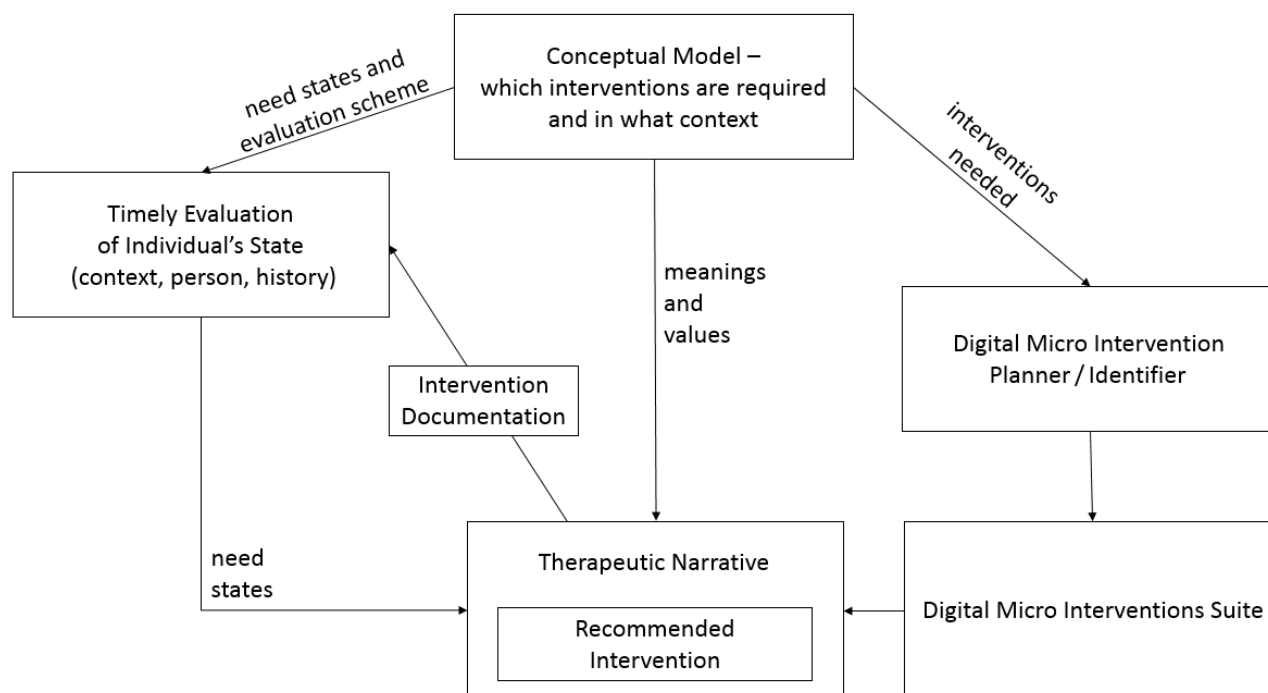

(4) *Timely evaluation of an individual's state*: The evaluation scheme is based on data that relates to the individual (eg, symptoms and demographics), context (eg, changes in the environment that may change an individual's needs), and details about past interventions and their outcomes. Need states can be alerted in two different ways. First, predefined rules can be made to trigger an evaluation based on a fixed time (eg, every 3 months) or context (eg, on a weekend when an individual is presumed to be more free or weekday when an individual is presumed to be working). Second, an individual can decide to report on his/her condition or the needs encountered, which will activate an evaluation.

(5) *Intervention phase*: The intervention phase is based on two different components. The basic component is the digital micro intervention itself. The second component represents the therapeutic narrative. The latter involves the following: (1) explaining the rationale for recommending the current micro intervention to the consumer, (2) clarifying how it relates to the general therapeutic process (if relevant based on the conceptual model), (3) integrating the current and past experiences (eg, success/failure in a previous intervention), and (4) relating to the future (eg, at the end of the intervention [what is going to happen next and why]) in relevant cases. Multimedia Appendix 1 presents an example of an automated therapeutic narrative that could be formed based on these subject matters.

(6) *Intervention documentation*: Summary data relating to engagement and outcomes are documented and used to feed the

timely evaluation of an individual's state. For example, if an individual disengages from an intervention without a clear change in symptoms and context, a different micro intervention can be offered.

**Figure 3.** Visualization of the relationship between core components of digital micro intervention care.

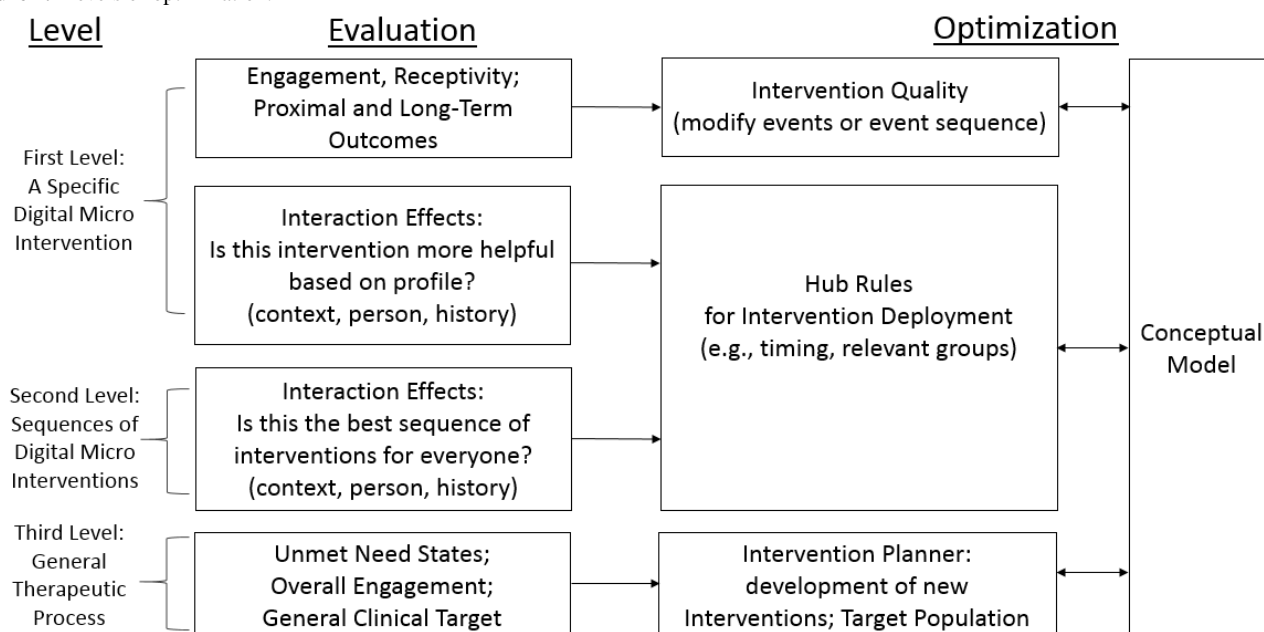

## Ongoing Optimization

The success of the therapeutic process is limited by each of the units (micro interventions) within it and the ways they are linked and interact with each other. An iterative approach may enable the identification of those interventions that are missing or less effective, or a need to refine the conceptual model, for ongoing development of the intervention ecosystem. This paper's focus is not on the methodological aspects of intervention optimization strategies; however, we refer the reader to the Multiphase Optimization Strategy as a good example for a methodological framework aimed at intervention optimization [62]. We find this framework to be relevant to digital micro intervention optimization because it is aimed at identifying the core sequence of elements that are efficacious, while providing a feasible method to account for potential intervening variables.

Figure 4 presents the different areas of evaluation that could be expected in order to build on past knowledge to optimize the system of care based on several levels of examination. The first level of optimization focuses on a specific digital micro intervention. The receptivity and impact of the intervention is measured by user engagement, proximal events, and long-term outcomes. These results lead to optimization of the

intervention's quality, and may raise subsequent questions about the intervention's impact that will require to add additional or alternative events or assessments. A subsequent evaluation involves the identification of specific populations and past experiences for whom/which the intervention was more or less successful (an interaction effect). The second level of optimization refers to the intervention sequence. Similar to the interaction effect examined in one digital micro intervention's context, it involves identifying the best sequence of *interventions* that may differ based on the client's context. The third and last level refers to the therapeutic process. It aims at understanding whether there are new need states that are not yet covered within the system, whether the clinical target is achieved, and in which cases. For example, if there are individuals who are properly engaged with the recommended sequence of micro interventions but do not reach the clinical target or individuals not engaged with any micro interventions that were offered. This will lead to optimizing the intervention planning and characterizing the user population for whom this system of care is relevant, and to the development of new interventions. The conceptual model is relevant in all levels of optimization because developers' understanding of what works and for whom enables refinement of the model itself, which is then used to optimize the interventions and their sequence.

**Figure 4.** Levels of optimization.

### Example: Digital Micro Intervention Care Versus a Stepped-Care Approach

In this final section of the paper, we compare the concept of digital micro intervention care to a stepped-care approach. Stepped care is a common conceptualization that combines a set of interventions within one therapeutic process [63-65]. A stepped care approach is defined by two main principles. First, the least intensive/restrictive treatment that is expected to provide the desired health gain is offered to the patient. Second, the model is adaptive in the sense that those individuals who do not reach a desired health gain in a predetermined time period will be assigned to a more intensive/restrictive treatment option. Therefore, a stepped-care approach is based on treatments designed to reach the desired health target, where these treatments differ in intensity. In contrast, a single digital micro intervention is not expected to support a full therapeutic target (eg, overcoming depression) but rather be a step along the way. This is reasonable given that when conceptualizing the use of multiple digital micro interventions, we do not assume that people are willing to invest as much effort as ideally needed to complete a whole target of therapeutic processes.

Figure 5 presents illustrations of the two frameworks, based on these underlying differences in delivery of care. In comparison to a stepped-care model, the following aspects are noted in digital micro intervention care: (1) Each intervention unit is highly focused and is generally short, reducing the effort needed for completion; (2) The setting of care does not prioritize intervention sequence based on treatment intensity, but rather based on a complex understanding of people's needs and preferences (as described in the conceptual model section). Therefore, we do not see a graded intervention sequence in terms of intensity; (3) The therapeutic sequence does not focus on a given time window in which an intervention occurs continuously until completion, as would be expected in traditional models of proactive treatment delivery. This means that the therapeutic sequence may be very long and that individuals are sometimes engaged and sometimes not engaged with any intervention. In some cases, people do not receive any intervention most of the time. Maintaining ongoing contact with users may be required to allow triggering of the right intervention at the right time; (4) There might be a large number of different digital micro interventions to achieve the target of the treatment process, in comparison to stepped care models that are mostly based on few interventions (although each standard intervention includes multiple components).

**Figure 5.** Illustrations of stepped care and digital micro intervention care models.

## Conclusions

Digital micro interventions may provide new ways to deliver behavioral and mental health interventions while meeting people's capacity to invest a small effort in beneficial therapeutics. The development of digital micro interventions, however, demands new thinking. We cannot merely take previous interventions based on other models and assume they will have the focused and immediate impacts required of micro interventions. As such, we have proposed a novel model of understanding digital micro interventions by identifying their component parts (events), how these parts work together (decision rules), and how digital micro interventions might be incorporated into a larger therapeutic process. This model is helpful to assist researchers in optimizing digital micro interventions, developing a conceptual understanding of each intervention's role within a larger process, and leaning on principles to best integrate between these interventions over time.

It is worth noting, however, that multiple issues related to digital micro interventions still need to be resolved. First, research methodologies that can facilitate the evaluation of micro interventions are required. Micro randomized trials are one such methodology that could be of use here, especially when research questions are related to dynamic processes of change over time [66]. Second, methods for optimizing digital micro interventions

and improving micro intervention suites need to be explored. Third, we need to understand the people and targets for which the delivery of digital micro intervention care is more or less suitable.

Much of the current innovation in micro interventions has made use of technological affordances as technology makes it more feasible to deliver digital micro interventions in various ways. However, again, it does not necessarily mean that this sort of intervention has to be digital by nature. Because technology is highly embedded in our lives, it is possible that digital capabilities such as automated monitoring, triggering, and instant messaging tools will be commonly integrated into care, making the differentiation between digital and nondigital tools less relevant.

Expanding the portfolio of behavioral and mental health interventions to include interventions that allow people to interact in various modalities, intensities, and styles is likely necessary to make such interventions available to the vast number of people who could stand to benefit from them. Digital micro interventions represent one example of such an expansion, as they are brief, focused, and potentially more appropriate for people who enter with various levels of motivation. We hope the model represented here will structure and speed the work in this area and improve the research and delivery of digital micro intervention care.

## Conflicts of Interest

SMS has received payment for consulting from Otsuka Pharmaceutical. TF is a co-developer of SPARX computerized cognitive behavioral therapy for adolescent depression. The IP for SPARX is owned by Uniservices at The University of Auckland. Developers can benefit financially from licensing or sales of SPARX outside of New Zealand. ## Abstract

**Background:** Medication adherence is important in managing the progression of chronic diseases. A promising approach to reduce cognitive burden when measuring medication adherence lies in the use of computer - adaptive tests (CATs) or in the development of shorter patient-reported outcome measures (PROMs). However, the lack of an item bank currently hampers this progress.

**Objective:** We aim to develop an item bank to measure general medication adherence.

**Methods:** Using the preferred reporting items for systematic review and meta-analysis (PRISMA), articles published before October 2019 were retrieved from PubMed, Embase, CINAHL, the Cochrane Library, and Web of Science. Items from existing PROMs were classified and selected ("binned" and "winnowed") according to standards published by the Patient-Reported Outcomes Measurement Information System (PROMIS) Cooperative Group.

**Results:** A total of 126 unique PROMs were identified from 213 studies in 48 countries. Items from the literature review (47 PROMs with 579 items for which permission has been obtained) underwent binning and winnowing. This resulted in 421 candidate items (77 extent of adherence and 344 reasons for adherence).

**Conclusions:** We developed an item bank for measuring general medication adherence using items from validated PROMs. This will allow researchers to create new PROMs from selected items and provide the foundation to develop CATs.

**KEYWORDS**

systematic review; patient-reported outcome measures; item bank; adherence

**Introduction**

Medication adherence is defined as the degree to which a patient's behavior corresponds with the agreed recommendations from a health care provider [1]. The average adherence rate ranges from 50% among patients suffering from chronic diseases in developed countries [2] to 79% among those receiving medical treatment prescribed by a nonpsychiatrist physician [3,4]. Nonetheless, medication nonadherence is recognized as a significant public health issue since it can result in poor health outcomes and increased health care costs [5]. Medication adherence, which is important in managing the progression of chronic diseases, may be assessed using patient-reported outcome measures (PROMs). Using PROMs to measure medication adherence may be susceptible to a social desirability bias [6]; however, PROMs are much more practical in daily clinical practice because of their relatively low cost and ease of administration as compared to pill counting or an electronic monitoring system such as the medication event monitoring system (MEMS).

PROMs are measures of the status of a patient's health condition that originate directly from the patient, without interpretation of the patient's response by a caregiver or physician [7]. Numerous PROMs have been developed and validated to measure medication adherence. These include instruments such as the Medication Adherence Report Scale (MARS) [8], the 4- and 8-item Morisky Medication Adherence Scale (MMAS-4 and MMAS-8) [9], the Hill-Bone Medication Adherence (HBMA) scale [10], and the Domains of Subjective Extent of Nonadherence (DOSE-Nonadherence) scale [11]. However, most self-report measures that were developed using classical test theory [12,13] are static and administered using a common item set regardless of the respondent's level of medication adherence [14]. Since patients are asked the same questions repeatedly, this approach results in significant cognitive burden [15], low precision [16], a waste of the patients' time, as well as a lack of additional, new information [17].

A novel approach to overcome this limitation lies in the use of a computer - adaptive test (CAT) to create new PROMs for measuring medication adherence. A CAT is a system for tailoring a test, whereby the next item administered to the respondent is determined by and adaptive to the patient's response to the previously-administered item [18]. The Patient-Reported Outcomes Measurement Information System (PROMIS) was developed through a CAT and item response theory (IRT). Instead of focusing on the entire test, IRT shifts the focus to the individual questions [19]. The use of IRT with a CAT allows for the identification, individualization, and administration of a feasible number of items that are likely to offer the highest precision [20]. In order to achieve higher precision, PROMIS investigators were required to identify and develop items covering the full range of experience in the domains the instrument was intended to measure (ie, content

validity) [14]. Thus, the first step to a CAT is an item bank consisting of questions from medication adherence PROMs. Therefore, this systematic literature review aims to identify and develop an item bank through a comprehensive summary of the questions from validated medication adherence PROMs.

**Methods**

This systematic review was guided by the preferred reporting items for systematic review and meta-analysis (PRISMA) statement [21]; standards published by the PROMIS committee [22] were adapted in the development of the item bank.

**Search Strategy**

Articles published before October 2019 were retrieved from PubMed, Embase, CINAHL, the Cochrane Library, and Web of Science. A search strategy (Multimedia Appendix 1) of 4 components was used as follows: construct of interest, population, instrument, and measurement properties. The searches focused on medication adherence PROMs. Where available, the sensitivity of the searches was enhanced using search filters developed by Terwee et al [23], which involves a combination of search terms designed to retrieve studies on measurement properties of measurement instruments. The search records were downloaded into Endnote X9 (Clarivate Analytics), and any duplicates were removed.

**Article Selection**

All titles and abstracts were screened independently by 2 reviewers (LJYO and SDW). A third reviewer (YHK) was consulted when a disagreement arose between the 2 reviewers. For articles that were potentially relevant, the full text of these articles was independently reviewed by the same 2 reviewers for inclusion or exclusion.

Articles were included if they were full-text original publications in English that validated PROMs for medication adherence. Articles were excluded if the PROMs were completed by proxy, or if they were conference abstracts, expert opinions, narrative reviews, or not peer-reviewed. Animal and case studies, as well as non-English language studies, were also excluded. These exclusions were not used to construct the search strategy to avoid the omission of relevant articles.

**Data Extraction**

Where available, 2 reviewers (LJYO and SDW) extracted study population characteristics (sample size, age, gender, and country) data from the articles.

**Identification of Existing PROMs for Inclusion**

The names of PROMs extracted from the previous step were consolidated. In order to optimize the number of relevant items for evaluation, the most recent and exhaustive version was included when multiple versions of the same PROM were found across the included studies.

For the assessment of PROMs for inclusion, reviewers obtained information regarding the PROM through internet searches. Copies of the shortlisted PROMs were retrieved either from sources available to the public (ie, official websites or research publications) or by requesting copies from the developers or study investigators of these PROMs. Permission was obtained from the study investigators for the inclusion of the PROM into the item bank. Where possible, permission from the PROM developers was sought in the case that the study investigators were not in a position to provide consent due to claims of intellectual property. After the initial contact, 2 follow-up reminder emails were sent to the unresponsive study investigators. This resulted in a final list of PROMs from which items were extracted and evaluated.

### Item Classification (Binning)

Item classification, or binning, refers to a systematic process for grouping items according to meaning and specific latent construct. This process aims to obtain a bin with the most exhaustive list of items, from which a smaller number of items may be chosen to adequately represent the bin. The number of items that would adequately represent a bin was not predetermined, as the purpose of this process was to identify sufficient items that encompass the meaning of the bin and to eliminate unnecessary redundancy in the pool of items [14].

Binning was done using terms in English, and each item was included in as many bins as was deemed fit. To ensure that the binning process was exhaustive, 2 independent reviewers (LJYO and DHFL) evaluated any one item for possible inclusion, and an item identified for inclusion to a bin by at least 1 reviewer was included in that bin.

A 2-stage process was carried out for binning. First-order binning was completed at the level of the domain: each item was evaluated for possible inclusion into (1) Extent of Adherence and/or (2) Reasons for Nonadherence. The domains were derived from the self-report measure developed by Voils et al [11].

For the Reasons for Nonadherence domain, second-order binning was completed at the level of the subdomain consisting of (1) social- and economic-related factors, (2) health care team and system-related factors, (3) therapy-related factors, (4) condition-related factors, and (5) patient-related factors. The subdomains were derived from the World Health Organisation (WHO) framework for medication adherence [2]. The

framework has been widely used in various literature [24-32]. Second-order binning was not deemed to be necessary for the Extent of Adherence domain.

### Item Selection (Winnowing)

The process of winnowing aims to narrow the large pool of items down to a representative set of items; this is done by identifying item characteristics that would either include or exclude items from the item bank based on the definition of the domains [14]. Winnowing was performed by 2 reviewers (LJYO and DHFL) independently assessing each bin, and items that best represented the respective domains were first selected. The process was carried out separately for each domain.

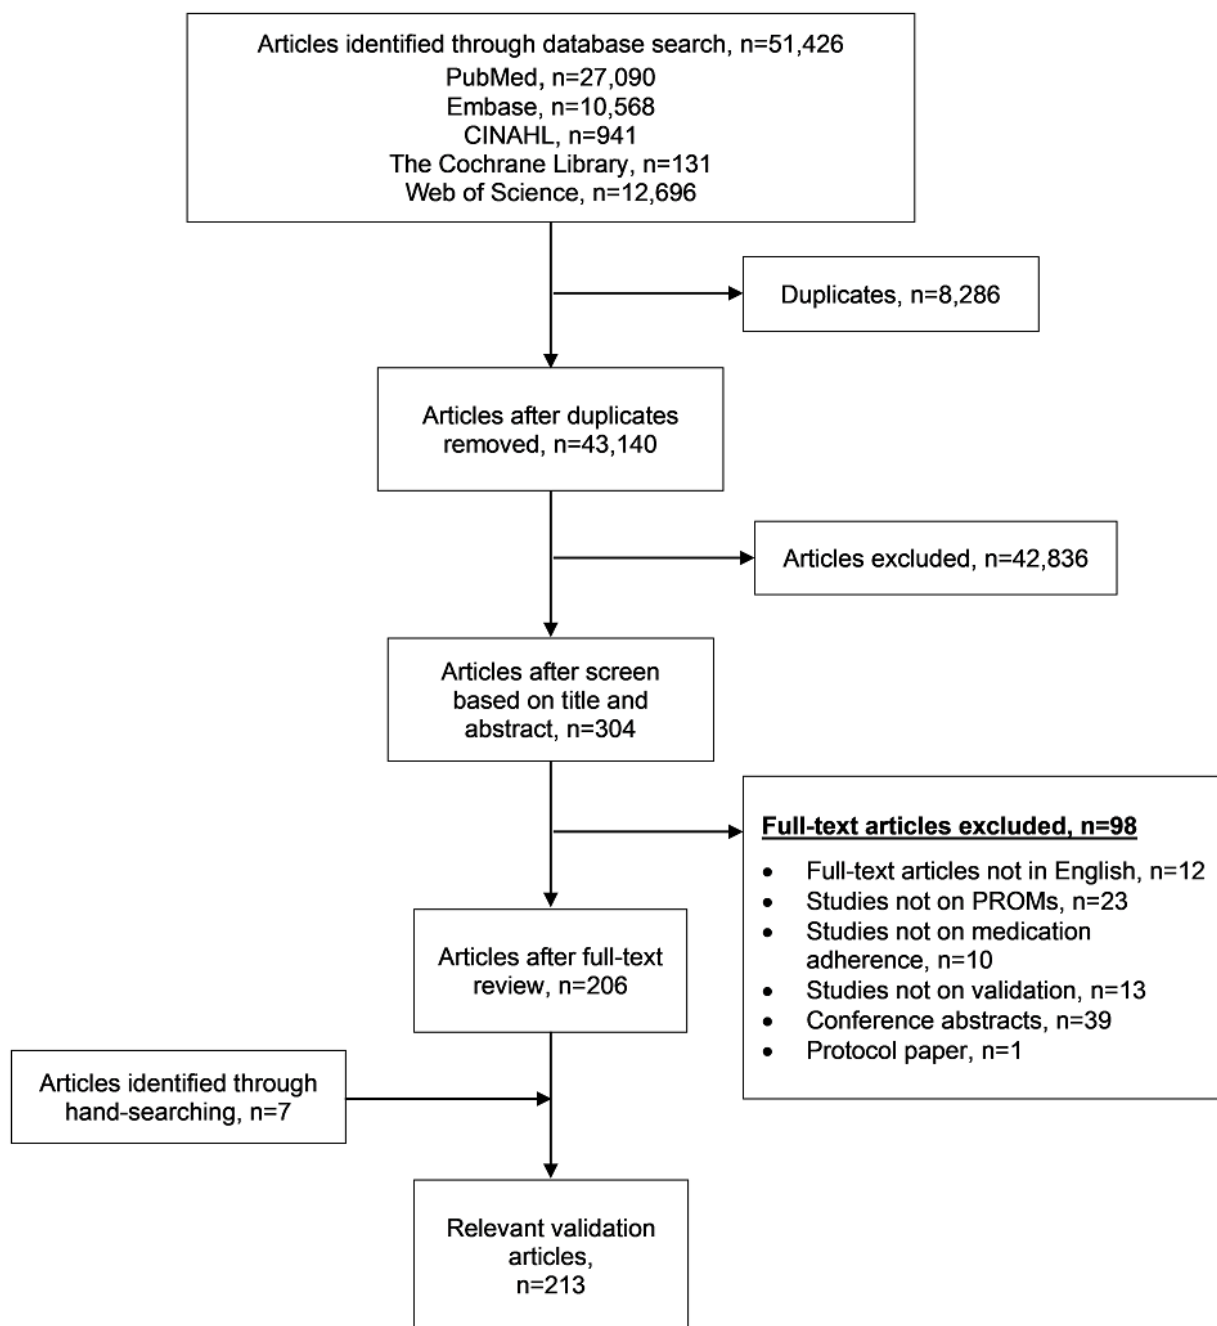

The following criteria were used to eliminate items from consideration [14]: (1) the content of the item was inconsistent with the definition of medication adherence, or with the scope of the extent of and reasons for medication adherence; (2) the item was semantically redundant with a previous item; (3) the content of the item was too narrow to be universally applicable; (4) the stem of the item was highly disease-specific, which reduces overall applicability and limits the adaptation of the item; (5) the item was confusing; and (6) the item was open-ended, which increases the difficulty of implementation.

After the pair of reviewers completed the item selection independently, a third reviewer (YHK), who is trained in measurement science and item banking and was not previously involved in the binning and winnowing process, was consulted to identify the items that best represented each domain, as well as the items for removal.

## Results

### Search Results and Characteristics of the Included Articles

A total of 51,426 studies were obtained from the database search, of which 8286 duplicates were excluded. A review of the titles and abstracts led to the exclusion of 42,836 studies. Subsequently, full-text review excluded 98 studies, with reasons provided in Figure 1. An additional 7 studies were identified through hand-searching of reference lists, resulting in 213 relevant validation studies for potential inclusion into the item bank. The characteristics of the relevant studies are presented in Table 1.

**Figure 1.** Flow chart of the systematic literature review.

**Table 1.** Characteristics of studies for potential inclusion into the item bank (n=213).

General Characteristics	Values
Number of unique countries involved	48
Number of unique PROMs <sup>a</sup> studied	126
<b>Sample size, n (%)</b>	
< 50	17 (8.0)
50 – 99	31 (14.6)
100 – 199	64 (30.0)
200 – 299	30 (14.1)
300 – 399	22 (10.3)
400 – 499	15 (7.0)
> 500	34 (16.0)
<b>Mean age in years, n (%)</b>	
0 < mean age ≤ 20	9 (4.2)
20 < mean age ≤ 40	28 (13.2)
40 < mean age ≤ 60	101 (47.4)
60 < mean age ≤ 80	54 (25.4)
≥ 80	2 (0.9)

### Identification of Existing PROMs for Inclusion

The review of the included articles identified 126 unique PROMs measuring medication adherence, which were validated in 48 countries. A majority of the identified PROMs were self-administered questionnaires.

After obtaining written permission from the study investigators and PROM developers for the use of the items as part of the item bank, 47 PROMs from 53 studies were included in the item bank, as presented in [Textbox 1](#). PROMs from the

remaining 160 studies ([Multimedia Appendix 2 \[33-189\]](#)) were excluded due to a lack of consent. Among the 53 included studies, the Modified Drug Adherence Work-Up (M-DRAW) tool, the Reduced Glaucoma Treatment Compliance Assessment Tool (GTCAT), and the 3-Item Self-Report Measure for Medication Adherence were each evaluated in 2 studies; the General Medication Adherence Scale (GMAS) was evaluated in 3 studies; and DOSE-Nonadherence was evaluated in 4 studies. PROMs included were mostly developed and validated in English. A total of 579 items were collated from these PROMs, including 71 non-English items.

**Textbox 1.** List of the patient-reported outcome measures (PROMs) that were included in the item bank. \*Instruments which were not named; \*\*instruments developed/validated in non-English but have an existing English-translated version for publication purposes; \*\*\*instruments developed and/or validated in non-English.

#### Generic PROMs

- Diagnostic Adherence to Medication Scale (DAMS) [190] (6 items)
- 7-Item Adherence to Refills and Medications Scale (ARMS-7) [191]\*\* (7 items)
- Adherence to Refills and Medications Scale (ARMS) [192] (12 items)
- Brief Medication Adherence Scale (BMAS) [193]\*\* (10 items)
- Domains of Subjective Extent of Nonadherence (DOSE-Nonadherence) Scale [11,194-196] (21 items)
- Every Visit Adherence Questionnaire [197] (1 item)
- General Medication Adherence Scale (GMAS) [198-200] (11 items)
- Medication Adherence Estimation and Differentiation Scale (MEDS) [201] (16 items)
- Modified Drug Adherence Work-Up (M-DRAW) Tool [202,203] (14 items)
- Self-Reported Adherence (SERAD) Questionnaire [204]\*\*\* (2 items)
- Simplified Medication Adherence Questionnaire (SMAQ) [205] (6 items)
- 3-Item Self-Report Measure for Medication Adherence [206,207]\* (3 items)

#### Disease-Specific PROMs

- 12-Item Medication Adherence Scale for Patients with Chronic Disease [208]\* (12 items)
- 5-Item Compliance Questionnaire for Rheumatology (CQR5) [209] (5 items)
- Adult Asthma Adherence Questionnaire (AAAQ) [210] (5 items)
- Antidepressant Adherence Scale (AAS) [211] (4 items)
- Antipsychotic Medication Beliefs and Attitudes Scale (AMBAS) [212] (12 items)
- Assessment Scale for Treatment Compliance in Type 2 Diabetes Mellitus [213]\* (30 items)
- Brief Evaluation of Medication Influences and Beliefs (BEMIB) [214] (8 items)
- Chinese and Western Medication Adherence Scale in Chronic Kidney Disease [215]\* (18 items)
- Chinese Diabetes Medication Self-Efficacy Scale (CDMSS) [216]\*\*\* (19 items)
- Combination Antiretroviral Therapy Adherence Questionnaire [217]\* (4 items)
- Diabetes Management Questionnaire (DMQ) [218] (21 items)
- Diabetes Medication Self-Efficacy Scale (DMSS) [219] (19 items)
- ICAMP Adherence Questionnaire [220] (10 items)
- Immunosuppressant Therapy Adherence Scale (ITAS) [221]\*\*\* (4 items)
- Iraqi Anti-Diabetic Medication Adherence Scale (IADMAS) [222] (8 items)
- IRT-30 [223] (10 items)
- Lasso-10 [223] (30 items)
- Measure for Intention to Adhere to HIV Treatment [224]\* (14 items)
- Medication Adherence Self-Reports in Adults with Type 2 Diabetes [225]\* (6 items)
- Medication Adherence Survey for Hemodialysis Patients [226]\* (23 items)
- Multiple Sclerosis Treatment Adherence Questionnaire (MS-TAQ) [227] (11 items)
- Outcome Expectations for Osteoporosis Medication Adherence Scale in Chinese Immigrants (OEOMA-C) [228]\*\* (5 items)
- Patient-Reported Measures Assessing Adherence Behaviors and Barriers in Patients Living with HIV [229]\* (7 items)
- Perceived Barriers to Antiretroviral Therapy Adherence (PEDIA) Scale [230]\*\* (18 items)
- Portuguese End-Stage Renal Disease Questionnaire (PESRD-AQ) [231]\*\*\* (46 items)
- Questionnaire for Adherence with Topical Treatments in Psoriasis (QATOP) [232] (9 items)
- Reduced Glaucoma Treatment Compliance Assessment Tool (GTCAT) [233,234] (28 items)

- Risk of Nonadherence to Antibiotic Treatment Questionnaire [235]\* (20 items)
- Self-Assessment Tool to Measure Imatinib Adherence in Patients with Chronic Myeloid Leukemia [236]\* (10 items)
- Self-Efficacy for Osteoporosis Medication Adherence Scale in Chinese Immigrants (SEOMA-C) [228]\*\* (14 items)
- Self-Report Measures in Assessing Antiretroviral Adherence [237]\* (3 items)
- Self-Reported Compliance to Metered-Dose Inhalers Questionnaire [238]\* (4 items)
- Self-Reported Questionnaire Assessing Adherence to Antiretroviral Medication [239]\* (5 items)
- Test of the Adherence to Inhalers (TAI) [240] (12 items)
- Treatment Adherence Survey – Patient Version (TAS-P) [241] (16 items)

## Item Evaluation

At the stage of winnowing, 319 items inconsistent with the definitions of the domains or subdomains were removed. The 2 independent reviewers achieved a 90.4% agreement on the items for removal. Most eliminated items were found to be highly disease-specific (eg, “I arrange my oral antidiabetic medication or insulin dose myself according to my food intake.”) or open-ended (eg, “How many doses did you miss?”).

In the Extent of Adherence, a total of 77 representative items were identified, while 344 items were included in the Reasons for Nonadherence, with an average of 70 items (SD 43.1; range 24–137) within each of the 5 dimensions. The breakdown of the number of items in each domain and subdomain is summarised in Table 2, and a representative table of the mapping of each item is presented in Multimedia Appendix 3. Binned and winnowed items that were granted approval by the study investigators or PROM developers to be openly listed in the item bank are presented in Multimedia Appendix 4.

**Table 2.** Summary of domains and the number of items in each bin.

Domain/subdomain	Number of items
Extent of adherence	77
<b>Reasons for adherence</b>	
Social and economic factors	32
Health care team and system-related factors	24
Condition-related factors	37
Therapy-related factors	114
Patient-related factors	137

## Discussion

This systematic review summarises the process of developing an item bank for the domain of general medication adherence. A multistep approach adapted from the PROMIS standards for the development of item banks [14] was used. In order to enhance the comprehensiveness of the item bank, items originating from both disease-specific and nondisease specific PROMs were considered and reviewed for inclusion. To the best of our knowledge, this is the first systematic review to collate items from various medication adherence PROMs into an item bank. As numerous PROMs have been developed and validated for use in the measurement of medication adherence, an item bank consisting of the most representative items may improve the relevance and precision of assessments [242].

The current item bank enables researchers to select items for the creation of new PROMs. The rare and highly disease-specific items were eliminated during the winnowing process; however, the items included in the item bank may be adapted for use in both specific patient groups and the general population. There have been conflicting results on the association between age and medical adherence, with some studies providing evidence

of an association between younger age and nonadherence [243] and others showing an association between older age and nonadherence [244]. A CAT that was developed using IRT based on our item bank can potentially examine the changing pattern of medical adherence during a lifetime more precisely than traditional PROMs that are developed using classical test theory [245,246]. In addition, previous studies have shown that adherence to different medications may vary within the same individual [247,248]. We can potentially overcome this issue by specifying the type of medication in the question stem in the CAT.

Towards the use of the item bank in CATs, the next steps are to revise and review the items through cognitive interviews, to calibrate the items using IRT, and to evaluate the validity of test scores when the items are administered adaptively. The items that underwent binning and winnowing originated from various PROMs. They were created in varying styles, phrasings, and sentence structures, with different response options for each item, including dichotomous, Likert, and semantic differential scales. Due to the discordances among the items, the item revision process would be prudent to facilitate the administration of the items as 1 coherent test. Once fully developed, the resulting instrument may potentially improve measurement

precision and allow for a reduction in assessment time [249] and, accordingly, patient cognitive burden. Furthermore, since the scores are directly comparable [250], such an instrument would allow health care providers to measure and compare the medication adherence of a patient from consult to consult. Alongside other clinical measures, such as symptom scores and quality of life scales, these measurements may enable physicians to detect issues in a patient's medication adherence, implement timely interventions, evaluate the effectiveness of the interventions, and make prompt modifications when necessary.

This study has several strengths; 5 databases, as well as sensitive search filters, were used to capture as many potentially relevant articles as possible. The rigor of this study was established using the PRISMA statement and PROMIS standards. The PRISMA statement was used because it enhances the transparency and clarity of systematic reviews [251]. The utilization of modern statistical methods to improve the functionality of PROMs has elevated the expectations of instruments beyond robust psychometric properties. As such, the PROMIS standards were adapted for use as they endorse the minimum standards for PROMs used in patient-centered health outcomes and facilitate the development of common metrics for accurate comparisons across conditions, healthcare systems, and geographical locations [252].

This systematic review has some limitations. Firstly, we only included full-text articles in English. Full-text articles were necessary as they are peer-reviewed and recommended by Terwee et al [253]. Nonetheless, the 12 foreign-language articles that would otherwise be eligible for full-text review made up only 3.9% of the included articles. Secondly, the item bank does not include items developed by the 160 authors (75.1% of the

articles assessed for inclusion) who either chose not to consent to the inclusion of their PROMs or were uncontactable. Of note, PROMs included in the item bank have adequately captured the concepts measured by the majority of items for which consent was not obtained. To ensure that no range of concepts has been overlooked from the exclusion of the studies, future studies can consider conducting interviews with patients, as well as conducting expert opinion reviews to elicit the conceptual model for medical adherence relevant to the local context. Thirdly, this systematic review only included validation studies of medication adherence PROMs. This was deemed appropriate given the importance of validation in justifying the use of the instrument [254]. Well-validated adherence scales have been strongly correlated with objective measures of adherence [255], allowing accurate and reliable assessment of medication adherence. In addition, expert review and patient feedback were not sought as part of the item evaluation process in this study. As the concept of medical adherence may differ between different sociocultural contexts [256,257], different countries should perform an expert review and gather patient feedback through cognitive interviews based on this item bank to ensure the development of a culturally sensitive instrument to measure medication adherence.

In conclusion, this study has identified and collated the items from 47 unique medication adherence PROMs into an item bank through a systematic review. Researchers are able to select appropriate items from the item bank for the creation of new PROMs. Future research may consider revising and reviewing the items through cognitive interviews, calibrating the items through IRT, and developing a CAT to measure medication adherence precisely.

## Abstract

**Background:** Medication adherence is essential for improving the health outcomes of patients. Various patient-reported outcome measures (PROMs) have been developed to measure medication adherence in patients. However, no study has summarized the psychometric properties of these PROMs to guide selection for use in clinical practice or research.

**Objective:** This study aims to evaluate the quality of the PROMs used to measure medication adherence.

**Methods:** This study was guided by the PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analysis) guidelines. Relevant articles were retrieved from the EMBASE, PubMed, Cochrane Library, Web of Science, and CINAHL (Cumulative Index to Nursing and Allied Health Literature) databases. The PROMs were then evaluated based on the CoConsensus-based Standards for the selection of health Measurement Instruments (COSMIN) guidelines.

**Results:** A total of 121 unique medication adherence PROMs from 214 studies were identified. *Hypotheses testing for construct validity* and *internal consistency* were the most frequently assessed measurement properties. PROMs with at least a *moderate* level of evidence for  $\geq 5$  measurement properties include the Adherence Starts with Knowledge 20, Compliance Questionnaire-Rheumatology, General Medication Adherence Scale, Hill-Bone Scale, Immunosuppressant Therapy Barrier Scale, Medication Adherence Reasons Scale (MAR-Scale) revised, 5-item Medication Adherence Rating Scale (MARS-5), 9-item MARS (MARS-9), 4-item Morisky Medication Adherence Scale (MMAS-4), 8-item MMAS (MMAS-8), Self-efficacy for

Appropriate Medication Adherence Scale, Satisfaction with Iron Chelation Therapy, Test of Adherence to Inhalers, and questionnaire by Voils. The MAR-Scale revised, MMAS-4, and MMAS-8 have been administered electronically.

**Conclusions:** This study identified 121 PROMs for medication adherence and provided synthesized evidence for the measurement properties of these PROMs. The findings from this study may assist clinicians and researchers in selecting suitable PROMs to assess medication adherence.

## KEYWORDS

systematic review; reliability and validity; medication adherence; patient reported outcome measures

## Introduction

Medication adherence is known as “the degree to which the person’s behaviour corresponds with the agreed recommendations from a healthcare provider” [1]. Medication adherence is essential when it comes to improving the health outcomes of patients, especially for chronic diseases [2,3]. However, only approximately half of the patients worldwide adhere to their prescribed medication regimen [4]. Reasons for medication nonadherence include complexity of the treatment regimen, poor communication with health care providers, and concerns about side effects from taking medications [5]. Poor medication adherence may lead to worse health outcomes and higher rates of mortality and morbidity [1,6]. Nonadherence also incurs a high cost burden to the health care system by increasing hospital visits as well as causing unnecessary escalation to more expensive treatments [1]. Therefore, improving medication adherence is key to improving treatment outcomes [7,8].

To successfully improve medication adherence, there is a need for the accurate assessment of medication adherence. Current practices for measuring medication include direct measures such as drug assays of blood or urine as well as indirect measures of adherence such as pill count, electronic monitoring devices, and the use of big data such as review of prescription records and claims [9,10]. Some of these measures are not time efficient and are likely to be unsustainable in clinical practice. Various patient-reported outcome measures (PROMs) such as the Morisky Medication Adherence Scale (MMAS) [11], Hill-Bone Compliance Scale [12], and Medication Adherence Rating Scale (MARS) [13] have been developed to measure self-reported adherence to medications. These PROMs may be useful in clinical practice because they are easy to administer. On the basis of the patients’ PROM ratings, health care professionals may be able to provide timely feedback. Thus, underlying issues that contribute to medication noncompliance can be addressed at the point of care [14].

A number of previous studies have been conducted to validate PROMs on medication adherence [12,15-17], and a previous systematic review found 14 PROMs that assessed adherence to inhaled asthma maintenance medication alone [18]. However, to date, there is no comprehensive review that summarizes the psychometric properties of PROMs for medication adherence, which is essential to guide the selection of suitable PROMs to evaluate medication adherence in patients. Hence, we carried out a systematic review to identify studies that investigated

PROMs for medication adherence and to evaluate the quality of these PROMs.

## Methods

This study was conducted with reference to the PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analysis) statement [19]. The measurement properties of each PROM were evaluated based on the COnsensus-based Standards for the selection of health Measurement Instruments(COSMIN) guidelines [20,21]. The COSMIN guidelines evaluate PROM development and the following 9 measurement properties: “content validity,” “structural validity,” “internal consistency,” “cross-cultural validity/measurement invariance,” test-retest “reliability,” “measurement error,” “criterion validity,” “hypotheses testing for construct validity,” and “responsiveness” [21,22]. Of note, the assessment of “convergent validity,” “discriminant validity,” and “known-group validity” falls under “hypotheses testing for construct validity” [23,24]. We also assumed that “concurrent validity” and “predictive validity” can be evaluated by the same measurement property, “hypothesis testing for construct validity,” and sensitivity to change can be evaluated under “responsiveness” as well [22,25,26].

## Search Strategy

The EMBASE, PubMed, Cochrane Library, Web of Science, and CINAHL databases were searched for relevant studies published before November 1, 2019. A search strategy (Multimedia Appendix 1) consisting of adherence, PROMs, and measurement properties was used. Search filters created by Terwee et al [27], which consists of a combination of search terms, were also used to enhance the sensitivity of searches, where available. For the adherence construct, synonyms such as compliance were used in the search. Duplicates were removed from the final search library.

## Study Selection

Articles included in this study were full-text publications in English, validating medication adherence PROMs, with the assessment of at least one measurement property listed in the COSMIN [24,28]. We excluded animal studies, case studies, narrative reviews, expert opinions, conference abstracts, and PROMs completed by proxy [29]. In total, 2 independent reviewers (SW and LO) screened the titles and abstracts of the studies according to the inclusion and exclusion criteria. Opinions from a third reviewer (YK) were sought in the event of any disagreements. The remaining full-text articles were then

evaluated by the same 2 independent reviewers for inclusion and exclusion. Additional articles for inclusion into the final pool of articles were also identified from the reference list of articles during the full-text screening phase [30].

### Extraction of Data

The following data were then extracted from the included articles by 2 independent reviewers (SW and LO), where available:

- General characteristics of the study population: age, sample size, gender, and country.
- Characteristics of disease or condition: disease studied, duration of illness, or treatment.
- PROM characteristics: methods of administration, availability of electronic administration, language, response scale, domains, and number of items.

### Assessment of Methodological Quality

The methodological quality of the studies was assessed by 2 independent reviewers (SW and LO). Any disagreement was resolved in consultation with a third reviewer (JP). Each measurement property was assessed based on a 4-point scale: “inadequate,” “doubtful,” “adequate,” or “very good” [20,22]. The item with the worst rating under each measurement property would determine the overall rating for the specific measurement property [31].

On the basis of the COSMIN guidelines, it is recommended for the review team to determine before assessing the methodological quality of studies which outcome measurement instrument can be considered a reasonable gold standard [32]. The study team decided that there is currently no gold standard in the field of patient-reported outcomes that measure medication adherence [33,34]; thus, the assessment of criterion validity of the PROMs was not performed except when an abridged PROM was compared with the original long version, which will be regarded as the gold standard. This is in line with the consensus from the COSMIN panel that no gold standard exists for PROMs [35].

### Assessment of Psychometric Quality

The psychometric quality for each medication adherence instrument was assessed using the quality criteria by Terwee et al [36]. For each of the measurement properties evaluated in the included studies, a “positive (+),” “indeterminate (?),” or

“negative (–)” rating was assigned based on the psychometric results. For example, for the internal consistency measurement property, the rating will be “+” if “at least low evidence for sufficient structural validity AND Cronbach’s alpha(s)  $\geq 0.70$  for each unidimensional scale or subscale.” The rating will be “–” if there is “at least low evidence for sufficient structural validity AND Cronbach’s alpha(s)  $< 0.70$  for each unidimensional scale or subscale.” The rating will be “?” if the “criteria for at least low evidence for sufficient structural validity is not met” [36].

### Evidence Synthesis

For each PROM, an evidence synthesis across studies was conducted. First, we determined whether each measurement property for a PROM had overall “sufficient (+),” “insufficient (–),” “inconsistent ( $\pm$ ),” or “indeterminate (?)” evidence for each measurement property of the PROM. For PROMs that were assessed in more than one study, the overall rating of the level of evidence for the PROM would be sufficient (+), indeterminate (?), or insufficient (–) if the individual studies were all consistently rated as positive (+), indeterminate (?), or negative (–), respectively. If the results of individual studies were inconsistent, the overall rating of the level of evidence for the PROM would be inconsistent.

We also graded the quality of evidence for each measurement property of PROM as “high,” “moderate,” “low,” or “very low” level of evidence based on the guidelines from the modified Grading of Recommendations Assessment, Development and Evaluation approach for systematic reviews of clinical trials [22,37].

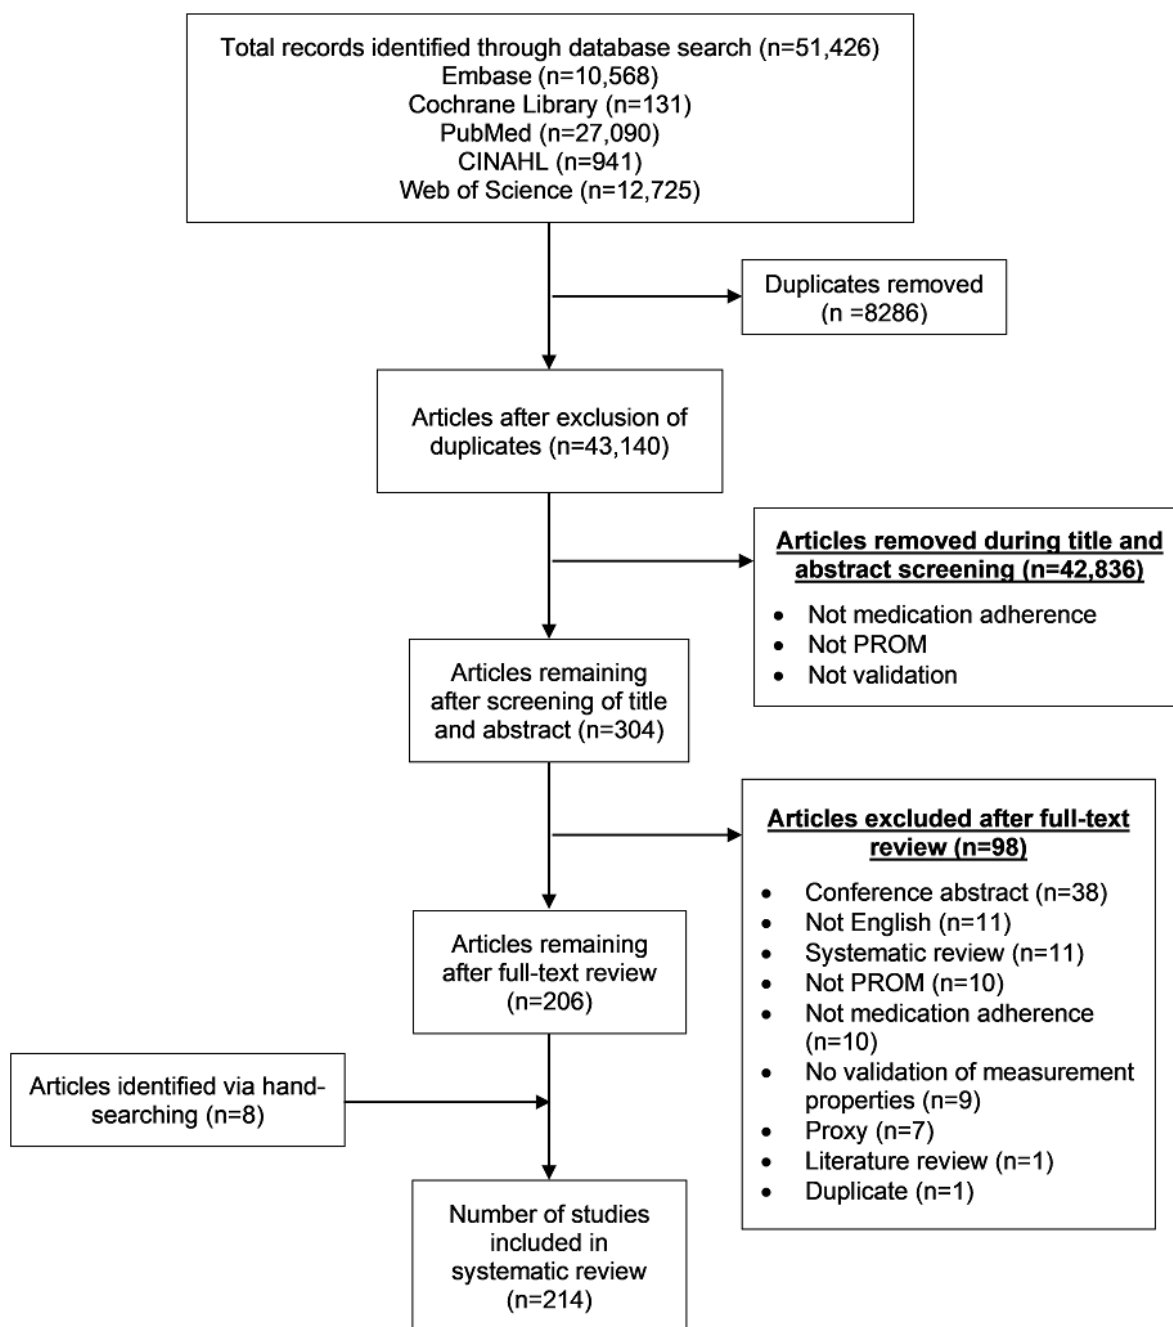

## Results

### Search Results and Study Characteristics

In total, 51,426 articles were retrieved from the 5 databases. After removing 8286 duplicates and 42,836 articles during title and abstract screening, 304 articles remained for full-text review. A total of 98 articles were further eliminated during full-text article screening. An additional 8 relevant articles were identified through hand-searching of the reference lists from the included articles to obtain a final list of 214 articles (Figure 1). A total of 240 PROMs were evaluated across 214 studies, and 121 unique medication adherence PROMs in 32 languages from 48 countries were identified (Table 1).

**Figure 1.** Preferred Reporting Items for Systematic Reviews and Meta-Analyses flow diagram for the systematic review. CINAHL: Cumulative Index to Nursing and Allied Health Literature; PROM: patient-reported outcome measure.

**Table 1.** Study characteristics of included articles (N=214).

## PROM Characteristics

The characteristics of the medication adherence PROM are presented in [Multimedia Appendix 2](#) [38-51]. The most extensively studied PROMs were the 8-item MMAS (MMAS-8) and 4-item MMAS (MMAS-4), which were studied in 27 and 18 studies, respectively. Among the 121 PROMs, 15 PROMs have been administered electronically—Adult AIDS Clinical Trials Group (AACTG) adherence items [52], Fredericksen et al [38], Item Response Theory-30 [53], Least Absolute Shrinkage and Selection Operator-10 [53], Medication Adherence Reasons Scale (MAR-Scale) [54], MAR-Scale (revised) [55], MARS [56], Medication Intake Survey-Asthma [57], MMAS-4 [54], MMAS-8 [58], Multiple Sclerosis Treatment Adherence Questionnaire [59], Probabilistic Medication Adherence Scale [56], Self-Rating Scale Item [52], visual analog scale [52], and WedAd-Q Questionnaire [60].

## Assessment of Methodological and Psychometric Quality

Outcomes on the assessment of methodological quality and study quality of PROMs are summarized in [Multimedia Appendix 3](#) [13,17,38-54,56,57,59,61-248]. In terms of validity, “hypotheses testing for construct validity,” “structural validity,” and “content validity” were assessed in 181, 92, and 92 studies, respectively. In terms of reliability, “internal consistency” and “reliability” were assessed in 138 and 27 studies, respectively.

No studies assessed “measurement error” or “cross-cultural validity/measurement invariance.” Of note, 46 studies performed translation of PROMs, but none of them assessed measurement invariance or differential item functioning. Furthermore, although 75 studies assessed *PROM development*, only one of them obtained *very good* methodological quality.

## Evidence Synthesis

The results for the evidence synthesis for the PROMs are summarized in [Table 2](#). PROMs with at least a *moderate* level of evidence for  $\geq 5$  measurement properties include the Adherence Starts with Knowledge 20 (ASK-20), Compliance Questionnaire-Rheumatology (CQR), General Medication

Adherence Scale (GMAS), Hill-Bone Scale, Immunosuppressant Therapy Barrier Scale (ITBS), MAR-Scale revised, MARS-5, MARS-9, MMAS-4, MMAS-8, Self-efficacy for Appropriate Medication Adherence Scale (SEAMS), Satisfaction with Iron Chelation Therapy (SICT), Test of Adherence to Inhalers (TAI), and the questionnaire by Voils.

**Table 2.** Evidence synthesis of measurement properties for each patient-reported outcome measure.

## Discussion

To the best of our knowledge, this is the first systematic review that comprehensively summarized PROMs for medication adherence based on the COSMIN guidelines [21,22]. Among the 214 included articles, we identified 121 unique PROMs for medication adherence. Our study revealed the most commonly evaluated medication adherence PROMs to be the MMAS-8, MMAS-4, AACTG, MARS, and MARS-5. However, being more commonly evaluated does not mean that these PROMs have the best psychometric properties. Moreover, based on the number of studies for each PROM in Table 2, most of the PROMs have too few studies to provide a strong evidence base for their use.

Among the 15 PROMs that have been administered electronically, 3 PROMs (MAR-Scale revised, MMAS-4, and MMAS-8) have at least a *moderate* level of evidence for  $\geq 5$  measurement properties. Electronic administration of PROMs to measure medication adherence may be appealing in health care settings, as it may reduce the administrative burden for data collection and data entry. In addition, as web-based interventions to improve medication adherence become increasingly commonplace [250], electronic PROMs may be incorporated into web-based platforms to assess the effectiveness of these web-based interventions.

Despite a few studies claiming the use of certain PROMs and objective measures as the *gold standard* for measuring medication adherence, we deliberately omitted evaluating *criterion validity* for these studies. As mentioned in the introduction, although objective measures such as pill count, electronic monitoring devices, and big data may measure adherence indirectly, these measures are laborious, costly, and sometimes invasive, making them unsuitable for routine clinical use. Furthermore, all these surrogate measures, including PROMs, do not predict any real biological outcomes such as a reduction in viral load, blood pressure, or glucose concentration in determining medication adherence in patients. Hence, none of these measures can be deemed as a *gold standard* [10].

Measurement error was not evaluated because none of the studies reported the standard error of measurement, smallest detectable change, or limits of agreements required by the COSMIN. In addition, although translations of PROMs were performed in 46 studies, none of these studies assessed measurement invariance or differential item functioning; therefore, cross-cultural validity was not evaluated for any of the PROMs in this study. Moreover, only one study examined the interpretability of PROMs in the form of minimal detectable change for the MMAS-8 [251]. Further study on measurement error, cross-cultural validity, and interpretability of medication adherence PROMs is warranted.

The strengths of this study include using COSMIN guidelines, which are well regarded as a consensus-based standard for

evaluating the measurement properties of PROMs [23]. The COSMIN Risk of Bias checklist employed in this study is an improvement from the original COSMIN checklist with several improvements in the standards for evaluation [21,22]. We also used sensitive search filters to retrieve and include as many potentially relevant articles as possible.

One limitation related to this study was that the selection of articles and evaluation of psychometric properties were subjective in nature and may have been prone to judgment bias. Nevertheless, the requirement by COSMIN to have 2 independent reviewers and the need for a third reviewer to reach a consensus in the case of any discrepancy occurring has helped reduce the risk of judgment bias [22,252].

## Conclusions

In summary, 121 unique medication adherence PROMs were identified in 214 studies. On the basis of the COSMIN guidelines, PROMs with at least a *moderate* level of evidence for  $\geq 5$  measurement properties include the ASK-20, CQR, GMAS, Hill-Bone Scale, ITBS, MAR-Scale revised, MARS-5, MARS-9, MMAS-4, MMAS-8, SEAMS, SICT, TAI, and questionnaire by Voils. Of these, only the GMAS has *sufficient* (+) ratings for at least four measurement properties. We believe this study would assist clinicians and researchers in selecting suitable PROMs to measure medication adherence among patients. Future research may consider validating measurement errors and cross-cultural validity to further improve the insights on the measurement properties of these PROMs.

## Acknowledgments

The authors would like to thank Librarian Ms Wong Suei Nee at the National University of Singapore Medical Library for her advice on search strategies. This research was supported by the SingHealth Regional Health System Population-based, Unified, Learning System for Enhanced and Sustainable Health (PULSES) Centre Grant—*Measuring Medication Adherence in Singapore* (CGDec19S03), and PULSES Fellowship (CGDec19F02).

Kwan Yu Heng, Weng Si Dun, and Dionne Hui Fang Loh contributed equally as co-first authors. Truls Østbye, Low Lian Leng, Hayden Barry Bosworth, and Julian Thumboo contributed equally as senior coauthors.

## Abstract

**Background:** Despite the acceptability and efficacy of e-patient-reported outcome (ePRO) systems, implementation in routine clinical care remains challenging.

**Objective:** This pragmatic trial implemented the PROMPT-Care (Patient Reported Outcome Measures for Personalized Treatment and Care) web-based system into existing clinical workflows and evaluated its effectiveness among a diverse population of patients with cancer.

**Methods:** Adult patients with solid tumors receiving active treatment or follow-up care in four cancer centers were enrolled. The PROMPT-Care intervention supported patient management through (1) monthly off-site electronic PRO physical symptom and psychosocial well-being assessments, (2) automated electronic clinical alerts notifying the care team of unresolved clinical issues following two consecutive assessments, and (3) tailored online patient self-management resources. Propensity score matching was used to match controls with intervention patients in a 4:1 ratio for patient age, sex, and treatment status. The primary outcome was a reduction in emergency department presentations. Secondary outcomes were time spent on chemotherapy and the number of allied health service referrals.

**Results:** From April 2016 to October 2018, 328 patients from four public hospitals received the intervention. Matched controls (n=1312) comprised the general population of patients with cancer, seen at the participating hospitals during the study period. Emergency department visits were significantly reduced by 33% ( $P=.02$ ) among patients receiving the intervention compared with patients in the matched controls. No significant associations were found in allied health referrals or time to end of chemotherapy. At baseline, the most common patient reported outcomes (above-threshold) were fatigue (39%), tiredness (38.4%), worry (32.9%), general wellbeing (32.9%), and sleep (24.1%), aligning with the most frequently accessed self-management domain pages of physical well-being (36%) and emotional well-being (23%). The majority of clinical feedback reports were reviewed by nursing staff (729/893, 82%), largely in response to the automated clinical alerts (n=877).

**Conclusions:** Algorithm-supported web-based systems utilizing patient reported outcomes in clinical practice reduced emergency department presentations among a diverse population of patients with cancer. This study also highlighted the importance of (1) automated triggers for reviewing above-threshold results in patient reports, rather than passive manual review of patient records; (2) the instrumental role nurses play in managing alerts; and (3) providing patients with resources to support guided self-management, where appropriate. Together, these factors will inform the integration of web-based PRO systems into future models of routine cancer care.

## KEYWORDS

patient-reported outcomes (PROs); eHealth; patient-centered care; electronic health record; nonrandomized controlled trial; emergency department presentations; pragmatic trial; symptom screening

## Introduction

Organizations delivering health care services increasingly incorporate patient-reported outcomes (PRO) to inform person-centered care and evaluate services. Well-implemented ePRO systems are associated with improved patient-provider communication, patient satisfaction [1], health-related quality of life [2,3], compliance with chemotherapy [3], earlier detection of relapse in patients with lung cancer [4], reduced emergency department (ED) presentations [5,6], and improved cancer survival [6,7]. However, implementation and effectiveness evaluations in real-world clinical practice settings are not well studied.

A systematic review of 6 reviews identified facilitators and barriers for the implementation of ePROs in health services, with 2 early stages in the implementation process being critical for organizational time and resource investment [8]. First, designing the processes for using PROs within an organization, with a focus on decisions about data use for clinical purposes, rather than just which PROs to collect and how to collect them. Second, preparing organizations and staff for using PROs, including highlighting their validity and value, training clinicians using them, and developing electronic systems that fit into the centers' patient workflow.

Our team developed PROMPT-Care (Patient Reported Outcome Measures for Personalized Treatment and Care), an ePRO system for routinely collecting PROs remotely from home for patients with cancer. PROMPT-Care provides real-time feedback of results to the cancer care teams to inform patient-centered care and deliver evidence-based self-management information to address patient-reported problems [9]. PROMPT-Care is fully integrated into the electronic oncology information system (OIS), which is acceptable to patients and oncology staff and feasible to implement clinically [10].

This multicenter, pragmatic [11] nonrandomized intervention study aimed to successfully implement PROMPT-Care Version 2.0 [12] into existing clinical workflows, evaluate its effectiveness in a diverse population of patients with cancer, and explore the system utility from patient and health care professional perspectives. We hypothesized that PROMPT-Care intervention patients would have significantly fewer ED

presentations during the study period compared to a usual care control group. The intervention was also expected to impact the time spent on chemotherapy and the number of health service referrals.

## Methods

### Study Design and Participants

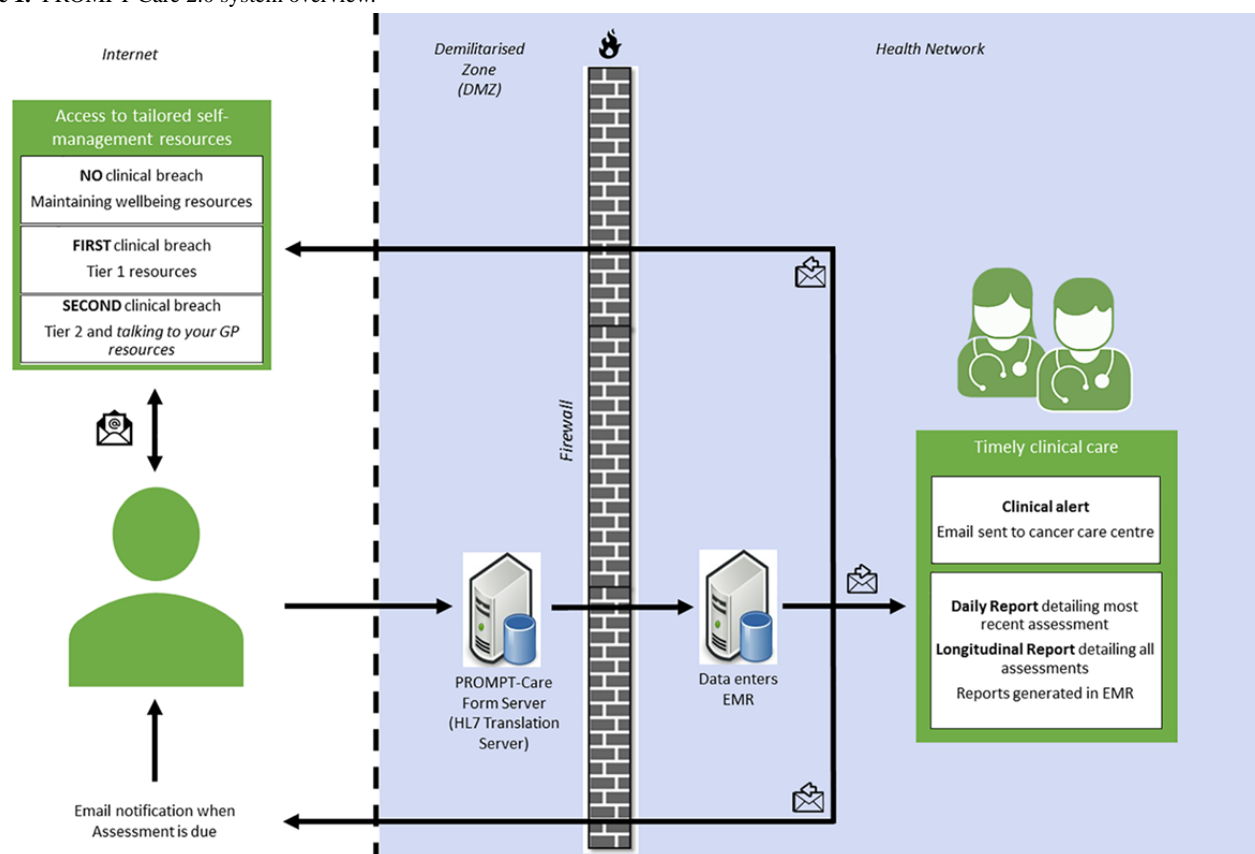

The trial protocol details the study design [12]. Briefly, we conducted a pragmatic, nonrandomized trial among patients with cancer throughout all stages of their cancer care trajectory, with different tumor types and receiving active treatment or follow-up care between April 2016 and October 2018 at four public hospitals in New South Wales, Australia. This study design [11] was chosen to inform external validity and determine this care model's suitability for broad cancer populations, including those in follow-up. Study participants were compared to the general population of patients with cancer receiving usual care at participating hospitals during the study period.

Eligible patients were adults with a confirmed diagnosis of a solid tumor and cognitively able to provide informed consent and complete the assessments in English. Patients without internet access outside the hospital were excluded. Patients with upcoming clinical appointments (treatment or follow-up) at participating hospitals were prescreened for eligibility by treating clinicians using lists extracted from the OIS every month and invited to participate by the nursing or research staff. Patients received written and verbal information about the study, provided their consent, and participated for a minimum of 6 months. Participants received monthly emails prompting them to complete the upcoming online assessment, with one reminder email sent a week later. The Human Research Ethics Committee of South Western Sydney and Illawarra Shoalhaven Local Health Districts (Reference No. HREC/15/LPOOL/287) granted ethics approval, and the trial was registered in the Australian New Zealand Clinical Trials Registry (ACTRN12616000615482).

### Intervention

Four key intervention components were standardized across participating hospitals: ePROs, clinical feedback reports, clinical alerts, and patient self-management (Figure 1).

**Figure 1.** PROMPT-Care 2.0 system overview.

### ePROs

Approximately once a month, patients were prompted via email to complete an online assessment of their physical and psychosocial well-being from home, which included the Distress Thermometer and checklist [13], the Edmonton Symptom Assessment Scale (ESAS) [14], and the Supportive Care Needs Survey-Screening Tool 9 [15]. Patients used an electronic device (eg, tablet, computer), with real-time electronic data transfer (using PROsaiq, DidymoDesigns) into the point-of-care OIS (MOSAIQ, Elekta Medical Systems), via automatic conversion into an Health Level Seven (HL7) message [16].

Patient privacy was maintained by ensuring the email did not contain identifiable patient information, in the event the email was intercepted or sent to the wrong email address. PROsaiq [16], which has restricted access, was located on a PROMPT-Care form server within the demilitarized zone of the health network. To complete an assessment, the patient opened the URL provided in the email, and the browser established a secure session to the PROMPT-Care system, where an SSL Certificate was installed. The patient was required to enter a unique medical record number and their surname to

access the system. The two identifiers were chosen to match the survey results to the correct patient in the OIS. Following the assessment completion, data were translated into a HL7 message by the OIS HL7 translation server, which also sat behind the health network firewall. If the medical record number and surname attached to the HL7 message matched to a patient in the OIS, the survey results were loaded into the OIS under the patient record. If a mismatch occurred, the data were not loaded and a failure was recorded in a log file. No patient information was stored on the PROMPT-Care form server.

### Clinical Feedback Reports

Any care team member could review the ePRO reports in real time with patients, or as required. The ePRO reports included (1) a 1-page summary of the most recent assessment results, including recommended clinical actions and referrals generated from algorithms to facilitate standardized care (Figure 2) [17,18], and (2) a longitudinal report of all assessments to date. Staff were oriented on clinical feedback report use and access at the start of the study, with a periodic refresher training and emails with brief instructions on accessing and using reports in practice throughout the trial.

Figure 2. Sample clinical feedback report.

**PROMPT-Care**  
Patient Reported Outcome Measures for Personalised Treatment and Care

Patient Name:	MRN:	DOB	Date of Assessment:
---------------	------	-----	---------------------

THIS PATIENT HAS A HIGH DISTRESS SCORE. Review remainder of report for potential causes of this distress and action the specific recommendations as detailed

<b>Emotional</b>	<b>Recommendation</b>
Wellbeing	Consider reasons for concern and, if required, refer to social work OR psychology OR clinical/health services for further assessment and care
<b>Physical</b>	<b>Recommendation</b>
Breathing, Diarrhoea, Fatigue, Mouth sores, Nausea, Pain, Tiredness, Drowsy, Appetite, Shortness of breath, Lack of energy/tiredness, Getting around	Clinically address as appropriate OR refer to relevant medical specialist OR allied health professional for further assessment and care
Bathing/dressing	Consider reasons for concern and, if required, refer to a physiotherapist AND/OR occupational therapy for further assessment and care
<b>Practical</b>	<b>Recommendation</b>
Being informed about things you can do to help yourself get well	Address educational/informational needs and identify appropriate sources of support and information

**1. Distress (Distress Thermometer & Problem Checklist)**

<b>Practical problems:</b>	<b>Emotional problems:</b>	<b>Physical problems:</b>
Childcare	Depression	Appearance
Housing	Fears	Bathing/dressing
Insurance/financial	Nervousness	Breathing
Transportation	Sadness	Changes in urination
Work/School	Worry	Constipation
Treatment decisions	Loss of interest in usual activities	Diarrhoea
Other:	Coping with illness	Eating
Spiritual/Religious	Losing Hope	Fatigue
<b>Family problems:</b>		Feeling swollen
Dealing with partner	Dealing with Children	Fevers
Ability to have children	Lack of support from family & friends	Getting around
Family health issues		

**2. Symptoms (ESAS)**

**Needs Follow-up**

Pain	3
Tiredness	9
Nausea	9
Depressed	0
Anxious	0
Drowsy	7
Poor Appetite	9
Poor wellbeing	8
Shortness of breath	5

KEY  
This issue is problematic for the patient

**3. Unmet Needs (SCNS-ST9)**

<b>Need</b>	<b>Issue</b>
Psychological	Fears about the cancer spreading Uncertainty about the future
Health system and information	Being informed about your test results as soon as feasible Being informed about things you can do to help yourself to get well
Physical and daily living	Lack of energy/tiredness Not being able to do the things you used to do
Patient care and support	Reassurance by medical staff that the way you feel is normal Hospital staff acknowledging and show sensitivity to your feelings and emotional needs
Sexuality	Changes in sexual relationships

### Clinical Alerts

An email alert was automatically generated whenever any individual ePRO item score breached a predefined threshold on two consecutive assessments. This email was generated by a SMTP server within the health network, where only approved health email addresses were able to receive this email alert ensuring that patient identifying data were unable to leave the organization. A designated member of the care team reviewed

emails at least once a day (Monday-Friday) and followed their cancer center's standard clinical care pathway.

### Patient Self-Management

Approved resources were hosted on a website to support patient self-management, [12,17], with domain-specific webpages—practical problems and emotional, physical, social and family well-being, and a “maintaining well-being” page to support general health. Immediately following ePRO

completion, patients received an email with links to pages related to the above-threshold ePROs (eg, a patient with a breached pain score received a link to the physical well-being page). Information resources, interactive resources (eg, videos, podcasts, self-help programs), and resources to facilitate effective communication with the general practitioner were provided. Patients with no breached ePROs received the “maintaining well-being” link. Resources were maintained on a public website, external to the health firewalls, and no identifiable information was included in the email.

### Selection of Controls

The “usual care” control group included all other patients receiving active treatment or follow-up care at participating centers during the study period. For comparability between the intervention and control samples, clinicians prescreened control patients as part of trial recruitment procedures; patients who did not meet the study eligibility criteria were excluded from the usual care group. Usual care consisted of standard clinical oncology practice, monitoring and managing patient issues, and management and OIS documentation of patient symptoms and issues as needed during clinical appointments.

### Outcomes

The primary outcome was ED presentations. Since patients could present at any hospital in their local health district, ED data was extracted from all hospitals with ED departments ( $n=8$ ) in the two local health districts, during the trial period. A presentation to ED may or may not have required an admission. Secondary outcomes were (1) total time receiving chemotherapy during the study period and (2) referral to in-hospital allied health services (eg, psychology, social work, nutrition and dietetics, occupational therapy, physiotherapy). Primary and secondary outcome data were extracted from patients’ OISs.

Receipt of clinical alerts was automatically logged via the PROMPT-Care system email monitoring and OIS records of clinician notes. Responses to email alerts were recorded in the OIS and research staff recorded clinical actions (eg, referrals, information provision, issue already being managed). The number of clinical feedback reports opened in response to patient assessment completion was tabulated based on medical record logs.

PROMPT-Care compliance was monitored by calculating the proportion of patients completing assessments at expected time points within the first 6 months. Patient views of self-management domain pages, monitored using Google Analytics, were summarized as counts and proportion of resources.

At enrolment, patients completed a demographics survey (sex, marital status, education, employment, and language spoken at home); clinical (cancer site and stage) and treatment (chemotherapy, radiotherapy treatments, active treatment, and follow-up care) details were extracted from the OIS.

Socioeconomic status was determined from the Index of Relative Socio-economic Disadvantage [19], a continuous score split into quintiles (1=most disadvantaged to 5=least disadvantaged).

### Sample Size

Propensity score matching was used to match control patients with intervention patients in a 4:1 ratio with regard to patient age, sex, and treatment status [20]. The study was powered to detect a minimum 14% between-group difference in the primary outcome—ED presentations. Assuming a 4:1 allocation to the control group versus intervention group and based on an assumed 1.4 ED presentations per patient during the study period for the control group [21], a minimum sample of 1760 patients (intervention:  $n=352$ ; control:  $n=1408$ ) was required to achieve 80% power and a two-sided statistical significance of 0.05.

### Statistical Analyses

Demographic and clinical characteristics were described as frequencies, mean scores, and percentages, with between-group comparisons using Chi-square tests or  $t$  tests. Intention-to-treat analyses were conducted in line with a prespecified analysis plan [12]. Multivariable negative binomial regression was used to identify between-group differences in ED presentation rates. To account for between-group differences in distribution of demographic and disease characteristics, we adjusted for disease stage, socioeconomic disadvantage, hospital site, and waiting time (time from diagnosis to start of PROMPT-Care). Allied health referrals were analyzed similarly. Multivariable Cox proportional hazards model was used to analyze length of time from start to end of chemotherapy, adjusting for stage of disease, treatment status, and socioeconomic disadvantage. A delayed entry model was used to specify how many days after the start of chemotherapy a patient started PROMPT-Care.

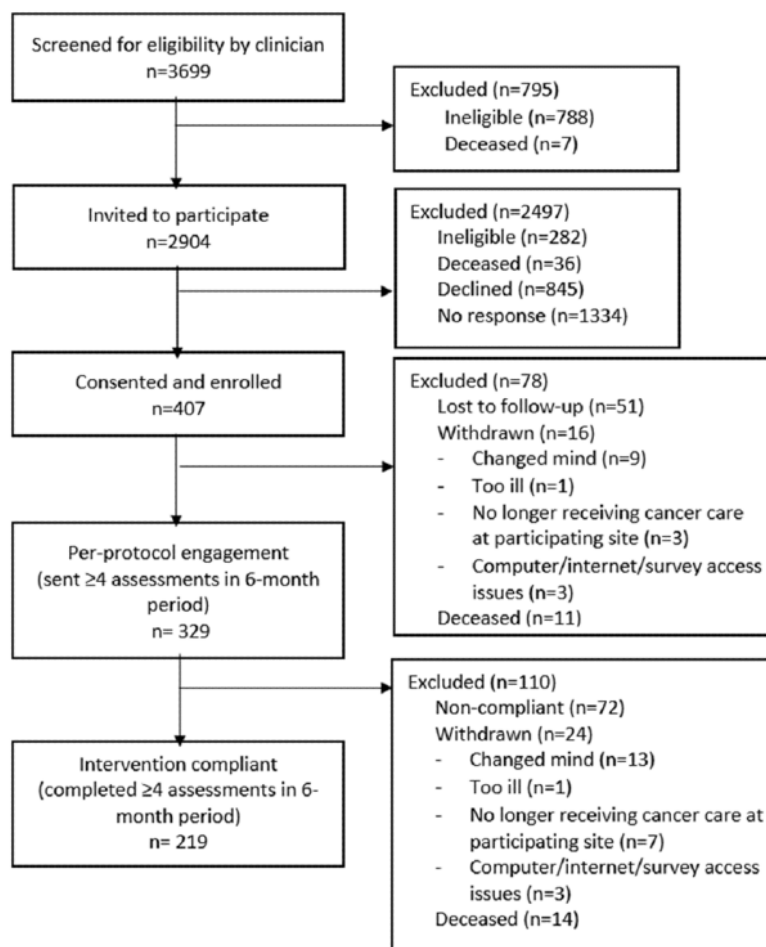

### Data Sharing

De-identified data will be available on request after all primary and secondary endpoints have been analyzed and published, and after signing of an agreement with the PROMPT-Care program. Requests for data sharing can be made to the corresponding author, including a research proposal that must be approved by the chief investigator team.

## Results

### Study Population

Between April 2016 and April 2018, clinicians prescreened 3699 patients against clinical and language exclusion criteria and invited 2904 (79%) to participate (Figure 3). A further 283 patients were ineligible, 36 were deceased, 845 declined, and 1334 did not respond. The remaining 406 patients were enrolled to the intervention group, with 328 (81%) receiving the “per-protocol intervention” (sent  $>4$  assessments within 6 months postenrolment), due to administrative staff error sending assessment emails.

**Figure 3.** CONSORT diagram.

### Propensity Score Matching

Propensity score matching was used to match age, sex, and treatment status. Prior to matching, there were no significant differences in age and sex between the treatment groups. However, there was a higher proportion of control patients on active treatment (1157/1911, 60.5%) compared with patients in the intervention group (139/328, 42.4%) ( $P<.001$ ). After

matching there were no differences in age, sex, and treatment groups (Table 1).

After matching, the study groups were not significantly different at baseline in the site of cancer and waiting time, but the control group included significantly more patients from the most socioeconomically disadvantaged quintile and at clinical stage IV ( $P=.01$ ; Table 1).

**Table 1.** Participant characteristics for intervention, control, and control participants matched for age, sex, and treatment status.

### Emergency Department Presentations

There were 314 ED visits from the 328 patients in the intervention group (0.96 ED visits per patient) and 1874 ED visits from the 1312 patients in the matched controls (1.4 ED visits per patient). After accounting for patient time in PROMPT-Care (intervention: 192,859 days; control: 1,006,956 days), the rates of ED visits were 16.2 per 100,000 patient days

in the intervention group and 18.6 per 100,000 patient days in the matched controls.

After adjustment for stage, socioeconomic disadvantage, recruitment site, and waiting time in the multivariable negative binomial regression model with an offset of time in PROMPT-Care (to account for maldistribution of these variables between the groups), ED visits were significantly lower by 33% ( $P=.02$ ) in the intervention group compared with the matched controls (Table 2).

## System Utility

Patients (n=328) completed 2746 PROMPT-Care assessments. At baseline, the most common PRO (above threshold) were fatigue (128/328, 39%), tiredness (126/328, 38.4%), worry (108/328, 32.9%), general well-being (108/328, 32.9%), and sleep (79/328, 24.1%), aligning with the most frequently accessed self-management domain pages of physical well-being (680/1867, 36%) and emotional well-being (429/1867, 23%). The majority of patients (218/328, 66.4%) used the system as intended, completing four or more assessments within the 6-month intervention period.

Overall, 32% (893/2751) of clinical feedback reports were reviewed, the vast majority (729/893, 82%) by nursing staff and 17% by oncologists (149/893).

In total, 71% (233/328) of intervention patients generated a clinical alert. A total of 877 clinical email alerts were generated, with a mean of 31 (range 2-78) alerts per month during the 30-month study. Overall, 44% (383/877) of clinical alerts were reviewed by designated nurse care coordinators, resulting in 496 actions: in-clinic or telephone patient follow-up (302/496, 61%), no further follow-up deemed necessary (83/496, 17%),

and telephone contact attempts but patient could not be reached (111/496, 22%). Issues were largely resolved through discussion (129/302, 43%) or information provision (98/302, 32%), with some health care professional referrals (75/302, 25%).

## Discussion

### Principal Findings

We investigated PROMPT-Care implementation into routine clinical practice among diverse populations of patients with cancer. For adult patients with cancer, receiving active treatment or in follow-up care, algorithm-supported web-based systems utilizing PROs in routine practice resulted in fewer ED presentations. Prespecified secondary analyses showed no statistically significant associations in allied health referrals or time on chemotherapy and were likely underpowered to detect any change. Another factor to consider is the multimodal nature of the intervention where, in addition to clinical follow-up for above-threshold PROs, patients also received targeted resources enabling patients to self-manage minor issues where clinically appropriate. Further research should explore multimodal interventions such as PROMPT-Care that combine ePRO clinical implementation and appropriate patient self-management, as

patients are responsible for managing their own care between hospital clinic visits.

The finding of reduced ED presentations observed in our study is also consistent with other web-based PRO studies. Basch et al [3,6] demonstrated that web-based symptom reporting with automated email alerts resulted in fewer ED visits. However, this was a single-site study, in a population with advanced disease receiving chemotherapy, with ED visits as a secondary outcome. Barbera et al [5] demonstrated that ESAS screening was associated with decreased ED visits, among patients with breast cancer; and Howell et al [22] showed reduced ED visits following ESAS screening in a prepost comparative cohort study. Additionally, to our knowledge, our study is the first to explore the impact of a multimodal intervention combining electronic PRO screening with clinical intervention and patient self-management.

### Integration and Clinical Use of ePRO Systems Into Routine Practice

In this pragmatic study, PROMPT-Care was implemented using available resources and workflows, with two important findings influencing future adoption. First, the automated clinical alerts prompted the majority of clinical report reviews, highlighting the importance of embedded triggers for reviewing above-threshold reports, which are otherwise passively accessible in the OIS. Second, nursing staff were instrumental in reviewing, triaging, and directly managing responses to clinical alerts, echoing many studies of nurse-led telephone navigator models of cancer care [23]. Additionally, with the relatively low number of clinical alerts generated each month, the automated alerts fit within existing workflows without creating onerous amounts of additional work. These findings will contribute to the evidence-based development and integration of ePRO systems into future models of routine care, to not only reduce the high demand on health services but also provide targeted systematic care to patients most in need.

### Strengths and Limitations

Our study addressed existing evidence gaps. We examined the impact on health service outcomes of an ePRO system implemented in routine practice settings, rather than a controlled research environment. We included a broad population of patients with cancer, enhancing generalizability. We monitored physical symptoms and psychosocial well-being and provided real-time feedback to care providers and patients. Intervention delivery to a broad cross-section of patients, across four centers providing comprehensive chemotherapy and radiotherapy treatment services, further enhances the study's external validity. Hence, our findings are potentially generalizable to other clinical settings in countries with similar health systems, highlighting the importance of informing ePRO system implementation more broadly.

Our study also has some limitations. In our study, the intervention did not reach 100% of patients. First, response rate was low, possibly contributing to recruitment bias in treatment status and socioeconomic disadvantage. Second, patients unable to complete assessments in English or without access to a device and internet outside the hospital were excluded. While we

acknowledge this limitation, our pilot study patients wanted remote electronic access to assessments [10], making this a critical component of our intervention design. Future interventions utilizing online or remote ePRO completion will likely be more accessible, with 86% of Australian households having internet access at home [24]. Third, due to administrative problems, only 81% of patients received the intervention per-protocol (sent  $\geq 4$  assessments in the first 6 months postrecruitment). Finally, there was limited follow-up (one email reminder) if monthly assessments were not completed, in contrast to nurses following up patients in the Basch et al [3] trial to ensure high adherence. Despite this, 67% of patients engaged with the system as intended, suggesting high intervention acceptability.

Clinically integrating PROs is challenging, even in centers with screening implemented for many years. Cancer Care Ontario's systematic ESAS distress screening commenced in 2007, with rates increasing steadily from approximately 20% in 2009 to 59% in 2015, but remaining below the provincial target of 70% screened (range 31% at lowest performing to 91% at highest performing centers). Chow et al [25] also found that patients completed a brief distress screener 75% of the time they received a text message, suggesting feasibility of remote ePRO screening, as per our PROMPT-Care model.

Our assessment and alert frequencies are other limitations. Monthly assessments were selected to accommodate the longest response timeframe for the selected scales (Supportive Care Needs Survey-Screening Tool 9 "in the past month..."), and inclusion of follow-up as well as on-treatment patients. The Clinical Advisory Group decided that clinical alerts should be generated following two consecutive breaches [17] to minimize false-positive alerts, since patients on treatment were in regular contact with the cancer service; hence, any additional concerning issues would be readily identified between assessments. However, increasing assessment frequency may identify more acute symptoms (eg, pain), which likely result in ED presentations. Finding the balance between screening burden and timely alerts is an ongoing challenge.

Retrospective interrogation of systematically collected data shows that with systematic clinical implementation of distress screening, distress levels significantly predicted service utilization and referral rates [26], particularly to social and psycho-oncology services [27]. A key component of our effectiveness evaluation was to observe nurse uptake into workflows as part of routine practice with minimal intervention. This likely resulted in the low observed opening rates of clinical alerts. Further research is needed to explore implementation strategies that would encourage and support clinical staff to embed ePRO review and action into routine workflows.

### Future Research

This study enhances our understanding of how PROs inform cancer care and patient self-management beyond a randomized controlled trial and raises priority research questions. We know very little about reaching underserved patient populations. In particular, the extent to which ePRO systems like PROMPT-Care are acceptable and feasible for (1) assessing PROs in languages other than English and (2) informing

patient-centered care in non-English subgroups is unknown. Furthermore, given the dearth of non-English resources to support patient self-management, applying cultural adaptation principles rather than simply translating existing resources into other languages [28] is a focus for future development.

## Conclusions

Although most previous research has evaluated ePRO systems with patients receiving adjuvant treatment, there is a compelling argument for eHealth systems like PROMPT-Care informing the care of the growing population of cancer survivors. Completing ePROs routinely can efficiently identify follow-up patients managing well, who can be supported with self-management resources rather than attending specialist follow-up appointments. ePROs can also detect issues of concern when patients do not have a scheduled appointment, prompting

timely clinical care if required to avoid escalation in severity of issues. Research into the acceptability and cost-effectiveness of this model of care is required, but our research supports its acceptability and feasibility to patients and oncology staff. Research to date has predominantly focused on testing ePRO intervention efficacy. We have purposefully undertaken a pragmatic trial to better understand the effectiveness of ePRO systems in real-world settings, demonstrating that ePROs are likely to be adopted in routine care when integrated into the patient OIS and existing clinical workflows, allowing easy access by the care team. However, significant barriers exist for many cancer centers to do this. It is imperative that future research explore implementation questions, focusing on evaluating the processes and outcomes of ePRO systems adopted as business-as-usual.

## Acknowledgments

We sincerely thank the following people who were integral to the development and delivery of the PROMPT-Care Program: Orlando Rincones, Kenneth Masters, Thomas T Tran, Martha Gerges, Tiffany Sandell, Kylie Smith, CheeFon Chang, and Janelle Levesque. We thank the patients who generously contributed their time and input to the development of PROMPT-Care. We gratefully acknowledge the significant input of the broader team, which includes care coordinators, clinicians and researchers from the South Western Sydney and Illawarra Shoalhaven Local Health Districts, and the Clinical and Technical Advisory Groups, which include more than 40 members from Local Health Districts across New South Wales as well as from the Cancer Institute New South Wales. AG is funded through Cancer Institute grants. This study was funded by the Cancer Institute New South Wales, Bupa Health Foundation, South Western Sydney Local Health Service, and Wollondilly Health Alliance.

## Authors' Contributions

AG and GD obtained study funding. AG was chief investigator; contributed to trial design, analysis plan, protocol development, data interpretation, and writing. GD and ID contributed to trial design, protocol development, analysis, data interpretation, and writing. AA, NK, ESK, AAM, WN, MGC, SDF, and SA contributed to the design and implementation of the intervention. JD contributed to development of analysis plan, conducted statistical analyses, and writing. All authors reviewed and approved the final manuscript.

## Conflicts of Interest

None declared.

## Abstract

**Background:** The number of electronic messages securely exchanged between clinic staff and patients has risen dramatically over the last decade. A variety of studies explored whether the volume of messages sent by patients was associated with outcomes. None of these studies, however, examined whether message content itself was associated with outcomes. Because secure messaging is a significant form of communication between patients and clinic staff, it is critical to evaluate the context of the communication to best understand its impact on patient health outcomes.

**Objective:** To examine associations between patients' and clinicians' message content and changes in patients' health outcomes.

**Methods:** We applied a taxonomy developed specifically for secure messages to 14,394 patient- and clinic staff-generated messages derived from patient-initiated message threads. Our study population included 1602 patients, 50.94% (n=816) of whom initiated message threads. We conducted linear regression analyses to determine whether message codes were associated with changes in glycemic (A1C) levels in patients with diabetes and changes in systolic (SBP) and diastolic (DBP) blood pressure in patients with hypertension.

**Results:** Patients who initiated threads had larger declines in A1Cs ( $P=.01$ ) compared to patients who did not initiate threads. Clinic nonresponse was associated with decreased SBP ( $\beta=-.30$ ; 95% CI  $-0.56$  to  $-0.04$ ), as were staffs' action responses ( $\beta=-.30$ ; 95% CI  $-0.58$  to  $-0.02$ ). Increased DBP, SBP, and A1C levels were associated with patient-generated appreciation and praise messages and staff encouragement with effect sizes ranging from 0.51 (A1C) to 5.80 (SBP). We found improvements in SBP associated with patients' complaints ( $\beta=-4.03$ ; 95% CI  $-7.94$  to  $-0.12$ ). Deferred information sharing by clinic staff was associated with increased SBP ( $\beta=1.29$ ; 95% CI  $0.4$  to  $2.19$ ).

**Conclusions:** This is the first research to find associations between message content and patients' health outcomes. Our findings indicate mixed associations between patient message content and patient outcomes. Further research is needed to understand the implications of this work; in the meantime, health care providers should be aware that their message content may influence patient health outcomes.

## Introduction

### Background and Significance

The use of secure messaging—email messages exchanged between patients and clinical staff through a secure platform—has increased significantly over the last 2 decades as patients' access to the functionality increased [1-5]. Patients reported that secure messaging offered convenience, with the added benefit of documenting the conversation so that it could be referenced later [6-9]. Although clinicians cited challenging workflows as the biggest barrier to use [10], they noted that secure messaging improved communication between visits and boosted patient engagement, satisfaction, and trust [7,9].

Communication between patients and clinicians should include information exchange, uncertainty management, relationship development and fostering, and activities that enable decision making and health self-management [11]. According to Street et al [11], these communication functions lead to proximal and intermediate outcomes that eventually result in improved patient health outcomes. Prior research provides evidence that secure messaging is a significant modality for patient-clinician communication [4,12,13]. As such, message threads that include communication functions identified by Street et al [11] should be associated with better health outcomes.

To the authors' knowledge, there is no published research to date that linked secure message content and patients' health outcomes. Rather, researchers have explored whether the number of secure messages, or secure message use more generally, was associated with outcomes for a variety of conditions. An equal number of studies found that secure message use was associated with improvements in blood pressure control [14-16], or no association between them [12,16,17]. While a number of studies identified positive associations between secure message use and controlled glycemic levels [12,14,17-19], 2 studies identified no association [18,20], and 1 found inconsistent associations [16]. Even within studies, findings varied across conditions. For example, Price-Haywood et al [16] assessed performance on population-level measures for glycemic and blood pressure control and found that both improved among some patients with diabetes with evidence of a dose response. This did not hold, however, among patients with diabetes who had glycemic levels over 8%, nor for blood pressure changes among patients with hypertension. Similarly, Harris et al [18] found that the highest users of secure messaging had better glycemic control but did not identify similar patterns with blood pressure control. An analysis by Shimada et al [17] separated prescription refill requests and other types of secure message use and found that improvements in glycemic control after 2 years were associated with secure message use but not with prescription refills. Interestingly, they found the reverse was true for blood pressure control. These mixed findings, particularly the findings from Shimada et al [17], suggest that we must move beyond counting messages and begin classifying and quantifying message content types in order to better understand how secure messages, and more specifically, secure messaging content, impact important patient health outcomes. This research study directly attempts to address this need.

### Objective

We created and applied a theory-based taxonomy developed specifically for secure messaging to a large sample of patient- and clinician-generated messages and explored whether certain types of message content were associated with changes in glycemic levels among patients with diabetes and changes in blood pressure among patients with hypertension [21,22]. Our taxonomy provides taxa (ie, codes) for patient- and clinic staff-generated content. [Multimedia Appendix 1](#) includes a complete list of taxa (ie, codes), their definitions, and examples of each taxon. We included taxa (italicized throughout this paper) to classify patient-generated *Information seeking* and *Information sharing* (eg, *Self-reporting* and *Clinical updates*), and *Task-oriented requests* such as *Appointment scheduling*, *Prescription refill requests*, and *Other administrative requests*. We used different taxa to classify clinic staff-generated *Information sharing* and *Action responses* that indicate the degree of request fulfillment, and *Information seeking*. Finally, we classified *Social communication* that may be related to fostering relationships and trust among messages generated by either party.

Based on Mishel's Uncertainty in Illness Theory [23] and Street et al's [11] framework, we anticipated that actions indicative of self-care, such as *Task-oriented requests* not associated with uncertainty (eg, routine appointment requests, prescription refills) and *Self-reporting*, would be associated with improved health outcomes. Similarly, actions from the patients that might be indicative of trust between patient and clinician, such as *Information sharing* and positive *Social communication*, would be associated with improved health outcomes. Clinicians' *Information sharing* and *Encouragement* could be a mechanism to mitigate patients' uncertainty and improve trust, so we hypothesized that receipt of this message content would also result in improved health outcomes. Conversely, we anticipated that clinician responses that did not mitigate patients' uncertainty would result in poorer outcomes. We included in this category lack of a response from clinic staff to patient-initiated threads and clinic staffs' *Information sharing/Deferrals*. Finally, we expected that patients who expressed negative *Social communication* (eg, *Complaints*) would also experience poorer health outcomes.

We present this nascent research to provide early evidence that the content of some secure messages between patients and clinic staff may be predictive of outcomes for patients with chronic illness.

## Methods

### Study Population

Our study population included adult patients who registered with the patient portal of a large urban academic medical center. The portal allowed registered patients to send and receive secure messages with clinic staff, request appointments and prescription refills and renewals, view upcoming appointments and notes from prior visits, and find links for health-related educational materials and bill pay. Patients could access the portal through any device with a web browser.

Patients had to have at least one inpatient or two outpatient visits in 2016 with ICD-10-DM diagnosis codes for either diabetes (E11) or hypertension (I10), and one visit in 2018. We stratified the sample based on health condition (diabetes only, hypertension only, or both conditions) and whether patients initiated a message thread between January 1 and December 31, 2017, then randomly selected samples from each stratum. Patients who lacked baseline or endpoint values for the outcomes of interest were excluded from this study.

We included 2 different conditions in our research to control for disease condition, not to provide specific recommendations relative to condition. Our message sample included all patient-initiated threads generated by those sampled patients and saved to patients' charts between January 1 and December 31, 2017. We included only patient-initiated threads because we felt these were the best markers of patient uncertainty and self-management. This research received approval from the VCUHS Institutional Review Board under expedited review. We manually extracted messages from patients' electronic health records and redacted all identifiable information during the extraction process. We coded those deidentified messages, which were linked with a unique identifier not linked to the patients' medical record.

Our study sample consisted of 1602 patients (full population), of whom 50.94% (n=816) initiated at least one message thread (secure message-only population). We included patients with diabetes only (n=347), hypertension only (n=751), and both conditions (n=504). We coded 5844 message threads initiated by these patients, which included 8008 patient-generated messages and 6386 messages generated by 496 unique clinic staff. Our sampled population generated an average of 9.81 messages (median 5; max 117). Message responses to patient-initiated messages came from physicians, nursing staff, administrative staff, pharmacists, physician assistants, medical assistants, podiatrists, social workers, and medical technicians from departments and clinics across the medical center. Clinics employed a triaging system whereby administrative or nursing staff review incoming patient-generated messages and determine the best response approach. Decisions about which staff would serve as the triage point, and the triaging process itself, varied across clinics.

## Independent Variables

Table 1 lists the taxa, or codes, used in these analyses. Multimedia Appendix 1 provides the taxa definitions and examples for each. We created the taxonomy by leveraging common taxa reported in other published literature. Our 2 patient-generated *Information seeking* taxa were selected based on Mishel's Uncertainty in Illness Theory [23], which identifies the reasons patients might outreach to clinicians to manage their uncertainty around their illness. We included *Information seeking* and *Information sharing* taxa for both patients and clinicians in recognition that information exchange is a communication function on the pathway to improved patient outcomes [11]. In addition, we included other constructs from the Street et al [11] pathway, including *Task-oriented* patient-generated requests that might be markers of patient self-management, and *Social communication*. We leveraged the Taxonomy of Requests by Patients [24] for clinic staff-generated *Action responses* to those patient requests. We piloted our taxonomy with a small sample to ensure that no constructs were missing and that the appropriate level of granularity was present in the taxa [22].

We used the taxa to distinguish between different types of patient-generated and clinic staff-generated message content. For these analyses, we report findings for the individual taxa as well as the level 1 groupings of taxa for patient *Information seeking*, patient *Information sharing*, patient *Social communication*; patient *Task-oriented requests* reflective of self-management; other patient *Task-oriented requests*; staff *Information sharing*; and staff *Action responses*. We based our independent variables on counts of taxa either sent or received by patients between January 1 and December 31, 2017. Because we found a strong correlation between the likelihood of sending and receiving a taxon based on patients' thread volume, our independent variables measure taxa as a function of volume. Each taxon is represented in the linear regression models as a proportion of the total patient-generated or clinic staff-generated taxa they sent or received.

We also created an independent variable that measured clinic nonresponse, defined as a thread that included no messages sent from clinic staff. We measured clinic nonresponse as a proportion of the total threads initiated by the patient.

## Dependent Variables

We created 1 dependent variable for patients with diabetes and 2 for patients with hypertension. For patients with diabetes, we measured the change between the endpoint and baseline measures of glycemic control (A1C). For patients with hypertension, we included dependent variables that measured

changes between baseline and endpoint measures for systolic blood pressure (SBP) and diastolic blood pressure (DBP). We used the last recorded value in 2016 as the baseline measure. Our endpoint value was the first measured value obtained between January and June 2018. If multiple blood pressures were taken on the same day, we averaged available values.

## Covariates

Based on prior literature relating to patient–clinician communication and electronic communication practices [25–29], we expected differences in taxa use based on patient and clinician characteristics. We therefore controlled for patient age as of January 1, 2017; patient sex; race (Black, White, and other); payer type (public, private, uninsured, or other); rural home location as a bivariate derived from Rural–Urban Commuting Area codes [30]; health condition (diabetes only, hypertension only, or both conditions); the number of outpatient and inpatient visits during 2017; and the number of threads initiated during 2017. We also included baseline A1C and blood pressure values in models measuring change in glycemic control and blood pressure, respectively. For models that included only patients who initiated message threads (ie, secure message–only population), we included the average distance between zip code centroids of patients’ homes and the clinics to which they sent messages.

## Qualitative Analyses

We assigned taxa to all messages—those generated by patients and clinic staff—that were saved to the patient’s chart and part of patient-initiated threads created and completed between January 1 and December 31, 2017. Our context unit was the message thread. Coding units were no longer than a single message but could be shorter depending on the content in the message (eg, if multiple taxa are applied to the message). A given message was assigned as many taxa as there were concepts in the message; however, we limited the number of times a given taxon (ie, a single code) could be counted for each message to 1 per message.

A primary coder (DH-G) assigned taxa to all messages while a secondary coder (JDS) applied taxa to a random sample of messages (n=1908). The primary coder trained the secondary coder based on a set of definitions and sample coded text collected from a pilot study [22]; these samples and definitions were refined as the coding process continued. We conducted

the coding in batches and discrepancies were discussed and reconciled following the completion of each batch. The primary coder recoded each batch as appropriate based on those discussions. [Multimedia Appendix 2](#) lists the interrater and intrarater reliability coefficients for the last coded batch. Intrarater reliability ranged from fair to excellent. Three taxa received a poor kappa rating when comparing the results from the 2 coders (interrater reliability): clinician-generated *Action response/Denies*, *Recommendation to schedule*, and patient-generated *Information seeking/Logistics*.

## Quantitative Analyses

We estimated unadjusted differences by patient characteristics based on use of secure messaging by applying chi-square analyses for categorical variables and unpaired *t* test of means for continuous variables. We executed 2 linear regression analyses for each combination of taxon and dependent variable. The first model used the full population and the second used the secure message–only population. The comparison in the full population models included all patients who did not initiate a message thread and those patients who sent or received messages with the selected taxon. Models that included the secure message–only population compared patients who sent or received messages coded with the selected taxon to those who sent or received other types of messages. We report results as the unstandardized regression coefficient ( $\beta$  weight). We conducted all analyses using SAS version 9.4 (SAS Institute).

## Results

[Table 2](#) presents the descriptive statistics for our study population, comparing the populations who sent messages in 2017 to those who did not. Among patients with diabetes, we observed differences in the use of secure messaging by age, condition, insurance type, and sex. Except for age, we observed similar differences in use of secure messaging among patients with hypertension.

### Change in A1C Among Patients With Diabetes

Among patients who initiated threads, we observed a mean A1C decrease of  $-0.56$ , with the 2018 value being statistically lower on average than the 2016 value ( $P<.001$ ). The same was not true among patients who did not initiate threads ( $P=.20$ ). We observed differential changes between 2016 and 2018 when comparing patients with a baseline A1C indicating controlled diabetes ( $<7.0$ ) versus uncontrolled diabetes ( $>7.0$ ). Among patients who sent secure messages, we observed a mean increase in A1C of  $.04$  for patients with controlled diabetes ( $n=151$ ), compared to a mean decrease of  $-1.22$  among patients with uncontrolled diabetes ( $n=138$ ).

Figure 1 displays statistically significant associations between taxa and A1C changes for the taxa. Taxa not represented in the table were not associated with A1C changes at  $P<.05$  but are available in Multimedia Appendix 3, which also lists the *P*-value

for all covariates. Baseline A1C was the only covariate with statistical significance ( $P<.001$ ) across all analyses.

As their proportion of *Information seeking* increased, patients experienced greater declines in their A1C values. This was true when comparing patients within the full population and among the secure message-only population. Conversely, patients who shared information with their clinic staff experienced A1C increases, compared to those who sent other types of messages to clinic staff. Three clinician-generated subtaxa were associated with A1C changes. Patients who received *Orientation to procedures and treatments* had declines in A1C compared to patients who did not initiate threads ( $\beta=-.07$ ; 95% CI  $-0.13$  to  $-0.01$ ), whereas patients who received *Medical guidance* had increased A1C compared to patients who received other content from clinic staff ( $\beta=.08$ ; 95% CI  $0.01$ - $0.16$ ). Similarly, patients who received *Encouragement* from clinic staff experienced increased A1C values ( $\beta=.16$ ; 95% CI  $0.02$ - $0.03$ ) between 2016 and 2018.

**Figure 1.** Associations between taxa and A1C changes.

### Change in SBP Among Patients With Hypertension

Overall, we observed an unadjusted average increase in SBP between 2016 and 2018 among patients who initiated threads (3.41-point increase;  $P < .01$ ) and patients who did not initiate threads (2.45-point increase;  $P = .02$ ). Among patients who sent secure messages, those with controlled systolic blood pressure ( $< 120$  mmHg) experienced a mean increase in SBP of 16.41 ( $n = 149$ ), compared to a mean decrease of  $-0.71$  among those with uncontrolled SBP ( $n = 471$ ).

Figure 2 presents the taxa associated with SBP changes among these populations. Full analysis results are available in [Multimedia Appendix 3](#). Two patient-generated taxa (*Self-reporting* and *Appreciation or praise*) and the clinician-generated taxon for *Information sharing/Deferral* were associated with increased SBP. This was true in both population comparisons. By contrast, we observed decreased SBP among patients who sent *Complaints* compared to patients who did not initiate threads. Covariates of statistical significance included baseline SBP ( $P < .001$ ), race (Black vs White;  $P < .05$ ), and, for some analyses, age ( $P < .05$ ) and number of outpatient visits ( $P < .05$ ).

**Figure 2.** Associations between taxa and SBP changes. SBP: systolic blood pressure.

## Change in DBP Among Patients With Hypertension

Among patients who initiated threads and those who did not, we found statistically significant unadjusted increases in DBP between 2016 and 2018 of 1.71 and 1.67, respectively ( $P=.007$  and  $P=.003$ , respectively). Among patients who sent secure messages, patients with controlled DBP ( $n=351$ ) at baseline ( $<80$  mmHg) experienced a mean increase in DBP of 6.57,

compared to a mean decrease of  $-4.62$  among patients with uncontrolled DBP ( $n=269$ ) at baseline ( $>80$  mmHg).

Figure 3 presents the associations between taxa and changes in DBP that were statistically significant at  $P<.05$ . Full analysis results are available in [Multimedia Appendix 3](#). Three covariates were statistically significant across all analyses (age [ $P<.01$ ], baseline DBP [ $P<.001$ ], and number of outpatient visits [ $P<.05$ ]).

**Figure 3.** Associations between taxa and DBP changes. DBP: diastolic blood pressure.

Three patient-generated taxa were associated with increased DBP (*Schedule request/Reschedule*, *Schedule request/New symptoms or conditions*, and *Appreciation or praise*). Similar effect sizes were observed across the 2 models for each taxon. We also observed that as the prevalence of clinic staffs' nonresponse increased, patients experienced greater declines in DBP. Similarly, patients who received proportionally more *Action response*-related content (including *Acknowledgment*, *Fulfills request*, and *Partially fulfills request*) had greater DBP decreases. Patients who received *Orientation to procedures or treatments* had correspondingly increased DBP, compared to patients who did not receive those kinds of messages from clinic staff.

## Discussion

### Principal Findings

We present here the first findings exploring associations between secure message content and patient health outcomes. Our research found associations between selected message content and changes in patients' glycemic levels and blood pressures. As we anticipated, patients who sent *Information seeking* messages, or who received *Orientation to procedures or treatments* messages from clinic staff, experienced greater decreases in A1C. Consistent with other research [12,14,16-19], we found an overall association between secure messaging use and improved A1C. Also as expected, we observed DBP

decreases among patients who received confirmation of action, SBP increases in response to *Information sharing/Deferral*, and DBP increases associated with *Scheduling request/New condition*.

Counter to our hypotheses, however, we found that A1C increased among patients who shared information with clinic staff. We were only able to identify a statistically significant association in the level 1 *Information sharing* taxon ( $P=.02$ ). Associations in the *Information sharing* subtaxa were not statistically significant ( $P>.05$ ). Detecting an association at the grouped *Information sharing* level makes it challenging to interpret these results, as patients who provide *Clinical updates* may be receiving care from multiple providers and may have other health conditions that impact their glycemic levels. Patients who self-report to their clinicians, however, may be practicing self-management of their condition which, according to Street et al [11], should be associated with improved patient health outcomes. Similarly, information exchange, as represented in the *Information sharing/Response to clinician's message*, should be associated with improved outcomes. Our inability to detect a statistically significant association at the subtaxa level for *Information sharing* makes it difficult to interpret these results further. Future studies should consider expanding the sample size to improve the ability to detect associations at the subtaxa level.

We also observed DBP increases associated with certain types of patient-generated *Scheduling requests* and *Information sharing* by clinic staff. It could be that these patients had new procedures or other treatments that contributed to their DBP increases which could be a confounder to any possible influence on outcomes. Although our analyses controlled for patients' number of outpatient and inpatient visits, we did not control for severity of co-occurring conditions or types of procedures patients may have undergone during the study period. We did find that baseline DBP was a significant ( $P<.001$ ) predictor of the patients' change in DBP between baseline and endpoint.

We also observed an inverse association between DBP and clinic nonresponse: patients' DBP decreased as nonresponse prevalence increased. Our findings should not be taken as advocating for nonresponse to improve patients' health, because there are many unanswered questions about what is driving these findings. It will be important to assess when nonresponse may be appropriate and when it might have deleterious effects. For example, it is possible that certain types of patient-initiated threads do not require a clinic response, such as when a prescription refill request is completed, and patients are notified by their pharmacy that the prescription is ready rather than the clinic. Future research should explore the best communication modality for responses.

In the analyses that used only patients who initiated message threads, we found that as the prevalence of *Schedule request/Reschedule* increased, so did patients' DBP. We interpreted a reschedule request as a manifestation of self-care, following Mishel's Uncertainty in Illness Theory [23], because patients are taking charge of their health care visits by rescheduling to a time more convenient to them, thereby leading to less stress. Our findings indicate this is not the case. Instead, the poorer outcomes associated with *Schedule request/Reschedule* may be a manifestation of stress in patients' lives that required rescheduling medical appointments, a lack of or decline in activation, or a deficit in access to care (eg, transport issues). If these patients were not managing their stress and not maintaining their levels of self-care, their health outcomes might suffer as their patient activation threshold declined [31-33]. Consistent with this, we observed similar poor outcomes—with slightly larger effect sizes—associated with appointment requests for new conditions or symptoms.

Our research identified different effects by health condition on outcomes associated with staff sharing *Orientation to processes and treatments*. Patients with diabetes who received these messages had lower A1C levels in 2018 but patients with hypertension experienced increased DBP. Clinician-generated *Information sharing/Deferral* was associated with increased SBP among patients with hypertension, but we did not observe similar associations for A1C changes. It will be important to apply this taxonomy to other conditions to determine if other differences between outcomes and communication content exist by condition, to better improve communication between patients and clinic staff in ways that advance patients' health.

We included a number of covariates in our analyses, selected based on previous research findings that indicated their relevance to secure messaging use or patient health outcomes.

Not surprisingly given the differences we reported in the unadjusted changes in outcomes by patients' control status, baseline values for all outcome measures were statistically associated with the change between baseline and endpoint. In our adjusted analyses, we did not find a statistical relationship with health insurance type, number of inpatient visits, number of message threads, rural home location, or differences between Whites and other races. We were unable to include ethnicity in our analyses due to limitations in the source data. Consistent with other research that has found disparities in health outcomes between Black and White patients [34,35], we observed that Black patients experienced increases in SBP when compared with White patients after controlling for all other covariates in the analysis. Given that some message content was associated with patient outcomes and that race is also associated with these outcomes, future studies should explore whether the message content patients send and receive is associated with their race.

A recent literature review found that the majority of studies detected no association between clinicians' implicit bias and treatment recommendations when clinicians were asked to provide a diagnosis or treatment recommendation based on a written scenario [36]. Conversely, a different review noted that 5 of 6 observational and patient-reported measure-based studies found that physicians provided Black patients with less information than Whites [37]. Understanding how secure messaging communication varies by patient demographic characteristics and social determinants of health will be important to understanding how secure messaging might be used to improve patient outcomes in the future.

## Study Limitations

It is important to remember that this study examines the taxa in isolation; that is, a taxon is one component of the overall electronic conversation represented in each thread. From this research, we do not know what patient-generated messages preceded the staff response, so we cannot determine if, for example, *Orientation to procedures and treatments* responses answered patients' questions or were appropriate responses to the patient-initiated request. Analyses that explore the call-and-response nature of the message thread—that consider the initiating request, final response, and the pathway to get to that final response—should yield more insight into these results. For example, patients who requested an appointment but received *Orientation to procedures and treatments* may have poorer outcomes than patients whose request was partially or completely fulfilled. It may also be that the number of clinic staff involved in responding to a thread, or the time taken to respond, has an impact on patient outcomes by increasing uncertainty or reducing patients' trust [23]. Examining these factors might help explain why some of our findings do not align with our study hypotheses.

An important consideration for this research is that it demonstrates correlations and not causation. We hypothesized that *Self-reporting*, patients' *Appreciation and praise* for clinic staff, and staff *Encouragement* would be associated with improved outcomes but we found the opposite: poorer DBP and A1C values in 2018 were associated with the *Encouragement* and *Appreciation and praise* taxa and patients who self-reported

biometrics experienced increased SBP between the 2 years. Our outcomes were based on measurements obtained before and after the message collection period. If instead we obtained measurements in parallel to the secure messaging period, it is possible that we might have different results. For example, effects observed in 2018 may have less relevance to messages sent earlier in the calendar year (eg, patients only sent messages in the first quarter or half of the year). Another avenue of future study would include adding in more frequent measurements and exploring ways to identify any long-term impacts associated with certain taxa.

The Street et al [11] framework highlights intermediate outcomes on the pathway between communication functions and health outcomes. A proxy for the access to care construct, for example, might be overall health care utilization or whether the patients follow routine guidelines for care (eg, diabetic eye and foot examinations, or routine follow-up or preventive care appointments). Other constructs that could be measured with existing secondary data include self-care which might include the appropriate medication refill rates. These proximal outcomes also align to ones known to be associated with patient activation [38,39], further reinforcing the benefit to conducting these analyses. Future studies should explore associations between these taxa and those proximal and intermediate outcomes.

Responses to patients' messages are typically triaged by clinic staff such that only the most complex messages are shared with physicians [40-42]. Effective workflow design may be critical to effective and efficient responses. These workflows, however, may be very clinic and physician specific. Our study did not incorporate this aspect into our analysis, because we did not have data on workflow practices utilized by different clinics. We also know that communication behaviors vary by patient and clinician characteristics [25-29,43-48]. Our study controlled for patient characteristics, but not clinician characteristics. Although we captured the type of clinic staff who responded to individual messages, we did not control for that in our analyses because we aggregated counts based on patient and patients typically had responses from a variety of clinic staff types. Future studies should conduct analyses at the clinician and clinic levels to account for workflow and communication practice differences.

Among our patient population, we found patients with controlled glycemic levels or blood pressure had a mean increase over the study period, whereas patients with uncontrolled glycemic or blood pressure had a mean decrease. Our study was not powered sufficiently to identify associations based on whether patients' A1C or blood pressure was controlled at baseline [21]. It is likely, however, that patients' communication and clinic staff responses differ based on patients' current health status. We controlled for patients' baseline values for each health outcome measure and these values were significantly associated with all the outcomes ( $P<.001$ ), indicating a need for further research to better understand the differences in taxa use based on patients' baseline health status.

We used only messages saved to patients' charts. If clinic staff did not opt to save a message to the chart, it would not be captured in this study. We expect, therefore, that the numbers

presented in this paper underestimate the number of messages sent and received by patients. We also expect that the number of nonresponses was underrepresented because it seems likely that if clinic staff did not respond to a message, they would be less likely to save the message as well. It is also possible that messages we classified as nonresponse had a response that was not saved to patients' charts. If we assume that our sample underestimated the number of messages sent and received by patients, we would expect a bias toward the null and our results should therefore be viewed as conservative estimates of effect.

To our knowledge, only one other study quantified clinic nonresponse to patients' messages. Our study is the first to quantify nonresponse with a large number of messages and to link nonresponse to patient outcomes. The study by Lanham et al [49] study conducted chart reviews to determine if response occurred through other modalities and found that almost half of their 11 unanswered messages were resolved through other mechanisms. Our study did not assess responses by other communication modalities nor did it determine whether a response was warranted, but if we extrapolate the Lanham et al [49] findings to our work, that implies that only about half of the threads lacking a message response would have received a response not accounted for in our research (eg, phone, discussion during appointment). To better understand our study findings, it will be important to account for these other response types in future studies.

It is possible that thread initiation may be an indication of patient activation and engagement and clinic nonresponse may not inhibit patients' activation. Patient activation follows 4 stages: belief in the importance of engagement in the care processes; knowledge in what is needed to improve health; taking action to improve or maintain health; and finally, maintaining or persisting in those actions even when stressed [31]. Patients at higher stages of activation generally experience better outcomes, have lower health care costs, and higher rates of health screening and prevention activities [32,38,39,50]. Alexander et al [51] found that patients who communicated outside of office visits had higher patient activation rates. Consistent with their research, we found that patients who initiated threads experienced A1C improvements compared to patients who did not initiate threads.

Several of our taxa had poor interrater reliability scores and as a result, these findings should be viewed with caution. It is notable that none of these taxa were statistically associated with our outcomes, perhaps due to the potential lack of clarity in their definitions. Future studies using this taxonomy should seek to clarify the definitions for these taxa.

## Conclusion

This is the first study to explore associations between message content and patient health outcomes. We identified associations between certain patient- and clinic staff-generated taxa and changes in patients' glycemic levels and blood pressure. We also found that staff nonresponse was associated with improvements in patients' DBP, although the reasoning behind this association is unclear. Significantly more research is needed to better understand what we observed in our study, including exploring the context of the full electronic conversation and

outcomes, examining the temporal relationships between outcomes and message content, evaluating the impact of the potential confounder of patients' activation, exploring other intermediate outcomes that might be better measures of effect, and incorporating other communication modalities to capture

responses that occur outside of secure messaging. In the meantime, health care staff should be aware that message content is associated with patients' health outcomes when corresponding with patients through this medium.

## Abstract

**Background:** The high demand for health care services and the growing capability of artificial intelligence have led to the development of conversational agents designed to support a variety of health-related activities, including behavior change, treatment support, health monitoring, training, triage, and screening support. Automation of these tasks could free clinicians to focus on more complex work and increase the accessibility to health care services for the public. An overarching assessment of the acceptability, usability, and effectiveness of these agents in health care is needed to collate the evidence so that future development can target areas for improvement and potential for sustainable adoption.

**Objective:** This systematic review aims to assess the effectiveness and usability of conversational agents in health care and identify the elements that users like and dislike to inform future research and development of these agents.

**Methods:** PubMed, Medline (Ovid), EMBASE (Excerpta Medica dataBASE), CINAHL (Cumulative Index to Nursing and Allied Health Literature), Web of Science, and the Association for Computing Machinery Digital Library were systematically searched for articles published since 2008 that evaluated unconstrained natural language processing conversational agents used in health care. EndNote (version X9, Clarivate Analytics) reference management software was used for initial screening, and full-text screening was conducted by 1 reviewer. Data were extracted, and the risk of bias was assessed by one reviewer and validated by another.

**Results:** A total of 31 studies were selected and included a variety of conversational agents, including 14 chatbots (2 of which were voice chatbots), 6 embodied conversational agents (3 of which were interactive voice response calls, virtual patients, and speech recognition screening systems), 1 contextual question-answering agent, and 1 voice recognition triage system. Overall, the evidence reported was mostly positive or mixed. Usability and satisfaction performed well (27/30 and 26/31), and positive or mixed effectiveness was found in three-quarters of the studies (23/30). However, there were several limitations of the agents highlighted in specific qualitative feedback.

**Conclusions:** The studies generally reported positive or mixed evidence for the effectiveness, usability, and satisfactoriness of the conversational agents investigated, but qualitative user perceptions were more mixed. The quality of many of the studies was limited, and improved study design and reporting are necessary to more accurately evaluate the usefulness of the agents in health

care and identify key areas for improvement. Further research should also analyze the cost-effectiveness, privacy, and security of the agents.

## Introduction

### Background

Conversational agents are among the many digital technologies being introduced into the health sector to address current health care challenges, such as shortages of health care providers, which reduce the availability and accessibility of health care services [1-3]. Conversational agents use artificial intelligence (AI), including machine learning (a statistical means of training models with data so that they can make predictions based on a variety of features) and natural language processing (NLP; the ability to recognize and analyze verbal and written language) to interact with humans via speech, text, or other inputs and outputs on mobile, web-based, or audio-based platforms [1,4]. Many of these agents are designed to use NLP so that users can speak or write to the agent as they would to a human. The agent can then analyze the input and respond appropriately in a conversational manner [5].

Conversational agents first emerged as a tool in health care in 1966, with the development of a virtual psychotherapist (ELIZA) that could provide predetermined answers to text-based user input [6]. In the decades since, the capabilities of NLP have significantly progressed and aided the development of more advanced AI agents. Many different types of conversational agents that use NLP have been developed, including chatbots, embodied conversational agents (ECAs), and virtual patients, and are accessible by telephone, mobile phones, computers, and many other digital platforms [7-10]. The types of input that conversational agents can receive and interpret have also expanded, with some conversational agents capable of analyzing movements, such as gestures, facial expressions, and eye movements [11,12].

Conversational agents have been developed for many different aspects of the health sector to support health care professionals and the general public. Specific uses include screening for health conditions, triage, counseling, at-home health management support, and training for health care professionals [8,13-15]. With phone, mobile, and online platforms being widely accessible, conversational agents can support populations with limited access to health care or poor health literacy [16,17]. They also have the potential to be affordably scaled up to reach large proportions of a population [3]. Due to this accessibility, conversational agents are also a promising tool for the advancement of patient-centered care and can support users' involvement in the management of their own health [17,18]. Personalizable features have the potential to further improve usability and satisfaction, although more research is needed to

evaluate their effectiveness in achieving their stated health outcomes and reducing costs and to ensure that there are no negative consequences for decision making or privacy [10].

Despite the large body of research concerning the application of conversational agents in health care, most reviews have limited their focus to a particular health area, agent type, or function [10,19-22]. Although there are a few recent systematic reviews that have examined a more comprehensive scope, they have presented an overall synthesis of the body of knowledge. One review developed a taxonomy that described the architecture and functions of conversational agents in health care and the state of the field but did not evaluate the effectiveness, usability, or implications for users [5]. Another systematic review investigated the outcome measures of the studies of conversational agents but limited the inclusion criteria to agents that used natural language input and had been tested with human participants [2]. Additionally, their initial database searches only retrieved 1531 articles, which raises the concern that some relevant articles may have been overlooked [2]. Their search was updated in February 2018, but given the rapid pace of technological development, there is a need to provide an update and expansion to these previous systematic reviews.

For conversational agents to be successful in health care, it is crucial to understand the effectiveness of current agents in achieving their intended outcomes. However, it is just as important to understand how users feel about and relate to these agents because the adoption of new health technologies depends on user perceptions (eg, whether they trust the technology, find it easy to use, and feel that privacy and data security are respected) [23]. User-identified problems will need to be addressed if conversational agents are to have a significant impact on health care, because their impact depends on people being willing to use them and preferring to use them over alternatives. The information gathered in this review identifies the current issues with conversational agents that need to be overcome and can be used to help determine which elements of the agents are most likely to be successful and useful in various aspects of health care. As conversational agents are often touted as having the potential to reduce the burden on health care resources, evaluations of the implications of the agents for improved health care provision and reduced resource demand also need to be assessed.

### Objectives

The primary objectives of this review are to describe the scope of conversational agents currently being used for health care activities (by patients, health care providers, or the general public), examine the user perceptions of these agents, and

evaluate their effectiveness. We developed 3 main research questions to address these objectives. First, are the conversational agents investigated effective at achieving their intended health-related outcomes, and does the effectiveness vary depending on the type of agent? Second, how do users rate the usability and satisfactoriness of the conversational agents, and what specific elements of the agents do they like and dislike? Finally, what are the current limitations and gaps in the utility of conversational agents in health care? These objectives build on previous systematic reviews while widening the scope of included studies to update the body of knowledge on conversational agents in health care and to inform future research and development.

## Methods

### Database Search

The full methods for this review have been published in detail in a systematic review protocol [24]. The population, intervention, comparison, and outcome framework [25] was used to develop the search strategy, which was implemented following the PRISMA-P (Preferred Reporting Items for Systematic Review and Meta-Analyses Protocols) checklist [26]. No study design filter was used; any type of study was eligible for inclusion. The search strategy was finalized and tailored to different databases in consultation with a medical librarian. PubMed, Medline (Ovid), EMBASE (Excerpta Medica dataBASE), CINAHL (Cumulative Index of Nursing and Allied Health Literature), Web of Science, and the Association for Computing Machinery Digital Library databases were searched. The search terms were grouped into 3 themes (conversational agents, health application, and outcome assessment) to capture all studies that fit the key inclusion criteria: evaluating conversational agents used in health care. These themes were subsequently searched with the structure: conversational agent (MeSH OR Keywords) AND health application (MeSH OR Keywords) AND outcome assessment (MeSH OR Keywords). The full search strategy can be found in [Multimedia Appendix 1](#). The search was completed on November 29, 2019.

### Inclusion and Exclusion Criteria

This systematic review aimed to assess conversational agents designed for health care purposes. Studies that evaluated at least 1 conversational agent were included. Studies targeting any population group, geographical location, and mental or physical health-related function (eg, screening, education, training, and self-management) were included. These broad inclusion criteria were established to enable an assessment of a wide range of applications of conversational agents. There were no restrictions on study type, as long as a conversational agent was evaluated, and intervention and observational studies such as cross-sectional surveys, cohort studies, and qualitative studies were included. Intervention studies were not required to have a specific comparator or any comparator.

During the screening process, studies of conversational agents that were not capable of interacting with human users via unconstrained NLP were excluded. These included conversational agents that only allowed users to select from predefined options or agents with prerecorded responses that

did not adapt to subsequent user responses. The basis for this exclusion is that, without the capability of using NLP, computational methods and technologies are rudimentary and do not advance the aims of AI for autonomous computational agents. As many studies did not explicitly state whether the investigated agent was capable of NLP, a description in the paper of the conversational agent allowing free-text or free-speech input was used as an indicator for NLP, and these studies were included. Studies that did not report the architecture of the agent were excluded.

Due to the number of conversational agents in development and/or those that did not progress to the evaluation stages of development, studies that were solely descriptive were excluded. Furthermore, because of the pace at which conversational agents have developed over recent decades, studies were limited to those published during or after 2008. In 2008, the first iPhone was released, and it marks an increase in the prevalence and capabilities of digital technology. Only studies published in English were included to ensure accurate interpretation by the authors. Conference publications were also excluded from the review of peer-reviewed literature.

### Outcomes

The primary objective of this review was to provide an overview of the use of NLP conversational agents in health care. Therefore, the primary outcomes evaluated were the effectiveness of conversational agents in achieving their intended health-related outcomes and user perceptions of the agents (including but not limited to acceptability, usability, satisfaction, and specific qualitative feedback). Secondary outcomes included improvement in health care provision and resource implications for the health care system.

### Screening and Study Selection

All studies retrieved from the databases were stored in the reference management software EndNote (version X9, Clarivate Analytics), which automatically eliminated duplicates. Due to time constraints, the EndNote search function was used to extract relevant studies before the screening of the citations against the inclusion and exclusion criteria by 2 independent reviewers. Where duplicates or publications from the same study were identified, the more recent publication or the one with the most detail was selected for inclusion in the review. All disagreements were discussed, and if a consensus was not reached, a third reviewer was consulted. Full EndNote search details are shown in [Multimedia Appendix 2](#).

The full texts of the articles that met the inclusion criteria were screened by one of the reviewers. Of the screened articles deemed eligible for inclusion, 58 were conference or meeting abstracts and did not have full texts available; therefore, they were excluded. This highlights the early developmental stages of many of these agents.

### Data Extraction

Data were extracted by 1 reviewer, and key data points from the studies, specified in the protocol and identified on further study of the publications, were recorded in a spreadsheet and validated by a second reviewer. The data extraction form was

based on the minimum requirements recommended by the Cochrane Handbook for Systematic Reviews [27]. The types

of data extracted from the studies are shown in Table 1.

**Table 1.** Data extracted from the studies.

Article information	Data extracted
General study information	<ul style="list-style-type: none"> <li>Title of publication</li> <li>Year of publication</li> <li>Authors</li> </ul>

### Risk-of-Bias and Quality Assessment

All quality assessments were conducted by 2 independent reviewers, with disagreements resolved by consensus. If this was not possible, the opinion of a third reviewer was sought. As there was a wide variety of study designs, the study types were classified by 1 reviewer and validated by a second

reviewer, with disagreements being resolved by discussion with a third reviewer. As the broad inclusion criteria were intended to capture all relevant studies, a few of the included studies used implementation models for artificial AI research that were beyond the scope of classic public health design methods. This resulted in some study designs being categorized as *other*.

The Cochrane Collaboration risk-of-bias tool was used to evaluate the risk of bias in randomized controlled trials (RCTs) [28]. The CASP (Critical Appraisal Skills Programme) tools for cohort and qualitative studies were used for the respective studies [29], and the Appraisal tool for Cross-Sectional Studies (AXIS) tool was used to assess the quality of cross-sectional survey studies [30]. Studies that were coded as *other* design types were also assessed using the AXIS tool, which was deemed to be the most rigorous and appropriate tool because it systematically evaluates elements of the introduction, methods, results, and discussion sections, and is not limited to the RCT-specific questions used in the risk-of-bias tool.

The results of the Cochrane Collaboration risk-of-bias tool were summarized using RevMan 5.3. CASP and AXIS scores were calculated using yes=1, no=0, and cannot tell or do not know=0 for each question. The scores for each question were summed to provide a score for each study, which were averaged according to study type and are presented in the results.

### Data Analysis and Synthesis

Due to the variability in populations, interventions, outcomes, and study designs, a meta-analysis of the studies was not possible. Therefore, we report a structured analysis of the findings to draw conclusions about the effectiveness and user perceptions of conversational agents in health care. For the purpose of this review, the agent was considered effective if there was a statistically significant ( $P<.05$ ) improvement in a given outcome as compared with a comparator or control, or over time. If no significance was reported or the difference was nonsignificant or significantly worse between groups or over time, the agent was considered to have no significant evidence supporting it. Limitations and future directions for research were also summarized.

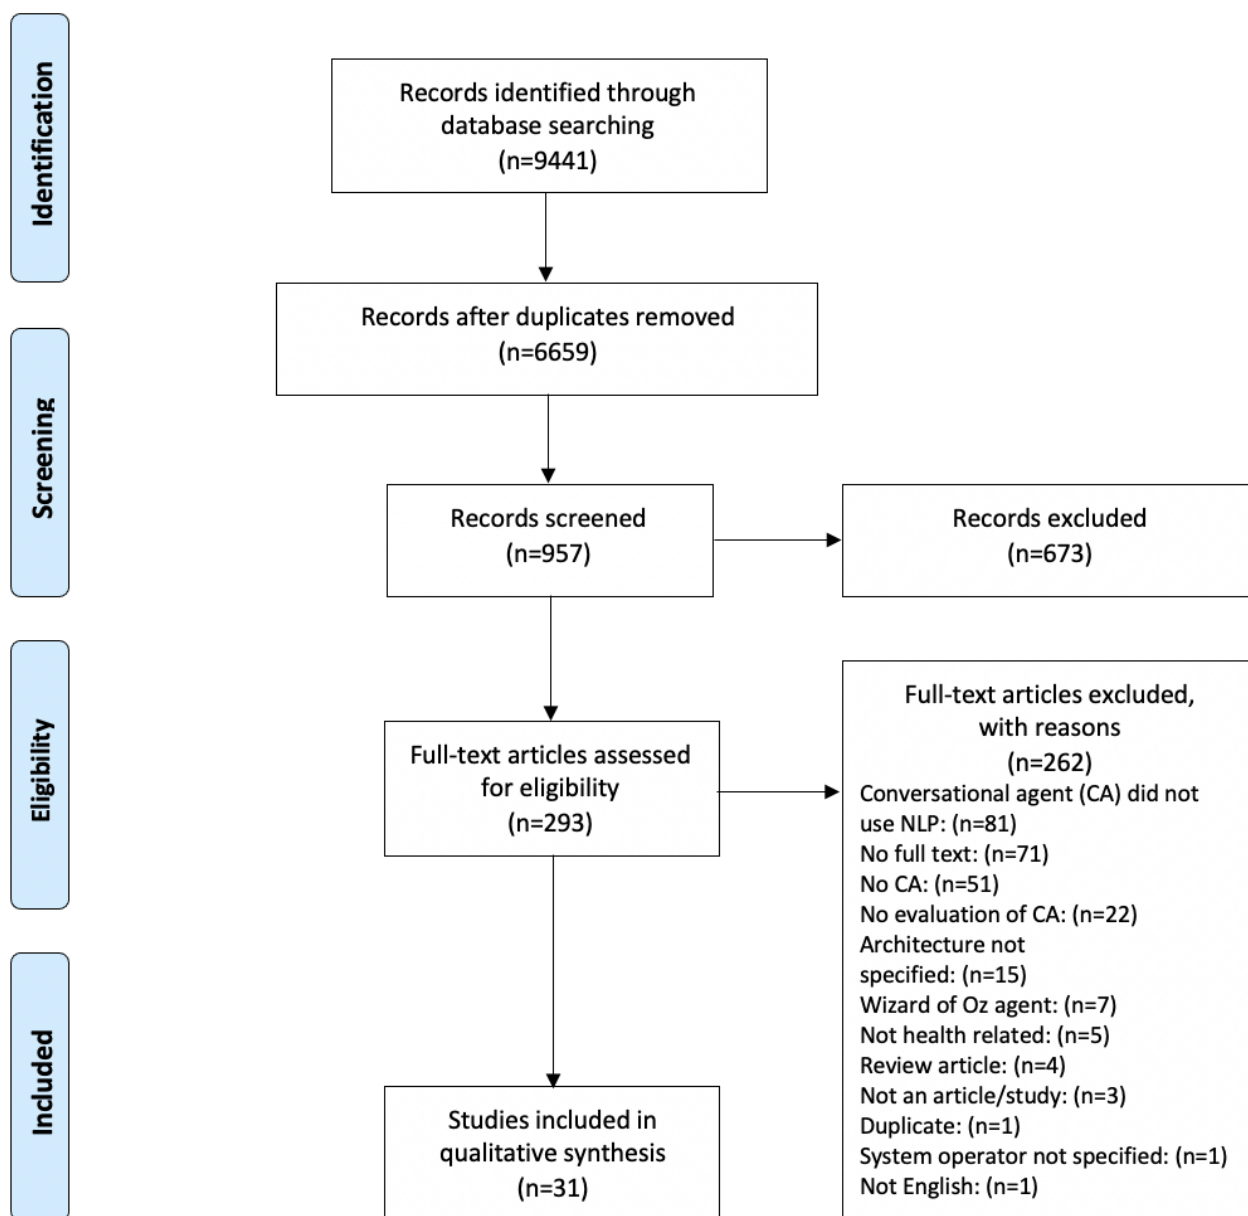

The synthesis framework for the assessment of health information technology (SF/HIT) was used to structure the evaluation of the studies because it included a whole system set of outcome variables [31]. These included effectiveness, satisfaction, and perceived ease of use or usefulness, among others. In accordance with the framework, evidence for each of the outcome variables was coded as *positive or mixed* or *neutral or negative*. If the study did not address the outcome in question, it was coded as *neutral or negative*.

Finally, where qualitative user feedback was reported by the studies, it was examined to extract common themes by extracting the sections of the original text that discussed the qualitative perceptions, reducing them to key themes, and then comparing those key themes across the different studies.

## Results

### Included Studies

Overall, 9441 studies were retrieved from the 6 databases, of which 2782 were duplicates. The reference management software EndNote was used for initial screening, with keywords based on the original search categories used to exclude studies that did not meet the criteria. After 6 passes, 957 citations remained for abstract screening. The primary reason for exclusion at the screening stage was that the study did not include an interactive, responsive conversational agent ( $n=470$ ), was a review paper ( $n=65$ ), was not health-related ( $n=48$ ), or did not report any evaluation of the conversational agent ( $n=46$ ). Of these 957 citations, 293 were selected for full-text review. In the final review, 31 papers were included. The reasons for exclusion after full-text review are detailed in Figure 1, with the most common reason being that the conversational agent did not use NLP ( $n=81$ ), the full text was not available ( $n=71$ ), or there was no conversational agent in the study ( $n=51$ ).

**Figure 1.** Preferred Reporting Items for Systematic Review and Meta-Analyses flow diagram. NLP: natural language processing.

## Study Characteristics

The characteristics of the 31 included studies are summarized in [Multimedia Appendix 3](#) [8,9,12-15,32-56]. Of these studies, 45% (14/31) evaluated conversational agents that had some type of audio or speech element. Of the agents, 45% (14/31) were chatbots (including 2 voice chatbots and 1 chatbot that also used a wizard), 19% (6/31) were ECAs (including 1 virtual doctor), and 10% (3/31) were interactive voice response (IVR) phone calls, virtual patients, and speech recognition screening systems. The final 2 comprised a contextual question-answering agent and a voice recognition triage system. In the 26 studies that reported the device that their conversational agent was used on; 35% (9/26) used computers, 27% (7/26) used web-based apps, 23% (6/26) used mobile phone apps, 15% (4/26) used telephone calls; 1 study used a tablet (the percentages do not add up to 100% because one agent could be used on a computer and also the telephone).

There were a wide variety of areas of health care targeted by the conversational agents of the included studies. The largest proportion of them (12/31, 39%) addressed mental health issues [13,32-42], with 19% (6/31) providing some form of clinical decision or triage support [8,12,40,42-44] and treatment support (including encouraging users to get screened) [9,45-49], 10% (3/31) being used to support training of health care students [15,41,50] and the screening or diagnosis of users [14,38,51], 7% (2/31) targeting physical health [52,53] and layperson medical education [54,55]; 1 agent was designed to help monitor users' speech [56]. The percentages do not add up to 100% because some of the studies that addressed mental health also fit into one of the other categories.

The study designs also varied widely, with 29% (9/31) using cross-sectional designs, 26% (8/31) using RCTs, 23% (7/31) using qualitative methods, 19% (6/31) using cohort studies, and 1 using a cluster crossover design. The full data extraction table is available in [Multimedia Appendix 4](#) [8,9,12-15,32-56].

### Overall Evaluation of Conversational Agents

Overall, about three-quarters of the studies (22/30, 73%) reported positive or mixed results for most of the outcomes. A total of 8 studies were coded as reporting positive or mixed evidence for 10 or more of the 11 outcomes specified in the SF/HIT; the analysis for this review was limited to the interpretation of impact as reported by study authors to reflect evaluation outcomes. Excluding 1 study, which was an acceptability study only and did not assess the other outcomes, the average number of outcomes that were coded as *positive or mixed* was 67% (7.4/11, SD 2.5). However, the number of outcomes met per study ranged from 1/11 to 11/11 (9-100%). Perceived ease of use or usefulness (27/30, 90%), the process

of service delivery or performance (26/30, 87%), appropriateness (24/30, 80%), and satisfaction (26/31, 84%) were the outcomes that had the most support from the studies. Just over three-quarters (23/30, 77%) of the studies also reported positive or mixed evidence of effectiveness.

However, very few studies discussed the cost-effectiveness (5/30, 17%, coded as *positive or mixed*) or safety, privacy, and security (14/30, 47%, coded as *positive or mixed*) outcomes for the agents being evaluated. About a quarter of studies (8/30, 27%) had neither positive nor mixed reported evidence for more than half of the SF/HIT outcomes. The evaluation of the SF/HIT outcomes is summarized in [Table 2 \[31\]](#).

**Table 2.** Summary of the studies based on the evaluation outcomes from the synthesis framework for the assessment of health information technology<sup>a</sup>.

First author (reference)	Preventive care	Adherence or attendance	Efficiency	Perceived ease of use or usefulness	Effectiveness	Performance	Safety or privacy or security	Acceptability	Cost-effectiveness	Appropriateness	Satisfaction	n (%)

<sup>a</sup>Positive or mixed results have been coded as 1, and neutral or negative results as 0.

When grouped by the agent's health care scope, studies of certain types of agents appear to do better than others (Table 3). Studies examining screening or diagnosis agents and treatment support agents had the highest average number of positive or mixed outcomes (mean 10, SD 0.6, and mean 9, SD 1.2, respectively). Treatment support agents had primary functions that included empowering patients to engage more

fully in clinical appointments, encouraging attending screenings for health care conditions, and supporting patient self-management. In contrast, mental health agents focused on addressing challenges related to depression, anxiety, and alcohol abuse, among others. However, given the small number of studies for each category of agents, these comparisons should be interpreted with caution.

**Table 3.** Summary of evaluation outcomes by the area of health care addressed by the conversational agent<sup>a</sup>.

Agent focus	Number of studies	Average number of outcomes coded positive or mixed, n (%)	Range of scores (SD)
Mental health [13,32-42]	12	7 (66)	5-11 (2.4)
Clinical decision or triage support [8,12,40,42-44]	6	7 (67)	5-10 (1.9)
Treatment support [9,45-49]	6	9 (79)	7-10 (1.2)
Health care training (students) [15,41,50]	3	7 (67)	5-10 (2.5)
Screening or diagnosis [14,38,51]	3	10 (88)	9-10 (0.6)
Health care education (laypeople) [54,55]	2	5 (45)	1-9 (5.7)
Physical health [52,53]	2	4 (32)	3-4 (0.7)

<sup>a</sup>The number of studies does not add up to 31 because some studies fit into 2 categories, and the study on monitoring speech was not included because it only addressed 1 of the 11 outcomes. The percentages associated with the average number of outcomes varied slightly because of rounding.

## Qualitative User Perceptions

A total of 18 of the 31 studies included more specific user feedback. The most frequently raised issue with conversational agents (9 studies) was poor understanding because of limited vocabulary, voice recognition accuracy, or error management of word inputs [13,32-37,41,52]. Related to this issue, as the conversational agents often had to ask questions more than once to be able to process the response, users in 3 studies noted disliking the repetitive conversations with the agents [13,36,37]. Both of these issues are key areas of improvement for future research and development of conversational agents because they represent limitations in the usability of the agents in a real-world context.

Feedback from users in 5 studies expressed a preference for interactivity, with users in 1 study noting that they liked the interactivity of the chatbot [35,37], and users in the other 4 studies expressed a desire for greater interactivity or relational skills in the conversational agent [14,32,34,53]. Similarly, users in 4 studies reported liking that the agent had a personality and/or showed empathy [13,32,34,42], whereas users in other studies reported disliking the lack of personal connection or had difficulty in empathizing with the agent [35,37,50] or reported disliking its limited conversation and responses [35,56].

Due to the wide variety of conversational agents, their aims and health care contexts, much of the qualitative user perception data concerned distinct aspects of the agents. However, several studies reported feedback concerned with customization or availability of feature options, with 2 studies commenting on it positively (eg, having both voice and touch modes to allow hands-free work and rapid data input on a triage system for nurses) [8,35], and 3 studies desiring more features and more control [33,37,48]. Additionally, users in 2 studies suggested that better integration of the agent with electronic health record (EHR) systems (for a virtual doctor [42]) or health care

providers (for an asthma self-management chatbot [48]) would be useful.

Other features of the agents that users reported liking were the reminders and assistance in forming routines [37,48] and that the agents provided accountability [13,34,48], facilitated learning [13,34,37], and were easy to learn and use [8,15]. In the included studies, 3 of the conversational agents were virtual patients, and users in all 3 studies reported liking that it provided a platform for risk-free learning because they were not practicing on real patients [15,41,50].

Several studies reported user feedback that was specific to that conversational agent. This included a preference for telephone IVR over web-based pediatric care guidance [9] and a simple avatar with a computer-generated voice over a more life-like agent with a recorded voice [42]. Users in 1 study reported liking that the agent initiated conversations [37]. There was opposite feedback in 2 studies about the format of the response, with users preferring preformatted options for one chatbot [36], whereas some users preferred the free-text responses for a diagnostic chatbot because it allowed them to provide contextual information. In contrast, others found it more difficult to know how to respond so the agent would understand [14].

Other agent-specific negative feedback was that the virtual doctor did not have the ability to go deep enough or provide access to other materials [42], that too much information was provided [13,33] or the interaction was too long [13], the use of nonverbal expressions by the avatar [35], and a lack of clarity regarding the aim of the chatbot [37]. Some students who used the virtual patients also reported that it was difficult to empathize [50] and that the agent did not sufficiently encompass real situational complexity [15]. The variety of specific feedback reports demonstrates the importance of examining usability for individual conversational agents and tailoring the design to the intended population. Although there were some preferences and

complaints that were frequently reported, much of the feedback was agent dependent. A summary of the thematic analysis is included in [Multimedia Appendix 5](#).

### Implications for Health Care Provision and Resources

Unfortunately, only a few of the studies discussed any improvement in health care provision or implications for resources; 2 of the studies that suggested improvement in health care provision were evaluating virtual patients [41,50], and students in 1 study reported significantly increased confidence in their clinical skills and ability to interview patients. Over 80% of users also reported that the agents helped them follow their treatment more effectively [45] and be more prepared for pediatric visits [9]. In a study of an ECA for sleep disorder screening, 65% of users reported thinking that the agent could provide significant assistance to physicians [51]. Regarding resource implications, the study of a preparatory IVR phone call before pediatric visits found that visit time was significantly reduced in the IVR group compared with the control group [9]. The use of an ECA to screen for depression [38] and a virtual doctor for suicidal patients in emergency departments (EDs) [42] were suggested by the authors to save physicians' time and reduce the costs associated with ED visits for suicidal ideation, but these outcomes were not evaluated. Similarly, another study suggested that mindfulness meditation could be of more use with more cost-effective training made available via a virtual coach [35].

Suggestions such as this, that conversational agents have the potential to improve health care provision, save health care providers' time, and reduce costs, were frequently made in the studies. However, as demonstrated above, very few studies quantified these claims and even fewer measured these outcomes with objective measures. This is a limitation of the studies as a whole. Although many were in the early stages of testing, claims about the potential value to the health care system in terms of time or money should be substantiated. However, as evidenced by the number of *neutral or negative* coding in the evaluation, many of the studies did not consider whole system implementation outcomes. It will be important for the future development of conversational agents to consider outcomes such as these from the beginning so that agents that are not only acceptable and usable but also provide value to the health care system can be built.

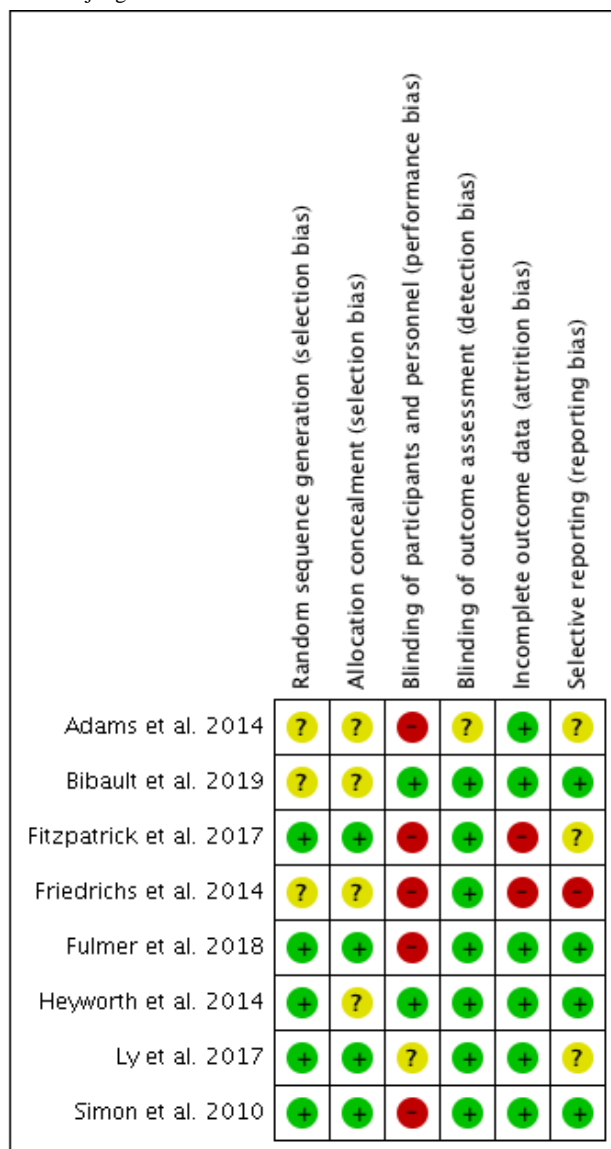

### Risk-of-Bias and Quality Assessments

There were a variety of study types included in this review; so several different quality assessment tools were used to assess the risk of bias and quality of the 31 included studies. A total of 6 studies could not be classified as RCTs, cohort, qualitative, or cross-sectional studies, and their study design was coded as *other* [12,39,40,44,52,55]. Most of these studies were papers describing the development and initial evaluation of conversational agents, and half of them did not have participants [40,44,55]. Initially, studies that did not have an explicit design were classified as qualitative or interpretative studies. However,

on further analysis, many of the studies did not fit the criteria for qualitative studies - evaluating subjective, thematic, and non-numerical data - because they evaluated performance metrics such as word error rates [52], accuracy [12,39,40,52,55], precision [44], and user experience quantified on Likert scales [39]. Therefore, these studies were coded as *other* and assessed using the AXIS tool for cross-sectional studies, which was deemed to provide the most systematic evaluation of the various elements of the studies [30]. The quality of these studies was assessed as best as possible; however, the judgments should be considered in the context of these limitations.

Overall, the quality of the studies was poor to moderate. On average, RCTs [9,13,34,37,46,47,49,53] and qualitative studies [41,48,56] evaluated were generally determined to have the highest quality and lowest risk of bias, with none of the other 3 study types meeting more than half the criteria for quality assessment. The evaluation of the risk of bias for the 8 RCTs ([Figure 2](#)) was carried out using the Cochrane Collaboration risk-of-bias tool [28], and the results were summarized using RevMan 5.3 software (Cochrane) [57]. Overall, the RCTs performed fairly well in the risk-of-bias assessment ([Figure 3](#)). About half the studies were assessed as having a low risk of selection bias because of proper random sequence generation (5/8) and allocation concealment (4/8), and a low risk of reporting bias (4/8), as outcomes reported could be compared with a priori protocols or trial registrations. Most studies reported blinding of outcome assessors (7/8) and a low risk of attrition bias because of low or equal dropout across groups or the use of intention-to-treat analyses (6/8). Most of the studies (5/8) had a high risk of performance bias, but this was predominantly because blinding was not possible given the nature of the intervention.

The cohort (n=9) and qualitative (n=3) studies assessed using the CASP checklists met, on average, 5/12 (range 1-10) and 7/10 (range 4-9) criteria, respectively [29]. Of the cohort studies, the questions with the best performance were, "Did the study address a clearly focused issue?" (8/9 yes), "Was the follow up long enough?" (8/9 yes), and "Do the results of this study fit with other available evidence?" (6/9 yes). Studies performed the worst, either by failing to meet the criteria or failing to report it, on questions about cohort recruitment (1/9 yes), identifying and accounting for confounding factors (1/9 yes), accurate exposure and outcome measurement (2/9 and 3/9 yes, respectively), and the applicability of results to the local population (3/9 yes). The qualitative studies, on the other hand, performed best on the questions about whether the qualitative methodology was appropriate, the consideration of ethical issues, clear statements of findings, and whether the results would help locally (3/3 yes for each). None of the 3 studies reported any consideration of the relationship between researcher and participant. They also performed poorly on questions about sample recruitment, data collection, and data analysis (1/3 yes for each).

**Figure 2.** Risk of bias summary: review authors' judgements about each risk of bias item for each included study.**Figure 3.** Risk of bias graph: review authors' judgements about each risk of bias item presented as percentages across all included studies.

The cross-sectional (n=5) and *other* (n=6) studies assessed using the AXIS tool met, on average, 50% (range 26-80%) and 42% (range 29-70%) of the criteria, respectively [30]. Percentages are reported instead of the exact number of criteria because

several of the questions were not applicable to the studies; so the total number of criteria assessed per study was not the same (averages 19 and 16; ranges 18-20, and 10-19, respectively). Overall, the cross-sectional studies performed best on questions

about the clarity of aims (5/5 yes), appropriate outcome variables for the aims (5/5 yes), internal consistency (5/5 yes), and adequate description of basic data (4/5 yes). They performed worst on questions about sample selection—whether it was taken from an appropriate base to represent the population (1/5 yes) and whether the process was likely to select a representative sample (0/5 yes)—the use of appropriate outcome measures (previously assessed; 0/5 yes), whether the methods were adequately described for replication (1/5 yes), and conflicts of interest (1/5 no, most did not report).

The *other* studies performed best on the questions about whether the study design was appropriate for the aims and whether the conclusions were justified by the results (6/6 yes for both). They also did well, overall, on the appropriate choice of outcome variables and internal consistency (5/6 yes for both). However, all the *other* studies for which the questions were applicable performed poorly on questions about the justification of sample size (0/5 yes), whether the selection process was likely to get a representative sample (0/5 yes), addressing nonresponders (0/2 yes), adequate description of basic data (0/4 yes), concerns about nonresponse bias (0/3 no), the presentation of results for all the analyses described in the methods (0/6 yes, although this was mostly because analyses were not adequately described in the methods), and conflicts of interest (0/6 no, again because nothing was reported). Furthermore, only 1 study adequately addressed the questions about the use of previously assessed outcome measures (1/5 yes), sufficient description of the methods for replication (1/6 yes), and discussion of study limitations (1/6 yes). It should be noted that the AXIS tool used to assess the *other* studies was designed for cross-sectional studies and does not fit exactly with the designs of these studies. Therefore, it is possible that these studies would perform better when assessed by a tool specific to their study type. Tables depicting the judgments for each question of the CASP cohort and qualitative checklists and the AXIS tool for the cross-sectional and *other* studies are included in [Multimedia Appendices 6-9 \[8,12,14,15,32,33,35,36,38-45,48,50-52,54-56\]](#).

## Discussion

### Principal Findings

In this systematic review, we examined 31 studies that evaluated the effectiveness and usability of conversational agents in health care. Overall, studies reported a moderate amount of evidence supporting the effectiveness, usability, and positive user perceptions of the agents. On average, two-thirds of the studies (67%) reported positive or mixed evidence for each evaluation outcome. However, this ranged significantly, with usability, agent performance, and satisfaction having the most support across the studies, and cost-effectiveness receiving hardly any support. It should also be noted that the definitions of *effectiveness* were highly varied and, as evidenced by the methodological limitations identified in the quality assessment, rarely evaluated with the scrutiny expected for medical devices. Although the results reported are promising for the use of conversational agents in health care, there are a number of limitations in both the studies analyzed and the structure of this review that questions the validity of this finding.

With regard to qualitative user perceptions of the agents, specific feedback was very mixed. Users highlighted many positive factors of the agents, particularly their personality and ability to provide empathy and emotional support, that they support learning, they are easy to use and access, and they help them be accountable, all of which support the generally positive evaluations of usability and satisfaction outcomes. However, there were a number of limitations of the agents that were consistently raised across the studies that reported qualitative feedback. These included the following: the agents had difficulty understanding them, the agents were repetitive and not sufficiently interactive, and the users had difficulty forming personal connections with the agents. This suggests that despite the generally positive usability reported by the studies, there are a number of barriers to the successful use of conversational agents in health care that will need to be addressed before they can achieve the greatest impact. It should be noted that this review only included studies of conversational agents that used NLP and that free-text inputs are likely to present greater difficulties for comprehension.

The results of this systematic review are largely consistent with the literature, particularly the previous systematic review evaluating conversational agents in health care [2]. They also found a limited quality of design and evidence in the included studies, with inconsistent reporting of study methods (including methods of selection, attrition, and a lack of validated outcome measures) and conflicts of interest [2]. The previous systematic review identified that high-quality evidence of effectiveness and patient safety was limited, which was also observed in this review. Similarly, it noted that high overall satisfaction was generally reported by the studies, but that the most common issues with conversational agents related to language understanding or poor dialogue management, which is consistent with our findings [2]. Some of this similarity in results is likely because of the overlap in included studies; 7 of their 17 included studies were also included in our review [2].

### Quality of the Evidence

As noted in a previous systematic review [2], there were significant issues with the quality of many of the included studies. One of the consistent issues among many of them was a high risk of selection bias. A large proportion of the studies relied on volunteers for the study, many of whom were recruited via self-selection means such as flyers and emails or by downloading the app being studied. The risk with self-selection recruitment is that participants who elect to take part in the study are already more positively predisposed to new technologies than those who do not participate, and would tend to evaluate the technology more positively. To make matters worse, several of the studies also did not sufficiently report their recruitment strategies, and so their potential selection bias cannot be accurately evaluated. In research such as this, where user perceptions are a main outcome, this is a serious concern. Future studies should take care to implement recruitment strategies that minimize this risk of selection bias or balance the potential bias in evaluations by actively recruiting participants who are less inclined toward new technology.

Another limitation of many of the studies was the small sample size. Almost two-thirds of the studies (19/31) used samples of less than 100 participants or items of analysis (eg, voice clips and clinical scenarios) with a median sample size of 48 across all the studies. Many also did not sufficiently report demographic data or whether their sample was representative of their target population. Although many of these studies were early feasibility and usability trials, this is an important issue to address in future research testing these agents to determine whether an agent will be used and used effectively by its target population.

## Limitations

The validity of the evidence extracted from the included studies was also affected by limitations in the structure of this review. The SF/HIT was used to provide a structured set of whole system implementation outcomes to evaluate the conversational agents [31]. However, an issue with the use of this framework, which was discovered during analysis, was that many of the included studies were describing system innovation. Therefore, they did not address or provide evidence for many of the outcomes described by the SF/HIT. Additionally, as the included data indicated a self-reported impact in the studies of effectiveness, the study effectiveness is biased favorably toward the authors' reporting of impact.

This limitation in the use of the framework for this review also highlights a limitation in many of these studies, namely, that they do not think about whole system implementation from the early stages of agent design, development, and testing. It is possible that the lack of evaluation of the implications of the agents for health care provision and resources was because of an emphasis on technology development and evaluation, rather than system integration. This is a pervasive issue in technological innovation, so much that it drove the development of the nonadoption, abandonment, scale-up, spread, and sustainability framework as a means of predicting and assessing the success of new health technologies [58] and the development and evaluation of new conversational agents to ensure that these later-stage implications of health care provision, cost-effectiveness, and privacy and security are sufficiently considered from the early stages of innovation. They must also be properly evaluated with a large sample of users, rather than be simply presented as unsubstantiated claims that the agent will reduce costs and save health care providers' time.

Additionally, in accordance with the SF/HIT framework, the impact of outcomes on each outcome was coded as *positive or mixed* or *neutral or negative*. However, this combination of positive and mixed outcomes reduces the granularity of the results. During the coding process, several outcomes were distinctly coded as *positive or mixed*, and collating the 2 outcome impacts into 1 reduces the precision of the information presented to the readers. Additionally, studies that did not assess the outcome in question were coded as *neutral or negative* because they did not provide explicit support for the outcome. In the analysis, outcomes were initially coded separately as positive, mixed, positive or mixed (for studies that reported a positive outcome but did not provide sufficient statistical evidence), and neutral or negative. This table is available in

[Multimedia Appendix 10](#). Positive and mixed outcomes were combined for the final presentation of the data in line with the framework. However, it might be more useful to distinguish between studies that attempted to find significant evidence for an outcome but did not and those that did not attempt it. This would provide a clearer picture of which outcomes are not being supported by the evidence and should be targeted for improvement, and which outcomes still need to be examined. In the future, it would be worth evaluating whether the coding system should be adjusted to provide a more detailed and informative summary of the evidence.

Further limitations of this review are that we limited the focus to include only unconstrained NLP and interaction. This was chosen as a focus because of the advantages NLP offers for simulating human-to-human interaction. However, it may have excluded studies of relevant conversational agents that could be satisfactory, useful, and effective in addressing current health care challenges. Additionally, no spidering searches were used to identify potentially relevant studies in the references of the included studies that were missed in the initial search. The exclusion of conference abstracts might also have caused relevant papers that were classified as abstracts to be missed; however, a previous systematic review that included conference abstracts in their search only had 1 included in their final selection [2]. The inclusion of only studies published in English is also likely to exclude relevant research on conversational agents conducted in other countries. These limitations should be addressed in future studies to ensure that the full body of relevant literature is examined.

## Future Directions

Future reviews of conversational agents in health care could be extended to include constrained NLP and non-NLP conversational agents. A synthesis of the evidence identified here with other types of conversational agents in health care, perhaps structured according to the taxonomy suggested by Montenegro et al [5], could be used to examine overall trends and provide a better picture of what is being used, what works, and what does not, to further guide the development of conversational agents that are most likely to be successful.

Future research should also include more qualitative evaluations of the features that users like and dislike. Only half (18/31) of the studies included in this review reported specific user feedback, despite the fact that 7 of the remaining 13 studies included some measure of usability or user perceptions. It will be important to identify all of the structural, physical, and psychological barriers to use if conversational agents are to achieve their potential for improving health care provision and reducing the strain on health care resources. To this end, it would be useful for future studies to structure their evaluation of conversational agents around a behavioral change framework (eg, the Behavior Change Wheel framework [59]). This is important not only when evaluating the effectiveness of behavior change-focused conversational agents, but also when determining whether and how the adoption of new conversational agent technology will be successful.

It will be important for future studies of conversational agents to take care to properly structure and report their studies to

improve the quality of the evidence. Without high-quality evidence, it is difficult to assess the current state of conversational agents in health care - what is working, and what needs to be improved to make them a more useful tool. Similarly, there is a gap in the evidence regarding the health economics of these agents. Very few studies in this review even discussed the cost analysis of the agent in questions, let alone provide substantive evidence about its cost-effectiveness. The evaluation of costs and outcomes of new technologies and their privacy, security, and interoperability will be necessary to advance value-based health care [60]. However, there is very little evidence to suggest that the conversational agents examined in this review considered or addressed these concerns. User feedback on 2 of the studies even noted that better interoperability between the agent and EHRs or health care providers would improve its usefulness.

## Conclusions

The objective of this systematic review was to synthesize evidence of conversational agents' usability, effectiveness, and

satisfaction in health care. Although the studies generally reported positive outcomes relating to the agents' usability and effectiveness, the quality of the evidence was not sufficient to provide strong evidence to support these claims. This study extended the literature by expanding its summary to examine a whole system set of evaluation outcomes, including cost-effectiveness, privacy, and security, which have not been systematically examined in previous reviews. In addition, it provides a distinct contribution by conducting a thematic analysis of the qualitative user perceptions of the agents. Further research is needed to examine the cost-effectiveness and value of these agents in health care, both in their current and potential states. Higher-quality studies—with more consistent reporting of design methods and better sample selection—are also needed to more accurately assess the usefulness and identify the key areas of improvement for current conversational agents. A more holistic approach to the design, development, and evaluation of conversational agents will help drive innovation and improve their value in health care.

## Acknowledgments

The authors would like to thank the outreach librarians Liz Callow (University of Oxford) and Kirsten Elliot (Imperial College London), for their assistance in developing search terms and reviewing search strategies. Specific funding for this work has not been acquired. EM's work on digital health solutions is currently supported by the Sir David Cooksey Fellowship in Healthcare Translation at the University of Oxford. The conclusions drawn in this paper were made by the authors and are not necessarily supported by the University of Oxford. The funding body had no role in the design, execution, or analysis of this systematic review.

## Authors' Contributions

CC and EM conceived the study topic and designed the review protocol. CC and MMI screened the studies. CC conducted the data extraction, which was validated by MMI, and MMI conducted the risk-of-bias and quality assessments, which were validated by EM. MMI and EM analyzed the extracted data. The methods section was drafted by CC, and the rest of the review was written by MMI with revisions from EM. MHS, EL, NP, EN and GM provided feedback on the final drafted text. EM supervised the study execution. The authors confirm that they have followed all the appropriate research reporting guidelines. The PRISMA checklist for systematic reviews has been uploaded as [Multimedia Appendix 11](#) along with other relevant materials.

## Conflicts of Interest

EL, NP, and GM are all employees of Ufonia Limited, a voice AI company. However, the paper was funded by the Sir David Cooksey Fellowship in Healthcare Translation at the University of Oxford, and Ufonia had no editorial influence on the final drafting. Their contribution was limited to feedback, given their applied voice AI expertise; therefore, no conflict of interest is identified.

## Abstract

**Background:** Federated learning (FL) is a newly proposed machine-learning method that uses a decentralized dataset. Since data transfer is not necessary for the learning process in FL, there is a significant advantage in protecting personal privacy. Therefore, many studies are being actively conducted in the applications of FL for diverse areas.

**Objective:** The aim of this study was to evaluate the reliability and performance of FL using three benchmark datasets, including a clinical benchmark dataset.

**Methods:** To evaluate FL in a realistic setting, we implemented FL using a client-server architecture with Python. The implemented client-server version of the FL software was deployed to Amazon Web Services. Modified National Institute of Standards and Technology (MNIST), Medical Information Mart for Intensive Care-III (MIMIC-III), and electrocardiogram (ECG) datasets were used to evaluate the performance of FL. To test FL in a realistic setting, the MNIST dataset was split into 10 different clients, with one digit for each client. In addition, we conducted four different experiments according to basic, imbalanced, skewed, and a combination of imbalanced and skewed data distributions. We also compared the performance of FL to that of the state-of-the-art method with respect to in-hospital mortality using the MIMIC-III dataset. Likewise, we conducted experiments comparing basic and imbalanced data distributions using MIMIC-III and ECG data.

**Results:** FL on the basic MNIST dataset with 10 clients achieved an area under the receiver operating characteristic curve (AUROC) of 0.997 and an F1-score of 0.946. The experiment with the imbalanced MNIST dataset achieved an AUROC of 0.995 and an F1-score of 0.921. The experiment with the skewed MNIST dataset achieved an AUROC of 0.992 and an F1-score of 0.905. Finally, the combined imbalanced and skewed experiment achieved an AUROC of 0.990 and an F1-score of 0.891. The basic FL on in-hospital mortality using MIMIC-III data achieved an AUROC of 0.850 and an F1-score of 0.944, while the experiment with the imbalanced MIMIC-III dataset achieved an AUROC of 0.850 and an F1-score of 0.943. For ECG classification, the basic FL achieved an AUROC of 0.938 and an F1-score of 0.807, and the imbalanced ECG dataset achieved an AUROC of 0.943 and an F1-score of 0.807.

**Conclusions:** FL demonstrated comparative performance on different benchmark datasets. In addition, FL demonstrated reliable performance in cases where the distribution was imbalanced, skewed, and extreme, reflecting the real-life scenario in which data distributions from various hospitals are different. FL can achieve high performance while maintaining privacy protection because there is no requirement to centralize the data.

## Introduction

### Background

Traditional machine learning and deep learning require a centralized dataset to train a model. Therefore, such methods not only require data transfer to collect data from many devices, people, or institutions but also have a high computational cost because they must be trained on large datasets. When collecting privacy-sensitive data such as medical data, privacy protection is a major hurdle. Centralized databases are the main targets of hacking attacks, and therefore the risk of a data breach is severely increased [1,2]. Moreover, data centralization increases the risk of reidentification of deidentified data because of the increased data size [3].

To reduce the computational cost, Google proposed a method known as federated learning (FL), which uses the computational cores in mobile devices [4-6]. In FL, training is performed at the individual client level, and then the local weights of each client are sent to the server. The server collects the updated local weights and calculates the new global weights. Subsequently, the client downloads the global weights from the server and continues the training process. Since its first use in mobile apps [7-9], many researchers have been studying and improving FL in various fields [10-14]. In particular, studies on heterogeneity of data [4,15], robust optimization [16-20], and security methods such as differential privacy and secure multiparty computation have also been conducted with an FL approach [12,21,22]. Research on FL has also been conducted in the medical field [10,13,19]. In particular, studies have been conducted using electronic medical records and brain tumor data [23-25]. However, the application of FL to real medical data has not been sufficiently studied.

FL can be used to resolve privacy issues and mitigate the risk of a data breach in clinical information, since transfer and centralization of data are not required. Privacy protection is particularly beneficial for medical data analysis, since medical data represent some of the most sensitive types of personal data. To protect patients' privacy, deidentification methods have typically been applied [26-28]. However, data centralization is required for both deidentifying data and evaluating the risk of reidentification. If the data are centralized, the risk of a data breach is increased. Moreover, when deidentifying the dataset, the direct or indirect identifiers in the medical data must be determined. This is challenging because of the lack of clear guidelines. The Health Insurance Portability and Accountability Act in the United States provides clear deidentification guidance; it defines 18 types of protected health information to be removed [29]. However, many researchers and social activists claim that this guidance should be revised to enhance privacy protection [30]. In contrast, FL does not require the centralization of raw

data. As a result, even the FL developers cannot access the raw data. Therefore, FL can solve privacy or deidentification issues that occur when using clinical data.

### Objectives

The aim of this study was to assess the performance of FL on three benchmark datasets: the Modified National Institute of Standards and Technology (MNIST) dataset, Medical Information Mart for Intensive Care-III (MIMIC-III) dataset, and PhysioNet Electrocardiogram (ECG) dataset. We also verified FL in environments that simulate real-world data distributions by modifying the MNIST, MIMIC-III, and ECG datasets.

## Methods

### FL Code and Server

FL is supported by several open-source projects, including TensorFlow Federated in TensorFlow 2.0 [31], PySyft [32,33], and Federated AI Technology Enabler [34,35]. However, there are limitations in using these libraries. First, most of these libraries only support a single server and not a network environment. Therefore, there is no control process for data communication. Second, as a prototype, the necessary features were not fully implemented to handle a complex dataset. For future research using real clinical data from hospitals, we implemented our own client-server version of FL using Python. The implemented server code is available on the FL\_Server repository [36] and the client code is available on the FL\_Client repository [37]. The MNIST dataset analyzed during the current study is available in the Keras package in the TensorFlow framework. Additionally, the original code used to generate and preprocess the MIMIC-III experiment used in this study referred to the mimic3-benchmarks repository [38]. The original MIMIC-III dataset analyzed during this study is available on the PhysioNet repository [39]. The ECG dataset analyzed during this study is available on the 2017 PhysioNet/CinC Challenge website [40]. The model and environment assessed in this study refer to Hannun et al [41].

The FL server was developed using the Django framework and Python in Amazon Web Services (AWS). The server provides several application programming interfaces (APIs) for communication with a client, as shown in Table 1, and performs federated averaging (FedAVG) [4], which calculates the weighted averages. FedAVG is a widely used optimization algorithm that calculates the average value when the local weights collected from the client reach a specific level. The implemented code was deployed and managed in AWS Beanstalk, which was continuously monitored during the training process.

**Table 1.** Application programming interface calls provided by the server.

Method	URL	Parameter	Description	Return
GET	/round	N/A <sup>a</sup>	Request current round	Number
GET	/weight	N/A	Request global weight	List
PUT	/weight	List	Update local weight	N/A

<sup>a</sup>N/A: Not applicable.

## Client

The client consists of three components. The first is the local learning component, which builds a suitable model for the dataset during the learning phase. The second is the communication component, which updates local weights according to the results of local training (the first component) on the server and downloads the global weights from the server. The third is the performance measure component, in which the performance of each client is measured using the downloaded global weights. The implemented code was deployed on an AWS EC2 instance. We used the specifications of g4dn.xlarge with the NVIDIA T4 Tensor core GPU for the Amazon instance.

## Communications

Client–server communication for FL was implemented based on the process described by McMahan et al [42]. However, the implemented code exhibits some differences. The communication assumes that all clients (hospitals) are always powered (as is the case for a typical computer but not for a mobile device) and that their online status is maintained by a wired network connection. In addition, rather than selecting clients via an eligibility criterion from multiple client pools (thousands or millions), the code was implemented to manage a predefined fixed number of clients. In other words, all clients could participate in each round.

A schematic diagram of the FL client–server communication is shown in [Multimedia Appendix 1](#). In brief, the client decides whether to participate in the current round through the API. If it has already participated (sending local weights to the server), it waits to participate in the next round. The server waits for the client's weight updates and ensures that no clients are eventually dropped. All communications are performed through the API provided by the server. The monitoring system is used to continuously observe system abnormalities.

## Datasets

### MNIST

The MNIST dataset, which consists of digit handwriting images, contained 70,000 samples (including 60,000 for training and 10,000 for testing). The basic model was a simple artificial neural network with an input layer, one hidden layer with 128 units with a rectified linear unit activation function, and an output layer. The hyperparameters for training were set as follows: batch size 32, maximum 1000 epochs, and early stopping. Stochastic gradient descent was used as an optimizer [43].

For FL, we used 10 individual clients to best mimic a real environment. We modified the datasets and hyperparameters

of the learning algorithms. The datasets were modified considering differences in the distribution of medical data between hospitals. Hyperparameters were adjusted for training in each client. The proposed approach was evaluated on the MNIST dataset in four different experiments.

We first evaluated the basic performance of the FL. Ten clients randomly selected 600 images from the basic dataset. We continued the process for up to 500 rounds and observed the results. For the imbalanced FL experiment, each client used different sizes of randomly selected data, ranging from 1 to 600, for training (ie, one client used 36 data points and another client used 537 data points). However, other environments such as hyperparameters and the number of rounds were the same as set in the basic FL experiment. In addition, the MNIST dataset was split into single-digit groups, ranging from 0 to 9. Each of the 10 numbers was assigned to 10 different clients. Consequently, each client had a single digit instead of 10. This modified MNIST simulated an extremely skewed data distribution. Each client randomly selected 600 images from a dataset with a single digit for training. The simple artificial neural network used in the basic model was also used in these experiments. The hyperparameters were set as follows: 5 epochs and a batch size of 10. We continued the process for up to 3000 rounds and observed the results. For evaluation, a model was created with the latest updated global weights using 10,000 test samples. Finally, we conducted an extension of the modified MNIST FL that represents a skewed distribution. Each client was trained on data with an imbalanced and skewed distribution. Hence, each client was trained only on a single digit using a randomly selected sample.

### MIMIC-III

The MIMIC-III dataset is a clinical dataset related to human health information, including demographics, vital signs, laboratory tests, and medications from intensive care units. MIMIC-III data were preprocessed using a state-of-the-art (SOTA) benchmark [44]. In this case, FL experiments with three individual clients were performed to predict in-hospital mortality, which is a classification problem that predicts death within the first 48 hours of an intensive care unit stay. After preprocessing the MIMIC-III dataset using the method described by Harutyunyan et al [44], the dataset contained 21,139 samples (including 17,903 for training and 3236 for testing). The basic model was a standard long short-term memory (LSTM) with reference to the benchmark [44]. The LSTM was chosen with 16 hidden units, depth 2, dropout 0.3, time step 1.0, batch size 8, and an adaptive moment estimation (ADAM) optimizer.

For FL, randomly chosen samples from the original dataset were divided into 3 datasets without duplication and assigned

to each client. This simulates having data from three different institutions. The same basic LSTM was used, and hyperparameters were set as follows: 2 epochs and a batch size of 4. We continued the process for up to 30 rounds and observed the results.

For the basic FL experiment, each client was trained on a subset of data that were split into three parts with the same data size without duplication. For the imbalanced FL experiment, all data were split into 50%, 30%, and 20% without duplication, and one subset was assigned to each client.

## ECG

The 2017 PhysioNet/CinC Challenge ECG dataset was used in this study [40]. This target problem is a multiclassification problem that classifies four signals: atrial fibrillation, normal sinus rhythm, alternative rhythm, and noisy using a single short ECG signal. The total data size is 8528 single-lead ECG data points. The dataset was divided into 90% training data (7676) and 10% test data (852). For traditional learning, a convolution neural network with 34 layers based on Hannun et al [41] was applied to the ECG dataset. The hyperparameters were chosen with a batch size of 32 and an ADAM optimizer.

For FL, randomly chosen samples from the original dataset were divided into 3 datasets without duplication and assigned to 3 clients. The same model was used, and hyperparameters were set as follows: 3 epochs and a batch size of 16. We continued the process for up to 30 rounds and observed the results.

For the basic FL experiment, each client was trained on a subset of data that were split into three parts with the same data size without duplication. For the imbalanced FL experiment, all data were split into 50%, 30%, and 20% without duplication, and a subset was assigned to each client.

## Evaluation

During training, we monitored the FL accuracy to evaluate performance. If the accuracy did not improve during the round, we completed the FL. Finally, we chose the best model and conducted bootstrapping to determine if there were significant differences between the experiments.

In all experiments, the area under the receiver operating characteristic curve (AUROC) score and F1-score were used as performance metrics. In addition, we evaluated the confusion matrix, precision, recall, or area under the precision recall curve (AUPRC) for comparison with the performance of the SOTA method. We calculated the 95% CIs and resampled the test set  $K$  times (for MNIST and ECG,  $K$  was 100, whereas for MIMIC-III,  $K$  was 10,000).

## Results

### MINST

The proposed approach was evaluated on the MNIST dataset for five different cases (as described in the Methods). Table 2 presents the values of the AUROC and F1-score for each case, and Multimedia Appendix 2 presents the confusion matrix for each case.

**Table 2.** Comparison of the experimental results for the five different MNIST cases described in the Methods.<sup>a</sup>

Experiments	AUROC <sup>b</sup> (95% CI)	F1-score (95% CI)	Precision (95% CI)	Recall (95% CI)
CML <sup>c</sup>	0.999 (0.999-0.999)	0.981 (0.978-0.983)	0.981 (0.972-0.989)	0.981 (0.971-0.989)
Basic FL <sup>d</sup>	0.997 (0.996-0.998)	0.946 (0.941-0.950)	0.945 (0.929-0.959)	0.945 (0.930-0.959)
Imbalanced FL	0.995 (0.994-0.995)	0.921 (0.917-0.927)	0.920 (0.904-0.937)	0.920 (0.903-0.937)
Skewed FL	0.992 (0.991-0.993)	0.905 (0.899-0.911)	0.905 (0.885-0.922)	0.904 (0.885-0.920)
Imbalanced and skewed FL	0.990 (0.989-0.991)	0.891 (0.884-0.896)	0.890 (0.869-0.909)	0.889 (0.868-0.908)

<sup>a</sup>All experiments used the same model and hyperparameters. All results are presented with a 95% CI by resampling the validation task 100 times.

<sup>b</sup>AUROC: area under the receiver operating characteristic curve.

<sup>c</sup>CML: centralized traditional machine-learning method.

<sup>d</sup>FL: federated learning.

Centralized machine learning (CML) is a baseline training method that was used as a control group. CML achieved an AUROC of 0.999 and an F1-score of 0.981. For basic FL, the AUROC and F1-score were 0.997 and 0.946, respectively. The initial performance of the basic FL was fairly high, with an accuracy of approximately 0.800, which continually improved (Multimedia Appendix 3A).

Imbalanced FL was designed to reflect a realistic clinical data distribution. As described in the Methods section, each client had a different training data size. Interestingly, the performance of imbalanced FL was significantly superior, with an AUROC and F1-score of 0.995 and 0.921, respectively. The initial

performance was rather poor, as expected. However, after several rounds of processing, the performance rapidly improved to reach an accuracy of 0.900, after which the performance improvement was slow (Multimedia Appendix 3B).

Skewed FL assumed an extreme case. Each client had only one digit from 0 to 9, thereby simulating a situation in which each hospital has a unique subpopulation of patients without overlaps. The final AUROC and F1-score were 0.992 and 0.905, respectively. As expected, the initial performance was poor; however, it rapidly improved after the initial rounds (Multimedia Appendix 3C).

The most extreme case was designed by combining an imbalanced and a skewed dataset. In this experiment, the AUROC and F1-score were 0.990 and 0.891, respectively. Similar to the skewed FL, the initial performance was very poor, but it rapidly improved after the initial rounds ([Multimedia Appendix 3D](#)).

Additionally, the precision and recall results for each digit class classification in each experiment are presented in [Multimedia Appendices 4-8](#).

### MIMIC-III

The proposed approach was evaluated on the MIMIC-III dataset in two different cases to compare the performance with a

reported benchmark. FL experiments were performed on three individual clients. Apart from the AUROC and F1-score, we also refer to the AUPRC, which is reported in the benchmark [44]. The results are presented in [Table 3](#) and in [Multimedia Appendices 9 and 10](#).

SOTA performance was achieved by executing the codes provided in Harutyunyan

[38]. FL achieved an AUROC, F1-score, and AUPROC comparable with those of the SOTA method. The imbalanced FL experiment, as an extension of the basic MIMIC-III FL, also achieved AUROC, F1-score, and AUPRC comparable with those of SOTA ([Table 3](#)).

**Table 3.** Comparison results of MIMIC-III.<sup>a</sup>

Experiments	AUROC <sup>b</sup> (95% CI)	F1-score (95% CI)	AUPRC <sup>c</sup> (95% CI)	Precision (95% CI)	Recall (95% CI)
SOTA <sup>d</sup>	0.857 (0.837-0.875)	0.944 (0.938-0.950)	0.505 (0.451-0.558)	0.973 (0.967-0.979)	0.773 (0.907-0.927)
Basic FL <sup>e</sup>	0.850 (0.830-0.869)	0.944 (0.938-0.950)	0.483 (0.427-0.537)	0.975 (0.969-0.980)	0.797 (0.906-0.926)
Imbalanced FL	0.850 (0.829-0.869)	0.943 (0.937-0.949)	0.481 (0.426-0.535)	0.981 (0.976-0.986)	0.714 (0.897-0.918)

<sup>a</sup>All results are presented with a 95% CI by resampling 10,000 times.

<sup>b</sup>AUROC: area under the receiver operating characteristic curve.

<sup>c</sup>AUPRC: area under the precision-recall curve.

<sup>d</sup>SOTA: state of the art.

<sup>e</sup>FL: federated learning.

### ECG

The proposed approach was evaluated on the ECG database using two different methods to compare the performance with a reported benchmark [41]. The results are presented in [Table 4](#) and [Multimedia Appendices 11-14](#).

Benchmark results were achieved using the code available on github [45]. The AUROC and F1-score of both basic and imbalanced FL were comparable with those of the benchmark ([Table 4](#)).

**Table 4.** Comparison results for the electrocardiogram dataset.<sup>a</sup>

Experiments	AUROC <sup>b</sup> (95% CI)	F1-score (95% CI)	Precision (95% CI)	Recall (95% CI)
Benchmark	0.954 (0.930-0.978)	0.814 (0.655-0.910)	0.820 (0.672-0.943)	0.814 (0.640-0.936)
Basic FL <sup>c</sup>	0.938 (0.860-0.978)	0.807 (0.651-0.931)	0.823 (0.645-0.942)	0.795 (0.660-0.925)
Imbalanced FL	0.943 (0.883-0.977)	0.807 (0.635-0.902)	0.830 (0.650-0.935)	0.788 (0.626-0.905)

<sup>a</sup>All results are presented with a 95% CI by resampling 100 times.

<sup>b</sup>AUROC: area under the receiver operating characteristic curve.

<sup>c</sup>FL: federated learning.

## Discussion

### Principal Findings

When comparing the performances of CML and FL in basic MNIST experiments, both the AUROC and F1-score were high. Unexpectedly, when using an imbalanced dataset, FL delivered good performance with only small differences (AUROC and F1-score of 0.003 and 0.035, respectively). When using a skewed dataset, FL also yielded remarkable results with respect to both the AUROC and F1-score. When comparing the confusion matrices for experiments with four datasets (ie, normal, imbalanced, skewed, and a combination of two distributions), FL showed some deterioration in performance

for visually similar numbers (eg, 3 vs 5; 4 vs 9). Even in the basic MNIST classification, the performance was relatively poor in these cases. However, this problem was not related to the small sizes of the training datasets. When we monitored the size of the training datasets for each client, the dataset for class 5 was not small. Moreover, depending on the experiment, the datasets for class 1 or 7 could be small, but superior classification performance was nevertheless achieved. This trend was maintained in the experiments with basic FL and imbalanced FL using the MIMIC-III dataset.

The FL experiments using MIMIC-III also exhibited good and competitive performance compared to a benchmark that has been trained on CML. The experimental results of in-hospital

mortality using the MIMIC-III dataset, which is a well-known dataset with real clinical data, also showed good performance. This experiment was performed by splitting the randomly selected MIMIC-III data into three parts (ie, from the perspective of each institution, learning one-third of the total data). However, the performances of FL and CML were almost the same, with only a 0.005 difference in AUROC detected compared with the SOTA performance reported by Harutyunyan et al [44]. Before the experiments, we expected that the performance of FL would be slightly inferior to that of CML because FL uses a distributed dataset instead of a centralized dataset. Nevertheless, no significant difference was found in well-known evaluation indicators such as accuracy, sensitivity, precision, and F1-score (except for AUROC). Experimental results with an imbalanced dataset were very similar to those of basic FL. Therefore, an individual client may only use a small amount of data for training in FL, and the results will be similar to those achieved when all available data are used for training.

The FL experiments using ECG data also exhibited good and competitive performance compared to CML. This experiment was performed by splitting the randomly selected ECG data into three parts (ie, from the perspective of each institution, learning on one-third of the total data) with each using different data distributions.

However, the performance of FL and CML was not significantly different. Experimental results with an imbalanced dataset were very similar to those for basic FL. As shown in [Multimedia Appendices 12-14](#), the noisy case was shown to have relatively low performance in precision and recall. This is because the data size for training was only 3% of the total size. However, the other classes performed well, such as atrial fibrillation, normal sinus rhythm, and alternative rhythm.

The performance of FL was verified using three datasets with changed data distributions: imbalanced (with disproportionately represented classes) and skewed (the distribution of the target variable was different) to imitate real-world medical data. As a result, FL was comparable to CML. During the initial rounds, only a relatively small amount of data was used on each client instead of an ensemble; therefore, the performance of FL was significantly inferior to that of CML. However, in the subsequent rounds, the performance of FL (with respect to AUROC and F1-score) became similar to that of CML. Typically, medical centers have datasets with very different distributions, and our results demonstrate that FL is suitable for real-world medical datasets without requiring data centralization.

One reason for the comparable performance of FL might be that the weight updates and the process of FedAVG could have a similar effect in mini-batches [46-48] and ensembles [49]. In FL, each client trains on a relatively small dataset and then transfers the local weights to the server. The server then collects

the local weights and updates the global weights that reflect all of the data through FedAVG. Subsequently, the round is repeated to improve the global weights. Hence, individual clients are an element of a mini-batch, and FedAVG is similar to ensemble processing. When implementing FL, we used the widely known FedAVG aggregation method [5], but this does not guarantee the best choice. To solve this problem, many researchers have studied aggregation methods that can work well with abnormal distributions, robust aggregation, and efficient communication such as FedProx [16], FSVRG [17], CO-OP [18], LoAdaBoost FedAVG [19], and RFA [20]. Hyperparameter selection also requires further research.

In addition, many researchers have studied methods to reduce communication costs. First, it has been suggested to reduce the communication round through methods such as client selection, peer-to-peer, and local update [11-13]. Second, a method such as sparsification, subsampling, or quantization has been suggested to reduce the communication message size [12,13]. Third, the asynchronous update method in traditional parallel computation methods can be applied.

FL can be used to build medical artificial intelligence apps by protecting patient privacy. Although the data themselves are not exposed or gathered in the central repository in FL, these data can nevertheless be guessed during the aggregation process in the network [12]. Therefore, other privacy preservation methods such as differential privacy, secure multiparty computation, and homomorphic encryption [11,12,21,22] might be necessary to protect privacy from diverse up-to-date privacy attack methods.

In future studies, we plan to use the proposed FL methods in real clinical datasets rather than benchmark datasets. First, we will try to improve the FL framework based on the results from this study. We will then compare the performance of a breast cancer recurrence prediction model using data from two different medical centers in Korea.

## Conclusions

Our experiments demonstrated the potential of FL in terms of performance and data protection, which is important for dealing with sensitive medical data. Specifically, in FL, only weights are transferred, and the participants are unaware of each other's local datasets. This can prevent personal information leaks. In addition, the proposed approach can be used to supplement existing approaches and to avoid problems that may occur during the deidentification process. The future direction of research is to use FL for actual medical data through collaborations with multiple institutions. Tasks such as expanding the client-server version of FL and improving communication will be expected to be important for the application of FL in real-world medical data with multiple institutions.

## Abstract

**Background:** Digital food registration via online platforms that are coupled to large food databases obviates the need for manual processing of dietary data. The reliability of such platforms depends on the quality of the associated food database.

**Objective:** In this study, we validate the database of MyFitnessPal versus the Belgian food composition database, Nubel.

**Methods:** After carefully given instructions, 50 participants used MyFitnessPal to each complete a 4-day dietary record 2 times (T1 and T2), with 1 month in between T1 and T2. Nutrient intake values were calculated either manually, using the food composition database Nubel, or automatically, using the database coupled to MyFitnessPal. First, nutrient values from T1 were used as a training set to develop an algorithm that defined upper limit values for energy intake, carbohydrates, fat, protein, fiber, sugar, cholesterol, and sodium. These limits were applied to the MyFitnessPal dataset extracted at T2 to remove extremely high and likely erroneous values. Original and cleaned T2 values were correlated with the Nubel calculated values. Bias was estimated using Bland-Altman plots. Finally, we simulated the impact of using MyFitnessPal for nutrient analysis instead of Nubel on the power of a study design that correlates nutrient intake to a chosen outcome variable.

**Results:** Per food portion, the following upper limits were defined: 1500 kilocalories for total energy intake, 95 grams (g) for carbohydrates, 92 g for fat, 52 g for protein, 22 g for fiber, 70 g for sugar, 600 mg for cholesterol, and 3600 mg for sodium. Cleaning the dataset extracted at T2 resulted in a 2.8% rejection. Cleaned MyFitnessPal values demonstrated strong correlations with Nubel for energy intake ( $r=0.96$ ), carbohydrates ( $r=0.90$ ), fat ( $r=0.90$ ), protein ( $r=0.90$ ), fiber ( $r=0.80$ ), and sugar ( $r=0.79$ ), but weak correlations for cholesterol ( $p=0.51$ ) and sodium ( $p=0.53$ ); all  $P$  values were  $\leq 0.001$ . No bias was found between both methods, except for a fixed bias for fiber and a proportional bias for cholesterol. A 5-10% power loss should be taken into account when correlating energy intake and macronutrients obtained with MyFitnessPal to an outcome variable, compared to Nubel.

**Conclusions:** Dietary analysis with MyFitnessPal is accurate and efficient for total energy intake, macronutrients, sugar, and fiber, but not for cholesterol and sodium.

## Introduction

Analysis of dietary records is an important part of nutritional and epidemiological research investigating the effects of diet on human health. Food composition tables are used to convert recorded food intake into nutrient intake. Individual food items from the dietary record are matched with an entry in the food composition table so that nutrient information can be extracted. This matching process is typically done manually and is therefore time- and labor-intensive, especially in large-scale studies or studies that require repeated dietary assessment over time [1].

Over the last years, a large number of mobile apps have been developed to track lifestyle habits such as physical activity, sleep, time management, and dietary intake. Such dietary intake digital platforms contain an online food database that immediately converts food items into nutrient values. With these online platforms, users electronically record their food intake and track the amount of calories and nutrients consumed. To do so, users select consumed food items from the associated food database or, in case an item is not registered, they add that item and the related nutritional information to the platform's database. Therefore, these databases are partially user-based. Generally, these platforms have been developed to promote weight loss by increasing the awareness of habits and progress through self-monitoring; however, they also appeal to nutritional research applications as well. Yet, the accuracy and reliability of these platforms rely on the quality of the associated databases.

The aim of this study is to evaluate the accuracy of nutrient intake values based on the database of MyFitnessPal [2]. MyFitnessPal is the most popular commercial nutrition weight loss app, with more than 165 million users in 2016 [3]. In the United States, 83% of the dietitians who participated in a survey held at the Food and Nutrition Conference and Expo 2015 recommended the use of nutrition and health-related apps, with MyFitnessPal and Fitbit mentioned most [4,5]. Furthermore, in a survey across the United Kingdom, Australia, Canada, New Zealand, and the United States, it was the preferred app for sports dietitians [6]. MyFitnessPal is characterized by its extensive and country-specific database of over 6 million food items and brands. This consumer app is user-friendly, contains a barcode scanner to rapidly add packed foods, and has both smartphone and web-based versions. In addition, the basic version of MyFitnessPal is freely available. We extracted values for energy intake and nutrient composition from dietary records entered in MyFitnessPal and compared them to the values calculated using the Belgian food composition database, Nubel [7].

## Methods

### Study Sample

This study used data from a previous intervention study that aimed to evaluate the impact of modified wheat bran on microbial fermentation and intestinal health [8]. We used 100 dietary records from 50 participants. Each participant used MyFitnessPal to complete a 4-day dietary record 2 times, with 1 month between the 2 records. These 2 time points generated

2 dietary intake datasets, referred to as T1 and T2. All participants used MyFitnessPal to record their dietary intake.

### Dietary Intake Assessment

Each participant received an account on MyFitnessPal and detailed instructions with illustrations about the use of MyFitnessPal. The manual included information on how to (1) select food items in the MyFitnessPal database, (2) indicate portion size, (3) register home recipes, and (4) use the favorites lists. To register packed food items, participants were instructed to scan the attached barcode or to select the corresponding item (correct brand) from the food item list within MyFitnessPal. If the item was not included in the list, participants were asked to enter the missing food item, including the nutritional data mentioned on the package. For generic food items such as bread, rice, pasta, fruits, and vegetables, we preregistered items in the MyFitnessPal database with the tag "Targid" (ie, the name of our research unit). These items contained nutritional information from the Belgian food composition database, Nubel. This preregistration of Targid-tagged food items was done for standardization purposes, as generic items often have multiple entries in MyFitnessPal with highly variable nutritional information. Participants were asked to preferentially select these items, and in case the searched item was not available in the Targid list, they were instructed to choose a green-flagged item. The green flag indicates that administrators of MyFitnessPal have revised the nutritional information. With regard to portion size, participants were instructed to weigh the consumed food items as much as possible, and when they were unable to do so, they were asked to select from listed portion sizes.

### Dietary Nutrient Quantification

Food items registered in MyFitnessPal were converted to nutrient values (ie, total energy intake, carbohydrates, fat, protein, sugars, fiber, sodium, and cholesterol), either using the MyFitnessPal database or using Nubel. The Nubel database contains the composition of 1194 basic food items, each product expressed per 100 grams. The MyFitnessPal food records are directly linked to the food composition data available in the MyFitnessPal app. Therefore, downloading the food records from the MyFitnessPal account immediately yields nutrient intake values. Conversion of the MyFitnessPal-registered food items to nutrient values using the Nubel database was performed according to a standard in-house procedure. Registered food items in MyFitnessPal with a food match in the Nubel database (eg, an apple, lasagne) were translated to nutrients using the Nubel food composition information. Homemade food without a match in the Nubel database (eg, Belgian endive with ham and cheese sauce) was translated to nutrients using the recipes described in a basic and comprehensive Belgian cookbook named *Ons Kookboek* [9]. For packed food, the nutritional information on the food label was used. If portion size was available in grams, nutrient values per consumed portion were calculated. Portion sizes defined in measurements (eg, "a slice of," "a piece of") were converted to grams using guidelines on the standardized quantification of food products [10].

## Data Cleaning

As MyFitnessPal is partially user-based and thus inherently prone to errors, we developed an algorithm that removes extremely high nutrient values very likely to be erroneous using Monte Carlo simulations [11]. Using the T1 dataset as a training set, we determined an upper limit of intake per food portion (using an in-house R script) for each nutrient. These limit values were obtained for each nutrient by iteratively increasing the putative limit value and including only intake values below the limit in the database (Multimedia Appendix 1). For each iteration, the correlation between the included Nubel and MyFitnessPal values was calculated. The nutrient intake value for which this correlation was maximal was defined as the upper limit for that nutrient. These cut-offs constitute the best compromise between removing erroneous values (ie, true positives) and not removing correct values (ie, false positives). Subsequently, these limit values based on the T1 dataset were applied to the MyFitnessPal values of the T2 dataset to remove extremely high values, using an in-house R script (Multimedia Appendix 2).

## Data Analysis

For each 4-day diary, mean energy intake and nutrient values were calculated with Nubel and the MyFitnessPal database. To evaluate the impact of the data cleaning procedure, both the original and cleaned T2 data from MyFitnessPal were correlated to the Nubel values. The normality of the data was checked with the Shapiro-Wilk test and with visual inspection of the residual histogram. Depending on normality, Pearson or Spearman rank were applied for correlation analysis. Bland-Altman plots were used to assess the degree of agreement between both methods and to evaluate bias [12]. In addition, a paired *t* test or a Wilcoxon signed rank test was performed. Data analysis was performed using SAS software (version 9.4; SAS Institute). *P* values less than .05 were considered statistically significant.

To further assess the practical implication of using the MyFitnessPal database, we simulated the loss of statistical power that occurs when using the MyFitnessPal database compared to the Nubel database in a study design that aims to correlate nutrient intake to a random outcome variable. In addition, we calculated the corresponding increase in sample size required to compensate for the loss in power. Given a nutrient quantified using Nubel and MyFitnessPal, named *N* and *M*, respectively, and given a variable defined as the outcome (*O*), we used the correlation *NM* (known from this study) and a simulated correlation *NO* to retrieve the correlation of interest (ie, *MO*). Simulations were performed according to Monte Carlo simulations [11]. Briefly, for each nutrient, we simulated 100 times a value for *O* and this for 100 correlations, with  $0 \leq \rho \leq 0.5$  and a step length of 0.005. Subsequently, for each correlation between *O* and the Nubel-calculated nutrient *N*, and with a known sample size, we derived the power for *NO*. Corresponding correlations between the *O* variables and the MyFitnessPal-calculated nutrients *M* were computed, followed by the resulting power of *MO*. The power of *MO* indicates the power to detect a true effect for the correlation of the MyFitnessPal nutrient data (*M*) and the outcome variable (*O*) (eg, a health parameter). This simulation was performed for a

sample size of 50, 100, and 500 observations. All simulation analyses were performed with R (version 3.5.1; R Core Team). Power calculations were performed with R package “pwr” (version 1.3-0; Stéphane Champely).

## Results

Of the 50 participants, 78% (39/50) were women and 22% (11/50) were men. Mean BMI was 25.3 (SD 5.1) kg/m<sup>2</sup> and mean age was 28.2 (SD 11.3) years. All dietary records covered 4 consecutive days, except for 1 diary with only 3 days of food registration. The upper limit values per food portion were 1500 kilocalories (kcal) for total energy intake, 95 grams (g) for carbohydrates, 92 g for fat, 52 g for protein, 22 g for fiber, 70 g for sugar, 600 mg for cholesterol, and 3600 mg for sodium. The clean-up of dataset T2 removed certain nutrient values from 79 of the 2826 recorded food items (2.8%). For carbohydrates, 46 values were removed; for protein, 17 values were removed; for fat, 2 values were removed; for sugar, 8 values were removed; for cholesterol and sodium, 3 values were removed. No values for fiber and total energy intake were removed.

In the original T2 dataset, strong positive correlations between Nubel and MyFitnessPal were obtained for total energy intake, the 3 macronutrients, and for sugar and fiber (Table 1). Nevertheless, fiber intake was significantly underestimated when calculated with the MyFitnessPal database ( $P < .001$ ). Correlations for cholesterol and sodium, however, were weak, and their intake was also strongly underestimated by MyFitnessPal. After the cleaning of the T2 dataset, correlations with Nubel data were stronger for carbohydrates, fat, sugar, and sodium than for the original data (Table 1). Mean energy and fat intake did not differ significantly between cleaned MyFitnessPal and Nubel values, whereas carbohydrate and protein intake became slightly but significantly lower using MyFitnessPal. Correlations for original and cleaned T2 MyFitnessPal data with Nubel were identical for fiber and total energy intake, as data cleaning did not remove any value.

Bland-Altman plots of the cleaned T2 data displaying the agreement between both methods for all nutrients and energy intake are shown in Figure 1. No proportional nor fixed bias was observed for the macronutrients, sugar, and energy intake. In contrast, fiber intake showed an average fixed bias of about 4 g/day, which is about 20% of average fiber intake. Furthermore, sodium and cholesterol intake were clearly underreported in MyFitnessPal [the mean difference MyFitnessPal-Nubel amounts to -1345 (SD 241) mg/day for sodium and -187 (SD 124) mg/day for cholesterol]. In addition, the difference between MyFitnessPal and Nubel for cholesterol intake proportionally increased with increasing cholesterol intake.

The power simulation quantified the statistical power that is lost when correlating MyFitnessPal-derived data instead of Nubel data to an outcome parameter (Figure 2) and the additional sample size needed to compensate (Table 2). For example, for an intended power of 80% with Nubel, the power will be decreased when using MyFitnessPal with 4% for total energy intake, 8% for carbohydrates, 10% for protein and fat, 15% for sugar, and 19% for fiber. Depending on the intended

sample size, the required increase in sample size to compensate for this loss in power ranged from 10% to 65% (Table 2). Furthermore, the simulation showed a complete loss of power if MyFitnessPal would be used to assess cholesterol and sodium intake, resulting in extremely high sample sizes.

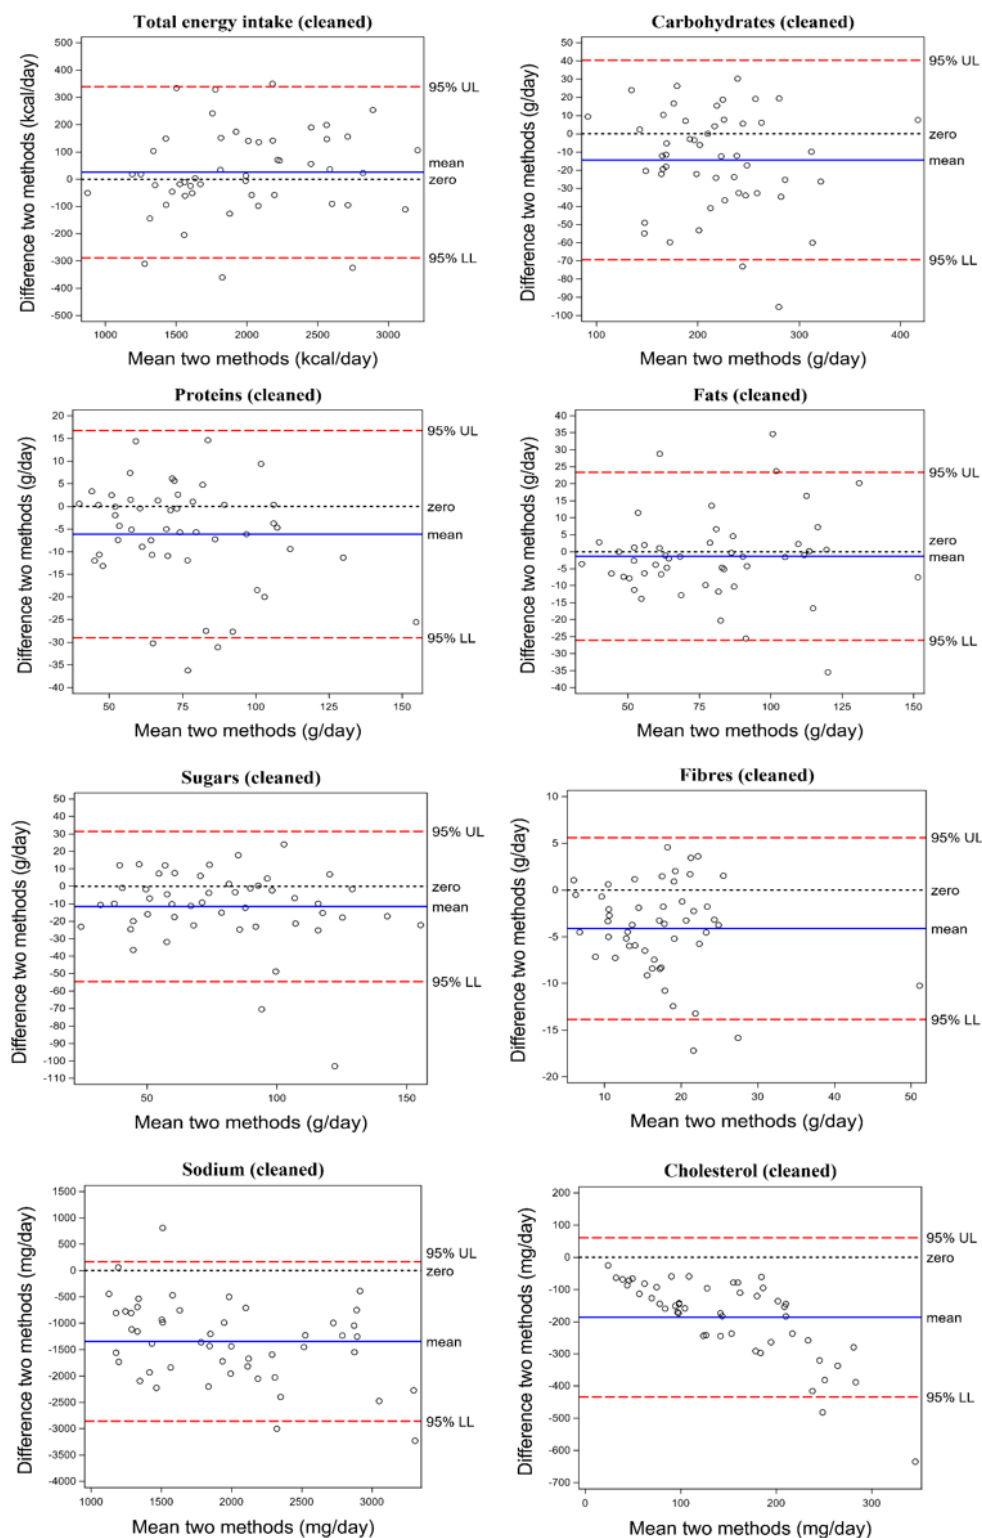

**Table 1.** Nutrient intake values of T2 data derived from Nubel and MyFitnessPal, prior to and after data cleaning (n=50).

Nutrient	Nubel		Original MyFitnessPal data				Cleaned MyFitnessPal data			
	Mean	SD	Mean	SD	<i>P</i> value <sup>a</sup>	Coefficient <sup>b</sup>	Mean	SD	<i>P</i> value <sup>a</sup>	Coefficient <sup>b</sup>
Energy intake (kcal/day)	1958	543	1984	567	.26	0.96	1984	567	.26	0.96
Carbohydrates (g/day)	225	61	241	80	.05	0.70	210	58	<.001	0.90
Fat (g/day)	81	27	82	31	.69	0.75	80	28	.44	0.90
Protein (g/day)	78	26	78	26	.85	0.94	72	23	<.001	0.90
Sugar (g/day)	85	35	80	40	.22	0.70	74	31	<.001	0.79
Fiber (g/day)	19	8	15	7	<.001	0.80	15	7	<.001	0.80
Sodium (mg/day)	2638	848	1551	1765	<.001	0.45	1293	607	<.001	0.53
Cholesterol (mg/day)	242	131	67	63	<.001	0.67	55	49	<.001	0.51

<sup>a</sup>Paired *t* test was used for energy intake, macronutrients, sugar, and fiber; the Wilcoxon signed rank test was used for for cholesterol and sodium.

<sup>b</sup>Pearson correlation coefficients were used for energy intake, macronutrients, sugar, and fiber; the Spearman rank correlation coefficients were used for cholesterol and sodium. Both Pearson and Spearman were significant at the level of .05, as they were all *P*<.001.

**Figure 1.** Bland-Altman plots for energy intake and nutrient values of the cleaned T2 dataset, with Nubel as the reference method and MyFitnessPal as the other method for nutrient intake analysis. The difference between the 2 methods is calculated as follows: MyFitnessPal – Nubel. The 95% upper limit (UL) and lower limit (LL) of agreement (SD 1.96) are depicted as long dashed lines. The full line and short-dashed line indicate the mean difference and zero, respectively.

**Figure 2.** Correlation analysis between the statistical power of Nubel and MyFitnessPal (MFP) to reject the null hypothesis that states there is no correlation between each of these methods and a simulated variable outcome. The total sample size is 100 power values. This correlation between the power of Nubel and MyFitnessPal was performed for all studied nutrients (macronutrients, sugar, fiber, cholesterol, and sodium) and for energy intake.

**Table 2.** Increase in sample size (%) required to maintain 80% power when using MyFitnessPal for nutrient analysis instead of Nubel to detect a true effect if correlated with an outcome variable.

Nubel sample size	Percentage (%) increase in MyFitnessPal sample size required to maintain a statistical power of 80%							
	Energy intake	Carbohydrate	Fat	Protein	Sugar	Fiber	Cholesterol	Sodium
50	11	28	21	33	64	65	347	364
100	10	27	20	32	60	65	277	307
500	10	25	19	28	40	36	68	72

## Discussion

### Principal Findings

This study evaluated the accuracy of the MyFitnessPal food composition database to assess energy and macro- and micronutrient intake. Strong positive correlations between MyFitnessPal and Nubel were observed for energy intake, macronutrients, sugar, and fiber, but not for cholesterol and sodium. Bland-Altman plots displayed a good agreement between MyFitnessPal and Nubel, except for cholesterol and sodium. Using MyFitnessPal over Nubel for quantifying total energy intake and macronutrients led to a power loss in studies that correlate nutrient values to an outcome variable of not more than 10%, which can be compensated by increasing the sample size.

Digital collection of food intake data facilitates the assessment of dietary intake, both at the level of dietary data registration and at the level of nutrient quantification [1,13]. Many studies

have compared digital methods with paper-and-pencil methods at the level of dietary registration using the same database for nutrient calculation. These studies, using digital registration tools such as My Meal Mate, YANA-C, Wellnavi, e-DIA or Easy Diet Diary, observed good agreement between the digital and paper method [14-18]. In this study, we used the same digital method for diet registration but applied 2 distinct databases to calculate the nutrient intake values. Our results indicate that the nutritional information extracted from MyFitnessPal is comparable to the information calculated with a standard food composition database (Nubel), except for cholesterol and sodium. Overall, dietary intake was slightly underestimated by MyFitnessPal, which is in agreement with previous studies [19,20]. The underestimation was even more pronounced after cleaning the dataset, a procedure that resulted in the rejection of extremely high and likely erroneous values. Compared to Nubel-derived values, MyFitnessPal underestimated protein intake by 7.8%, carbohydrate intake by 6.4%, and fat intake by 1.7%. In contrast, energy intake was

slightly overestimated (1.3%). In a study applying the Brazilian food composition data table as a reference, the MyFitnessPal database underestimated energy (0.7%), fat (16.8%), protein (11.9%), and carbohydrate intake (10.8%) [19]. In another study, nutrient intake estimates from thirty 24-hour dietary recalls collected using the Nutrition Data System for Research (NDSR) were compared with intake calculations from these recalls entered by the researcher into MyFitnessPal [20]. Compared to NDSR, a similar underestimation by MyFitnessPal was observed for energy (4.1%), fat (14.1%), and protein (8.0%), while carbohydrate intake was overestimated by 1.6% [20]. A reason for the underestimation by MyFitnessPal is most likely incomplete or missing information about nutrient composition for some food items in the database. Indeed, some entries in MyFitnessPal only have a value for total energy content without values for macronutrient composition or cholesterol and sodium content. Selecting such items for inclusion in the dietary record results in inaccurate information.

The use of digital platforms like MyFitnessPal has several advantages over other methods. Platforms available as a smartphone app allow participants to report food intake conveniently on their smartphones, regardless of their whereabouts or the occasion. In this way, the time delay between consuming and registering food data is reduced, which increases data quality [21]. Compared to food frequency questionnaires and 24-hour recalls, prospective food recording is less prone to memory bias [22,23]. Additionally, recording with a mobile app increases the satisfaction and adherence of the participants, further enhancing dietary assessment [24,25]. Moreover, the direct link of the consumed items to the nutritional facts facilitates and accelerates the work of the investigator. In contrast to paper data, MyFitnessPal food data do not require transfer to an electronic database, which reduces errors. In this way, the use of MyFitnessPal can reduce the high financial and human resources required for standard nutrient quantification [26]. A potential concern of digital platforms is the fact that the immediate feedback and nutritional information provided to participants may alter their eating behavior and induce misreporting. This is called the “reactivity effect” and should be taken into consideration when deciding on the use of a digital platform in a study design [27].

An important source of error in dietary assessment, independent of the registration method and database used, is the estimation of the portion size by the participant. A study that compared meals recorded by the participants with a personal digital assistant (PDA) against actual meals assessed by dietitians reported portion size to be the greatest source of error, accounting for 49% of the errors between recorded and actual meals [28]. Other major errors in food registration by participants included reporting incorrect food (25%) and omitting food (15%). In addition, in a study with the digital My Meal Mate diary, an incorrect portion size was the cause of most

errors, with users selecting the standard listed portion sizes rather than providing the true portions consumed [14].

An effective strategy to improve the accuracy of dietary assessment with digital platforms is to provide adequate training to the participants, in the form of a manual or a training session. A study of 78 adolescents showed a significant increase in proficiency and perception in the use of a mobile phone food record after additional training was provided [29]. Accordingly, the application of MyFitnessPal in a naturalistic setting (ie, without the provision of instructions to subjects unfamiliar with the app) resulted in poor correlations for 4-day mean energy and macronutrient intake (ranging from 0.21 to 0.42) compared to a 24-hour recall analyzed with the Australian Food, Supplement, and Nutrient Database (AUSNUT) 2011-2013 database [30]. Therefore, it is crucial that the training includes information on how to select items from the database and clear instructions on how to provide portion sizes. We assume that the high correlations between MyFitnessPal and Nubel found in this study are partly due to the extensive manual that was provided to the participants and the fact that we predefined a number of generic items to increase standardization. In daily life, this manual is not available, and as MyFitnessPal is a user-based platform, errors in nutritional information arise in the database. However, MyFitnessPal itself has built-in tools to enhance food registration, such as bar code scanning and the green flagging of items. If the user is motivated, MyFitnessPal may be a useful tool to track nutrient intake in daily life. Using MyFitnessPal as a self-guided approach was as effective in inducing weight loss as a combination of the app with dietary counseling in 100 obese subjects [31]. Another trial highlighted the importance of motivation when using MyFitnessPal for weight loss management in combination with dietary counseling [25]. In addition, it is important to realize that our study was performed in the context of a trial evaluating the health benefits of wheat bran. Therefore, participants were likely biased towards persons interested in human health. Good motivation and background knowledge on nutrition and food are known predictors for reliable and accurate reporting with digital dietary records [22]. Consequently, these predictors may have driven our study participants to select those food items with accurate nutritional information and may have directed our results.

## Conclusion

MyFitnessPal provides accurate estimates for energy, macronutrients, fiber, and sugar intake, but not for cholesterol and sodium, in a research setting. We advise the use of both a data cleaning procedure and a clear manual on dietary reporting for participants, as they contribute to better nutrient assessment. A manual on MyFitnessPal usage should include instructions on proper food item selection, portion size recording, and the use of features such as scanning bar codes of food items. To enhance standardization, it is useful to add entries with a tag for generic items, as the MyFitnessPal database contains many entries with considerable differences in nutritional information.

## Abstract

**Background:** Clinical decision support (CDS) is a tool that helps clinicians in decision making by generating clinical alerts to supplement their previous knowledge and experience. However, CDS generates a high volume of irrelevant alerts, resulting in alert fatigue among clinicians. Alert fatigue is the mental state of alerts consuming too much time and mental energy, which often results in relevant alerts being overridden unjustifiably, along with clinically irrelevant ones. Consequently, clinicians become less responsive to important alerts, which opens the door to medication errors.

**Objective:** This study aims to explore how a blockchain-based solution can reduce alert fatigue through collaborative alert sharing in the health sector, thus improving overall health care quality for both patients and clinicians.

**Methods:** We have designed a 4-step approach to answer this research question. First, we identified five potential challenges based on the published literature through a scoping review. Second, a framework is designed to reduce alert fatigue by addressing the identified challenges with different digital components. Third, an evaluation is made by comparing MedAlert with other proposed solutions. Finally, the limitations and future work are also discussed.

**Results:** Of the 341 academic papers collected, 8 were selected and analyzed. MedAlert securely distributes low-level (nonlife-threatening) clinical alerts to patients, enabling a collaborative clinical decision. Among the solutions in our framework, Hyperledger (private permissioned blockchain) and BankID (federated digital identity management) have been selected to overcome challenges such as data integrity, user identity, and privacy issues.

**Conclusions:** MedAlert can reduce alert fatigue by attracting the attention of patients and clinicians, instead of solely reducing the total number of alerts. MedAlert offers other advantages, such as ensuring a higher degree of patient privacy and faster transaction times compared with other frameworks. This framework may not be suitable for elderly patients who are not technology savvy or in-patients. Future work in validating this framework based on real health care scenarios is needed to provide the performance evaluations of MedAlert and thus gain support for the better development of this idea.

(*J Med Internet Res* 2020;22(10):e22013) doi:[10.2196/22013](https://doi.org/10.2196/22013)

**KEYWORDS**

blockchain; health care; alert fatigue; clinical decision support; smart contracts; information sharing

## Introduction

### Background

Clinical decision support (CDS) is a tool to facilitate medical decision making by generating clinical alerts [1], ranging from simple medication-specific alerts based on stored clinical rules and information to more complex patient-specific alerts by integrating CDS with electronic health records (EHRs) [2]. For example, CDS warns clinicians by generating an alert if a new prescription poses a threat to patients [3]. This real-time alert disrupts the workflow and draws clinicians' attention so they can evaluate and make appropriate decisions in a quick and efficient manner [4]. CDS has replaced previous situations in which clinicians make decisions solely on the basis of their knowledge and past experience [5]. CDS is now considered an essential health information technology that improves the overall quality of health care [6]. However, current CDS tools generate a high volume of irrelevant alerts, resulting in alert fatigue [7].

Alert fatigue or alert burden is defined as the mental state that results when alerts or reminders consume too much time and mental energy, which can cause clinicians to override or ignore both clinically irrelevant and relevant alerts unjustifiably [8]. Clinicians are now drowning with alerts and gradually becoming less responsive to and less respectful of them [9]. This is mainly because generated alerts are mostly irrelevant or low priority, and fortunately, they are not life threatening. In the long term, these *cry-wolf* alerts have desensitized clinicians, resulting in high overriding rates ranging between 77% and 90% [10-12], which opens the door to preventable medication errors.

Alert fatigue started becoming increasingly common in the health care sector decades ago and is now widely recognized as a national concern, often due to the lack of a corresponding action plan [13]. CDS failures and errors caused by individuals have resulted in direct costs of more than US \$20 billion in the United States [14,15]. Alert fatigue is perceived as a major problem because it extends beyond the health care industry. Other sectors, such as off-shore oil drilling [16] and heating, ventilation, and air-conditioning systems in buildings [17], are also experiencing alert fatigue. For example, fault detection systems generate high volumes of alerts, leading to operator alert fatigue and resulting in energy wastage in buildings. Currently, there is a persistent upward trend and increasing requests for new alerts [13], which does not help alert fatigue. This only exacerbates the alert fatigue and makes it more widespread.

Overriding alerts is clinically appropriate if the alert generated is incorrect [7]. However, due to the low specificity and high volume of alerts generated by CDS, relevant alerts may also be dismissed, resulting in preventable prescription errors and adverse drug events. Deactivation [18] or running low-priority alerts in silence [19] are among the suggestions for reducing alert fatigue. However, these approaches in managing alerts

effectively are difficult because of strict regulatory bodies and other external pressures. Many are in fact pushing for more rather than fewer alerts to reduce or avoid preventable medication errors [13].

In Norway, approximately 12% of patient harm is caused by the incorrect use of drugs [20]. One in three elderly people have been given the wrong medication, and an estimated one thousand deaths per year are thought to be due to medication errors, despite the use of e-prescriptions [21,22]. During a meeting at the Norwegian University of Science and Technology (NTNU), a health care representative from Innlandet Hospital presented in his presentation that approximately 8% of total health care spending went on correcting medication errors within the Innlandet region. [23]. We, therefore, agree with Wright et al [24] that the health care sector can only benefit from the potential value of CDS-generated alerts when they are well designed and properly implemented. Thus, there is a need to seek an alternative, innovative approach to improve the management of clinical alerts and reduce alert fatigue among clinicians.

### Objectives

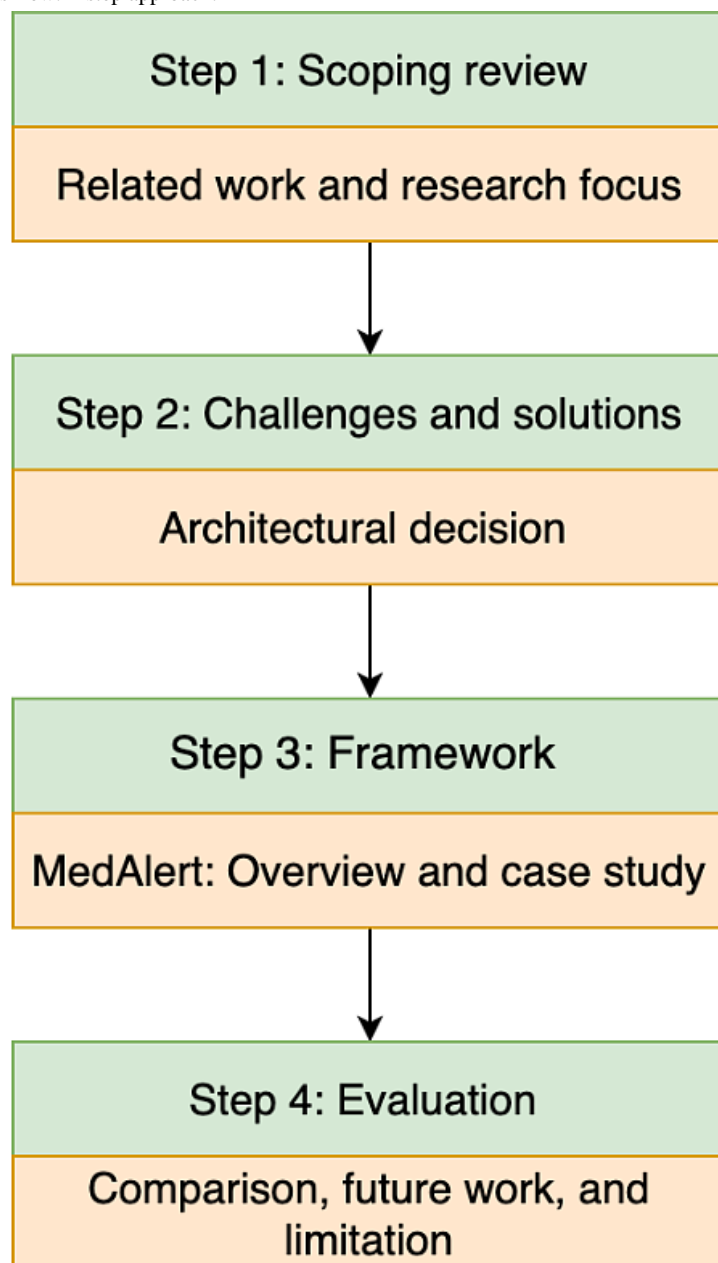

Blockchain technology has gained attention as a potential solution in the health care sector, mainly due to its potential in moving toward collaborative treatments and decision making [25-27]. A large range of literature has been published anticipating this technology with a view to improving the health sector with respect to the overall well-being of clinicians and the quality of patients' health care by sharing medical records and history [26]. However, studies focusing on clinical alerts using blockchain remain limited. This has led us to our main research question in this paper, which is to explore and understand how a blockchain-based solution can help to reduce alert fatigue in the health sector by sharing alerts and thus enhancing collaborative decision making. To answer this question, we designed a 4-step approach, which is explained in the *Methods* section.

## Methods

### Design Approach

The 4-step approach, shown in Figure 1, is designed to answer our research question and explain how the paper is organized. The first step is to conduct a scoping review to explore the current state of the art in this area. The literature we finally selected and the existing solutions we have chosen are then analyzed in step 1. Step 2 is designed to identify potential challenges and technical solutions for reducing alert fatigue. Architectural decisions are explained in this step. The framework is designed in step 3. An overview of MedAlert, together with a case study, is elaborated in this step. Finally, the framework is evaluated by comparing it with other proposed solutions. The comparison, future work, limitations, and benefits are also discussed in step 4.

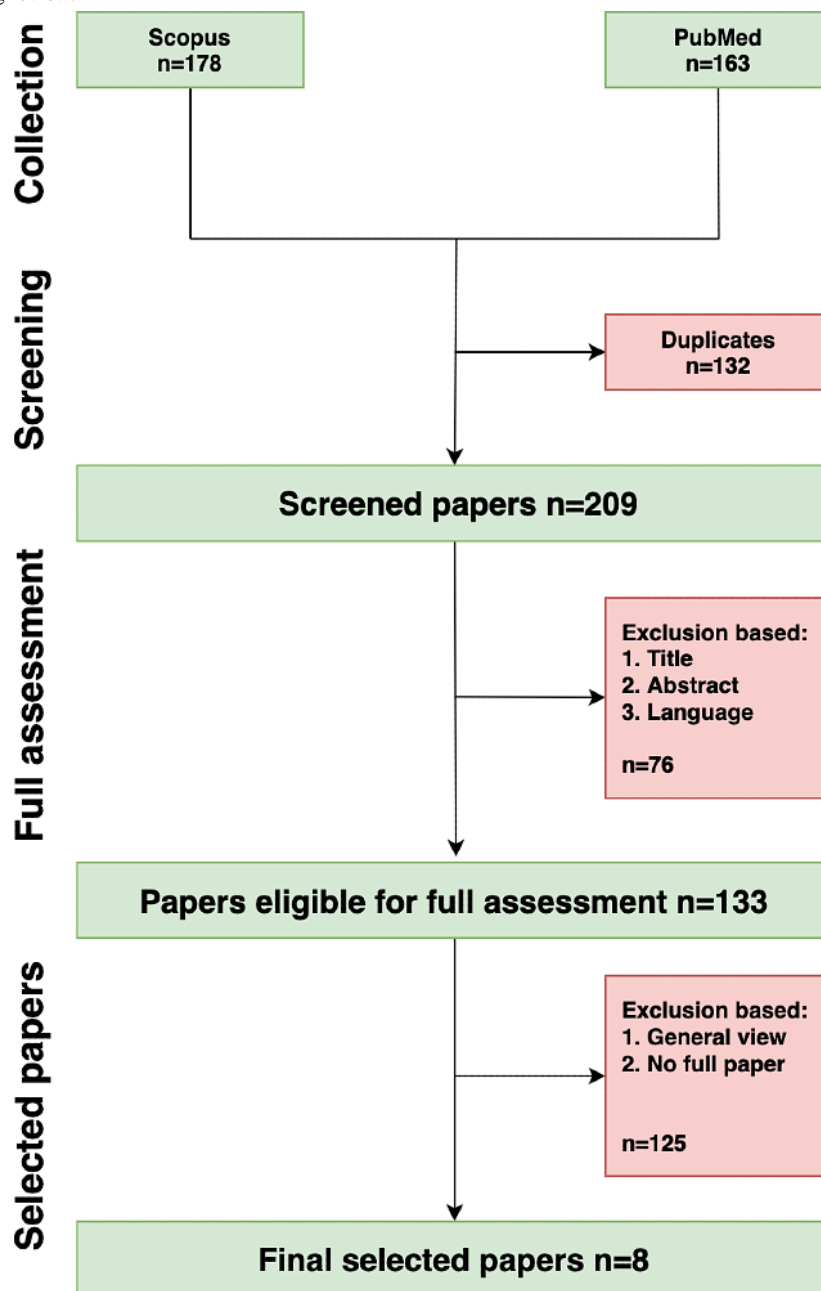

**Figure 1.** Research design process flow: 4-step approach.

### Scoping Review: Search Strategy

A scoping review was conducted with the aim of exploring the current state of the art in academic research with the widest possible coverage of all the published literature. The reporting of this scoping review was guided by PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-analysis extension for Scoping Reviews) [28]. We performed searches on 2 bibliographic databases, Scopus and PubMed. To be as comprehensive as possible, generic keyword strings such as *blockchain*, *clinical decision support*, *alert burden*, and *alert fatigue* were used as search criteria. [Multimedia Appendix 1](#) details the structures of the keyword strings.

We acknowledge that industries are also working on blockchain-based solutions within the health care sector, but often, the details of the frameworks are not disclosed. Therefore, in our research, we focus primarily on the academic sphere because the architecture frameworks and solutions are described in published work. Peer-reviewed articles, conferences, reviews and proceedings, and dissertations are included to provide a broad overview of different aspects of alert fatigue resulting from CDS. Only English papers were included, with no restrictions on the year or country of publication. We excluded general views, no full paper, and conference abstracts. The selection process for the scoping review is summarized in [Figure 2](#).

**Figure 2.** Process of scoping review.

## Results

### Related Work and Research Focus

Alert fatigue is a major problem faced by clinicians and is now a rising concern in the health care sector. The published literature on alert fatigue in the academic sphere started as early as 2007. We collected a total of 341 published items and finally selected a total of 8 [13,15,29-34] that fit our research criteria based on the scoping review in Figure 2. We then entered these items in Microsoft Word and Excel for deeper analysis. We summarize and sort these literatures according to their different key foci, methods, and benefits in Multimedia Appendix 2 [13,15,29-34].

Carli et al [35], Powers et al [36], and Hussain et al [37] pointed out that the high degree of alerts with low clinical relevance is one of the root causes of alert fatigue in their systematic

literature reviews. This is because hospitals and other private health care institutions use or purchase commercial CDS tools to improve the overall quality of their health care systems. It is common for vendors and designers of commercial CDS tools to sharply restrict the ability to modify the setup for alert systems, resulting in a high volume of low-relevance alerts [2]. The strict, low-specificity settings imposed by vendors are due to their fear of being exposed to potential litigation if the removal of alerts fails to prevent a potential medication error.

One common attempt to address alert fatigue is to reduce the number of alerts of low clinical relevance by clustering alerts with similar clinical management options [32] or better specifications to generate useful alerts [31]. The machine learning algorithm-based CDS is another suggested method to generate more context-driven alerts [15] and patient-centric alerts [34]. Soundararajan et al [30] designed a blockchain architecture framework to leverage blockchain and smart

contracts in support of clinical support tools that generate more patient context-appropriate alerts and thus generate fewer inappropriate alerts, which could reduce physician burnout. However, the actual benefits to patients and the extent of the positive impact on alert fatigue remain unclear.

All these efforts have managed to reduce the total number of alerts generated, but the fundamental issue of alert fatigue has still not been tackled. Bryant et al [38] pointed out that despite intensive efforts to reduce irrelevant alerts of commercial systems, overriding rates remain as high as reported over a decade ago. Medical experts suggested that improving alert fatigue should go beyond just reducing the total number of alerts [39].

Getting someone to attend the alerts is one way to reduce alert fatigue. Smithburger et al [5] suggested a potential strategy for directing alerts to medical professionals other than clinicians, for example, nurses. A study conducted in three academic medical centers in the Netherlands evaluated shifting time-dependent drug interaction alerts to medical staff such as nurses or pharmacists [40]. These results demonstrated the ability to improve the efficiency and effectiveness of such alerts and showed that incorrect administration times were reduced by 29% when they were directed at nurses. This can enable more collaborative treatment and decision care, whereas blockchain technology can be leveraged to enable alert sharing [25].

In our work, we have explored how blockchain can be leveraged to reduce alert fatigue by directing low-level alerts to patients in achieving high-quality collaborative clinical decisions. There has been a recent shift toward a more patient-centric data sharing for better collaborative decision making within the health care sector [41]. However, the relevant work remains limited. Thus, we contribute by designing an exploratory blockchain-based framework that enables low-level alert sharing with patients to enable more collaborative decision making while maintaining a high level of privacy and security. To design a sound framework, we need to understand and consider the challenges involved in facilitating the sharing of clinical alerts.

Data integrity and user privacy are two of the main concerns of the health care industry worldwide [42]. One of the reasons for this is that most of the current health care systems have weak and vulnerable centralized data storage procedures for preserving and managing sensitive medical data [43]. In 2019, the database of the Health Sciences Authority in Singapore was hacked for the third time in less than a year because of security loopholes, and more than 800,000 personal details were exposed [44]. Identity theft is another issue of concern in the health sector. According to Pandey et al [43], 10% of data breaches in the health industry in the last 10 years were categorized as identity theft.

There is a range of literature on blockchain-based frameworks that serves as an alternative to current vulnerable centralized database systems. EMRshare [45], Medchain [46], FHIRchain [25], and MedBlock [47] are examples of blockchain-based solutions that ensure high levels of data integrity and privacy for sharing medical records. In addition, smart contracts can enable a new service for health care to facilitate information sharing without a third party. For example, Medchain enables medical record access between multiple roles, such as patients, requesters, and health care providers, and helps them to achieve higher levels of efficiency and to satisfy security requirements [46]. This can improve collaborative decision making between different stakeholders, for example, clinicians and patients, in the health care sector.

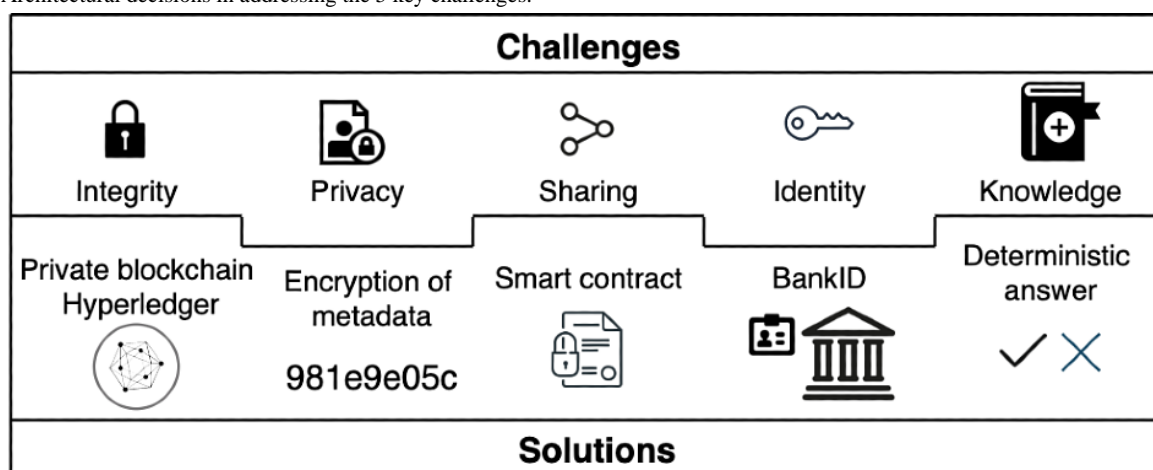

Five key challenges must be addressed to develop a secure and effective blockchain framework and thus reduce the alert burden within health care. These 5 key challenges are as follows:

1. Data integrity
2. Privacy issues
3. Verifying and authenticating participants' identities
4. Lack of secure information sharing
5. The extent of patients' knowledge in the medical field

### Architectural Decisions to Address These Five Key Challenges

In this section, we address the challenges suggested in the previous section. The architectural decisions are summarized in Figure 3.

**Figure 3.** Architectural decisions in addressing the 5 key challenges.

## Challenge 1: Data Integrity

### Context

Health information is sensitive and must be highly secured, without the possibility of any data manipulation. Any alteration in a patient's medical history could result in severe medication errors and even death. Medical data are often stored in and managed by centralized trusted third-party databases. However, such a centralized database can be vulnerable to single-point failures, resulting in loss or corrupted medical data and blocking of access deliberately during disputes by service providers [48]. Some modern EHR systems can be configured to have a backup and data redundancy mechanism that improves data storage resilience, but it requires additional configuration and maintenance that might be error prone due to human factors. According to some security experts, current systems in protecting our health data do not achieve the desired modern security standards [49].

### Solution

A solution that offers resiliency out of the box and a tamper-sensitive storing environment to prevent any *silent* manipulation by making alterations obvious to members in the network.

### Technical Requirement

Blockchain technology is a distributed ledger that contains replicated and synchronized digital data. It provides a platform for real-time data sharing between a large number of members in a network with a higher level of data trust [50,51]. *Data trust* denotes the reliability of the information and data provided [52]. A high level of data trust is important for decision making.

The data storage structure is a salient feature of blockchain, which ensures that information and data are stored in a tamper-evident environment [53]. All valid transactions are recorded in a block format, and each block is linked with a time stamp and hash references forming a chain of blocks [54]. Any attempt to alter information, for example, in the off-chain database, regardless of the intention, breaks the hash reference and thus makes it obvious to the other members of the network. This way, a hash reference creates a tamper-evident environment that maintains and ensures data integrity. The transactions recorded on the blockchain remain immutable and tamper-proofed owing to the structure and writing rights of the blockchain itself, which can guarantee a high level of data integrity.

## Challenge 2: Privacy Issues

### Context

Medical information, including medical records, prescription histories, patients' personal information, and surgical records that are stored in digital formats, are classified as digital assets. This information requires high levels of privacy protection because it relates to the patient's current physical or mental health and can reveal information about his or her health status [55]. Ensuring that current or new health services are in compliance with standards, such as General Data Protection Regulation (GDPR) is crucial to avoid unlawful behavior. For example, encryption, pseudonymization, or anonymization of

personal data, whenever possible, to prevent unlawful data processing [55].

### Solution

A private permissioned blockchain is a better option when it comes to ensuring on-chain data privacy and compliance with privacy regulations because transactions are visible only to members. Certain members of the network are granted permissions to read and write on the blockchain. By storing only metadata instead of actual health data, we can avoid exposing actual sensitive personal data, such as full name, diagnoses, and prescribed drugs, which could violate a patient's privacy.

### Technical Requirement

To increase the level of privacy protection, private blockchains such as Hyperledger are preferred over public blockchains, primarily because of the lower degree of visibility and level of *openness*. Information on private blockchains is only accessible to authorized members of the network and not just anyone with internet access. Only an authorized member, in our case clinician, has permission to write and store on the blockchain. This allows the framework to be more compliant with data protection regulations such as GDPR or HIPAA (Health Insurance Portability and Accountability Act) without compromising the privacy of patients [49].

Encrypting metadata in blockchain provides a higher level of security and protection for patients [25] because metadata are treated as sensitive data in health care. This prevents any unauthorized hacker from obtaining actual health information improperly. Encrypted metadata can act as a reference pointer to the patient's prescription profile in the health system. The reference pointer links transactional data from the blockchain to the actual data stored on an off-chain database. This acts as a form of protection because it isolates the patients' actual medical information from the reference itself. The pointer breaks and becomes invalidated when any alteration to the patient's data occurs in the off-chain database. Another benefit in storing encrypted metadata is the lightweight reference pointer, which is more suitable and efficient to store on blockchain, which currently has limited storage capability. This can be a scalable alternative [25].

## Challenge 3: Verifying and Authenticating Participants' Identities

### Context

It is important to ensure that the right patient receives the designated clinical alert from the clinicians. Clinicians working in hospitals can verify and authenticate themselves with the credentials offered by health care institutions through logging into the health care system. However, health care systems today lack a standard platform [56], particularly for patients, to verify and authenticate their digital identities.

### Solution

Use a trusted digital identity management system to verify patients' digital identities. Digital identity denotes the digital representation of entity attributes such as birth or other registered name, national ID number, and registered mobile number to

access systems and applications using an identity mediation process [57-59]. This allows patients to authenticate their identities accurately and thus either authorize or revoke access to certain requestors. This is a way of protecting patients' sensitive data, including managing their medical records, and it guarantees that security and privacy are compliant with local legislation and laws [60,61].

### Technical Requirement

Federated digital identity management, registered once and trusted by many concepts, is widely used in consumer spaces such as Facebook and Google and is trusted by many applications [62]. Unlike traditional centralized identity management, users do not need to set up and register their digital identities with every service provider. In this system, mutual trust is established by receiving components of proof distributed by two or more centralized owners or by mutually recognizing each other's trust and proofing standards [62]. Consortiums of leading banks and mobile operators have created private federated identification procedures, such as BankID in Norway [63] and Smart-ID in Estonia [64], to facilitate the distribution of verified and authenticated identities, thus enabling their citizens or users to access various portals, services, and platforms directly.

### Challenge 4: Lack of Secure Information Sharing

#### Context

Each medical institution has its own way of governing medical records and data. Often, moreover, they are not interaccessible, thus making information sharing difficult. Along with strict legal regulations and the lack of trust in medical institutions outside the organization, information exchange becomes more challenging [45].

#### Solution

Use a common layer to enable information sharing securely without altering the current health care IT infrastructure and to enhance collaborative decision making.

#### Technical Requirement

Smart contracts can govern and facilitate information exchange between two different actors accurately and verifiably without the intervention of an intermediate third party. It also enables autonomous self-execution, once a set of predefined rules is met [65]. For example, when an alert is generated from CDS, it triggers a smart contract to direct the alert to the identified patient. The integration of smart contracts can increase the efficiency of members' real-time decision making and overall information exchange. All events are recorded in the blockchain with a time stamp, and the blockchain structure can act as a common layer of information storage without changing the existing IT infrastructure. Smart contracts can track real-time

performance and also query past events for the purposes of analysis.

### Challenge 5: The Extent of Patients' Knowledge in the Medical Field

#### Context

When directing alerts to patients for a collaborative decision, the main problem is that they may not have sufficient knowledge to make the correct decision. Making a wrong decision can be fatal to patients.

#### Solution

Only low-level and nonlife-threatening alerts are directed to patients governed by smart contracts. Patients will receive clinical alerts and then provide information back to the clinician. The aim of directing alerts to patients is bring the alert to their attention, instead risking its rapid dismissal by clinicians due to the high volumes of alerts. This could reduce alert fatigue and the total number of alerts because clinicians can place the emphasis on higher-level alerts.

#### Technical Requirement

Smart contracts execute actions by sending notifications to patients when the CDS generates an alert. The alert is then directed to the patient in the form of a question with a deterministic answer, either *Yes* or *No*. Given a real-time response, the clinician is able to modify the prescription accordingly and eliminate medication prescription errors based on the responses provided by patients.

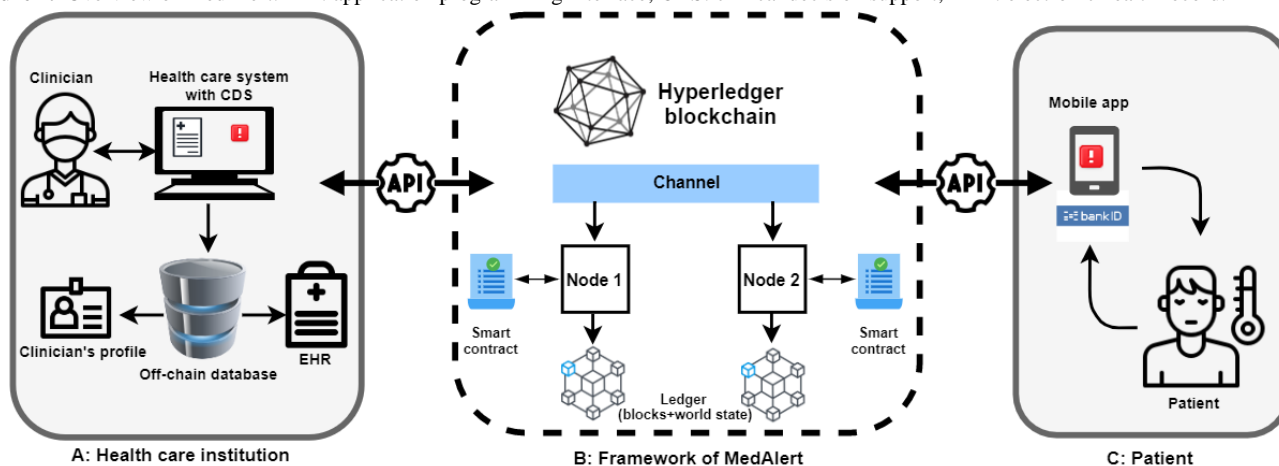

### Principal Finding: MedAlert

#### Overview

This section provides an overview of MedAlert as a potential solution for reducing alert fatigue and enabling a more collaborative process of clinical decision making. This case study is developed as a two-step scenario: (1) *how a patient logs in with BankID to verify and authenticate his or her identity before revealing the alert* and (2) *how a patient is involved in the decision-making process*.

Figure 4 shows how MedAlert (B) enables the interaction between a clinician in a health care institution (A) and a patient (C). The MedAlert is hosted in a private blockchain framework such as Hyperledger. The clinician authorizes through logging into his or her profile with their credentials issued by the health care institution, whereas the patient can log in with BankID to verify and authenticate himself or herself. The blockchain nodes can be administered by a collection of health care organizations such as hospitals but not on a patient's mobile device due the high requirement of computational resources and a consistent network connectivity. These nodes host ledgers and smart contracts that can be queried and updated by peer-connected applications.

**Figure 4.** Overview of MedAlert. API: application programming interface; CDS: clinical decision support; EHR: electronic health record.

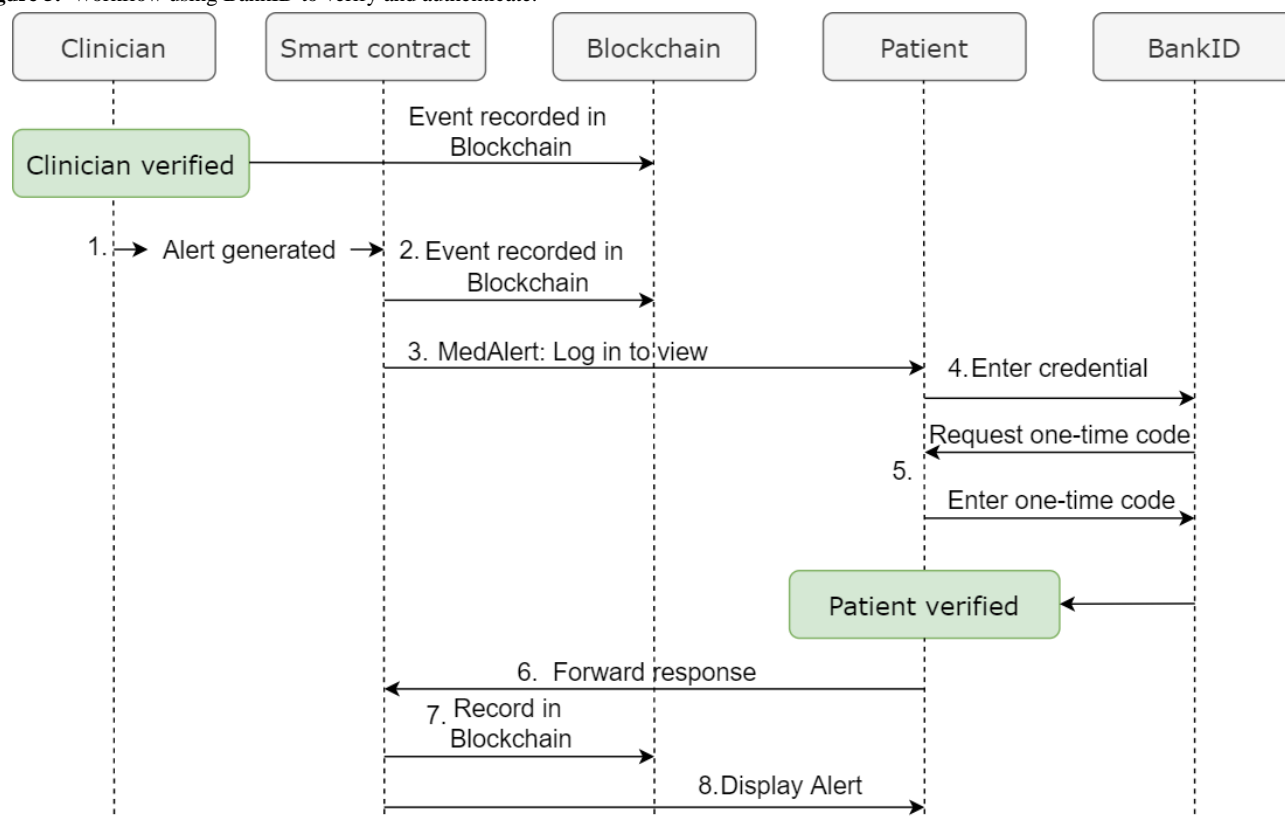

Application programming interfaces (APIs) can enable alert sharing with multiple health care systems. Representational state transfer (REST) APIs can establish communication between mobile client apps and the blockchain network. A client app sends a transaction proposal using organization-specific REST APIs that enable apps to connect to nodes; invoke smart contracts that generate transactions; submit transactions to the network that will be ordered, validated, and committed to the distributed ledger; and receive events when this process is complete.

The consensus protocol in the private blockchain enables transaction data integrity. For every transaction, each node will verify that the transaction has been endorsed by the required organizations according to the endorsement policy of the smart contract that generated the transaction. For example, some

transactions may only need to be endorsed by a single organization, whereas others may require multiple endorsements before they are considered valid. This process of validation verifies that all relevant organizations have generated the same outcome or result.

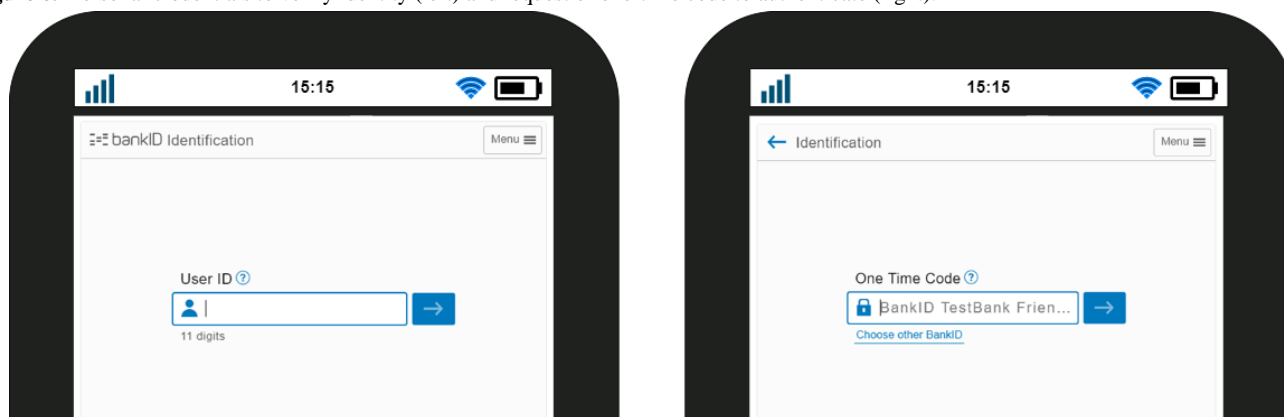

#### *How a Patient Logs In With BankID to Verify and Authenticate His or Her Identity Before Revealing the Alert*

This section describes the step-by-step workflow, as shown in Figure 5. Before clinicians can access patients' EHRs or prescribe new drugs, they need to authenticate their identities by logging in their credentials into the health care system. This event is recorded in the blockchain. When the clinician prescribes a drug to a patient and assumes that it could pose a threat to the patient:

**Figure 5.** Workflow using BankID to verify and authenticate.

1. A clinical alert (red exclamation mark) is generated from the CDS system, as shown in Figure 4. This triggers the smart contract.
2. This event is then recorded in the blockchain.
3. The smart contract also sends the alert to the patient's registered mobile number.
4. The patient receives a message with a link to verify and authenticate his or her identity. Then he or she must log in to verify and authentic himself or herself by providing his or her registered user ID (eg, the 11 digits of a social security number) as sketched in Figure 6 (left).
5. The patient is then required to enter his or her one-time code for final authentication, as shown in Figure 6 (right).
6. When the authentication and verification is successful, the response is forwarded to the smart contract.
7. This event is also recorded in the blockchain.
8. The patient is then able to view the alert.

**Figure 6.** Personal credentials to verify identity (left) and request of one-time code to authenticate (right).

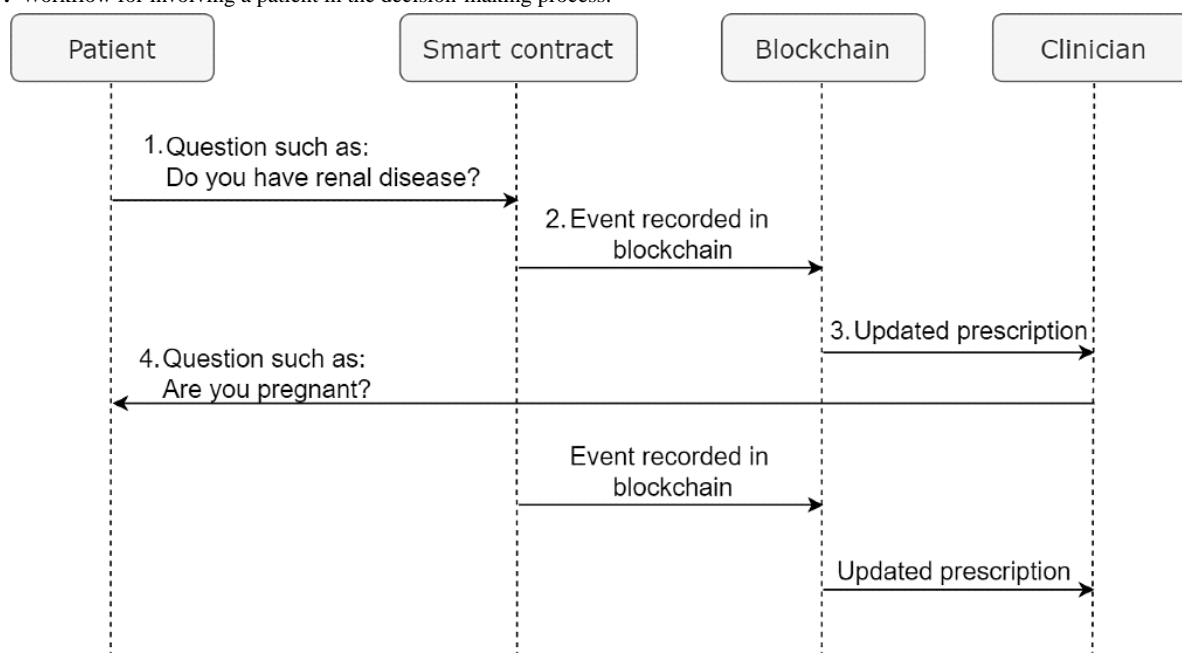

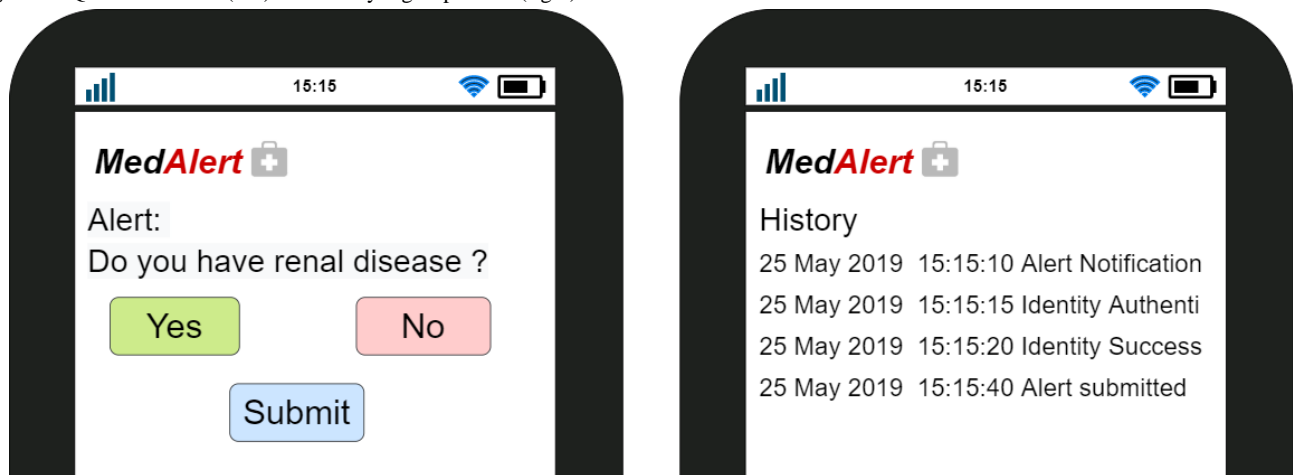

### How a Patient Is Involved in the Decision-Making Process

After the patient has verified and authenticated his or her identity, the patient can access and read the information in the alert. The workflow is shown in Figure 7.

1. The first alert asks: "Do you have renal disease?" The answer to the question is either *Yes* or *No*, as shown in Figure 8 (left).
2. When the patient responds, the smart contract is then triggered, and the patient sends the response back to the clinician. The transaction is recorded in the blockchain.
3. The clinician updates the prescription according to the answer provided.
4. If another low-level alert pops up, the patient has to respond in real time before the prescription is finalized. The patient can view his or her history, as shown in Figure 8 (right).

**Figure 7.** Workflow for involving a patient in the decision-making process.

**Figure 8.** Question in alert (left) and history log of patients (right).

## Discussion

### Comparison With Prior Work

Three different frameworks (MedAlert, MedRec, and MedAware) are compared in Table 1. These solutions can reduce the total number of alerts generated but with fundamentally different technologies. Both MedRec and MedAware focus on reducing alert fatigue by filtering irrelevant alerts. MedRec

utilizes a smart contract embedded in a blockchain platform, from which CDS retrieves medical records via MedRec to retrieve relevant patient information and generate alerts that are more context based. MedAware uses a machine learning algorithm to flag more relevant and accurate alerts in real time after analyzing patients' historical medical records. However, improving alert fatigue should go beyond just reducing the total number of alerts [39]. These two solutions only capture the clinician's attention.

**Table 1.** Comparison of different framework solutions.

Solution	MedAlert	MedRec	MedAware
Alert reduction	Yes	Yes	Yes
<b>Alert capturing</b>			
Clinician	Yes	Yes	Yes
Patient	Yes	No	No
<b>Privacy</b>			
Ownership	Clinician and patient	Clinician and patient	N/A <sup>a</sup>
Encryption	Yes	No	N/A
<b>Blockchain</b>			
Type	Private: Hyperledger	Public: Ethereum	No, machine learning
Smart contract	Yes	Yes	N/A
Miners	No	Yes, medical background	N/A

<sup>a</sup>N/A: not applicable.

Unlike MedRec and MedAware, MedAlert reduces alert fatigue by capturing the attention of both clinicians and patients. We believe that the way to reduce alert fatigue is to get the clinician's attention, but there is no *perfect* solution in which clinicians are able to pay attention to all alerts [15], not even after the removal of irrelevant alerts. Therefore, MedAlert directs low-level alerts to patients and induces them to pay attention to provide real-time responses. This is a novel initiative moving toward a clinician-patient collaborative decision-making process to avoid potential medication errors resulting from action being overridden. This can improve the quality of the health care domain with respect to better patient outcomes and reducing physician burnout.

MedAlert runs on the private Hyperledger blockchain, which ensures a higher privacy compared with MedRec, which runs on the public Ethereum blockchain. This is because private blockchain is better suited to a highly regulated industry such as health care due to the stricter requirements regarding patient privacy and data protection. To avoid information leakage, both MedAlert and MedRec record only metadata or reference pointers rather than patient's medical data on blockchain. To enhance patients' data privacy, all metadata is encrypted and stored on MedAlert blockchain, where only authenticated patients can view the transactions and authorized clinicians can read and write transactions. This makes MedAlert better

compliant to standards such as GDPR (Art. 32. Security of processing) compared with MedRec.

Apart from ensuring a higher-level privacy environment, MedAlert, deployed in private Hyperledger, has a better performance than MedRec, deployed in Ethereum. The assessments from Pongnumkul et al [66] show that Hyperledger outperforms Ethereum in 3 evaluation metrics: execution time, latency, and throughput. For example, the average latency of Ethereum is about 2 times at a low number of transactions and can increase up to 14 times that of Hyperledger at a high number of transactions. This is important when fast information sharing is needed between a clinician and a patient during collaborative decision making.

MedAlert can improve the flow of communication between clinicians and patients. Clinicians may need to ask for and validate information with patients because without this step, there is a significant risk of error in ordering or prescribing medication [67]. This risk can increase when alerts generated by CDS are simply overridden. MedAlert can reduce this and prevent it from happening by sharing clinical alerts with patients. Patients can receive the alert and be asked to provide information. If they are uncertain, they can enter into direct communication with the clinician and deal with the alert that way.

### Future Work

Validation work such as threat analysis is needed in future work to elucidate the effectiveness and the potential vulnerabilities of using MedAlert before deploying it in the eHealth sector [68]. This would provide a documented performance evaluation of MedAlert to persuade health care leaders of the benefits of this new digital tool and gain sufficient support from them for its deployment. Despite numerous published literature on how blockchain can record immutable transactions and enhance interoperability and thus improve health care, many leaders remain unsure about what blockchain has to do with health care. Proof of validation is an important step in scaling up this framework and making it applicable to the real world [69].

Second, sorting and tiering alerts based on severity, for example, sorting into 3 tiers: low, mid, and high, are needed as a part of future work to validate MedAlert. This is to determine which low-level alerts are suitable for patients because clinicians tend to accept high-severity alerts slightly more often than mid- or low-severity interaction alerts [11]. However, the process of tiering alerts is highly subjective when it comes to deciding which alerts are considered low level and time consuming for all medical experts before reaching a common consensus. Thus, this initial step in selecting which alerts are to be shared with patients can be challenging.

Decentralized identity management is an alternative way of verifying and authenticating users. It eliminates the limitations of centralized identity systems, helps achieve compliance with the most comprehensive national data protection laws, and returns ownership and control of identity data back to the individual. Various decentralized identity management systems exist that provide solutions using a distributed ledger technology. Evernym [70], uPort [71], and Sovrin [70] are some examples

of identity projects that are working on decentralized identity platforms. However, these sophisticated solutions are still at a provisional stage, where more validation, discussion, and investigation are needed [60].

### Limitations

MedAlert is suitable for a specific group of users. Collaborative decision making may be challenging for patients who are less technology savvy, particularly for elderly patients, who may not be able to use MedAlert effectively. For example, the steps where patients need to verify and authenticate themselves and thus gain access to alerts could be confusing for the elderly and may induce unnecessary stress on them. MedAlert is not suitable for in-patients either where they require constant monitoring. This is because they may not be able to provide a response when they are unwell in the hospital.

Directing low-level alerts to patients may create ethical issues where the responsibility is indirectly shifted on to them in cases when they provide incorrect responses. In a study conducted in medical centers in the Netherlands where alerts were directed to nurses, despite improvements in efficiency and effectiveness, the study concluded that such alerts should not be directed to nurses [40]. It is difficult to find the right balance of responsibilities between clinicians, nurses, and patients in a collaborative decision-making process.

Privacy concerns are covered by the GDPR. Storing digital assets, such as medical records on blockchain, could violate personal privacy. Although MedAlert only stores patients' metadata on blockchain, it is not entirely anonymous. Malicious acts include attempting to learn about and identify actual personal patients based on the pseudo-anonymous information on blockchain. In addition, the permanent storage of information, both data and metadata, belonging to a person could violate GDPR (Art. 17 Right to erasure or to be forgotten) in cases when users want to have their data completely erased or deleted.

### Conclusions

CDS supports the decision-making process in preventing medication errors by generating alerts. Clinicians can now rely on these alerts along with their knowledge and past experience to avoid medication errors. Due to the low specificity and highly restricted modifications of the CDS setting, a high volume of irrelevant alerts has caused clinicians to experience alert fatigue. This results in a high overriding rate, which can cause medication errors.

From our scoping review, we found different methods of reducing the number of alerts, such as machine learning algorithms and blockchain technology, by filtering out irrelevant alerts. We developed a different solution that is similar to what medical experts pointed out, where improving alert fatigue should go beyond just reducing the total number of alerts.

In line with this idea, we designed MedAlert, a blockchain-based solution, by sharing low-level alerts with patients where clinicians typically have a greater tendency to override low-level alerts. The goal is to ensure that alerts catch the attention of both patients and clinicians, thus preventing medication errors, instead of being habitually overridden. In our own work, we

introduced a second layer by engaging patients in providing a response and making them, at least, partially responsible for alert verification. This second layer reduces alert fatigue of clinicians and, at the same time, engages patients in the collaborative process, making it harder for medication errors to occur.

Other potential advantages of MedAlert over other frameworks include ensuring a greater degree of patient privacy and the ability to establish a new communication layer between patients and clinicians. Smart contracts and the use of BankID (federated identity management) are useful in authenticating patients and ensuring that the right person receives the alert.

Directing alerts to patients faces challenges such as finding a balance between patients and clinicians without raising ethical issues. This solution may not be suitable for elderly patients or in-patients where they require constant monitoring. Sorting and tiering the alerts based on levels of severity is also challenging because it is subjective and may vary between different panels of medical experts.

For the health care sector to benefit from the potential value of this innovative idea, future work, for example, on the validation of MedAlert based on real-world scenarios, such as the degree of compliance with GDPR, is needed. Providing documented evaluations of the performance of MedAlert is crucial to gain the support of health care leaders in nurturing this idea as a potential solution to reducing alert fatigue.

## Abstract

**Background:** Facial nerve palsy leaves people unable to move muscles on the affected side of their face. Challenges exist in patients accessing facial neuromuscular retraining (NMR), a therapy used to strengthen muscle and improve nerve function. Access to therapy could potentially be improved through the use of digital technology. However, there is limited research available on patients' and clinicians' views about the potential benefits of such telerehabilitation based on their lived experiences of treatment pathways.

**Objective:** This study aims to gather information about facial palsy treatment pathways in the United Kingdom, barriers to accessing NMR, factors influencing patient adherence, measures used to monitor recovery, and the potential value of emerging wearable digital technology.

**Methods:** Separate surveys of patients with facial palsy and facial therapy specialists were conducted. Questionnaires explored treatment pathways and views on telerehabilitation, were co-designed with users, and followed a similar format to enable cross-referencing of responses. A follow-up survey of national specialists investigated methods used to monitor recovery in greater detail. Analysis of quantitative data was conducted allowing for data distribution. Open-text responses were analyzed using thematic content analysis.

**Results:** A total of 216 patients with facial palsy and 25 specialist therapists completed the national surveys. Significant variations were observed in individual treatment pathways. Patients reported an average of 3.27 (SD 1.60) different treatments provided by various specialists, but multidisciplinary team reviews were rare. For patients diagnosed most recently, there was evidence of more rapid initial prescribing of corticosteroids (prednisolone) and earlier referral for NMR therapy. Barriers to NMR referral included difficulties accessing funding, shortage of specialist therapists, and limited awareness of NMR among general practitioners. Patients traveled long distances to reach an NMR specialist center; 9% (8/93) of adults reported traveling  $\geq 15$  miles. The thematic content analysis demonstrates positive attitudes to the introduction of digital technology, with similar incentives and barriers identified by both patients and clinicians. The follow-up survey of 28 specialists uncovered variations in the measures currently used to monitor recovery and no agreed definitions of a clinically significant change for any of these. The main barriers to NMR adherence identified by patients and therapists could all be addressed by using suitable real-time digital technology.

**Conclusions:** The study findings provide valuable information on facial palsy treatment pathways and views on the future introduction of digital technology. Possible ways in which emerging sensor-based digital technology can improve rehabilitation and provide more rigorous evidence on effectiveness are described. It is suggested that one legacy of the COVID-19 pandemic will be lower organizational barriers to this introduction of digital technology to assist NMR delivery, especially if cost-effectiveness can be demonstrated.

## Introduction

### Facial Palsy

Bell palsy is an acute unilateral paralysis of the facial nerve, resulting in a patient partially, or completely, losing the ability to voluntarily move facial muscles on the affected side of the face [1]. It is the most common acute disorder affecting a single nerve, and its cause is unknown [2]. Each year, the condition affects 11 to 40 people per 100,000 in the population, most commonly in the age group of 30 to 45 years [3]. The annual incidence of Bell palsy in the United Kingdom is currently 37.7 per 100,000 population [4]. Bell palsy represents only approximately 60% of all facial nerve paralysis (FNP) cases [5]. The total number of FNP cases occurring annually in the United Kingdom is estimated to be at least 22,500, and 1 in 60 individuals will be affected over the course of their lifetime [6,7].

Epidemiological studies indicate that this neurological condition occurs more commonly in those with diabetes, obesity, hypertension, and upper respiratory conditions and people who are immunocompromised or pregnant [2,6,8] or following infection by a virus such as herpes simplex [9]. Data from the United States show a recent rise in incidence, possibly linked to increasing rates of herpes infections [10]. Without intervention, some patients will show an element of recovery within 2 to 3 weeks and complete recovery within 3 to 4 months [2,3]. However, although normal facial function is completely restored in approximately 70% of cases, 30% will have a poor recovery [11,12] with facial disfigurement and sometimes facial pain [3,13], and up to 16% of those affected will have residual involuntary movements known as synkinesis [3]. Research shows that people with these residual deficits experience a long-term reduction in quality of life, psychological distress, depression, and social alienation, often relinquishing a previous public-facing role [3,13-16]. As a result, patients with FNP continue to have relatively low public visibility, unless a high-profile international star reveals their own diagnosis [17].

### Available Treatments

Although various treatments are available, uncertainty exists regarding the effectiveness of many of these. Cochrane systematic reviews have confirmed the effectiveness and cost-effectiveness of corticosteroids (prednisolone) administered within 72 hours of onset of symptoms [18-20]. Beyond this initial treatment, for those with incomplete recovery, there are a number of medical options available. Various surgical

procedures, together with botulinum toxin injections can attempt to normalize facial appearance [21-25]. However, a Cochrane review of surgical interventions has reported that there is insufficient evidence to decide whether such procedures are beneficial and has also concluded that further trials are unlikely [26].

Physical rehabilitation therapy can be used as an adjunct to medical treatments. The use of facial neuromuscular retraining (NMR) to strengthen muscle and improve nerve function has been evaluated more than other physical therapies [27-32]. A 2011 Cochrane review has concluded that there is some evidence that NMR can improve facial function (for moderate nerve paralysis and chronic cases) and reduce sequelae in acute cases, although it was recommended that both need to be confirmed in randomized controlled trials [33]. An update of this systematic review is currently underway [34]. A recent review of physical therapy combined with standard drug treatment (SDT) has reported evidence of positive effects on grade and time to recovery compared with SDT alone [35].

### Practice Guidelines and Patient Involvement

In the context of an incomplete evidence base, current international guidelines highlight the need to consider patients' experiences and preferences [2,36]. Recent clinical practice guidelines from the United States, which conclude that physical therapy can provide potential functional and psychological benefit, add that there is a "large role for shared decision making" [2]. Although Canadian guidelines make no recommendation regarding the use of facial NMR in the acute phase, owing to a lack of good quality trials and risk of bias, its use is suggested for patients who do not have complete facial recovery [36]. In the United Kingdom, clinical guidelines produced by the National Institute for Health and Care Excellence (NICE) recommend rapid initial medication (prednisolone) and referral to a range of hospital-based medical specialists [37]. Guidelines for commissioning neurology services in the United Kingdom also include a recommendation to consider new *transformational technologies* [38].

### Objectives

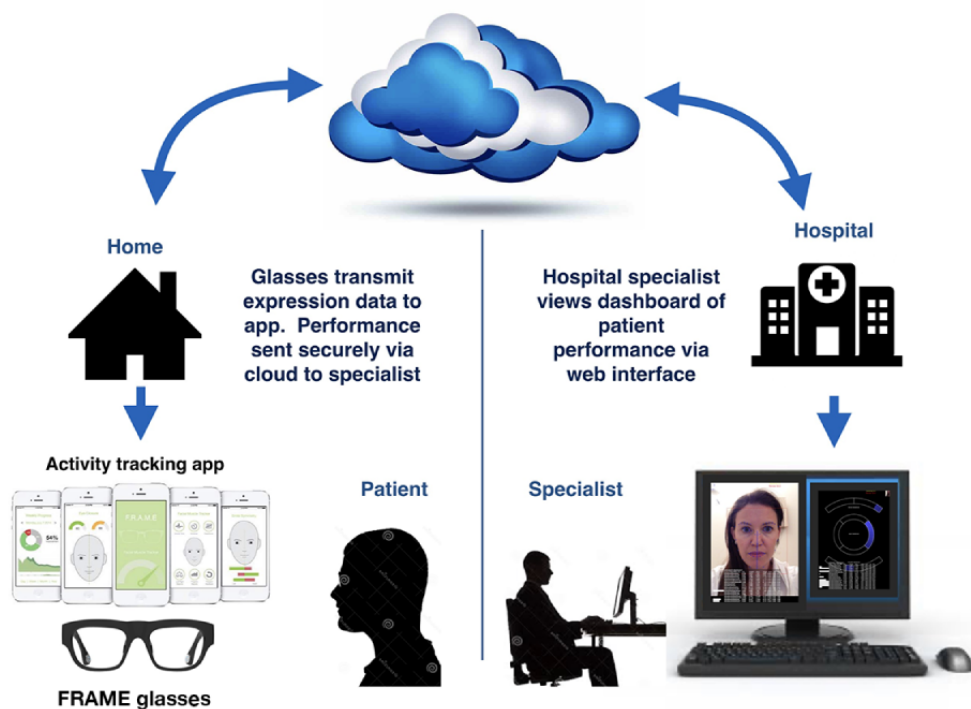

The potential for the "digital patient" to transform the delivery of care has been demonstrated in many clinical areas [39], but there is a lack of evidence for FNP. The aim of this study, conducted in collaboration with patients and specialist clinicians, is to gather evidence about FNP treatment pathways in the United Kingdom, the referral process and timing of NMR, current outcomes used to monitor recovery, and the potential

role of digital technology to assist in rehabilitation. The study was conducted as part of a research program (Facial Remote Activity Monitoring Eyewear [FRAME]) funded by the UK National Institute for Health Research (NIHR). The FRAME program aims to develop inconspicuous miniaturized sensor

devices in spectacle frames to measure facial movement, providing biofeedback to patients and access for clinicians to outcome data, and to conduct early health technology assessment of the wearable FRAME digital technology shown in Figure 1 [40].

**Figure 1.** Facial Remote Activity Monitoring Eyewear (FRAME) system overview.

## Methods

### National Surveys

To provide context for technology introduction, national surveys were conducted to explore patients' and specialist therapists' experiences of FNP care pathways in the United Kingdom and the potential role of digital technology. Separate questionnaires were co-designed for patients and therapists, piloted, and refined following feedback. Each questionnaire included a mix of closed and open-ended questions (Multimedia Appendix 1) and followed a similar format to enable cross-referencing of some responses [41]. Questionnaires collected demographic details, information on treatment pathways, and ratings of the importance of treatments personally experienced. Respondents were encouraged to add textual comments to expand on responses to closed questions. Further open-ended questions explored the potential value of the emerging FRAME technology. Both questionnaires were uploaded on a web-based platform.

### Recruitment to National Surveys

For patients, an open recruitment strategy was adopted to achieve geographical spread. People with experience of FNP were recruited in collaboration with the national charity, Facial Palsy UK [42]; the patient survey was advertised widely, including via social media. Recruitment of specialist therapists was coordinated through a nation-wide professional group,

Facial Therapy Specialists UK [43]; all members were emailed a personal invitation containing a link to the questionnaire, and the initial email was followed by 2 reminders over a period of 5 months.

### Follow-Up Survey

A preliminary analysis of responses uncovered a range of methods used to report treatment outcomes. Therefore, a further survey was conducted to examine these in greater detail, especially any use of validated scales, and whether there is consensus on the definition of a clinically significant change for these measures. A convenience sample of 50 clinicians attending the Facial Therapy Specialists Annual Meeting held in London (October 1, 2018) were invited to complete this questionnaire.

### Analysis of Responses

The closed questions were analyzed using SPSS (version 25, IBM Corporation). Response patterns were summarized using mean and SD or median and IQR, depending on data distribution. Certain variables were grouped to explore changes over time (eg, time since diagnosis). Open-text comments expanding on responses to closed questions and text replying to open questions were analyzed using thematic content analysis [44]. Inductive coding was used, following a flexible analysis approach that helped account for any further themes emerging during the coding process [45]. Data were coded and analyzed

for thematic patterns and meanings within the data until saturation was reached.

### Ethics

Ethical approval was granted by the Health and Life Sciences Research Ethics Committee, University of Coventry (ref: P48908).

## Results

### Respondent Rate and Participants

#### *National Surveys*

The response rate (RR) for patients was calculated based on the number of people accessing the invitation link (after viewing an advertisement) versus the number of patients completing the questionnaire (216/216, 100% RR). Patients were resident in England (all 9 English regions), Scotland, Ireland, and Wales.

The RR for clinicians was based on the number of UK therapists contacted who completed the questionnaire (25/49, 51% RR); 5 responses from therapists not currently practicing in the United Kingdom were excluded.

Analysis of patient responses identified that 77.3% (167/216) of patients had acquired FNP as adults, 12.0% (26/216) acquired it at birth or during childhood, 7.9% (17/216) were carers of a child with the condition, and 2.8% (6/216) had another personal or professional connection. Patients with adult-acquired FNP had a mean of 6.96 (SD 7.00) years of experience since first being diagnosed. [Table 1](#) shows that the most common cause of their condition reported by patients was Bell palsy. Specialist therapists were mainly physiotherapists by training (22/25, 88%), with the remainder being speech and language therapists. Clinicians had a mean of 9.72 (SD 7.68) years of experience in treating FNP cases.

**Table 1.** Patients in the United Kingdom with adult-acquired facial nerve paralysis: reported diagnosis and treatment pathways (n=167).

Patient question	Response	Values, n (%)
<b>Cause of condition (164 responses)</b>		
	Bell Palsy	89 (54.3)
	Acoustic neuroma or vestibular schwannoma	27 (16.5)
	Ramsay Hunt syndrome	23 (14.0)
	Salivary gland or parotid tumor	4 (2.4)
	Facial nerve neuroma	3 (1.7)
	Birth trauma	1 (0.6)
	Lyme disease	1 (0.6)
	Stroke	1 (0.6)
	Other <sup>a</sup>	8 (4.9)
	Do not know	7 (4.3)
<b>Treatments provided to date (166 responses)</b>		
	Advice on eye care	111 (66.9)
	Prednisolone or other corticosteroids	100 (60.2)
	Antivirals	43 (25.9)
	Antibiotics	26 (15.7)
	Botox injections	71 (42.8)
	Facial neuromuscular retraining	101 (60.8)
	Electrical stimulation therapy	35 (21.1)
	Plastic surgery <sup>b</sup>	33 (19.9)
	Psychological therapy (eg, cognitive behavioral therapy)	16 (9.6)
	Other <sup>c</sup>	12 (7.2)
	No treatment <sup>d</sup>	6 (3.6)
<b>Stage at which first treatment started (164 responses)</b>		
	Within 72 hours following symptoms	109 (66.4)
	Within 1 month of onset	18 (11.0)
	1-6 months postonset	9 (5.5)
	6-9 months postonset	6 (3.7)
	>9 months postonset	11 (6.7)
	Do not know or other	11 (6.7)

<sup>a</sup>Other causes include the virus of the brain stem, postoperative complications, otitis media, skull fracture, side effect of radiotherapy, and accidental injury.

<sup>b</sup>Plastic surgery includes face lift, brow lift, eyelid surgery, and facial sling.

<sup>c</sup>Other treatments provided include acupuncture, self-funded chiropractic, and massage.

<sup>d</sup>No treatment group includes 2 patients diagnosed with acoustic neuroma or vestibular schwannoma and 4 with Bell palsy (1 assigned to the trial control group).

### Follow-Up Survey

The follow-up questionnaire was completed by 28 of 50 clinicians (RR 56%); 75% (21/28) were facial therapists, 11% (3/28) were hospital doctors, 8% (2/28) were neurological physiotherapists, and 4% (1/28) were clinical psychologists.

### Treatment Pathways

An analysis of treatment pathways was conducted for patients with adult-acquired FNP. Respondents reported receiving an average of 3.27 (SD 1.60) different treatments following initial diagnosis, most commonly corticosteroids, advice on eye care, and facial NMR, as shown in [Table 1](#).

### Diagnosis and Initial Treatment

Overall, 66.4% (109/164) of adult-acquired cases who reported the timing of their first treatment said this was within 72 hours of symptom onset (Table 1); for those most recently diagnosed ( $\leq 1$  year ago), this figure was 91% (31/34) versus 47% (32/68) for patients diagnosed 5 to 18 years ago. The average time to first review of their case was 64 (SD 26.8) days; for those diagnosed  $\leq 1$  year ago, this figure was an average of 6 (SD 28.8) days. Fewer than 9.6% (16/166) of patients had been referred for psychological therapy.

### Referral for NMR

Of 167 respondents with adult-acquired FNP, 98 (58.6%) had been referred for facial NMR, and these patients were treated

in 35 different centers. Table 2 shows that nearly half (44/98, 45%) were referred for NMR by a hospital consultant following other treatments; only 28% (27/98) were referred by their general practitioner (GP), and a further 14% (14/98) indicated that they initiated the referral themselves (usually via their GP) following information provided by friends, family, or patient support groups or based on their own research. Therapists reported that their specialist center received a mean of 73.2 (SD 75.5) new facial NMR referrals in an average year, with a large variation between centers (median 30, IQR 123). Table 3 indicates that the mean percentage of referrals from a GP is 37% (SD 32%), with hospital consultants accounting for between 11% (11/98) and 18% (18/98), depending on the specialty.

**Table 2.** Patients with adult-acquired facial nerve paralysis referred for facial neuromuscular retraining (n=98).

Patient question	Response	Values, n (%)
<b>Referral route to therapy (98 responses)</b>		
	General practitioner	27 (27.6)
	Self-initiated (usually via a general practitioner)	14 (14.3)
	Plastic surgeon	18 (18.4)
	Ear, nose, and throat specialist	15 (15.3)
	Neurologist	11 (11.2)
	Other <sup>a</sup>	11 (11.2)
	Do not know	2 (2.0)
<b>Any problems with referral (97 responses)</b>		
	Yes	22 (22.7)
	No	69 (71.1)
	Do not know	6 (6.2)
<b>Feedback provided during therapy<sup>b</sup> (96 responses)</b>		
	Yes	70 (72.9)
	No	11 (11.5)
	Do not know	15 (15.6)

<sup>a</sup>Referral routes—Other includes solicitor, speech and language therapist, and Botox consultant.

<sup>b</sup>Feedback tended to be given verbally, with the addition of photographic evidence, sharing of electromyography results, scores from the Sunnybrook Scale, or via percent recovered score.

**Table 3.** Current referral and treatment pathways reported by facial therapy specialists in the United Kingdom.

Referrals	Values
<b>Source of referral (24 responses) , mean percentage (SD)</b>	
General practitioner	37 (32)
Plastic surgeon	18 (25)
Ear, nose, and throat specialist	14 (15)
Neurologist	10 (11)
Eye specialist	7 (18)

<b>Treatments pathway, n (%)</b>	
<b>Wait for first appointment following referral (weeks; 25 responses)</b>	
<1	4 (16)
1-2	3 (12)
3-4	8 (32)
5-6	4 (16)
8-12	5 (20)
<b>Treatments patients receive before referral (25 responses)</b>	
Advice on eye care	14 (56)
Facial neuromuscular retraining	6 (24)
Prednisolone or other corticosteroids	20 (80)
Botox injections	12 (48)
Plastic surgery	11 (44)
Psychological therapy (eg, cognitive behavioral therapy)	4 (16)
Other <sup>b</sup>	6 (24)
<b>Follow-on referral to other specialists (25 responses)</b>	
Ophthalmology	18 (72)
Botox injections	19 (76)
Psychological therapy	16 (64)
Surgery (dynamic facial reanimation)	13 (52)
Other <sup>c</sup>	7 (28)
<b>Feedback provided to referring clinician (25 responses)</b>	
Feedback on progress and final outcome	13 (52)
Feedback on final outcome only	10 (40)
No feedback provided	2 (8)

<sup>a</sup>Other sources of referral: community pediatricians, neurosurgical or maxillofacial consultants, physiotherapists, speech and language therapists.

<sup>b</sup>Other prior treatments: blood tests, magnetic resonance imaging, electromyography, referral to peer support group, education, soft tissue mobilization, facial massage, and taping.

<sup>c</sup>Other follow-up referrals: radiology; nerve conduction studies; maxillofacial; ear, nose, and throat; speech and language therapy; restorative dentistry; vestibular physiotherapy; and audiology.

Figure 2 shows that the referral for NMR occurs at different points following the onset of symptoms. Overall, 15% (15/98) of adult cases were referred within 1 month; 38% (8/21) of people diagnosed most recently ( $\leq 1$  year ago), compared with 0% for those diagnosed  $>18$  years ago. Once referred, patients reported that they had to wait an average of 7.14 weeks (range 0.5-23 weeks) for a first appointment. Table 3 shows that

therapy centers currently record a mean wait time of 4.67 (SD 3.35) weeks. One in 4 adult patients (22/97, 23%) described experiencing difficulties with their referral, most commonly owing to problems accessing National Health Service (NHS) funding, a shortage of specialist therapists, or difficulties in persuading their GP to refer. Overall, 80% (20/25) of centers were aware that some patients experienced difficulties; the 2

main causes identified were limited awareness of facial NMR among GPs and a shortage of NHS funding.

**Figure 2.** Timing of referral for tailored facial exercise therapy following onset of symptoms.

### Other Treatments

Therapists reported that before referral for NMR, their patients usually received a number of other treatments, as detailed in Table 3, most commonly corticosteroids, advice on eye care, Botox injections, and plastic surgery. In addition, 24% (6/25) of centers reported receiving referrals following failed NMR, presumably provided by a nonspecialist. On completion of facial NMR, 64% (16/25) of centers regularly refer some patients for psychological therapy, 72% (18/25) to ophthalmology, and 52% (13/25) to surgery (dynamic facial reanimation). Although several specialties are involved in the treatment pathway, only 52% (13/25) of therapists had participated in a multidisciplinary team (MDT) review. Similarly, only 23.0% (38/165) of adult patients were aware of such a review of their case, and a further 24.8% (41/165) were uncertain.

### Views on Treatment

When asked to rate the importance of various treatments, based on their own experience, both patients and therapists rated the same 6 most highly, although median scores indicated little discrimination among them. Patients' scores produced the following ranking: 1st—advice on eye care, 2nd—facial NMR, 3rd—psychological therapy, 4th—corticosteroids, 5th—Botox injections, and 6th—plastic surgery. Therapists identified a similar order, although they ranked psychological therapy lower as 4th and surgery higher as 5th. All other treatments were rated as important by fewer than 4% of respondents.

### Adherence to NMR

Adult patients reported varying levels of adherence to their prescribed NMR program, with only 33% (32/97) recording very high levels, 41% (40/97) reporting medium-to-high adherence, 21% (20/97) recording poor-to-medium levels, and 5% (5/97) being uncertain about adherence. An analysis of patients' open-text comments identified 3 main barriers, regardless of the level achieved: "difficulties in fitting facial exercises into daily life," "using a mirror while completing exercises," and "insufficient regular follow-up." Patients who reported a very high level of adherence described 3 further facilitating factors: "observing improved outcomes in self,"

"belief that the treatment will work," and "observing positive outcomes in others." These patients also highlighted a common fear that acted as a spur: "scared of not recovering." An analysis of comments made by the medium-to-high adherence patient group uncovered 2 additional demotivating factors: an "inability to see any improvement" and "lack of funds to travel for check-ups." In terms of travel, distances can be considerable. Although most adult patients (75/97, 81%) were referred to a center within their own region, 9% (8/93) reported traveling  $\geq 115$  miles to reach a specialist center. Among patients with poor-to-medium adherence, 2 further barriers were identifiable: "pain associated with facial exercises" and "exercises can be tiring", possibly indicative of poor execution of a prescribed facial exercise regime.

When asked to describe their patients' level of compliance, 36% (9/25) reported very high levels, 56% (14/25) reported medium-to-high adherence, 4% (1/25) recorded poor-to-medium levels, and 4% (1/25) were uncertain about adherence. Interestingly, therapists appear to have underestimated the level of poor-to-medium adherence, perhaps suggesting overoptimistic feedback by patients. The thematic content analysis shows that therapists identify the same 3 barriers limiting adherence (ie, "fitting exercises into daily life," "lack of evidence of improvement," and "use of a mirror"). Unlike patients, therapists did not identify patients' travel costs. However, they did additionally think that the timing of other treatments influences adherence, for example, "poorer adherence post-surgery because this may be viewed as the primary treatment for managing their condition" and "Botox given too early may reduce compliance if patients rely on this to relieve feelings of tightness and synkinesis."

### Feedback on Recovery

Table 2 shows that 73% (70/96) of patients received regular feedback on their recovery during the course of treatment. This is provided in a number of ways with no consistent pattern nationally. Table 3 indicates that the regularity of feedback to referring physicians varies; 52% (12/25) of therapists provide feedback throughout treatment, but 40% (10/25) only report a final outcome. Final discharge summaries also vary, some

include validated measures such as the Sunnybrook Scale and others provide photographs showing the patient's progress.

In response to the follow-up survey, clinicians reported the experience of using various methods for recording treatment outcomes ranging from photographic evidence to recognized disease-specific scales. When asked to name scales they had used, 17 different instruments were identified (Table 4). The

most frequently cited was the Sunnybrook Scale (26/28, 93% of respondents) [46], followed by the Facial Disability Index (FDI) identified by 54% (15/28) of respondents [29], and the House-Brackmann (HB) Scale identified by 50% (14/28) of clinicians [47]. Relatively few respondents were able to define a clinically significant change for these measures: 27% (7/26) for Sunnybrook, 7% (1/15) for FDI, and 21% (3/14) for HB. Where answers were provided, there was no consensus.

**Table 4.** Follow-up survey: outcome measures and minimum clinically significant change (n=28).

Outcome measure	Experience of use, n (%)	Minimum clinically significant change
Sunnybrook Scale	26 (93)	<ul style="list-style-type: none"> <li>Change by 10 points (4 respondents)</li> <li>Change by <math>\geq 5</math> points (1 respondent)</li> <li>5:1 change (2 respondents)</li> <li>No comment (19 respondents)</li> </ul>
Facial Disability Index	15 (54)	<ul style="list-style-type: none"> <li>Change by <math>\geq 5</math> points (1 respondent)</li> <li>No comment (14 respondents)</li> </ul>
House-Brackmann Scale	14 (50)	<ul style="list-style-type: none"> <li>Change by 1 grade (2 respondents)</li> <li>Grade 3 eye closure or above (1 respondent)</li> <li>Not sensitive enough for therapy outcomes (2 respondents)</li> <li>No comment (9 respondents)</li> </ul>

<sup>g</sup>Angle between the cheilion, contralateral cheilion, and ipsilateral endocanthion.

## Digital Technology

A thematic analysis of open-text comments on the potential value of digital technology identified 4 superordinate themes, as shown in Textbox 1. The first theme, *System*, was

predominantly voiced by specialist therapists who highlighted the potential for this technology to help reduce pressure on their time, improve their ability to monitor a patient's progress, increase coverage, and reduce travel for outpatient reviews. An extra subtheme, expressed by patients within the *System* theme,

was that new technology could help raise medical awareness, especially in primary care. A second theme, *Self-management*, was identified by both groups. This focused on improving treatment adherence and emphasized factors such as enabling people to fit facial exercises into their daily routines and providing motivational feedback through regular review of daily performance.

The third theme, *Identity*, emerged mainly from patients' responses. This highlighted psychological benefits such as improved confidence in people who are frightened to draw attention to themselves and hope in individuals that their

condition might improve. The final theme, *Innovation*, encompassed views, such as, that innovation is natural and that it can bring positive societal benefits, together with an awareness that funding constraints limit implementation of innovations. Patients demonstrated a great willingness to support future introduction of digital technology, but they also emphasized the need to raise awareness among GPs alongside implementation. Therapists expressed a similarly positive view of telerehabilitation, with a clear consensus that digital technology could not replace the initial face-to-face consultation because patients need to be carefully trained to be able to complete their exercises properly.

**Textbox 1.** Themes and subthemes: representative quotes from questionnaires.

## System:

- Therapist time
  - “It is a good adjunct to one-to-one therapy for most patients.” (Therapist)
  - “I think that for our patient group and geography, Telerehab would work well... we have no dedicated time for facial therapy. It’s included as an acute treatment” (Therapist)
- Monitoring
  - “To be able to monitor a patient's progress remotely will be of great value. It also has the potential to generate and collate a lot of objective data on facial function which will be invaluable in efficient data collection for future research.” (Therapist)
  - “Any technology in the form of an app and use of EMG biofeedback would be massively useful. This would offer real time feedback about how facial muscles are performing and how successful they are in performing their exercises.” (Therapist)
- Access
  - “Our community colleagues I think would benefit greatly and more the patients as many travel from long distances to see the team here as rare specialism.” (Therapist)
  - “I am always interested in new advances in medicine. I think if it can provide cover for patients in areas where there is no specialism [in facial neuromuscular], then it will be invaluable.” (Therapist)
  - “These are essential for the future of intervention with this patient group especially as there are few specialists and patients are currently having to travel long distances.” (Therapist)
- Medical awareness
  - “It [technology] needs to be embraced, further developed and used to educate the medical profession about the condition, its treatments, causes and correct treatment regime.” (Patient)
  - “New technology can be useful, but primary diagnosis is important - this [facial palsy] needs more awareness.” (Patient)

## Self-management:

- Exercise performance
  - “It would benefit some patients and encourage those patients who find it hard to fit exercises into their daily routine.” (Therapist)
  - “Using the 'Fitbit' technology whereby users are given rewards for exercising, can check on their daily performance and review weekly summaries of how well they have done. Pop up reminders to do exercises may also [be] very useful.” (Therapist)
- Motivation
  - “May be very useful to provide motivational feedback.” (Therapist)
  - “Technology could give users rewards for exercising, check on their daily performance and review weekly summaries of how well they have done.” (Therapist)

## Identity:

- Confidence
  - “Anything that can help the physical issues as well as facial symmetry/making someone feel better about themselves/more confident is so important.” (Patient)
  - “If facial palsy patients can be helped by the use of new technologies; they should be. They are hardly likely to fight for treatment as we are traumatised, embarrassed and scared about bringing attention to themselves.” (Patient)
- Hope
  - “Personally, I would try whatever technology was available!” (Patient)
  - “I am open to trying absolutely anything that could help my symptoms.” (Patient)
  - “I would try any new technology in the hope my palsy is improved. Living with it can make you have low self-esteem.” (Patient)

## Innovation:

- Natural
  - “I think it’s great, it’s good to know there is always research into new ways to aid recovery.” (Patient)

- “I think novel ways of assessing and treating patients using technology must be embraced.” (Therapist)
- “I am all for new technology if it proves helpful to the patient.” (Patient)
- Societal benefit
  - “This is exactly what we need! We need to move forward with the times. I feel many new treatment may be expensive initially but if it can change a person life then it is worth it.” (Patient)
  - “In the long term it may work out cheaper ... [the patient] may have their confidence back and be able to work and contribute back to society.” (Patient)
- Funding
  - “This is a very interesting area however costing and funding within NHS would be a concern for clinical use.” (Therapist)
  - “I would like to see it made available on the NHS.” (Patient)
  - “Financial pressures on health services, the relative rarity of facial therapists, the increasing familiarity / dependence of many people with / on evolving technologies all make it an important part of facial palsy interventions.” (Therapist)

## Discussion

### Principal Findings

This exploration of the experiences of patients with facial palsy and their clinicians provides new information on UK treatment pathways, access to facial neuromuscular retraining, the methods in use to monitor recovery, and patients' and clinicians' views on the introduction of an emerging digital technology to support facial NMR. The findings highlight the need to understand patients' and clinicians' experiences before introducing such a technology. As funding barriers currently limit access to routine NMR, evidence of cost-effectiveness may be needed before implementation.

### Treatment Pathways

Although variations were observed in the treatment pathways experienced by patients, there are signs that more recent cases (diagnosed  $\leq 1$  year ago) received treatment sooner than cases diagnosed  $>5$  years ago. For the only medical treatment supported by Cochrane systematic reviews (rapid initial prednisolone treatment [19]), we observed high adherence by GPs, especially for patients diagnosed most recently (91%, 31/34 treated). For facial NMR therapy (partially supported by Cochrane review evidence [33]), this study found a move toward earlier NMR referrals in more recent cases. Even so, 1 in 4 patients experienced difficulties with their referral, commonly citing poor GP awareness. The fact that guidelines currently contain no firm guidance on referrals for NMR may offer some explanation [37].

In the United Kingdom, NICE advises that uncomplicated FNP cases can be managed by primary care to include referral to various hospital medical specialists and therapists [37]. This is challenging because an average GP will only see one patient every 2 years [48]. An earlier UK study identified an overall reduction in GP referral rates of patients with FNP to hospital medical specialists over the period 2001 to 2012 [4]. In this study, twice as many referrals to specialist facial therapists were initiated by hospital consultants compared with GP referrals, with patients often prompting the GP referrals. The NICE guidance for GPs does not specifically mention NMR referral,

instead indicating a need for confirmatory trial evidence as suggested by the Cochrane review [33]. An update to this review may help inform future guidance on referrals [34]. Finally, although patients in our study ranked psychological therapy third highest in terms of its importance, fewer than 10% had been referred; this is presumably linked to the fact that NICE guidelines only contain a weak recommendation for GPs to consider referral for counseling [37].

Once referred for NMR, access to an appropriate therapist can be problematic. Several patients reported traveling very long distances to reach a specialist center; the cost of travel for regular checkups was also identified as a barrier to adherence by patients. Specialist centers reported receiving patients previously referred to a nonspecialist therapist, reinforcing the need for increased access to appropriately trained professionals [49]. Patient adherence to prescribed facial exercises will influence treatment effectiveness. Both patients and therapists identified the same barriers: fitting exercises into daily life, the use of a mirror, and the need for regular feedback. The fact that clinicians perceive higher levels of adherence than those reported by patients indicates a need for improved monitoring of adherence. Other research has shown that a collaboration between specialists can reduce the burden of long-term disability for acute onset FNP [50]. In this study, although patients experienced care pathways that involved referral to several medical specialties, such collaboration was limited; just over half (52%) of the therapists had any experience of participating in an MDT review, and only 23% (38/165) of adult patients were aware of such a review of their case. Interestingly, reports are now emerging of efforts to integrate physical therapy with treatment by ophthalmologists, oculoplastic surgeons, and ENT and other specialists [51]. It is also considered that MDTs are likely to play an important role in standardizing outcome measures and implementing relevant data collection [52].

Evidence of effectiveness of FNP treatments currently remains reliant on subjective measures, including reduction in *crocodile tears*, *incomplete recovery of motor function*, and *cosmetically disabling sequelae* [19,33]. This study identified inconsistency in the methods used in the United Kingdom to report treatment outcomes. In addition to photographs, various validated scales

are used. Among these, the Sunnybrook Scale, mentioned by 96% of specialists, is considered to grade patients in a more objective and continuous manner than the HB Scale, which was mentioned by half [53]. However, FDI, mentioned by 54% of clinicians, better represents impairment, disability, and psychosocial status than the 36-item Short Form Survey (SF-36) health status measure, mentioned by 14% [54]. In addition to variation in the scales used to record treatment outcomes, there was no consensus on what represents a clinically significant change in any scale.

Interestingly, very few clinicians (14%) reported the experience of using EuroQol-5D, the health-related quality of life (HRQoL) measure used for NHS reimbursement decisions [55]. Converted into incremental quality-adjusted life years (QALYs), this is used to quantify long-term treatment outcomes [56]. QALYs are particularly relevant as 30% of patients with FNP will continue to live with reduced HRQoL over the rest of their lives [3,13-15]. In addition, because such individuals may give up their original employment [57], this can lead to a significant long-term societal cost burden, especially if the condition was acquired in early life [58]. An international collaboration has recently been established, focusing on pediatric patients with FNP (using a patient-centered approach, similar to this study) with the aim of comparing FNP treatment pathways, standardizing outcome measurement, and developing value-based reimbursement strategies [59].

### Digital Technology

To our knowledge, this is the first UK study to explore the potential use of wearable digital technology to support facial NMR therapy. The findings show that patients and therapists both demonstrate a positive attitude toward the introduction of such technology, with patients recognizing benefits centered on better self-management and improved confidence, therapists identifying better monitoring of patients' progress and reduced work pressures, and both highlighting the potential for improved adherence to facial exercise programs. The main barriers to adherence could all be addressed by an appropriate real time (synchronous) digital solution that addresses patients' and clinicians' feedback. A review of telerehabilitation articles has recently concluded that patients' feedback will help improve future areas of applications, although no FNP telerehabilitation studies were identified [60]. A review of real time, web-based consultation has highlighted a number of general barriers and facilitators [61]. The key barriers and facilitators mirror those found in this study. Asynchronous methods for monitoring FNP treatment outcomes have also recently been evaluated by 2 research teams. Tan et al [62] reported that the assessment of videos using the Sunnybrook and HB scales is as good as a face-to-face assessment, although the lack of real time

interaction was judged to limit the value of this approach. Mothes et al [63] found that automatic Sunnybrook grading of photographs using machine learning can deliver fair agreement compared with the subjective rating of the same photographs. Neither study addressed real time monitoring and biofeedback.

### Limitations

A number of limitations should be borne in mind when considering this research. First, patient respondents may not be representative of the wider population because participants were recruited via a specialist support group. Second, there may be recall inaccuracy when participants are asked to provide information sometime after the event. Third, the therapist RR (51% national survey and 56% follow-up survey) means that data may not fully reflect the national picture. Finally, although the greatest care was taken in the questionnaire design, as with all surveys that record individuals' views, the validity and reliability of the data could not be tested independently.

### Conclusions and Implications for Technology

#### Introduction

To date, little research has explored the potential value of digital technology in assisting facial NMR therapy. This study provides a baseline overview of FNP treatment pathways in the United Kingdom, the factors limiting access to NMR and influencing therapy adherence, the main methods used to record treatment outcome, and the potential role of digital technology. The study indicates that harmonization of outcome measures is required to both strengthen the evidence on treatment effectiveness and to better support MDT management. The main factors limiting NMR adherence could all be addressed through the use of real time digital technology. However, for the type of wearable technology being considered, product design will be an additional factor likely to influence adherence [64], especially in the younger 30- to 45-year age group affected by this condition [3]. However, although the study clearly demonstrates positive attitudes toward the introduction of digital technology, economic barriers may prove to be a challenge. Previous research has identified funding as a barrier for access to surgical treatments for FNP in England [65] and more recently in Wales, Scotland, and Northern Ireland [66]. This study has similarly identified funding barriers to NMR referral. Finally, organizational and cultural factors are acknowledged to act as important barriers to implementation for all digital health innovations [67], often reinforced by policy priorities [68]. One legacy of the COVID-19 pandemic is that health systems worldwide are rapidly adopting digital options in many clinical areas [69]. Thus, barriers to the introduction of digital technology to assist facial NMR therapy may now be lower, especially if cost-effectiveness can be demonstrated.

### Acknowledgments

The authors would like to thank all the patients and clinicians who took the time to complete detailed questionnaires describing their experiences.

This study is funded as part of the FRAME program, an inconspicuous, noninvasive, mobile sensor device for real time control of assistive technologies through facial expression, which is supported by the NIHR (reference number II-LA-0814-20008). The

research funder had no role in study design; in the collection, analysis, and interpretation of data; in the writing of the manuscript; or in the decision to submit the paper for publication.

## Abstract

**Background:** Wearable sensors connected via networked devices have the potential to generate data that may help to automate processes of care, engage patients, and increase health care efficiency. The evidence of effectiveness of such technologies is, however, nascent and little is known about unintended consequences.

**Objective:** Our objective was to explore the opportunities and challenges surrounding the use of data from wearable sensor devices in health care.

**Methods:** We conducted a qualitative, theoretically informed, interview-based study to purposefully sample international experts in health care, technology, business, innovation, and social sciences, drawing on sociotechnical systems theory. We used in-depth interviews to capture perspectives on development, design, and use of data from wearable sensor devices in health care, and employed thematic analysis of interview transcripts with NVivo to facilitate coding.

**Results:** We interviewed 16 experts. Although the use of data from wearable sensor devices in health and care has significant potential in improving patient engagement, there are a number of issues that stakeholders need to negotiate to realize these benefits. These issues include the current gap between data created and meaningful interpretation in health and care contexts, integration of data into health care professional decision making, negotiation of blurring lines between consumer and medical care, and pervasive monitoring of health across previously disconnected contexts.

**Conclusions:** Stakeholders need to actively negotiate existing challenges to realize the integration of data from wearable sensor devices into electronic health records. Viewing wearables as active parts of a connected digital health and care infrastructure, in which various business, personal, professional, and health system interests align, may help to achieve this.

wearable sensor devices; health care; data; qualitative

## Introduction

Many countries now see digital transformation and digitally enabled self-management as a way to tackle key challenges of delivering health and well-being with limited health care resources to an increasingly aging population [1]. The

transformatory potential of wearable devices forms part of a pervasive set of technological innovations characterized as Internet of Things (IoT) technology; these devices are typically mounted on wireless broadband technologies (ie, mediated by smartphones or equivalent devices) and are often linked to social media platforms. IoT refers to interconnected physical objects,

devices, and systems that electronically communicate, receive, process, and transfer digital data with limited direct human input [2-5]. In health care practices, IoT connectivity allows the sharing of data from wearable sensor devices across various contexts, potentially encompassing the user, caregivers, clinicians, and the health record. Wearable sensor devices include tracking devices with capabilities to count steps, measure activity, and check heart rate. Advanced smartwatches have sensing capabilities that include temperature, blood pressure, stress, sleep quality, respiratory rate, physical activity, electrocardiograms, acceleration, and oximetry [6]. These capabilities are also present in wearable sensor devices used in hospitals and clinics, albeit with less investment in the device aesthetics. Technologies are considered “smart” if they monitor, collect, and send data. They differ from mobile devices such as smartphones in that they are wearable and do not require active data input or curation from the user.

The promise of IoT in health care lies in its potential to realize business benefits while providing a valuable, integrated health and social care service and superior experience for citizens and patients [7]. Growing internet connectivity and the increasing availability of smartphones and multiple portable devices facilitate digital information sharing, connected devices, and the possibilities for digital health care [8]. These interrelationships are part of a societal reorientation of new networked organizations that use information and digital data to allow new insights for business, populations, and health care delivery [9]. Here, wearable and sensor devices enable health and care practices through internet connectivity combined with mobile, miniature, pervasive computing [10,11]. It is hoped that emerging technologies will achieve a similar return on investment, productivity, and efficiency savings as seen in the financial and manufacturing industries [12,13]. Existing empirical studies of wearables in health care demonstrate the feasibility of creating technologies [14] and running data analytics [15,16]; small pilot studies have demonstrated the use of wearables in managing specific chronic conditions, including diabetes and high blood pressure, as well as contributing to data analytics [17-20]. There is also some evidence from trials that wearables can promote healthy behavior [21-23]. However, because these technologies have transformative potential, and there is limited adoption experience, their ultimate outcomes and significance cannot reliably be assessed at this moment. Nevertheless, the area is full of potential, with many apps already becoming routinely integrated with everyday life, with 1 in 5 Americans now possessing a smartwatch or fitness tracker [24].

There are a number of challenges associated with the use of wearable and sensor devices. Firstly, they are often conceptualized as consumer goods, which potentially limits their use as health apps. Secondly, they can change health care delivery models and also impact on the collection and dissemination of sensitive personal data. For example, continuous monitoring data collected through IoT technologies has the potential to improve the knowledge base for decision making but stands in contrast to the intermittent nature of clinical consultations. Health care professionals already feel overwhelmed with data, and patients may not wish to be

monitored [25,26]. In addition, studies from the field of dependable computing have shown that systems produce many false-positive alerts, calling the usefulness of these applications into question [27,28]. Such issues may lead to unintended consequences that can, in turn, result in poor patient outcomes and safety risks [29-32]. Health care data are subject to particular concerns and special privacy and confidentiality protections. The use of wearable sensor devices for health care therefore introduces additional layers of complexity surrounding information privacy, data sharing, autonomy, consent, ownership, data access, and data valuation [25].

Industry reports suggest that as a system, IoT, including wearable sensor devices, is an established emerging technology, estimating 5-10 years until it reaches its “plateau of productivity” [33]. The area is, therefore, ripe for scientific investigation. Here, it is crucial to identify emerging risks and challenges in order to anticipate and mitigate them. Therefore, we aimed to explore the opportunities, gaps, and challenges of wearable sensor devices, as one component of an IoT system, in health and care settings.

## Methods

### Overview and Ethical Approval

We conducted a qualitative interview-based study with international experts and stakeholders involved in designing, developing, and implementing wearable sensor devices in health care [34]. This work was theoretically informed drawing on sociotechnical systems theory [35]. Institutional ethical approval was obtained from the University of Edinburgh Usher Research Ethics Group.

### Sampling and Recruitment

We developed a sampling frame by searching the technical, cultural, media, academic, and health care literature to capture the various perspectives and areas of expertise surrounding wearable sensor devices in health care settings. This was used as a basis for recruitment and was supplemented by consulting with local experts at the University of Edinburgh in culture, science and technology, and IoT studies. We used a purposive sampling strategy aiming for maximum variation in order to gain insights into the range of perspectives that need to be taken into account when considering the implementation and adoption of wearable sensor devices in health care settings. In so doing, we sought out experts with experience across a range of health care settings, technological functionalities, and disciplinary backgrounds [36]. This purposive sampling approach was supplemented by snowball sampling using recommendations from the initial purposive sample [37].

Participants were recruited by emails that were sent to publicly available email addresses; each message introduced the project and requested an interview. Interviews were scheduled with respondents who replied and provided informed consent to participate. We sent a total of 79 emails to potential participants. A follow-up email was sent to nonresponders 1 week later, after which we ceased further contact assuming no interest in participation. We stopped recruitment when we reached thematic

saturation (ie, when no new themes emerged in the concurrent analysis) [38].

## Data Collection

We collected data through in-depth, semistructured, one-to-one, qualitative telephone and video interviews from May to July 2019. Identified experts were located in various international settings. Interviews were guided by a topic guide exploring personal and professional backgrounds and experiences of, and involvement with, wearable sensor devices in health and care

settings (see [Textbox 1](#)) [39]. The questions were based on the existing literature in order to understand the current opportunities, gaps, and challenges associated with the use of wearable sensor devices in health and care settings. They were tailored to the specific characteristics of participants and evolved in light of emerging findings. In doing so, we explored visions of technologies; experiences of implementing, using, and researching technologies, including benefits and risks; and features conducive to accelerating the use of wearable sensor devices in health and care settings.

### Textbox 1. Example topic guide.

1. Interviewee's background: current position and role in relation to health information technology.
2. Their vision surrounding the use of wearable sensor devices in health care:
  - What different models of wearable sensor devices in health care exist?
  - Most promising developments to look out for and their benefits
  - Devices and technologies to collect and analyze data
  - Integration with clinical data and interfacing with other technologies.
3. Experiences of technological innovation in health care:
  - Experiences and lessons learned (eg, consent models, data security, motivating users, scale, and data analytics)
  - How does health care differ from other sectors? Anything we can learn?
  - Which factors hinder developments and how might these be addressed?
4. Accelerating innovation in health care:
  - Perceived risks
  - How can this approach be scaled up?
  - What is the role of regulation and government?
5. Anything else?

The interviews were recorded using Zoom conferencing (Zoom Video Communications) or an encrypted digital audio recorder. We read transcripts multiple times annotating with notes to immerse ourselves in the data. We also kept a field journal noting impressions and emerging analytical thoughts.

Following the interviews, the digitally recorded audio files were transferred via a secure virtual private network to a secure site for professional transcription. Interview transcripts, notes, and file names were anonymized.

## Data Analysis

IA, a surgeon and health services researcher, led the data analysis. The analysis drew on sociotechnical systems theory, which assumes reciprocal shaping of technologies and people by their interactions with each other [40]. Through this lens, we viewed the process of integrating wearable sensor devices into health care practices as a sociotechnical practice where technologies shape human behaviors and these, in turn, shape technological design. We analyzed data concurrently with ongoing data collection and stopped collecting new data when no new themes emerged in the analysis.

Completed transcripts and field notes were organized and coded using NVivo 12 (QSR International) [41]. We used a concept-driven thematic approach based on the interview guide

and key concepts in health [42], technology [43,44], unintended consequences in health information technology (HIT) [45], and innovation to analyze the data [46]. In doing so, we adhered to the six key features of an inductive and deductive coding approach, namely (1) developing the codebook with key themes a priori, (2) testing code reliability, (3) summarizing data and identifying key themes, (4) applying coding templates and new codes, (5) connecting codes and identifying themes, and (6) corroborating and legitimating coded themes [47]. We used constant comparison to examine themes, irregularities, and patterns across interviews [48].

## Results

### Overview

We conducted 16 in-depth, semistructured interviews lasting between 30 and 75 minutes with experts in technology, business, health care, and innovation (see [Table 1](#)); 1 interview was conducted in person and 15 interviews were audio recorded. All study participants had at least 5 and up to 20 years' experience in their fields. Contributing participants were located in Europe, the United Kingdom, and the United States.

The analysis generated data around four main themes that demonstrated the significant potential of wearable sensor IoT

in health care, but also highlighted issues around data provenance and quality; transforming health and care relationships; blurring of business, consumer, health, and clinical boundaries; and issues around privacy, confidentiality, and data ownership (see [Textbox 2](#)).

Participants agreed that the application of wearable sensor devices in health and care has significant potential to positively transform health outcomes. Interviewees gave examples of the potential to enhance alerting, increase patient and public involvement, facilitate processing of information, and improve efficiency, while increasing the reliability and reducing the cost of manual data capture. Participants emphasized different issues, according to their professional backgrounds. For example, academics and researchers focused on social implications; technologists and engineers on increased connectivity; and clinicians on patient safety, care processes, and quality of care.

*So a lot of what I'm more focused on is wearables in everyday life, so the way in which they inspire people to adapt particular modes of care and wellness, so the idea that one wears a Fitbit as a motivational tool or a social tool to share their step counts with people as then creating another form of motivation.* [Participant #3, historian, United States]

*By delivering care outside the hospital you save a lot more money. By keeping patients outside the hospital with these devices that can proactively monitor and*

*maybe even prevent certain events. That gives significant cost savings to the industry.* [Participant #12, engineering and business, United States]

Notably, participants expressed little dissonance in conceptualizing wearable sensor devices as a component of an information ecosystem consisting of various technologies and humans. As such, technological functions were seen as vessels that collected and disseminated data that would then travel through the ecosystem and impact human and organizational behavior, as data were interpreted and acted on.

*I realized that the real value in this whole equation is data, and if you can get the data and you can own the data from a wearable device, then we can turn that into meaningful value for someone with an ecosystem, whether that's patients, providers, caregivers, sports teams, someone within the health universe.* [Participant #5, business and innovation, United States]

However, many of these hopes were associated with future developments, interoperability of technologies, improved fidelity to physiology, and enhanced machine learning and predictive capabilities. For the most immediate future, participants highlighted a number of concerns that were perceived to inhibit the potential of wearable sensor devices in health and care settings. These all related to the intersection of social and technological dimensions and will be discussed in turn.

**Table 1.** Study participants' expertise, industries, and work locations.

Participant No.	Expertise	Sector	Location
1	Product developer	Technology	United States
2	Science and technology studies	Academia	United Kingdom

**Textbox 2.** Key themes and subthemes identified in our analysis.

Significant potential of wearable sensor devices in health and care:

1. From data to action: the role of data provenance and data quality:

- Issues of objective measurement of activity and translation into signals for effective evidence-based decision making
- Data provenance and quality as central considerations for effective adoption and diffusion
- Risk of data overload among health care professionals.

2. Transforming relationships through wearable sensor devices and associated data:

- Integration of devices and data with existing workflows of health care professionals
- Wearable sensor devices as potentially perceived mechanisms of surveillance and control
- Disruption of the traditional hierarchy of specialist information processing through health and care professionals
- Impact on the provider and patient relationship.

3. Increasing blurring of business and consumer as well as health and care boundaries:

- Tension between consumer product and use for wider public good
- Asymmetry of interests through financial sustainability of wearable sensor devices
- Need for new business models.

4. Privacy, confidentiality, and data ownership:

- Lack of regulation of data flows between health care, commercial, and private spaces
- Need for development of standards, especially for apps that were not designed primarily for use in health- and care-related settings.

## From Data to Action: The Role of Data Provenance and Data Quality

Participants highlighted that incorporating unannotated data into health and care practices was, at present, problematic, as it decoupled social and technological dimensions and thereby assumed that (1) data presented a robust and consistent measurement of activity, (2) data could be translated into recognizable signals, and (3) data were appropriately situated in context for dependable, effective, and evidence-based decision making. A key issue here was establishing baseline, “normal,” pathologic, and “unusual” not otherwise-specified activity. High hopes were placed on algorithms to support the recognition of unusual signals that could then trigger clinical intervention.

*...using algorithms to interpret what normal activity for a patient is, or what a normal baseline is for that patient preoperatively. And then using algorithms and AI [artificial intelligence] to try and refine that and improve, either predicting that patients are deteriorating at an early stage; or purely for providing individual feedback to say, “actually, you’re progressing well,” or “you’re not progressing as much as we’d expect.”* [Participant #13, surgery, United Kingdom]

Data provenance and quality, therefore, became central considerations for effective use of data generated by wearables in health and care settings. This was particularly true where observed data patterns may not have distinct correlates to disease mechanisms or physiology. This makes it difficult to confidently base clinical decisions or interventions on them. Here, participants made distinctions between clinical, health, and

well-being data. For example, variability in data used for individual empowerment was sufficient and acceptable (eg, increasing a person’s daily step count), while variability in clinical parameters (eg, the measurement of blood glucose levels that may indicate the need to give an insulin injection) was viewed as problematic, as resulting human actions had potentially impactful consequences.

*...now we’ve got abundant data and we train algorithms, particularly if I do things like I drive a deep learning algorithm hard, then I’m going to find some pattern and some interesting stuff emerging about how you...you know, is that actually an artefact of the data? Yes, it’s a real pattern, but is it actually meaningful in any true physiological sense that’s a response of causal reality or only correlative?* [Participant #4, engineering and innovation, United States]

In addition, participants raised concerns that health care staff were already overloaded with data and that the integration of further, potentially irrelevant, data from additional devices could unnecessarily burden already-busy professionals and, therefore, fail to mobilize an important actor in the ecosystem. The interviews broadly reflected a presumption that device data would be actioned in consultation with a clinician and that the devices would serve to augment the clinician’s capability in making decisions, rather than eliminate them from the care process.

*The challenge is that, as yet, data that’s collected from wearables is very difficult to integrate into the health record of a patient. So, a patient turning up at their doctor’s with a whole list of data and tracking*

*information from their wearable isn't necessarily going to find a welcome recipient, in terms of the doctor.* [Participant #8, consulting, United Kingdom]

### Transforming Relationships Through Data Generated by Wearable Sensor Devices

Integration of devices and data with existing workflows of health care professionals was viewed as crucial for wearable sensor devices to become active parts of the ecosystem, as this was seen to facilitate the exchange of information between social and technological dimensions. However, participants shared concerns about the impact of new types of data on care processes and relationships in clinical work practices. Some participants viewed the increasing focus on data as challenging the autonomy of health care professionals in making decisions about how and when to provide care and as a method of surveillance and control. This was particularly apparent in interviews with clinicians.

*One of the biggest issues that we faced was with our nursing staff and their concern over sort of this idea of big brother and "people watching over what I'm doing," and "I'm a nurse, I know how to turn a patient, I really don't need a device to tell me how to do that."* [Participant #16, quality improvement and nursing, United States]

There were also some concerns that the wide availability of data generated by wearable sensor devices to a range of actors, including device companies, family members, and caregivers, may disrupt the traditional hierarchy of specialist information processing through health care professionals. Traditionally, clinicians captured and interpreted information in context at discreet moments in the consultation, and wearable sensor devices may disrupt this information flow.

*There are a lot of people who are contacting clinicians or caregivers and saying, "what's this?" On one hand, it's positive, but on the other hand, the health care system isn't structured for that type of engagement. And so, I think you're seeing a range of engagement from people around these devices.* [Participant #5, business and innovation, United States]

Health care providers raised concerns about becoming increasingly distanced from the patient, as they were getting health- and care-related information from sources other than the patient directly, and without recognized professional interpretation. This distance has implications on responsibility and accountability for information collected and the subsequent decisions and actions taken, or missed.

*For doctors, I think their big concern is, well, is my relationship with my patient now going to be diminished 'cause they have another place that they can go to track their symptoms and get information, so maybe I don't become that first-line person that they want to talk to?* [Participant #9, health care design and innovation, United States]

### Increasing Blurring of Business and Consumer as well as Health and Clinical Boundaries

Wearable sensor devices were seen as a key example of blurring boundaries between business and consumer as well as health and care worlds, and this posed challenges associated with the assumptions underlying the design of the technology and the contexts of use. Technology and business actors saw the promotion of a commercial market for consumer technology health and care applications, aligning this unproblematically with promoting public health.

*Companies like Samsung and Alexa, Apple, Google, they see health care as a potential pinpoint that their technology could potentially solve, and so it's a good thing, I think.* [Participant #5, business and innovation, United States]

However, for others, aligning actors around financing and development was a major rate-limiting step for the potential wider public good, as companies came with their own commercial strategies tied to their own proprietary standards. These participants were skeptical that data generated by wearable sensor devices could be used to allow better management of individual health conditions. This indicates a misalignment of higher-level health policy goals and the reality of evidencing improved outcomes for patients and business functions using technology in health and care.

*One of the upshots is it's encouraging healthier behavior overall, I'm for that. I want people to live their healthiest best lives. And if there's a technology that allows us to do that, I'm a little skeptical, but if there is, I'm for it.* [Participant #6, law, United States]

Payments and financial sustainability of wearable sensor devices in health care was raised as a concern about the technology partners' motives, perhaps contributing to a lack of adoption in clinical contexts. In addition to creating products and services to support good health outcomes, uncertainty remained about sustainability. This included issues around maintenance and product iteration, updating equipment and devices, continued use of devices by health care professionals and patients, aligning of different interests over time, and financing of ongoing data analyses. These queries indicated a desire to rethink how goods and services are designed and delivered when technology is closely intertwined with health care. Existing business models reflected in existing technological designs were considered inappropriate.

*Our business model was one which we assume we'd have to make money on subscription income, because in order to deliver a good experience, the bill or materials costs can be high, and to make the economics stack up, you couldn't do it by charging somebody up front for the device. The price would be too high, it could be a couple thousand dollars at that point.* [Participant #4, engineering and innovation, United States]

### Privacy, Confidentiality, and Data Ownership

Participants also raised questions about misuse of data, balancing how much data to collect, data ownership, data portability, and

implications for insurability. It was unclear how the data generated in devices were regulated, and many participants raised concerns of data flows between health care, commercial, and private spaces. The overarching concern of clinicians in this area was the impact of altered data flows on trust, given the lack of clarity over control, sharing, and repurposing of health-related data.

*I think the big question [that] will come about is actually, well, who owns that data? And who uses that data? Because the problem is, if you then have it on a Google server, then is it not only accessible by the researchers and by the clinicians but accessible by the company themselves. Then it only takes, kind of, one example of that industry partner using that data for something else, that potentially patients haven't consented for, that it then starts to become quite a big issue and then trust, kind of, is degraded...* [Participant #13, surgery, United Kingdom]

Important considerations for developers and implementers included the development of technology standards, especially as many applications were not designed primarily for use in health- and care-related settings. This was perceived to promote trust among the user community and ensure a closer fit between technological design and clinical practice.

*What is needed also are some standards. So a lot of these technologies, particularly in the consumer technologies, have been developed as a consumer product and they won't necessarily conform to the health care standards that are needed, either in terms of the technology, the interoperability standards, in terms of the health care side of it, they won't have passed as a medical device for health care.* [Participant #8, consulting, United Kingdom]

Similarly, participants also called for increasing regulatory efforts to ensure that devices that were applied to health and care systems achieved maximum benefit, while minimizing harm.

*It's to work collaboratively with regulators so that we expedite and maximize the potential of the technologies that we have without doing any harm to patients.* [Participant #14, biomedical engineering and consulting, United States]

## Discussion

### Principal Findings

Wearable sensor devices have significant potential, particularly in relation to promoting patient engagement. However, achieving these potential benefits is dependent on addressing the current gap between data created and meaningful interpretation in health and care contexts. Current applications cannot fulfill their potential if they do not yield benefits for clinical users and thereby integrate effectively within the existing ecosystem of social and organizational actors. This may be achieved through modifying technological design to allow data to integrate effectively into health care professional decision making, negotiating of blurring lines between consumer and medical

care, and appropriate regulatory contexts incorporating pervasive monitoring of health.

### Strengths and Limitations

We have drawn on a range of perspectives from various sectors to explore the potential benefits and challenges of incorporating data generated by wearable sensor devices into health and care settings. The breadth of participant expertise across disciplines, projects, and national contexts allowed triangulation and constant comparison of generated data. These in-depth interviews have identified a range of barriers that stakeholders need to negotiate and provide an overview of the extended health care ecosystem of care providers and technology developers that can help to maximize the potential benefits of this technology. Actively anticipating and mitigating risks, before they impact negatively on the safety and quality of health and care, can help to inform future system design, implementation, and optimization.

Some limitations of this study include the diversity of applications and contexts discussed, so that it was at times difficult to extract common themes, and a potential lack of generalizability of findings across settings with different regulatory environments (as most participants came from the United States). Providing accessible and broad coverage of key concerns in the field of applying wearable sensors in health care may also have compromised in-depth insights into the concerns of different stakeholder groups. Unfortunately, none of the insurance companies that we reached out to on multiple occasions responded to our invitation to be interviewed, so we were not able to gain insights into these perspectives. There may also have been pressure on participants to construct knowledge during the interviews. For example, participants responded to a handful of the interview questions with "good question," and their responses likely represented efforts to collate their thoughts and experiences into durable representations of the subject [49].

### Integration of Findings With the Current Literature

The value of this work lies in providing accessible and broad coverage of key concerns in the field of applying wearable sensors in health and care settings. It shows that wearable sensor devices should not be viewed as stand-alone technologies in isolation, but as part of an emerging IoT ecosystem of actors. In doing so, they emerge as a key driver of service redesign in health care innovation. Our analysis revealed tensions in overlapping goals and agendas that challenge the effective integration of data generated by wearable sensor devices into health and care settings. This finding is similar to other sociotechnical studies of HIT where a range of actors with different agendas have to align for successful adoption [50-52].

Wearable sensor devices and associated data, however, do add an extra layer of complexity. Data fluidity means that many stakeholders have to be mobilized in different ways to ensure that data are captured and relayed meaningfully to various actors. In addition, this case also vividly illustrates tensions between visions and real-life challenges of using mobile devices to connect health-related data to meet public health and consumer market agendas. It further highlights the need to

develop new business models that do not exploit certain groups of stakeholders for commercial agendas.

Data generated by wearable sensor devices also create new challenges and opportunities for health care professional work practices and relationships with patients. Previous work has surfaced unintended consequences of HIT on communication, coordination of care, and clinical work practices that our findings confirm [53]. In addition, we have shown how data from wearable sensor devices can introduce new insights for, but also disruptions to, communication and work practices of health and care professionals [54].

Given the potential consequences of acting on data improperly, or of acting on improper data, this study highlights the importance of addressing data provenance and quality and of presenting relevant information. Existing commercial stakeholders are increasingly building on this. Health data aggregation companies, such as 1upHealth [55], Open mHealth [56], Validic [57], Seqster [58], Human API [59], and Apple combine information from many data sources, wearables, apps, sensors, and electronic health records, producing information for health care organizations, clinicians, and users. New start-ups like Conversa and LifeWIRE have added human and nonhuman intermediaries to help patients and providers navigate aggregated health data [60,61]. Generally, efforts promoting solutions that blur lines between consumer and medical care too much are unlikely to be effective, as a functioning ecosystem requires clinicians to be active actors to realize the potential benefits of wearable sensor devices in health and care settings. Nevertheless, changing social contexts, as seen in the COVID-19 pandemic, may change these dynamics. For example, companies like Current Health have expanded their range of sensors and connections to peripheral devices providing patient health data for remote monitoring [62].

Overall, while there is, at present, limited interest in bringing data generated by wearable sensor devices into the care consultation from the provider side [63-65], the ongoing COVID-19 pandemic has mandated a reconsideration for how best to provide care at a distance using wearable sensor devices. Even within this unexpected contextual shift, interconnected devices and data will need to represent the communications, contexts, conversations, and social connectedness of care interactions in order to maximize usefulness and effectiveness for a range of stakeholders [66-68].

### **Policy Recommendations and Implications for Practice Emerging From This Work**

Wearable sensor devices are best conceptualized as data-generating components within a distributed information system. They are not a simple device implementation; rather, such devices are key components of regular input into an IoT platform in a health care ecosystem. Further mixed methods research now needs to demonstrate effects of these devices on cost and health care outcomes, how data are used, and how health care knowledge and practices are presented and represented in the data obtained.

Implications for accelerating the integration of data generated by wearables into health care practices include negotiating the fit with existing health care professional and patient relationships, mitigating adverse unintended consequences, and aligning interrelated agendas. Triangulation of the agendas of providers and those that organize care will be key, as this seems to be crucial for promoting effective self-management. Conceptualizing specific solutions as complex public health interventions with aligned business models could help to achieve this, facilitated by rigorous evaluation to achieve mainstream utility and use [69,70].

Interviewees highlighted that regulatory guidance was lacking in the field; there were also international differences in regulatory contexts. Regulators do not classify most wearable sensors as medical devices, despite increasingly blurring lines [71,72]. There is evidence to support that regulation can both facilitate and stifle innovation [73,74]. The regulatory landscape for wearable sensor devices in health care is challenging because of the distributed stakeholder network, the involvement of technical specialists, tight regulations, and privacy and security concerns. Whether data generated by wearable sensor devices will contribute to the transformation of health and care will, in part, depend on deliberate and consistent regulatory policy to reduce uncertainty around investments [75].

In the United States, such efforts are likely to be most effectively led by national bodies to facilitate widespread diffusion and sustain wearable sensors in routine practices. The United States Centers for Medicaid Services proposed rules to take effect in 2021 that clarify that devices supporting remote physiological monitoring must be defined as medical devices by the United States Food and Drug Administration and must be “reliable,” “valid,” and collect data “electronically” to qualify [76]. This proposal follows expansion of physician reimbursement fees for remote physiological monitoring in 2020. These fee schedules create a favorable environment for expansion of existing and emerging digital health services using devices to take physiological and biometric measurements [77].

### **Conclusions**

Our work suggests that meaningful use of wearable sensor devices in health and care settings occurs through a platform of interconnected devices and data users around a specific use case. This platform represents the sum of knowledge, practices, and contexts of health care, oriented to improve a system of care, rather than a singular focus on a specific device. Engaging the range of relevant stakeholders who participate in design and development of systems is therefore essential to maximize scale, impact, and adoption.

Wearable sensor devices have great potential in improving patient engagement and thereby contributing to preventive, diagnostic, and treatment approaches. Such technologies are, however, most likely to be successful in achieving this potential if systems can align business, professional, personal, and health systems agendas.

## Abstract

**Background:** Large-scale national eHealth policy programs have gained attention not only for benefits but also for several unintended consequences and failed expectations. Given the complex and mixed accounts of the results, questions have been raised on how large-scale digitalization programs are governed to reach health policy goals of quality improvement and equal access along with necessary digital transformations. In this qualitative systematic review, we investigate the following question: How is governance implemented and considered in the studies included in the qualitative review?

**Objective:** The aim of this study is to arrive at informed and recognizable conceptualizations and considerations of models of governance connected to eHealth, as presented and discussed in the scientific literature. In turn, we hope our results will help inform the discussion of how to govern such processes to obtain collectively negotiated objectives.

**Methods:** A qualitative systematic review is a method for integrating or comparing with the findings from qualitative studies. It looks for “themes” or “constructs” that lie in or across individual qualitative studies. This type of review produces a narrative synthesis with thematic analysis and includes interpretive conceptual models. The goal is an interpretation and broadens the understanding of a particular phenomenon. We searched the PubMed database using predefined search terms and selected papers published from 2010 onwards. We specified the criteria for selection and quality assessment.

**Results:** The search returned 220 papers. We selected 44 abstracts for full-text reading, and 11 papers were included for full-text synthesis. On the basis of the 11 papers, we constructed four governance models to categorize and conceptualize the findings. The models are political governance, normally depicting top-down processes; medical governance, which normally depicts bottom-up processes; the internet and global model, emphasizing international business strategies coupled with the internet; self-governance, which builds upon the development of the internet and Internet of Things, which has paved the way for personal governance and communication of one’s own health data.

**Conclusions:** Collective negotiations between the nation-state and global policy actors, medical and self-governance actors, and global business and industry actors are essential. Technological affordances represent both positive and negative opportunities concerning the realization of health policy goals, and future studies should scrutinize this dynamic.

**KEYWORDS**

digital transformations in health care; health policy goals; national and international governance models

## Introduction

### Background

Over the last two decades, large-scale digital health programs and services, such as electronic health records (EHRs), have proliferated with equal access, improved quality, and resource optimization as wider health policy goals. National eHealth policy programs have gained attention not only for their benefits, but also for several unintended consequences and failed expectations. Given the mixed, complex results of these programs, questions are increasingly being asked about the executive power of political-governance strategies and how large-scale digitalization programs are governed to achieve the health policy goals of quality improvement and equal access with the necessary digital transformations.

In this study, based on a qualitative systematic review, we take a closer look at how governance has been implemented and considered in the realm of digitalization in health care by scholars in health care and the health sciences. The objective of the review is to arrive at an informed, recognizable conceptualization and consideration of governance. By summarizing existing and emerging models and the ways they are considered, including suggestions for improvement, we analyze the features of each model and how they possibly interfere with each other. In turn, we hope to inform the discussion on improving governance to obtain eHealth policy goals.

In a 2013 editorial in the *British Medical Journal*, the English national program for information technology (IT) was discussed 10 years after its inception [1]. This program promised to revolutionize care in the English National Health Services (NHS) and was originally scheduled to run for 2 years and 9 months starting in April 2003 [2].

The editorial summarized the results of the national program for IT and discussed its flaws and benefits. We draw attention to the following conclusion on governance: “There have been substantial improvements in the technical knowledge base underpinning information systems in the NHS, in organizational capacity to introduce any new IT system, and in information governance processes and procedures. Ten years on, only a handful of hospitals can be described as paperless, and most communication between NHS organizations still occurs by snail mail, fax, or patient messenger” [1].

Governmental opponents of the program described it as a huge disaster, but in the final benefits statement released by the Department of Health, its proponents largely described it as a success. They predicted that by 2022, financial benefits would be £10.69 bn (US \$13.86 bn), outweighing the cost of £9.78 bn (US \$10.09 bn).

Similar accounts of the contested, intended, and unintended results of eHealth programs were described in the United States in 2019: “The US health system has recently achieved widespread adoption of EHR systems, primarily driven by financial incentives provided by the Meaningful Use (MU) program” [3]. Although successful in promoting EHR adoption and use, this program and other contributing factors also

produced important unintended consequences, such as failed expectations, EHR market saturation, innovation vacuum, physician burnout, and data obfuscation, with far-reaching implications for the United States health system [4]. To avoid unintended consequences, these authors proposed improved governance, including efforts from diverse players such as health care providers, administrators, health information technology (HIT) vendors, policymakers, informatics researchers, funding agencies, and outside developers. The authors also argued for the promotion of new business models, collaboration between academic medical centers and informatics research departments, and improved methods for evaluating HIT.

These accounts of mixed, complex results, challenges to the realistic calculation of benefits and costs, and implementations of intentional changes constitute the background of this paper. Perhaps unintended consequences could have been minimized through stronger, better governance of these processes in England and the United States.

At the outset, we understand health care governance as a political process regarding national eHealth goals. National health care services differ between countries and regions, and they are broadly categorized into 2 systems: single-payer and multi-payer systems [5]. National authorities are responsible for governing their respective national health care services, including eHealth governance strategies that are often top-down through legal regulation and reimbursement schemes, where resources are allocated to prioritized service providers. However, political governance can be driven by evidence-based medical imperatives, which are bottom-up strategies [6]. National eHealth policy adjustment in such cases occurs according to new medical evidence.

Governance is extensively discussed in social and political sciences and is one of the most common social science terms [6]. One prominent definition is “an interactive process through which society and the economy are steered toward collectively negotiated objectives” [6]. Political goals are normally the result of compromises obtained through collective negotiations between stakeholders. “Public governance should thus be considered as composite and mixed with inbuilt tensions between competing concerns, actors, ethics, resources, and time horizons” [6,7].

This paper considers eHealth governance as a dynamic process in which development, decisions, implementation, evaluation, and adjustments overlap and interact. The development grows out of conscious and unconscious interdependencies. To realize deliberate policies in such interdependent situations, collective negotiations might be increasingly important. In Norway, the word “co-management” captures this process, which blurs the strict distinction between bottom-up and top-down governance.

One group of researchers has emphasized the need for more empirical studies in the field of governance to strengthen both conceptual and empirical knowledge [8].

We report on the results of a systematic, qualitative review of how eHealth governance has been conducted and experienced. We investigate how governance has been addressed and has played out in eHealth programs as described in the health

sciences literature. We do not aspire to compare different enactments of governance, but instead, perform a descriptive analysis by conceptualizing the characteristics of governance and the experiences presented in the cited papers. We also discuss how different models interfere with each other and summarize suggestions for improvements.

We have restricted our search to PubMed because digital health is a popular emerging topic, and it is of interest to learn how governance is addressed and considered in health sciences. On the basis of political and social sciences, we contribute to a cross-fertilization of scientific traditions by communicating with practitioners, medical internet researchers, and political health authorities.

## Question

How do the papers included in the qualitative review define and consider governance?

## Objectives

The objective is to arrive at informed, recognizable conceptualizations and considerations of governance models of eHealth, as presented and discussed in the scientific literature. In turn, we hope our results will help inform the discussion on how to govern such processes to obtain collectively negotiated objectives.

## Outline

The remainder of the paper contains an account of the methods used, quantitative and qualitative results, and a discussion section in which we distinguish between and elaborate on models based on our constructs from interpreting the empirical results of the cited papers. We discuss suggestions for governance improvements, present our conclusions, and point to areas for further research. We also discuss the limitations of this review. Due to the coronavirus pandemic, we have provided a postscript that connects our models and conclusions to possible (eHealth) governance in the COVID-19 era.

## Methods

### Qualitative Systematic Review

A qualitative systematic review is a method for integrating or comparing with the findings from qualitative studies. It looks for themes or constructs that lie in or across individual qualitative studies and may employ selective or purposive sampling. This type of review produces a narrative synthesis with a thematic analysis and includes interpretive, conceptual models. The accumulated knowledge resulting from this process may lead to the development of a new theory, an overarching narrative, a wider generalization, or an interpretative translation. The goal is not aggregative in the sense of adding studies together, as with a meta-analysis; rather, it is interpretative and broadens the understanding of a particular phenomenon [9].

### Search Strategy and Information Sources

Our search was performed in November 2018 using the previous version of PubMed. PubMed was updated in the spring of 2020.

We searched “All fields” with the following search criteria:

Search (“governing reforms” OR (telemedicine governance) OR (governance “national telemedicine programme”) OR (governance “national ehealth programme”) OR (governance “national ehealth programme”) OR (governance innovation ICT) OR (“innovative procurement” health\*) OR (“innovative procurement” health) OR (“whole system demonstrator programme” lessons) OR (Sundhedsplatformen) OR (Governance “regional EHR implementation” Denmark)).

The search was restricted to scientific papers, including systematic reviews published in peer-reviewed journals. A systematic review was defined as an overview with an explicit question and a methods section with a clear description of the search strategy and methods used to produce the review. The review was also expected to report on and analyze empirical data. As many papers were retrieved (220), we included only reviews and papers published from 2010 onwards in the final review for pragmatic reasons.

### Inclusion Criteria

#### *Population and Participants*

We included papers on the governance of national, regional, or global eHealth programs focusing on population, public health, hospitals, communities, patients, consumers, health professionals, and family caregivers, regardless of diagnoses or conditions.

#### *Interventions and Issues*

The review included governance issues connected to all eHealth interventions, information and communication technologies (ICT) for communication in health care, and internet-based interventions for diagnosis, self-management, and treatments. Social care was considered relevant if it was an important part of health care and occurred in collaboration with health care for patients with chronic conditions.

#### *Comparisons*

Papers that compared governance of eHealth and governance of standard care or other types of care were included in the review.

#### *Outcomes*

Only papers and reviews that reported relevant outcomes were included. Relevant outcomes were specified as eHealth governance with health-related outcomes (morbidity, mortality, quality of life, and patient satisfaction), process outcomes (quality of care, professional practice, adherence to recommended practice, professional satisfaction, governance strategies, organizational aspects, policy and implementation), and costs or resource use. Systematic reviews and papers reporting on emerging issues, such as unexpected findings or important new insights, were also included.

#### *Languages*

Articles published in English, French, or a Scandinavian language were included.

### Exclusion Criteria

The governance of general health reforms, innovation programs, public reforms, and innovation programs was excluded, as were

conference papers, dissertations, proceedings, and irretrievable papers.

### **Design**

Papers and reviews considered nonsystematic or nonrigorous, such as commentaries, editorials, and proceedings, were excluded, as were systematic reviews with major limitations (low quality) according to a revised checklist for systematic reviews from the Cochrane Effective Practice and Organisation of Care Group. If the same authors had produced several publications of the same review, the most updated and/or the fullest review was selected while other versions were excluded.

### **Participants**

Studies with participants considered irrelevant to the review were excluded, such as studies on the use of ICT outside the health care domain. Animal studies were also excluded.

### **Interventions Considered Irrelevant to the Review**

Studies on the governance of interventions considered irrelevant to the review included internet-based education of students and health professionals, medical technology in clinical practice in general, such as medical and surgical examinations and treatments based on computer technologies, except when used in remote diagnosis and treatment (telehealth); the use of telephones (including cell phones) only; eHealth as only a limited part of an intervention; and the use of the internet for surveys, research, web-based prescriptions, mass-media interventions, and veterinary medicine.

### **Outcomes**

Articles without relevant outcomes were excluded, that is, those not meeting the inclusion criteria.

### **Study Selection**

Articles were stored in the free software Rayyan, where we inserted the selection criteria and read the abstracts [10]. On the

basis of the inclusion and exclusion criteria, two reviewers independently screened the list of the titles and abstracts from the literature searches and identified potentially relevant studies, the full-texts of which were then retrieved. We resolved any disagreement through dialogue between the two reviewers based on the selection criteria. The citations were then exported to EndNote.

### **Data-Collection Process**

Data collection was carried out using a web-based data-extraction form created by the authors in Google Docs, which is enclosed in Appendix 1. The 2 authors collected data based on full-text papers. The following quality domains were assessed to identify, include, and critically appraise the studies: explicit accounts of data-collection methods, explicit accounts of methods used to analyze the findings, and overall assessments of the qualities of the papers and reviews.

### **Analytical Perspective**

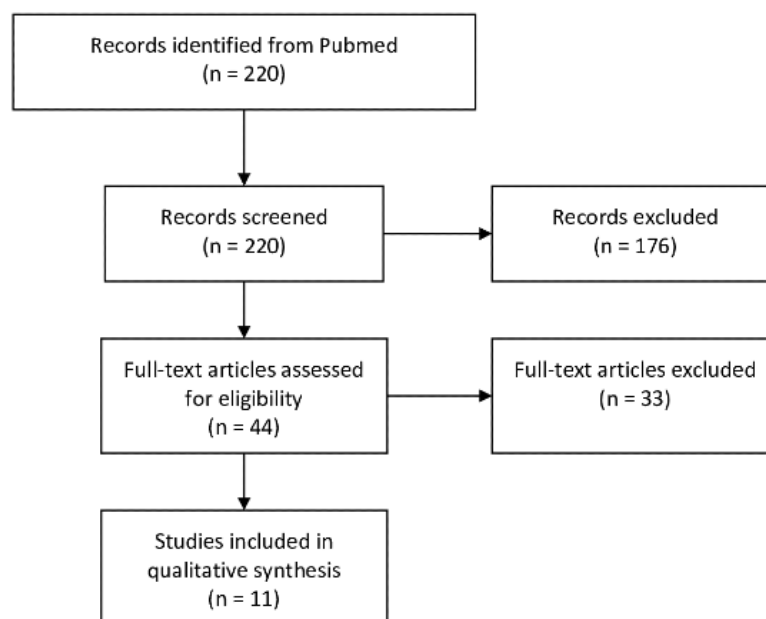

We analyzed the papers from a grounded perspective by interpreting the qualitative data in the included papers. Grounded theory is a form of empiricism that emphasizes inductive reasoning and hypothesis generation, in contrast to the hypothetic co-deductive model of the positivist scientific method [11]. Our interpreted models can be used as working hypotheses for further empirical development and research.

## **Results**

In total, we included 44 of the 220 abstracts extracted from PubMed.

### **Quantitative Results**

The Preferred Reporting Items for Systematic Reviews and Meta-Analyses diagram below (Figure 1) presents the quantitative results [12].

**Figure 1.** PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.

### Qualitative Results: Governance Models

In the background section, we briefly indicated 2 broad governance strategies: political governance, which normally depicts top-down processes and medical governance, which normally depicts bottom-up processes. On reviewing the 11 papers, we found it difficult to subsume all of them under either political or medical strategies.

Therefore, we constructed four governance models to categorize and conceptualize our findings. We chose to construct models because “Models seek to simplify phenomena as an aid to conceptualisation and explanation” [13]. They are also tools to realize a narrative synthesis, which includes thematic analysis and interpretive, conceptual models.

The 4 models are: political governance, medical governance, internet and global business governance, and self-governance. We briefly describe the models below before sorting the different papers into them.

1. **Political governance:** Health policy and implementation are nation-state responsibilities. However, nation-states are also members of the World Health Organization, which has a global perspective on governance. Regional or local authorities are also responsible for collectively negotiating goals. National authorities can choose top-down governance approaches or delegate responsibility to the regional and local levels to facilitate bottom-up strategies. Some papers described this up-and-down process as a national “middle-out” approach to eHealth decision-making. We have conceptualized all these strategies as political strategies, implying that the top-down perspective is broad and dynamic, as our background section indicates.
2. **Medical governance:** The medical model implies that governance initiatives and executive agencies rest with medical and health care professionals and professional

organizations, which provide the terms of development. This model also comes with dynamic adaptations, such as adjustments to the political model. In radiology, for instance, which was fully digitalized at an early stage, radiologists saw its national medical potential and consequently influenced political strategies.

3. **Internet and global business governance:** In this category, we include governance mechanisms by nongovernmental organizations, the health care industry, and private internet companies. The structure of the internet facilitates new business models, which may challenge political strategies and national control. The internet is accessible to almost everyone, and no international quality assurer exists, which prohibits the diffusion of information or services that might contradict medical evidence and challenge public health. Illicit drug sales on the internet is an example of a new business model.
4. **Self-governance:** This model builds on the development of the internet and the Internet of Things (IoT), which has paved the way for the personal governance of health by storing, developing, and communicating one’s own health data. This model considers eHHealth to be developed by individuals’ efforts to optimize their own health. The self-management of diabetes through apps, for instance, may facilitate individual governance (by patients and citizens) of eHealth services through demand for new apps and simultaneously empower patients and strengthen their digital literacy.

### The Political-Governance Model

The following 4 papers align with the political-governance model: Atalag addresses a single content model for eHealth interoperability and secondary use in New Zealand [14]; Park and Atalag address the national approach to health care ICT standardization and focus on progress in New Zealand [15];

Kierkegaard addresses interoperability after EHR deployment and describes persistent challenges and how the Danish government applied a combination of bottom-up and top-down strategies to realize full-scale EHR implementation [16]; de Riel et al [17] address success factors for implementing and sustaining a mature electronic medical record, iSante, in a low-resource setting in Haiti (Table 1).

In the political-governance model, eHealth is governed top-down through a national eHealth strategy. The papers included in this model describe national top-down strategies on technical infrastructure, legal frameworks, and institutional structures,

such as national advisory boards or a multi-editorial expert group [15,16] (Table 1).

Atalag describes the national top-down strategy of New Zealand as a “middle-out transitional approach to achieving semantic interoperability in eHealth” [14]. Kierkegaard describes how the Danish authorities combined top-down and bottom-up approaches to realize national eHealth goals: “Changes in the organizational setup and redistribution of responsibilities between the Danish regions and the state play a pivotal role in producing viable and coherent solutions in a timely manner” [16].

**Table 1.** Included papers, governance models, and strategies.

<sup>a</sup>N/A: not applicable.<sup>b</sup>PACS: Picture Archiving and Communication System

### The Medical-Governance Model

The following 4 papers align with this model: Wade et al [18] presented a qualitative study of ethical, medico-legal, and clinical governance matters in Australian telehealth services; Sutton considers a Picture Archive Communication System and diagnostic imaging service delivery from the UK perspective [20]; Bagot et al [21] performed a qualitative analysis comparing with the experience of Australia and the United Kingdom in integrating acute stroke telemedicine consultations into specialists' "usual practice"; and Crocker et al [19] address patient safety and image transfer between referring hospitals and neuroscience centers, exploring possible methods of improvement.

The bottom-up strategy may grow out of local needs [18,20], and sometimes it is picked up and transformed into a national top-down strategy. For instance, Crocker et al [19] claim that "Part of the remit of the National Programme for Information Technology in the NHS (NPfIT) was to improve neuroscience teleradiology." The researchers wanted to evaluate whether their experiences were part of the national top-down strategy; so the paper describes how the medical society experienced their recommendations presented in an NHS report from 2004 being "largely ignored" in the national program. National top-down strategies do not necessarily align with bottom-up strategies [19].

Wade et al [18] state that, from a medical point of view (bottom-up), concerns about data security in telemedicine need to be governed through national top-down guidelines.

### The Internet and Global Business–Governance Model

The following 2 papers align with this model: Mackey et al [23] addressed health domains for sale and argued for the need for global political health governance on the internet, and Mackey et al [23] discussed a call for a moratorium on the top-level domain "generic health" to prevent the commercialization and exclusive control of web-based health information [22].

These authors argue that the national jurisdiction of privacy and data protection is largely ignored and challenges existing international governmental organizations, such as the World Health Organization and European Union [7]. According to the authors, the business interests of large actors and market mechanisms overrule both political and medical governance.

Mackey et al [22] claim that the processes of the Internet Corporation for Assigned Names and Numbers (ICANN) "appear to favour business interests and generation of profits over the future integrity of the Health Internet, failing to make any tangible commitments to protect public health or enforce norms as would be found in a responsible global governance Framework."

However, they also state that "Direct-to-consumer advertising of prescription products is not allowed in the vast majority of countries other than the United States and New Zealand, and it may be unlawful for pharmaceutical manufacturers to engage in multijurisdictional web-based advertising that could occur through future gTLDs (generic top-level domain name)" [23]. There is a lack of global governance in health that may challenge human rights in public health [23].

### The Self-Governance Model

We have included one paper in this category by Williams et al [24], who discussed governance in terms of individual agency as opposed to political governance. They also envision the opposite of individual agency: the ways in which digitalization and the use of technological affordances change individuals and identities. The paper describes a complex model, a dynamic dualism between the governance of individuals by eHealth versus the self-governance of eHealth.

We have presented the included papers under 4 governance models: political governance, which is normally limited to nation-state jurisdiction, international, evidence-based medicine and health care guidelines, large-scale industries governed by business goals, and self-governance by consumers.

### Summary of Empirical Results

Table 1 lists the 11 papers by author, year published, country in which the governance model is discussed, and model or strategy. Some papers do not refer to a specific country because they describe global models or models related to the consumers' use of the IoT products and services.

Table 2 lists the included papers by author, year published, country in which the characteristics, experiences and challenges are described, and the suggested improvements related to a specific governance strategy. Three papers do not relate to a specific country but describe aspects related to global governance and self-governance models.

**Table 2.** Included papers, considerations, and emerging governance trends.

Reference	Country	Experience and performance (descriptive)	Considerations and suggested improvements (descriptive)	Trends and emerging governance models
Atalag K, 2013 [14]	New Zealand	Suggesting a “middle out” approach; a single top-down approach does not produce the expected outcome; success relies on a relationship based on trust between the authorities and the medical society	The national Single Content Model is flexible and “enables smooth transition to a comprehensive solution through gradual replacement over time”	The openEHR trend and Archetypes; governance based upon a top-down strategy for interoperability
Park YT, 2015 [15]	New Zealand	Strong top-down governance strategy and organizational structures and rules has been the most important factors for successful eHealth governance	Next steps will be to analyze how the eHealth structure influence health outcomes and minimize errors	Strong belief in strong government involvement leads to successful goal attainment in eHealth
De Riel E, 2018 [17]	Haiti	A key learning is leadership engagement to create an understanding of how the system works	Haiti’s health care service is dependent on national and third-party funding; realizing a sustainable information and technology communications infrastructure is a muddle-through process	System migration to the OpenMRS platform to take advantage of a global community and ensure sustainability
Kierkegaard P, 2015 [16]	Denmark	Setting national goals and adapting the middle-out approach as part of a national strategy is the best way to realize full-scale implementation of electronic health records, an approach based on cross-regional coordination	A collective phase-out of all systems may be costly, but it may be the only way to create a common national platform of high interoperability; risk of regions working with one vendor, which creates regional dependency on an actor with market monopoly	The Danish framework is flexible and in line with the European Union eHealth Interoperability framework
Wade VA, 2012 [18]	Australia	This study indicates that telehealth can be a tool to realize medical quality of care governed bottom-up and in line with evidence-based medicine	The medico-legal aspects did not seem to be as difficult as anticipated; national reimbursement schemes may increase substantial system benefits	N/A <sup>a</sup>
Crocker M, 2010 [19]	United Kingdom	Image transfer is delayed by an immature technology infrastructure	Bottom-up recommendations from the teleradiology society in United Kingdom has been ignored by the top-down process	N/A
Sutton LN, 2011 [20]	United Kingdom	Creation of a UK reporting “Grid” with remaining organizational and governance challenges	Telehealth challenges around “team organisation” when the reporter and doctor are in separate organizations at a distance	Creation of a medical governance model in radiology across the United Kingdom which harmonize with the national top-down strategy of National Health Services
Bagot KL, 2017 [21]	Australia and United Kingdom	UK model: telemedicine integrated in the specialist work plan; Australia telemedicine was ad hoc	Both networks see telemedicine as part of future organization; can reduce workload by a “follow-the-sun model”	N/A
Mackey TK, 2014: (A call for a moratorium) [22]	Global	The governance of health-related internet domains should be run by international organizations and not by a for-profit company like Internet Corporation for Assigned Names and Numbers, which does not respond to actors who want this policy change	The international society should stop the Internet Corporation for Assigned Names and Numbers governance model	Is it feasible to realize a global internet governance model based on international interstate cooperation?
Mackey TK, 2014 [23]	Global	The governance model of dot-health and other internet health domains is not run by the World Health Organization or another international health organization, which may represent a global threat to public health: access to evidence-based medicine and quality assured health information	The main challenge is to realize a shift from a privately-run model to an international model governed by legitimate international public health actors	The combination of internet and global markets challenges political and medical governance

Reference	Country	Experience and performance (descriptive)	Considerations and suggested improvements (descriptive)	Trends and emerging governance models
Williams, SJ, 2015 [24]	Global	Health apps are a growing trend that realizes “the quantified self”: blurring the lines between health care and wellness through data sharing	N/A	“Quantified-self” apps contribute to a growth of health and wellness data; a “global health and wellness data governance model”?

<sup>a</sup>N/A: not applicable.

## Discussion

### Elaborating Models, Experiences and Suggestions for Improvement

This section focuses on the features and considerations of the different models, the ways in which they interfere with each other, and suggestions for improved governance.

### Features and Considerations of the Different Models

#### *Features and Considerations of Political Governance*

The 4 papers in this category describe top-down governance models and discuss how top-down national policy has used regional eHealth models as tools to implement wider national health strategies through a defined framework and governmentally assigned top-level working groups.

When, for instance, the Danish government wanted to speed up EHR implementation, they focused on regional governance to replace their former top-down strategies. Likewise, when the government found it more suitable to decrease the number of existing EHR systems, they strengthened the top-down national model by using regional middle-out strategies [16]. The government encouraged cross-regional coordination as part of the national eHealth strategy (Table 2).

The history of Denmark’s health care system demonstrates the inherent difficulties of a state-centric approach to technology harmonization. Similar results have been obtained when other countries applied a top-down approach to national-level shared medical records, such as the ambiguities in the NHS National Programme for IT (NPfIT). Moreover, Denmark’s methods for overcoming the interoperability issues between EHRs demonstrated that health information exchange is not merely a technical issue, “but a challenge fraught with organisational and political complexities” [16].

In New Zealand, the government governs the top-down implementation of eHealth using a national eHealth strategy and standards. Atalag argued that it was difficult to achieve a high level of interoperability through a top-down strategy, partly because of resistance from different organizational actors. The model was therefore replaced by “a middle-out (transitional) approach to achieve semantic interoperability in eHealth” [14]. This approach was strategically used temporarily until the top-down approach was resumed (Table 2).

The Haitian model included three multi-site electronic medical records as the cornerstone of the broader planned national eHealth architecture, eventually feeding into an overarching system to aggregate health-indicator reporting (called *Système d’Information Sanitaire National Unique*). The Haitian Ministry of Health set this model as a priority in 2013 [17], a middle-out

approach that included both the top-down governmental strategy, the bottom-up medical strategy, and the donor strategy as a third actor. This middle-out approach helped realize health policy goals related to sustainable health service.

The case from Haiti shows that a top-down strategy may apply in low-resource, donor-dependent settings. “Strong leadership was essential to system continuity and expansion. In addition, many developing countries may not have a legal framework that addresses management or protection of health information” (Table 2).

In New Zealand, Atalag emphasized that “the success of the described approach relies heavily on appropriate governance, and it is imperative to put in place new models of collaboration” [14]. The government of New Zealand, unlike those of other countries, established specific HIT bodies to drive and support standardization, including the National Health IT Board and the Health Sector Architects Group, which actively participated in the standardization processes (Table 1). They collected ideas from the health care industry and the public sector and developed HIT standards. In the second paper, Park and Atalag further emphasize that New Zealand’s governmental structures and processes may be a direct and efficient way of achieving the benefits of HIT standardization because government power has a strong influence on markets, and many health care organizations are under government control [15].

In summary, political-governance models encompass bottom-up, top-down, and middle-out approaches. We chose to label them top-down however, because even bottom-up strategies are a part of top-down governance since health care is a nation-state responsibility. These strategies seem to fluctuate dynamically within the nation-state, following a thesis-and-antithesis curve. Bottom-up and middle-out strategies seem to be shifting to improve top-down governance incrementally and instrumentally. The models enact governance *through* and *of* eHealth: influential human actors use eHealth programs as tools, and shifting strategies are applied to obtain wider health political goals.

#### *Features and Considerations of Medical Governance*

The political-governance model’s top-down focus on governance by standards, legal frameworks, and national boards may lead to an underestimation of other important aspects affecting governance, such as knowledge, identity, roles, cultures, trust, quality, and asymmetric power relations.

Medical governance may shed light on these aspects of governance in eHealth. Medical governance is enacted within medical networks by medical and health care professionals, who see potential in technology and create networks to maximize its benefits and improve medical practice. “Clinical governance is a systematic approach to implementing quality

and safety in health care, which aims to maximize evidence-based practice and reduce risk” [18]. In this paper, Wade et al [18] suggest that various examples have shown that telemedicine can be used to enforce medical governance as a driving force to support the uptake of evidence-based care because it has been difficult to change organizational cultures in health care systems. The literature on the organizational effects of telehealth has been sparse and has focused on the details of implementation. Wade et al [18] further comment on governance within eHealth communities: “Telehealth could be a key factor in quality improvement as it produces immediate contact between providers, is based on the management of real patients and promotes trust in interprofessional relationships” (Table 2).

Bagot et al [21] argue that clinicians must adapt to this new way of delivering services; adaptation subsequently affects the trust and roles and responsibilities between organizations that collaborate on eHealth governance: “Successful telemedicine networks require specialists adapting clinical practice to provide remote consultations.” The authors indicate a knowledge gap with respect to medical governance between different countries (Table 2).

Sutton discusses experiences in medical governance as part of the development of telemedicine networks: “It is important for local health care communities and their patients to ensure teleradiology does not destabilize or de-skill smaller departments. Teleradiology should be complementary and not an alternative to progressing development of the service locally by enhancing the expertise of the local radiology workforce” [20].

Radiology in England has undergone reorganization due to digitalization. Currently, following the merger of clusters into three main areas across England, there are three major Picture Archiving and Communication System providers with associated storage archives [20]. This process includes the medical society bottom-up: “The Radiology Service Improvement Team of the NHS . . . is now part of the NHS Institute for Innovation and Improvement” [20] (Table 2).

Other authors also note that the medical society opined that the teleradiology recommendations of the 2004 NHS Modernization Agency Neuroscience Critical Care Report have been largely ignored, even though “part of the remit of the National Program for Information Technology in the NHS (NPfIT) was to improve neuroscience teleradiology” [19].

The included papers demonstrate that implementing telemedicine services requires inter- and intraorganizational cooperation and raises questions that transcend standards, infrastructures, and legal frameworks. These include implementation challenges, clinicians’ trust, and the associated uncertainty around how best to ensure stable access to skilled personnel at local departments. There is also uncertainty about clinical accountability and responsibility. Clear governance of these aspects is considered crucial to clinicians.

Including high-ranking medical professionals in the implementation process of national programs, such as the NPfIT, is suggested to increase clinicians’ trust in national

implementation. In cases where the medical society considered their input largely ignored, trust was lost in the top-down strategy. However, these papers do not describe how the implementation process is affected by the lack of trust from the medical society.

Other scholars who have evaluated national EHR implementation programs point out similar results: Strategic, organizational, and human challenges are usually more difficult to master than technical aspects” [25].

In summary, the medical model addresses governance within and by professional eHealth communities. Medical governance represents the bottom-up and middle-out perspectives. The papers describe how medical governance systematically outlines how digitalization maximizes evidence-based practice, reduces risk, and thereby increases quality and access to care. Trust, responsibility, role definition, and skill development are considered crucial to obtaining evidence-based results. This model also faces ongoing challenges that require serious effort to succeed.

### ***Features and Considerations of Internet and Global Business Governance***

In the governance literature, the term “organized anarchy” is used to describe a “loosely coupled” organized structure, which refers to a “relatively open and unspecialized” structure [7]. We interpret this model to denote the internet as a technology with affordances that facilitate organized anarchy. It transcends the jurisdictions and economies of the nation-state and allows global discovery and innovation. Technology facilitates the realization of this anarchy, opening the possibilities for actors to create organizations and services beyond national jurisdiction. eHealth can be part of this global development.

The 2 papers included describe how the internet, which consists of a hierarchical domain-naming system for the internet protocol addresses of computers, services, and other digital resources, relies on domain names as an easily recognizable way for users to search and navigate web-based content. “The Internet Corporation for Assigned Names and Numbers (ICANN), a nonprofit corporation founded in 1998 that controls this system, is currently undergoing the largest expansion of the internet in history” [23].

ICANN is a nongovernmental organization established by the United States government but is notionally independent of it. It manages this hierarchical naming system and roughly 500 accredited domain-name registrars. “ICANN relies on an international Board of Directors consisting of various ICANN constituents, a CEO, staff, and advisory committees consisting of stakeholders from national governments, Internet technical experts, and Internet organizations to inform its decisions” [22].

The authors of the two papers are critical of the ways ICANN governs, noting that it has created “the largest expansion of the Internet in history . . . adding over a thousand new generic top-level domain names (gTLD), potentially including a new .health domain and close to 20 other gTLDs related to medicine and health” [23]. They consider that ICANN’s complex, highly political process of awarding health-related gTLDs profoundly impacts information privacy, use, and sale as well as health

marketing and content quality, which could influence future trust, security, and credibility of the Health Internet. Hence, they argue that it is critical that applicants are carefully scrutinized to ensure that they are abiding by ethical principles, practices, and rules with respect to public health and the public interest.

More than 100,000 health-related websites are estimated to exist, and internet users may have difficulty accessing evidence-based sources and often seek information through simple search-engine queries (eg, Google, Yahoo, and Bing) that may prioritize sites of lower quality, undisclosed commercially sponsored content, irrelevant information, and/or misinformation. “For example, illicit online pharmacies have been detected illegally marketing and selling pharmaceuticals without prescriptions, misrepresenting crucial risk information, and not disclosing other risks of their often counterfeit and otherwise dangerous products” [23]. “Because it governs the majority of the domain name system, ICANN bears great responsibility for those standards, and how the Internet can be used to help or harm individual users” [22].

Objections to ICANN’s governance model have come from the World Health Organization, scholars, and international public health organizations. In 2000, the World Health Organization and other stakeholders proposed the formation of health top-level domain names (TLD), but ultimately their proposal was not chosen as one of the seven proof-of-concept names for new TLDs in that round [23]. The authors underline that ICANN lacks “enforceability, because it has no appeal process to take proactive action against websites that violate laws that accredited registrars fail to report. Consequently, many websites feature illicit online content with clear public health and patient safety concerns that registrars take no action against, such as websites selling medicines without a prescription and that also potentially traffic counterfeit or falsified medicines” [22].

The authors give reasons to worry that the situation will be exacerbated by simply awarding new health domains to the highest bidders. “ICANN’s processes appear to favor business interests and generation of profits over the future integrity of the Health Internet, failing to make any tangible commitments to protect public health or enforce norms that would be found in a responsible global governance framework” [22].

According to the United Nations, health is a fundamental human right. More people than ever are using the Health Internet to seek information and make behavioral choices. “Now is not the time either to compromise this legal right or complicate the factual reality, in favor of profit-making interests merely for the sake of unlimited Internet expansion” [22].

The authors argue that governing health-related internet domains should be a priority for international public health organizations as well as global IT organizations, such as ICANN, the World Health Organization, the International Telecommunication Union, the World Summit on the Information Society and its Internet Governance Forum. ICANN, as a nongovernment organization with a global autonomous governance structure, does not seem to make any tangible commitments to protect public health or enforce norms, as would be found in a responsible global governance framework [22].

In summary, this model exceeds the political and medical governance models and puts international business actors in a dominant role. The authors envision a rather dystopian future, especially for the governance of health data and services on the internet, and they argue for action by global health authorities.

### ***Features and Considerations of Self-Governance Models***

We have included one paper in this category. It describes how sleep-monitoring and diagnosing sleep problems and treatment were moved from medical governance to a self-governance model. This “health service” takes place outside health care institutions and is facilitated by the IoT, which may exist at the global level beyond nation-state jurisdictions. In this model, nongovernmental or private actors may deliver services outside the national health system, as discussed in the previous chapter.

The difference between these devices and previous portable devices is that the user–technology relationships configured by new digital sleep-monitoring technologies are primarily between sleepers and devices. “The information about sleep feeds directly back to the user, providing sleepers with new knowledge about their dormant (or not-so-dormant) body/self; knowledge that itself is imbued with a sense of responsibility for them to act to improve their sleep” [24]. The authors argue that sleep, or the sleeping body or self, is yet another site for improvement or optimization in terms of performance, and that health is important well beyond the clinical sphere.

Further, they point out a certain seductive power in tracking, monitoring, and managing ourselves in the interest of self-knowledge, or even self-governance, for self-improvement or self-optimization.

Referring to Deleuze, the authors warn against forms of more or less continuous control [23,26]. Further, they envision submission and postpanoptical surveillance, referring to Massumi, Foucault, and Bauman [27–29].

In summary, self-governance enacts a dynamic between global internet governance that forces or nudges humans, on the one hand, to adhere to technologies and connected health businesses, and on the other, to rely on them as sources of individual self-governance and control. Governance is characterized by a shifting, dynamic tension: governance of the individual by eHealth (submission) versus self-governance within eHealth services, involving empowered, conscious citizens.

### ***The Ways the Models Interfere With Each Other***

Wade et al [18] argue that medical governance needs help from political governance to regulate responsibility, ethics, and accountability by stating that it is unclear whether responsibility should rest with the primary clinician or be divided between the local clinician, the distant clinician, and the technology provider. They substantiate this by asserting that this responsibility is not regulated in Australian law, noting that there is “no case law relevant to telehealth in Australia” [18]. In addition, they expect this to change: “These matters have not been resolved in Australia, although with the advent of universal telehealth rebates, standards for practice are under development by the professional colleges” [18].

Top-down political-governance strategies are used by national authorities to ensure national frameworks of standards and legal aspects, and medical governance seems to be used as a bottom-up model and strategy to ensure that the process is anchored and incorporated into medical practice. In the cases in Denmark and New Zealand (Tables 1 and 2), both governance models were expected to work in tandem. When the tension between them grew or the governments became aware of possible tensions that could slow the process, they used a middle-out approach to increase the legitimacy of the top-down eHealth strategy.

The middle-out approach is often defined by national advisory boards, which include multiple stakeholders. This was the case for Denmark, New Zealand, and Haiti, which recognized tensions between stakeholders and consequently included medical professionals, vendors, patients, and bureaucrats in their eHealth governance models to facilitate and enforce negotiations. eHealth governance is recognized as an arena for collective negotiations to co-manage tensions to realize national health policy goals.

The global internet and business model describes challenges concerning forces that are complex, ubiquitous, unpredictable, and ungovernable by established policy structures and strategies. This model defines governance in terms of challenges in the governance of health-related data and digital services. Such challenges occur because of interactions between technological affordances and international business actors.

According to the 2 papers on ICANN, the internet and global model interferes with the other 3 models because the ICANN overrules World Health Organization efforts.

The political models were based on the abilities of nation-states to regulate and govern eHealth policy alone or through international cooperation in international governmental organizations or supranational organizations. The anarchical structure of the internet adds a challenge to the political and medical governance of eHealth; however, combined with the internet's global outreach, it facilitates business growth and reduces political and medical governance, leaving it up to the consumer to validate services and products. The European Union passed the General Data Protection Regulation to precisely address this challenge and protect consumers [30].

Self-governance may fit into wider patterns of voluntary and involuntary submission, particularly in the digital era of big data, which Williams et al [24] call "creeping forms of monitoring and surveillance that seem to characterize our lives today within and beyond the medical and health domains."

Such submissions may also be used by global web-based businesses to target services to specific user groups and control markets. Thus, there is a tension between self-governance and global internet and business governance concerning control and manipulation.

### Elaborating Suggestions for Governance Improvements

Scholars in the political-governance category articulate the need for more documentation of the successful, locally-led governance of donor-funded systems, including any

capacity-building for local responsible entities and joint system design, planning, and implementation [17]. Experiences with political strategies point to a demand for ongoing efforts to improve them, with stronger political executive power building on medical relevance to achieve wider goals.

In the medical-governance category, scholars point out the need for continued monitoring of a more robust image-routing system across the NHS and audits of its functionality by the Connecting for Health Safety Team and the National Patient Safety Authority to combine bottom-up and top-down strategies [19].

In support of this argument, Sutton claims that "There is much hope that despite the current economic climate, the established IT programmes in the UK are able to continue to facilitate the development of new solutions. In 2010, the Department of Health in England adopted the 'Quality, Innovation, Productivity and Protection' agenda to maximize the benefits of existing IT systems and promote improved patient care and productivity" [20].

In a paper concerning ethical and legal matters in Australian and UK telehealth, the authors reported that Conducting organizational case studies would give a deeper understanding of the matters identified, particularly those of governance and system change" [18]. In their comparison of the integration of acute stroke consultations and specialists' usual practice, the authors suggest that "Future research might investigate the transferability of UK and Australian experiences to broader European, Asian and American networks" [21]. In general, medical culture is similar across national borders.

The medical society is global and agrees on evidence-based medicine being the core driver of medical diagnoses and treatment procedures. However, integrating telemedicine into care requires juggling international medical culture and local cultural variations in medical delivery. Medical-governance strategies need to embed evidence-based medicine and telemedicine into different organizational set-ups. Incremental "juggling" is considered useful for solving organizational challenges.

Regarding internet and global business governance, the authors of the two reviewed papers suggest that "Focusing on the public good can be a first and crucial step to ensure an accurate, reliable, and evidence-based online presence for health for this generation and the next" [23]. They recommend that the "Internet community needs to be vigilant to ensure the reliability and trustworthiness of health information online, and take immediate action to secure the future integrity and proper governance of this important namespace for the health internet" [22]. The authors hope to encourage ICANN to appoint the World Health Organization and a multitude of governmental and health nongovernment organizations as sponsors. This presupposes that the World Health Organization has executive governance power with the ability to overrule the global internet market and the political governance within each member state. They express a need for political governance to dominate global business strategies.

The papers propose solutions for "future e-Health governance approaches to ensure the appropriate management of health

could be accomplished by requesting ICANN to recategorize health as a sponsored gTLD and proactively appoint WHO as its sponsors” [23]. They suggest that the World Health Organization should develop policies to ensure accountability and transparency in gTLD operations that meet the best interests of the global health community and enforce eligibility rules regarding all future health registrants.

They propose that the World Health Organization’s possible appointment as a gTLD sponsor should be governed by a diverse, globally representative board of health stakeholders in partnership with responsible internet service providers. “This governance mechanism can have representation and be organized into subject-specific advisory panels to review and recommend content to be included on for health” [23].

In the self-governance category, consciousness and data activism is important, which resonates with an argument from Alan Peterson, who calls for “algorithmic accountability” which highlights the potential for citizens to create alternative futures—ones oriented to fulfilling human needs rather than techno-utopian visions” [31].

### Limitations of the Review

By limiting our inclusion criteria to 2010 onwards, we might have missed important papers that could enhance the review. Qualitative reviews are not all-embracing, and the results are colored by the search criteria. Nevertheless, our paper provides valuable insights into various governance strategies at play in the realm of eHealth and valuable suggestions for further work to improve governance and scientific knowledge.

### Postscript – Governance and the Coronavirus Pandemic

The current coronavirus pandemic might provide an excellent illustration of our findings and main conclusions.

To govern and control the pandemic, collective, transparent efforts are in demand: political decisions followed by financial incitements, firm global medical knowledge and advice, international business actors’ financial and ethical decisions, and personal decisions by citizens to adhere to the advice. Following a process when the collectively negotiated goal to fight the pandemic is at stake, puts strong demands on each of these “nodes” in dynamic co-governance.

### Conclusions

We have identified 4 different governance models linked to national eHealth programs, national health ICT infrastructures, regional and local professional networks, Health Internet

businesses, consumer-driven self-management solutions, and virtual health services beyond national health services.

The political model depicts governance through various management strategies to influence wider health political goals and innovation. The model also enacts eHealth governance by establishing financing schemes, infrastructures, standards, and laws. Stronger leadership, by involving stakeholders in national health IT boards, is suggested to achieve goals. The medical-governance model enacts governance within and by eHealth communities grounded in evidence and trust. The authors of papers addressing this model argue that evidence-based medicine should be the basis for the development of political-governance strategies. The internet and global business model put international business actors in dominant roles in eHealth governance, challenges the jurisdictions of nation-states, and limits the influence of international health actors, such as the World Health Organization. The authors of papers that address this model envision a dystopian future, especially for the governance of health data and services on the internet, and they argue for action by global health authorities. In the self-governance model, governance is characterized by shifting, dynamic tensions: governance and control of the individual by their submission to eHealth versus self-governance within eHealth by empowered, conscious citizens.

On the basis of this review, we conclude that to achieve health policy goals in large-scale eHealth policy programs, collective negotiations between nation-states, global policy actors, medical and self-governance actors, and global business and industry actors are essential. Digital technology affordances present opportunities for both benefit and harm concerning the realization of health policy goals, a dynamic that future studies should scrutinize. Technological affordances and both optimistic and pessimistic views deserve serious consideration.

According to our findings, further research is needed to produce knowledge about

1. How large-scale eHealth programs are realizing national and international health goals through collective negotiations
2. How the interference dilemmas between models are (creatively) accommodated and dealt with by patients or consumers to obtain quality and equal access
3. How the consequences of interference between models are (creatively) co-managed by global vendors, regional, national, and international governmental actors, and national and international nongovernment organizations to achieve health policy goals?

### Acknowledgments

The authors are grateful to the research librarian Karianne Lind, who performed the search and was an outstanding resource concerning search terms and technical-search issues. The work was funded by the Norwegian Centre for eHealth Research.

## Abstract

**Background:** The introduction of next-generation sequencing (NGS) into molecular cancer diagnostics has led to an increase in the data available for the identification and evaluation of driver mutations and for defining personalized cancer treatment regimens. The meaningful combination of omics data, ie, pathogenic gene variants and alterations with other patient data, to understand the full picture of malignancy has been challenging.

**Objective:** This study describes the implementation of a system capable of processing, analyzing, and subsequently combining NGS data with other clinical patient data for analysis within and across institutions.

**Methods:** On the basis of the already existing NGS analysis workflows for the identification of malignant gene variants at the Institute of Pathology of the University Hospital Erlangen, we defined basic requirements on an NGS processing and analysis pipeline and implemented a pipeline based on the GEMINI (GENome MINing) open source genetic variation database. For the purpose of validation, this pipeline was applied to data from the 1000 Genomes Project and subsequently to NGS data derived from 206 patients of a local hospital. We further integrated the pipeline into existing structures of data integration centers at the University Hospital Erlangen and combined NGS data with local nongenomic patient-derived data available in Fast Healthcare Interoperability Resources format.

**Results:** Using data from the 1000 Genomes Project and from the patient cohort as input, the implemented system produced the same results as already established methodologies. Further, it satisfied all our identified requirements and was successfully integrated into the existing infrastructure. Finally, we showed in an exemplary analysis how the data could be quickly loaded into and analyzed in KETOS, a web-based analysis platform for statistical analysis and clinical decision support.

**Conclusions:** This study demonstrates that the GEMINI open source database can be augmented to create an NGS analysis pipeline. The pipeline generates high-quality results consistent with the already established workflows for gene variant annotation and pathological evaluation. We further demonstrate how NGS-derived genomic and other clinical data can be combined for further statistical analysis, thereby providing for data integration using standardized vocabularies and methods. Finally, we demonstrate the feasibility of the pipeline integration into hospital workflows by providing an exemplary integration into the data integration center infrastructure, which is currently being established across Germany.

## Introduction

### Background

Combining omics data with other clinical patient data has been the focus of multiple studies in the past years [1-3]. In particular, the emergence and widespread use of next-generation sequencing (NGS) for the identification of pathological gene variants has led to an increase in the amount of data available for diagnosis. This has directly improved the quality of medical care for many diseases [4-6]. The meaningful combination of NGS data with other patient data from varying sources has been challenging for a number of reasons. First, the amount of data generated by NGS is vast compared to other data such as laboratory and clinical data, data derived from classical diagnostic tests, and demographic data, for example, age and gender. Second, NGS data typically contains many data points, which might not be relevant for subsequent analysis. Third, NGS data are highly sensitive in terms of privacy and more difficult to anonymize in a meaningful way. Therefore, any analysis within and across institutions will have to be carefully considered and crafted in a privacy-preserving manner. Many different studies have been conducted to investigate the feasibility of directly integrating omics data into clinical data repositories such as OMOP (Observational Medical Outcomes Partnership) [7], i2b2 (informatics for integrating biology and the bedside), and transMART [2]. The OHDSI-OMOP (Observational Health Data Sciences and Informatics-OMOP) common data model (CDM) focuses on observational research, and i2b2 focuses on the integration of different types of data into 1 clinical repository. These systems require an extra genomics pipeline to be run before the data can be loaded and integrated into the data repositories. Many of the proposed methods are not optimized for initial data investigation, automatic annotation of the data, or privacy-preserving cross-hospital analysis.

This study focusses on bridging this gap by creating a system that supports the whole process. It starts from variant call format (VCF) files. The data are then annotated and preanalyzed. In the final step, selected genomics data are combined with other structured and standardized patient data in 1 data set in a table format for further statistical analysis. We achieve this by extending the open source framework GEMINI (GENome MINing) [8]. It allows a user to load VCF files and places genetic variants, sample phenotypes and genotypes, as well as genome annotations into 1 database. This supports powerful exploration of genetic variations for disease and population genetics. GEMINI makes it possible to analyze the NGS data using structured query language (SQL), which allows researchers to filter variants by clinical relevance, rarity, and read quality. Our proposed system then combines GEMINI with the Fast Healthcare Interoperability Resources (FHIR) [9], a standard for health care data exchange. FHIR describes the clinical information in so-called resources. These modular components describe different elements found in electronic

health records, for example, a patient or a clinical observation such as a laboratory result. It was developed to address the shortcomings of the previously developed HL7 clinical care document standard. The FHIR standard aims to improve interoperability, and its lightweight nature and direct use of common data formats such as JSON and XML allows it to easily integrate with lightweight web services, similar to the ones created in the pipeline described here.

In order to create a pipeline on standardized data such as FHIR, heterogenous hospital data need to be transformed into a standardized format first. The German Medical Informatics Initiative (MI-I) [10] has recently funded 4 consortia of mainly university hospitals across Germany to investigate how heterogenous clinical data, including omics data, can be integrated into clinical data repositories. One aim of the MI-I is to establish data integration centers (DICs), which are the backbone of the cross-hospital and cross-consortia communication. The DICs will provide different services, including data integration, data harmonization, standardized data repositories, consent management, and ID management [11-14]. This study builds on efforts of 2 use cases from the MIRACUM (Medical Informatics in Research and Care in University Medicine) [14], particularly on 1 use case, which aims to establish a genomics pipeline to support NGS data interpretation and clinical decision making at molecular tumor boards. This MIRACUM-Pipe [15], similar to other genomics pipelines, creates VCF files in the process. These VCF files provide a good point of integration for further data analysis beyond the use for the molecular tumor board. Another use case of the MIRACUM consortium focuses on analyzing data within and across hospitals in a privacy-preserving manner, as well as deploying prediction and decision support models in a clinical context.

### Aim of the Study

In order to treat individual patients within the molecular tumor board, individual sequencing data are generated in VCF. Our study supports research by building on these data, aggregating them across multiple patients and enriching them with clinical data. These integrated data sets are analyzed with open-source analysis tools and frameworks to generate or validate hypotheses. Our proposed system extends GEMINI with multiple web services and a user interface to support the whole data flow as well as the subsequent integration with the already established FHIR [9] data repository, KETOS [16], and DataSHIELD [17] platforms for statistical analysis. To validate our approach, we implemented and applied this data analysis pipeline to data from the 1000 Genomes Project, which yielded highly consistent results. We then applied our pipeline to high-throughput gene panel sequencing data from a cohort of 206 patients from the Institute of Pathology of the University Hospital Erlangen and compared the findings with the results of the established Illumina genomics pipeline [18]. Finally, as a proof of concept, we combined the selected data from this patient cohort with diagnosis codes from the local FHIR server

and analyzed the correlation between locations based on the diagnoses and gene mutations to demonstrate one potential use of the system.

## Methods

### Common Requirements for NGS Analysis

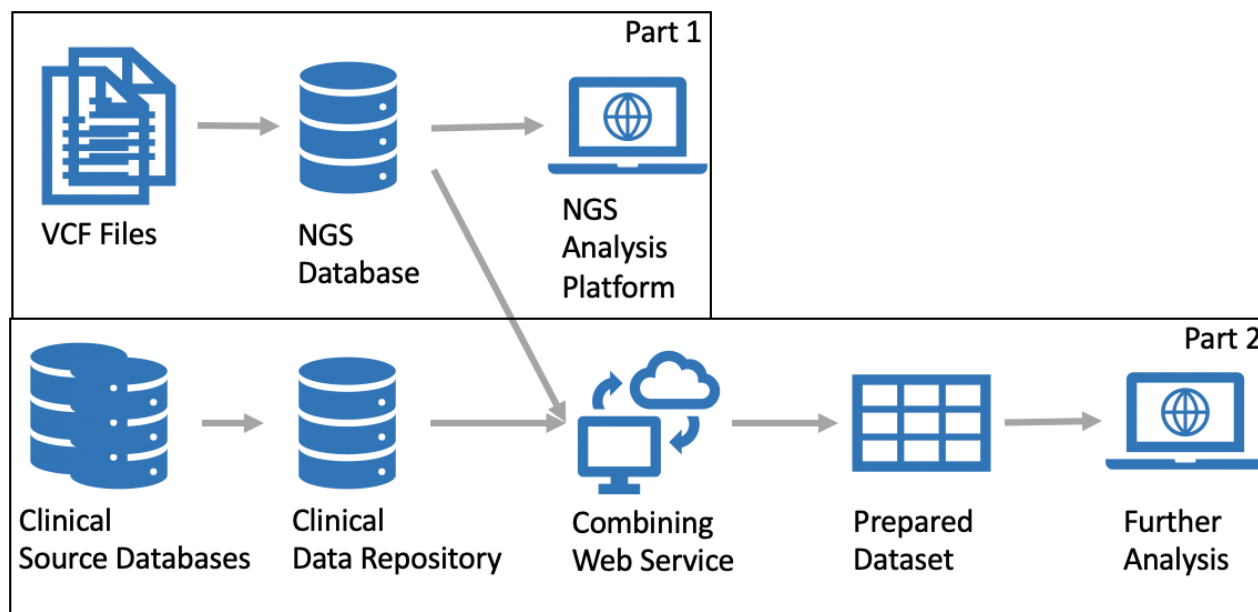

To understand the requirements for NGS analysis, we studied the status quo of the Institute of Pathology of the University Hospital Erlangen. The institute analyses gene mutations by using a commercial pipeline provided by Illumina and presents its findings to the local molecular tumor board. A detailed description of the DNA and RNA library preparations from patient tissues can be found in [Multimedia Appendix 1](#). The pipeline currently used by the institute has limited capabilities when it comes to performing cross-patient analysis and is not easily integrated with other open-source solutions. Therefore, the following requirements were defined, which need to be met: be on-premises, be open-source, deliver the same results as a commercial product, allow analysis across multiple patients, and possibility of web-based integration with existing and new infrastructure to be developed.

### Data Analysis

The biggest drawback of the current system is that it does not support cross-patient analysis and integration of additional

patient data, as the patient data are distributed across multiple systems in the hospital. The system therefore does not currently support a way to, for example, correlate a patient's diagnosis with particular gene mutations as is done in our exemplary analysis shown below. We therefore propose a new pipeline, which improves on these drawbacks. [Figure 1](#) depicts the multistep analysis workflow of such a genomics pipeline. In the first step, VCF files are uploaded into a database for gene annotation and, subsequently, gene variant filtering and analysis. To allow further processing of the data, it is crucial to filter variants that are irrelevant for a particular research question. The amount of data and noise must be reduced. For this, researchers need to be able to query and filter the genomic database. This would satisfy any research only focusing on NGS data; however, in a clinical setting, NGS data become truly meaningful when clinical patient data are available. To achieve this, a standardized way to combine genomics data with clinical data is essential. Finally, combined data needs to be transformed to a common format that can easily be analyzed, processed further, and integrated into existing data analysis frameworks. The resulting system described in [Figure 1](#) can be split into 2 larger parts: (1) Part 1: an NGS processing and analysis pipeline and (2) Part 2: a system for integrating clinical patient data for further analysis.

**Figure 1.** Genomics pipeline and analysis system. NGS: next-generation sequencing; VCF: variant call format.

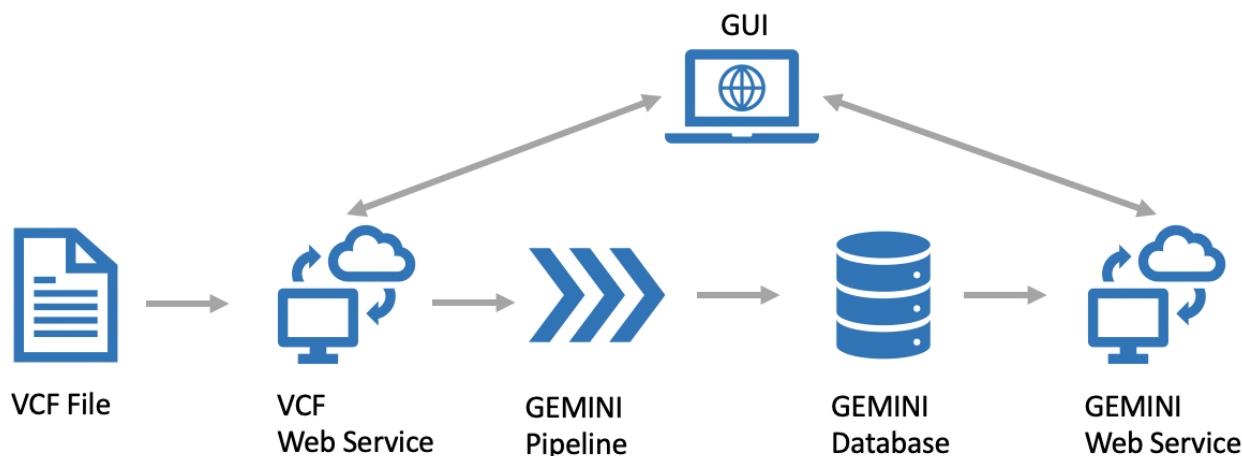

### Part 1: NGS Processing and Analysis Pipeline

[Figure 2](#) shows the first part of the architecture of the implemented genomics pipeline and analysis system. The proposed system includes a graphical user interface (GUI, [Figure](#)

[2](#)), which supports all steps. The GUI is used to upload a VCF file via the VCF web service, which is then processed and loaded into GEMINI via the GEMINI web service. The web service then uses our integrated GEMINI pipeline ([Figure 3](#)) to process and load the data into GEMINI.

**Figure 2.** Part 1: Next-generation sequencing processing and analysis pipeline architecture. GUI: graphical user interface; VCF: variant call format; GEMINI: GEnome MINIng.

**Figure 3.** GEMINI pipeline schema. SnpEff: single nucleotide polymorphism effect; GEMINI: GEnome MINIng.

This GEMINI pipeline (Figure 3) first decomposes the VCF file using the Variant Tools software [19] decompose functionality, which splits up multiallelic variants of a VCF file, resulting in a separate row for each reference sequence/alternative sequence pair. The decomposed VCF file is then normalized using the normalize function of the Variant Tools software. This step ensures that each VCF entry is left aligned and parsimonious, as described by Tan et al [20]. The resulting VCF file is then automatically annotated using the SNP (single nucleotide polymorphism) effect (SnpEff) tool, reported by Cingolani et al [21]. The SnpEff annotation process enriches the VCF file with information about possible effects or malignancies. One important functionality of GEMINI is the addition of multiple extra annotations during the load process.

This is the last step of our GEMINI pipeline (GEMINI-Load, Figure 3) and includes the following annotation sources: 1000 Genomes Project (population data, allele frequencies) [22], dbSNP (reference snp IDs according to the National Center of Biotechnology Information) [23], and ClinVar (disease information, eg, disease name or clinical relevance) [24].

Once loaded, data can be analyzed using the user interface (GUI, Figure 4) and the GEMINI web service. The user interface allows one to download a GEMINI database in the form of an SQLite file for further use. It further implements a web-based query tool for the GEMINI database. The advantage of this web-based query tool is that the researcher does not need to learn how to use the command line tool, while still providing full GEMINI query functionality.

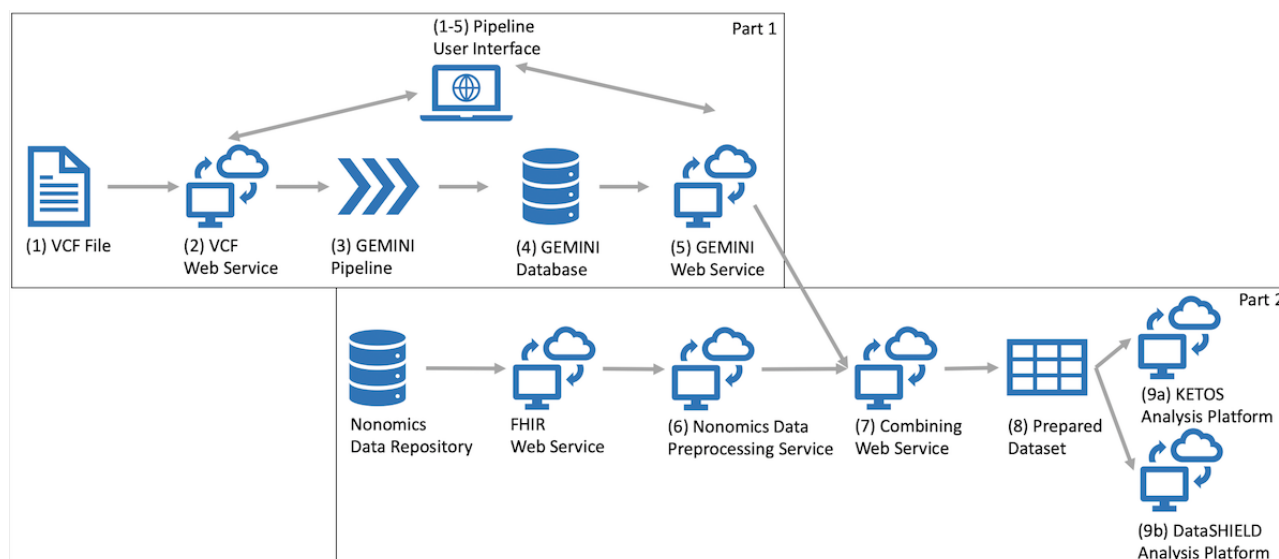

**Figure 4.** Exemplified user interface.

## Part 2: A System for Integrating Clinical Patient Data for Further Analysis

Figure 5 depicts the structure of the complete system (numbers indicate the order of the executable steps). A VCF file (Step 1) is read, annotated, and loaded into GEMINI (steps 2-4). Then, NGS data are combined with nonomics, clinical patient data in an FHIR format using the patient ID as a link in a prepared data set (steps 5-8) for the final analysis. The combining of the NGS and clinical patient data is performed by the combining web service, which is described in more detail with an example in

the Results section. One of the advantages of an on-premises open source solution is the straightforward extendibility with the other already established web services. Here, we used the KETOS analysis platform established as part of the local DIC. Further, the creation of a prepared data set in the form of a comma-separated values (CSV) file allows a direct import into the DataSHIELD platform for privacy-preserving cross-hospital analysis (steps 8, 9a, and 9b). DataSHIELD supports this as its underlying data warehouse supports the loading of CSV files for further analysis.

**Figure 5.** Combining genomics and patient data. VCF: variant call format; GEMINI: GENome MINIng; FHIR: Fast Healthcare Interoperability Resources.

## Results

### Overview

We implemented and deployed the above-described architecture at the University Hospital Erlangen. Its functionality was then validated by comparing the results of our analysis system to the results from the 1000 Genomes Project [22] and subsequently by assessing the ability of the system to identify relevant tumor-associated gene variants. Finally, we used the system to combine gene mutation data from 206 patients with diagnosis codes from the local FHIR data repository. We analyzed the resulting prepared data set by using KETOS and Jupyter

Notebook (interactive cell-based code development in a web browser) [25].

### Comparison with the 1000 Genomes Project

To demonstrate the accurate functionality of the pipeline, we investigated the genomic variations of the X-chromosome in a cohort of 1092 individuals, which were studied in the initial phase of the 1000 Genomes Project [26]. First, we loaded the publicly available VCF file data supplied by the study into a GEMINI database by using our pipeline. Then, we compared the variation data in our database to the results from the 1000 Genomes Project [27] (Table 1).

**Table 1.** Comparison of the statistical evaluation of the 1000 Genomes Project and GEMINI (GEnome MINIng) pipeline.

Mutations	1000 Genomes Project (n)	GEMINI (n)
<b>Single nucleotide polymorphisms</b>		
Total variants	~1,300,000	1,275,275
Average per sample	~105,000	104,757
<b>Indels</b>		
Total variants	~59,000	59,157
Average per sample	~13,000	12,715
<b>Large deletions</b>		
Total variants	432	432
Average per sample	26	26

As shown in Table 1, results generated with our system were identical to the results generated by the 1000 Genomes Project. The analysis, including converting and loading the data into GEMINI, took approximately 3 hours to run on a MacBook Pro (15-inch, 2016)-System with 2.7 GHz Intel Core i7-Processor and 16 GB 2133 MHz LPDDR3-RAM. Once loaded, the SQL queries took approximately 120 seconds to complete. This clearly demonstrates that the bottleneck is loading the data rather than the subsequent analysis using GEMINI.

### Comparison With Illumina Pipeline and Genomic Analysis

#### Single Patient Analysis

We loaded individual patient-derived VCF files into the GEMINI database and prepared an SQL query according to

established filter criteria used in the Illumina pipeline at the Institute of Pathology. In the first iteration, the resulting SQL query (Multimedia Appendix 2) filtered the following: all variants that failed to pass any of the variant quality filters, all variants that displayed a low impact in regard to protein functionality, and all variants that were not considered pathogenic as they did not change the coding protein (eg, synonymous variants, intronic variants, upstream/downstream variants). In addition, all variants with a population-based allele frequency of  $\geq 2\%$  were also excluded. Table 2 shows an exemplary comparison of the results from the Illumina versus the GEMINI pipeline. Illumina VariantStudio yielded 16 variants, while GEMINI yielded 15 variants. The Illumina VariantStudio included chromosome 4 position 10085736. GEMINI also included chromosome 9 position 21970916.

**Table 2.** Comparison of the filtered results of the mutations in the GEMINI (GEName MINIng) and Illumina pipeline.

Based on this result, we revised the filter criteria ([Multimedia Appendix 3](#)) so that only variants with the filter impact\_severity *high* or one of the impact types (disruptive\_inframe\_deletion, disruptive\_inframe\_insertion, missense\_variant) were included in the results. Furthermore, the ClinVar database was used to assess the pathogenicity of individual gene alterations, which is readily available in the annotated GEMINI database. All mutations that were classified as benign, likely\_benign, and benign/likely\_benign according to the ClinVar database were deleted from the data set. Mutations without known ClinVar status were kept and manually classified by interrogating web-based variant repositories. The adjusted SQL query yielded the same results as the Illumina pipeline, which qualifies the open source solution for routine use in clinical practice. Finally, the automation of the filtering steps saves hands-on time of approximately 30 minutes per patient analysis.

### Multiple Patient Analysis

We used gene sequencing data of 206 patients from the University Hospital Erlangen. To analyze the data, the 206 individual VCF files were first merged and then loaded into GEMINI. Each file had a size of 57 MB, which adds up to a total file size of 12 GB. The merged VCF file had a size of 4.8 GB, and the GEMINI database a size of 664 MB. To analyze the whole patient cohort, we first created an SQL query to provide simple descriptive statistics of the cohort, such as the overall number of mutations by *impact\_severity* and *type* (snp, indel). As expected, most mutations were classified with a low impact severity. We then further analyzed the merged data with another SQL query to determine the occurrence of gene mutations, impact, and codon\_change ([Multimedia Appendix 4](#)). This analysis revealed that impact\_severity is not a suitable filter for dichotomizing high impact variants from synonymous

variants. Therefore, specific impacts (impact column) were used instead. In addition, the same filter criteria as described for the adjusted query were used for further analysis ([Multimedia Appendix 3](#)). Looking at the results in more detail, it became clear that many of the mutations were sequencing artefacts, which would have to be excluded before further analysis. Especially critical is the fact that merging of multiple VCF files leads to information loss and reduces the quality of the sequencing data. We discovered that the merge function vcf-merge of VCFtools only keeps the lowest passed quality filter for each variant. This means that a higher quality grade will only be listed in the FILTER column if it was passed by each sample for a variant. Other merge functions such as the merge function of BCFtools allow the user to choose between either keeping the lowest passed or the highest passed filter for each variant. However, in all cases, the quality criteria of each individual sample cannot be reconstructed. This poses a potential problem for further analysis as 1 low-quality read for a variant in 1 sample would obscure potential good results in others, leading to the exclusion of good-quality reads; vice versa, 1 high-quality read may mask low-quality reads, which might impact the data analysis. A solution for this problem is to either exclude particularly poor-quality samples before joint analysis is executed or to load and analyze samples individually in an automated way. This will preserve sample quality information in a combined data set.

### Creating a Prepared Data Set for Combined Analysis

To create a combined prepared data set and to make it available for further analysis, we integrated the combining web service with the KETOS platform by making the web service, which combines the NGS data with the nonomics data, available to the KETOS host by using internet protocol address restriction

as well as password protection. The combined prepared data set is a combined subset of all the available NGS and clinical data, which were prepared for 1 specific research question. The combining web service data for a particular research question is identified using JSON syntax. It includes an *fhir* part to specify patient data in the form of the required FHIR resources and a GEMINI part to specify the filtered variants to be included. The specification also requires patient IDs to identify the patient cohort for further analysis (see [Multimedia Appendix 5](#)). In an initial combining web service specification, we required the user to specify the exact variant positions and alleles. This

returned a data set in which the variant-specific fields are connected to the variant via a prefix, which is added to all extracted variant fields. The prefix contains the chromosome, chromosomal location of the variant, as well as the nonreference allele, for example, chrX#154158284#154158285#C#. The web service collects the data for the prepared data set and returns the data either as a JSON array or as a CSV file. The resulting data set in the CSV format is then created as shown in [Table 3](#). It contains 1 row for each patient. Each row includes the patient ID as well as other fields specified by the user.

**Table 3.** Example of a prepared data set.<sup>a</sup>

Patient_ID	Gender	Date of birth	Disease	<prefix> <sup>b</sup> ref	<prefix> <sup>b</sup> alt	<prefix> <sup>b</sup> gts
28	male	01.10.41	1	G	C	C

<sup>a</sup>This table shows only the examples of values.

<sup>b</sup><prefix> is the concatenation of the chromosome, chromosomal location of the variant, and nonreference allele, eg, chrX#154158284#154158285#C#—this would, for example, result in the following column name: chrX#154158284#154158285#C#ref.

In our further analysis, we found this specification of the combining web service to be limiting. We therefore extended the web service to allow the researcher to specify the GEMINI query used to collect the NGS data directly in SQL, rather than being limited to extracting fields by variant position only. The resulting request specification is analogous to the one described in [Multimedia Appendix 5](#), except for the following extending fields inside the GEMINI part: *sql\_mode*, *sql*, *columns*, *rows*. This allowed us to create an example of a data set by using a query similar to that shown in [Multimedia Appendix 6](#), which

resulted in a data set similar to [Table 4](#). This allowed us to avoid information loss regarding read quality, as the combining web service can query an individual database for each patient, thereby omitting data-merging steps. The resulting data set could then be imported into the KETOS analysis environment where further analysis could be conducted within a Jupyter Notebook [25] by using a researcher's favorite tools. Further, the comma-separated nature of the data set means that it could also be imported into DataSHIELD, which supports further privacy-preserving analysis across institutions.

**Table 4.** Format of the initial raw data set.<sup>a</sup>

Patient_ID <sup>b</sup>	Gender <sup>c</sup>	Date of birth <sup>d</sup>	Diagnosis <sup>e</sup> (ICD <sup>f</sup> 10 Code)	Gene <sup>h</sup>
PSEUDO-ID-1	Female	01.01.50	2019-01-01T00:00:00+00:00	<i>PIK3CB</i>
PSEUDO-ID-2	Male	01.01.50	2019-01-01T00:00:00+00:00	<i>PIK3CB</i>
PSEUDO-ID-3	Male	01.01.50	-	-
PSEUDO-ID-4	Male	01.01.50	2019-01-01T00:00:00+00:00	-

<sup>a</sup>Since the combined data set comprised 206 patients, 135 diagnoses, and 152 genes, values shown in this table are only examples, as the entire data cannot be represented here.

<sup>b</sup>Examples of IDs of patients.

<sup>c</sup>Examples of genders.

<sup>d</sup>Examples of birth dates of patients.

<sup>e</sup>Example value, C20 or C61; timestamp diagnosis. (One column per diagnosis - if there is no diagnosis for a patient, the column will be empty in this patient's row.)

<sup>f</sup>International Classification of Diseases.

<sup>h</sup>Gene name examples. (One column per Gene - if there is no gene mutation for a patient, the column will be empty in this patient's row.)

## Exemplary Analysis of Tumor Entity and Diagnosis Inside KETOS by Using Jupyter Notebook

As a proof of concept for our system, we created a data set with combined diagnostics and tumor mutational data for further analysis. The initial data set included 206 patients. In the first step, we identified 135 cancer-related diagnosis codes across our cohort. We then used the revised GEMINI query ([Multimedia Appendix 3](#)) to collect the gene mutations across our cohort. The combined data set comprised 206 patients, 135

diagnoses, and 152 genes. The final raw data set had the format shown in [Table 4](#).

Using Jupyter Notebook in one of the analysis environments inside the locally installed KETOS data analysis platform; we requested the data from our combining web service. Patients without diagnosis were removed. We removed all secondary tumor diagnoses from our data set and focused on primary tumor locations. Tumor entities represented by less than 4 patients were regarded as underrepresented and were also removed prior

to further analysis. This yielded a sample group of 124 patients across 12 tumor entities. A total of 142 unique genes with mutations were identified across this population. As a proof of principle, we aimed to identify the driver mutations for each tumor entity. Therefore, we included only genes that were mutated in more than 50% of the patients, resulting in the heat map depicted in Figure 6. This filtering step identified 14 frequently mutated genes within the patient cohort, mainly *bona fide* tumor suppressor genes such as *APC*, *ATM*, *BRCA2*, or *TP53* and well-known protooncogenes such as *GNAS*, *KRAS*, and *NRAS*. Notably, this analysis revealed tumor characteristic

mutational profiles. For instance, the colorectal cancer cohort displayed a characteristic rate of *APC*, *TP53*, *KRAS*, and *NRAS* mutations when compared to previously reported data [28]. Likewise, *KRAS* mutations were highly prevalent in the pancreatic cancer cohort, a malignancy with an observed *KRAS* mutation rate of up to 95% [29]. Since patients with cancers were distributed across multiple sites and the number of patients for some locations was small, a very accurate distribution by location might have been lost in the analysis process. This could be remedied using a larger sample size and factoring the multisite cancers into the analysis.

**Figure 6.** Distribution (%) of the gene mutations by location. Y-axis: location (number of patients); x-axis: gene, eg, 80% for stomach for *TET2* means that 4 of 5 patients with stomach cancer had a mutation in *TET2*.

## Discussion

### Overview

We presented an open-source web-based NGS annotation pipeline based on the GEMINI database, which produced the same results as the established Illumina pipeline used in routine diagnostics. We then extended our pipeline to combine the annotated NGS data with other clinical data and demonstrated the feasibility of our approach in an exemplary analysis, which combined gene mutation data with clinical diagnosis codes.

The new pipeline improved on the current pipeline by supporting this cross-patient analysis. This allowed us to combine the NGS data with other patient data from other systems across the hospital in 1 data set. The source code of this project is open to the public and is available on GitHub [30].

Previous studies have investigated the integration of omics with other clinical data. In particular, 2 larger systems, which have recently seen efforts to achieve this integration, are the OHDSI-OMOP CDM and i2b2. Murphy et al [2] compared 3 different strategies for integrating omics data into i2b2, 2 of which combined omics and clinical data in the same database. The third approach is similar to the one described in this study. It kept omics data in a separate database. For the OMOP CDM, NGS data were integrated into 1 database with clinical data by creating additional tables for the omics data. All approaches had 1 thing in common that they did not provide a user interface for loading data into the respective databases. In contrast, our pipeline significantly improves usability by providing a user interface, which allows a user to process VCF files and load them into the GEMINI analysis database. Additionally, using an established omics database allowed us to fast-track querying and preanalysis of the genomics data, thereby significantly reducing the amount of data at an early stage in the process.

GEMINI is part of the pipeline used by the MIRACUM consortium and therefore provides us with a clear point of integration. This means that once the MIRACUM-Pipe has been established across the different DICs, it can potentially replace the Illumina pipeline and integrate directly with the solution described here.

### Generalizability of the Pipeline

In this paper, we focus on the integration with the DICs currently being established across Germany. However, as the system relies on common formats (VCF for NGS data and FHIR for clinical patient data), it could easily be applied to other hospitals. The FHIR format, in particular, is currently seeing a rise in popularity and as electronic health record vendors will provide more and more data in the FHIR format, establishing a local FHIR store with patient data should be feasible for many institutions. However, as with any standardized format, studies that have captured data in their own format or another standard format such as OMOP would have to convert their data into FHIR formatted data in order to take advantage of this solution. As the whole solution can be deployed on premises, acceptance for the solution should be high as the deployment can be tailored to the specific needs of individual institutions and no data has to leave the institution at any time. In our example, we show how the prepared data sets, which result from the pipeline, can be analyzed in Jupyter Notebook and KETOS, a web-based analysis platform. Generally, the prepared data sets in the CSV format could be read into many other analysis platforms such as DataSHIELD, converted into table-like formats, and analyzed further.

### Potential Use of the System

We have demonstrated in this paper how our system can be used to combine diagnoses with NGS data for further analysis. Connecting the system to an FHIR repository of standardized data means that there is a great opportunity to undertake further analyses in the future with other data available in an FHIR store. The MIRACUM FHIR store at the University Hospital in Erlangen currently has information about patients, encounters, diagnoses, laboratory results, procedures, and medications. The system described here would, for example, support further investigation of the correlation between the diagnosis of COVID-19, disease outcome from hospital discharge information, and gene mutations. The prerequisite for this would be that the gene sequences of respective patients are sequenced as part of a wider investigation.

### Lessons Learned

We were able to augment the existing GEMINI software with web services. The resulting pipeline, which is based on the open source project, could be hosted on premises. It fulfilled the requirement of producing the same results as the established commercial pipeline. One of the biggest drawbacks of the GEMINI database is that it does not allow the uploading of the data of multiple patients directly into 1 database. Instead, data from multiple patients have to be merged first, which leads to a loss of information regarding the sequencing quality for a particular variant. This may impact analysis and data interpretation as low-quality reads and high-quality reads would

be interpreted in the same way. However, this limitation can be augmented by preselecting files with good-quality reads or loading each file individually and focusing only on variants that are relevant to the particular research question. The combining web service in `sql_mode` described above can also be used for this type of analysis by simply requesting GEMINI data from individual databases. Once loaded into the GEMINI database, queries for a particular variant were very fast and results were returned within seconds, making the analysis across multiple patients feasible.

### Limitations

The web-based user interface provides direct access to different databases. However, exporting prepared data sets is currently not supported and has to be triggered using a web service representational state transfer call. Therefore, the platform presented here requires the user to be proficient with SQL and basic programming skills in order to extract and analyze the data, making it unsuitable for users with no programming or SQL skills. The chosen method of prefiltering data for further analysis using an established, fast open source tool allows one to avoid large data volumes. However, it also limits the explorative analysis of NGS with other patient data. The medical device regulations in Germany approves the use of the system described above for research purposes only. The MIRACUM DICs follow these regulations. The reliance on FHIR requires the infrastructure to provide an FHIR server. However, the MI-I initiative has already set FHIR as the format of choice for interconsortia communication [31].

### Future Directions

In this study, we focused on 1 hospital to show how a potential analysis can be made possible within a hospital. In the future, it would be of interest to duplicate the platform across multiple hospitals to establish cross-hospital analysis pipelines and run analyses across institutions by using DataSHIELD. Pipeline automatization, ie, automated variant annotation and execution of predefined variant filtering/classification steps as well as automated inclusion of results in clinical reports could lead to significant time savings. Another prospective extension would be the integration of therapy suggestions from different web-based databases such as Somatic Mutations In Cancer [32], My Cancer Genome [33], and ClinicalTrials.gov [34]. The prepared data set or combining web service should be integrated further into existing workflows to automate data selection and preparation as well as to make the data provision easier. The FHIR standard for patient data is constantly being developed and has been standardized to integrate omics data directly. Our approach could be extended to load selected data directly into an FHIR database, which would make explorative analysis easier.

### Conclusion

In this study, we successfully demonstrated how NGS genomics data can be combined with FHIR clinical data to provide accessory analysis to existing gene variant analysis solutions in clinical settings. The chosen method of prefiltering data for further analysis by using an established database, which is based on the fast GEMINI open source tool, means that large data

volumes can be avoided. In addition, we showed that a pipeline and web services built on open-source tools delivered the same results as a commercial product and could be hosted on the premises, and be integrated well within a clinical DIC, building

on existing structures, and benefiting from the data standardization DICs provide. Finally, we showed how the system could be used to create and analyze a data set, which included gene mutation and diagnosis data.

## Acknowledgments

The present work was performed in fulfilment of the requirements for obtaining the degree “Dr. rer. biol. hum.” from the Friedrich-Alexander-Universität Erlangen-Nürnberg (JG). This work was supported by grants from MIRACUM project, which is funded by the German Ministry for Education and Research (BMBF) (FKZ 01ZZ1801A).

## Abstract

**Background:** In the prevention and control of infectious diseases, previous research on the application of big data technology has mainly focused on the early warning and early monitoring of infectious diseases. Although the application of big data technology for COVID-19 warning and monitoring remain important tasks, prevention of the disease's rapid spread and reduction of its impact on society are currently the most pressing challenges for the application of big data technology during the COVID-19 pandemic. After the outbreak of COVID-19 in Wuhan, the Chinese government and nongovernmental organizations actively used big data technology to prevent, contain, and control the spread of COVID-19.

**Objective:** The aim of this study is to discuss the application of big data technology to prevent, contain, and control COVID-19 in China; draw lessons; and make recommendations.

**Methods:** We discuss the data collection methods and key data information that existed in China before the outbreak of COVID-19 and how these data contributed to the prevention and control of COVID-19. Next, we discuss China's new data collection methods and new information assembled after the outbreak of COVID-19. Based on the data and information collected in China, we analyzed the application of big data technology from the perspectives of data sources, data application logic, data application level, and application results. In addition, we analyzed the issues, challenges, and responses encountered by China in the application of big data technology from four perspectives: data access, data use, data sharing, and data protection. Suggestions for improvements are made for data collection, data circulation, data innovation, and data security to help understand China's response to the epidemic and to provide lessons for other countries' prevention and control of COVID-19.

**Results:** In the process of the prevention and control of COVID-19 in China, big data technology has played an important role in personal tracking, surveillance and early warning, tracking of the virus's sources, drug screening, medical treatment, resource allocation, and production recovery. The data used included location and travel data, medical and health data, news media data, government data, online consumption data, data collected by intelligent equipment, and epidemic prevention data. We identified a number of big data problems including low efficiency of data collection, difficulty in guaranteeing data quality, low efficiency of data use, lack of timely data sharing, and data privacy protection issues. To address these problems, we suggest unified data collection standards, innovative use of data, accelerated exchange and circulation of data, and a detailed and rigorous data protection system.

**Conclusions:** China has used big data technology to prevent and control COVID-19 in a timely manner. To prevent and control infectious diseases, countries must collect, clean, and integrate data from a wide range of sources; use big data technology to analyze a wide range of big data; create platforms for data analyses and sharing; and address privacy issues in the collection and use of big data.

**KEYWORDS**

big data; COVID-19; disease prevention and control

**Introduction**

Big data are complex data sets that traditional data processing systems cannot efficiently and economically store, manage, or process. Compared to traditional data, big data has five “V” characteristics: volume, variety, velocity, veracity, and value [1]. In the digital economy era, data are a fundamental strategic resource for countries, enhancing the government’s social governance capacity and public service levels. Big data technology supports a wide range of health care functions, including clinical decision support, population health management, and disease monitoring [2,3]. By discovering correlations in data and understanding patterns and trends, big data technology can improve health care, save lives, and reduce health system costs. Through the analysis of patient characteristics and patient nursing costs, the most clinical cost-effective treatment methods can be determined; the application of big data analysis technology to patient files can identify individuals who may benefit from preventive care or lifestyle changes; the collection and analysis of medical procedure data can determine the most valuable patient nursing programs; and through analysis and drug treatment data, the health status of the population can be monitored and the health status of patients maximized through drug treatments [4]. In the prevention and control of pandemics, large data technology can be used for epidemic prediction, pandemic alerts, tracking and tracing of infected individuals, identifying potential pharmacological treatments, and optimal resource allocations within the health system [5-10].

Big data analytics is fast becoming a crucial component for the modeling of virus transmission, aiding infection control measures and emergency response analyses required during local or international disease outbreaks [11]. In the prevention and control of infectious diseases, previous research on the application of big data technology has mainly focused on the early warning and monitoring of infectious diseases. Four data streams are used for early warning and monitoring infectious diseases: medical health data, participatory syndromic data, internet data, and nonhealth digital data [12]. Medical health data include electronic records of medical institutions, medical insurance claims, discharge records, and death certificates. Such data can provide information about disease conditions and can be monitored at various levels or aggregated by geographic location before reporting [13-15]. Participatory syndromic data are data from crowdsources, where volunteers report a series of symptoms on their own. These data streams do not provide the confirmed infection status of specific pathogens but provide personal-level health data in almost real time [16-18]. Internet data does not depend on a specific patient or medical condition but originates from the use of internet search engines, social media, or online consumption. In addition to self-reporting health results, these data streams also provide information about health-related behaviors, including contact and travel patterns,

and vaccine status, which are key elements to understanding the spread of diseases [19-24]. Nonhealth digital data mainly include social and natural factors such as weather, temperature, humidity, population movement, transportation, infrastructure, and medical environment [25-28]. With the development of computer and space technology, geographic information system remote sensing is increasingly used in infectious disease monitoring and early disease warning research because of its powerful geospatial data acquisition, management, processing, analysis, and display capabilities [29,30].

Before the outbreak of COVID-19, China mainly used infectious disease case data reports for disease early warning and monitoring. In recent years, China has been working to advance the informationization process of medical institutions, store information related to medical services in computer network systems, and accumulate a large amount of medical service data. For example, the hospital information system (HIS) is an important source of medical health data. HIS mainly includes a hospital management information system, laboratory information system (LIS), medical image archive and communication system (picture archiving and communication system), radiation information management system (radiology information system), and clinical decision support system. The electronic medical record system (EMRS) in the medical and health departments includes data on patient name, treatment data, illnesses, test results, orders, operation records, and nursing records.

After experiencing the severe acute respiratory syndrome (SARS) outbreak in 2003, the Chinese government formulated plans to identify the early signs of infectious diseases, setting in law the requirement under the Emergency Regulations for Public Health Emergencies that units that discover infectious diseases must report the disease one level up within a specified time frame. These reports contain information on patient’s name, ID number, age, occupation, residential address, date of disease onset, date of diagnosis, type of infectious disease, and route of transmission. In addition, China has established a service network that links disease control institutions, hospitals, and primary medical and health institutions. Under the National Infectious Disease Report Information Management System (NIDRIMS), institutions immediately report new infectious disease cases online. Those institutions without direct network reporting capabilities were instructed to immediately report the case to the local district-level disease control institution and complete an infectious disease report card within 2 hours. Based on the newly entered data on the direct network reporting system and the historically accumulated infectious disease data, an automatic national infectious disease early warning and surveillance information system was created in April 2008, and an infectious disease monitoring data system trailed in December 2009. For example, a doctor diagnosing a patient with tuberculosis can use the test results to extract the information needed to complete the infectious disease report from the

patient's electronic medical records, which is submitted to the NIDRIMS. NIDRIMS can query the detailed information of the case to monitor and provide an early warning of infectious diseases. The national infectious disease early warning system and surveillance system significantly facilitated the prevention and control of infectious diseases in China. In the H7N9 epidemic in 2013, although the virus spread widely and affected more than ten Chinese provinces and cities, the actual number of infected people was only 132, with 29 deaths and no medical staff infected.

After the outbreak of COVID-19, the Chinese government and social organizations actively used big data technology to prevent and control the disease. At the Scheduling Meeting on Big Data Supporting the Prevention and Control of Corona Virus Disease 2019 held by the Ministry of Industry and Information Technology on January 26, 2020, a joint antiepidemic prevention and control mechanism was proposed, and big data analysis was mobilized to guide research and predict the epidemic's developments, including the deployment of antiepidemic work and monitoring the health of mobile personnel. On February 14, 2020, the government further ordered the use of digital technologies including big data, artificial intelligence (AI), and cloud computing to include epidemic monitoring and analysis, tracing of virus sources, epidemic prevention and treatment, and resource allocation.

Existing papers on COVID-19 big data provide limited discussion and analysis on specific big data applications [10,31]; address the application of big data in a subdivision of COVID-19 prevention and control, and discuss the application of specific types of data in the prevention and control of COVID-19

[6,7,30,32]; or mainly discuss the application methods and achievements of big data technology outside of China [8,9]. Adding to the existing literature, this paper reviews the data collection methods and data information that existed in China before the outbreak of COVID-19. We introduce China's post-COVID-19 data collection methods and data information analyses. Based on the increased data collected, China's experiences in applying big data technology for personnel tracking, epidemic surveillance, early warning, tracing of virus sources, drug screening, medical treatment, resource allocation, and production recovery are detailed. We also analyzed the issues, challenges, and responses encountered by China in the application of big data technology to prevent and control COVID-19 from four perspectives: data access, data use, data sharing, and data protection. Suggestions for further improvements are made from four perspectives, data collection, data circulation, data innovation, and data security, to help understand China's response to the epidemic and to provide lessons for other countries facing the COVID-19 pandemic.

## Methods

By June 2019, the number of mobile internet users in China was 847 million [33]. In recent years, the degree of informatization by the Chinese government and various social organizations has continuously improved. China's data collection methods and data reserves also increased. [Textbox 1](#) summarizes the pre-COVID-19 key data collection methods and data information that helped prevent and control COVID-19, while [Textbox 2](#) provides an outline of the newly added data collection methods and data information implemented after the outbreak of COVID-19.

**Textbox 1.** Pre-COVID-19 disease prevention and control data from government, commercial and public welfare sources and websites, academic papers, public reports, institutional reports, and fieldwork.

**Location information data**

- Telecommunication operators
  - Mobile phone signaling generates location data allowing the user's location to be identified and tracked based on the location of the base station. The acquisition of these data requires the authorization of the Public Security Department. In addition to operators, some government departments, large internet companies, and map service providers can apply for the acquisition of these data.
  - When applying for a mobile phone number, you need to provide the user's name, ID number, residential address, and other information, which can be accessed by the operator and government departments.
- Mobile payment
  - The electronic wallet is bound to the user's ID card and mobile phone number. The payee is usually a store or an enterprise and has location information on the map. Mobile payment is widely used in China.
- Takeaway
  - Can provide the user's residential address
- Online shopping
  - Requires mobile phone number and residential address
- Courier
  - Courier requires customer's ID card number, mobile phone number, and residential address.
- Internet Protocol address
  - Users will leave location information when they go online.

**Travel data**

- Ticket purchase information
  - Purchase of train tickets, plane tickets, ferry tickets, and bus tickets require the user's name, ID number, and mobile phone number information.
- Toll station vehicle information
  - At the entrance and exit of the road, the license plate number is bound to the ID card information.
- Taxi software
  - Online car-hailing software (Didi, Shenzhou special car, Shouqi car-hailing, etc) collect the departure and destination addresses.
- Map data
  - Automatically locates the user's location when running map software
- Card swipe information data
  - The bus and subway provide payment records.

**Medical health data**

- Electronic medical records
  - Includes data on patient name, treatment data, illnesses, test results, orders, operation records, and nursing records
- National Health Commission
  - Name, ID number, age, occupation, residential address, date of onset, date of diagnosis, and type of infectious disease when encountering infectious disease cases

**Internet Data**

- Consumer data
  - Online shopping

- News data
  - Online news media information
- Social data
  - Communicated by the public through social software
- Retrieve data
  - User search history

**Government data**

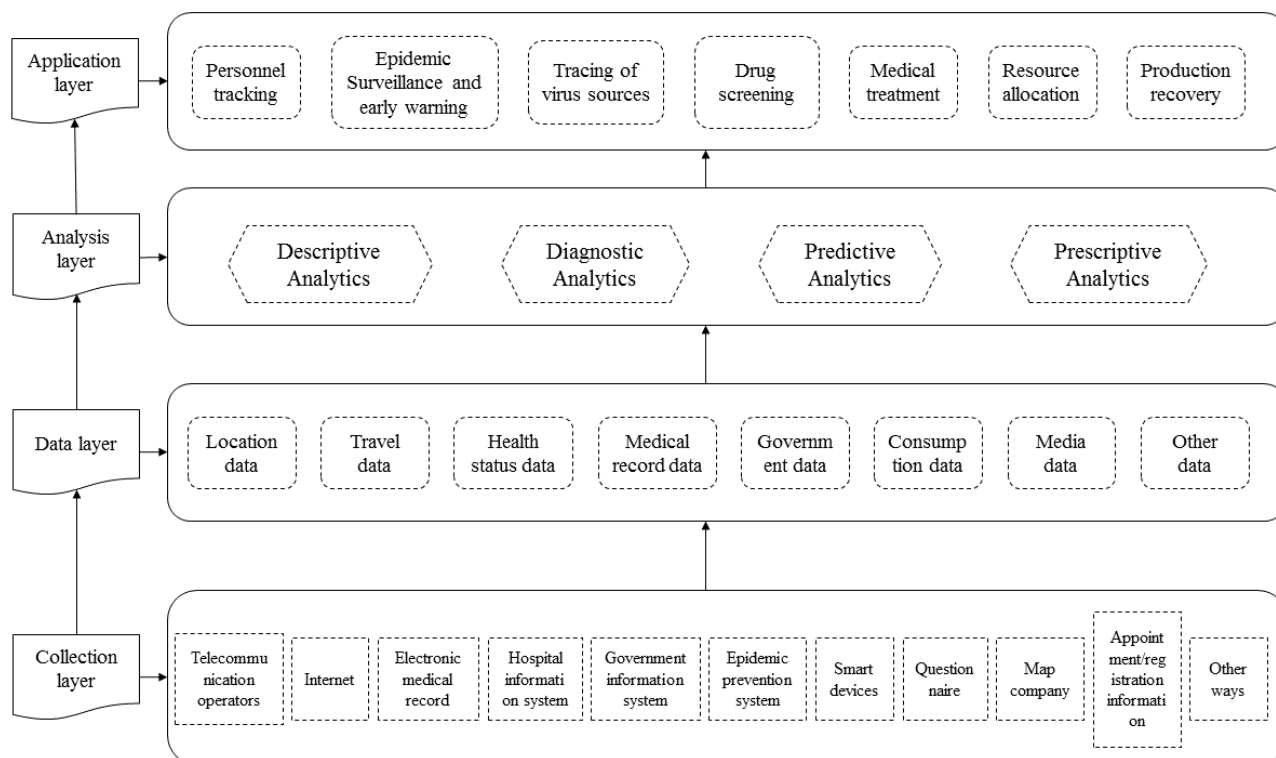

- Tax data
  - Tax department continues to collect
- Electricity data
  - The energy department will continue to collect and record
- Legal data
  - The legal department will continue to collect and record

**Textbox 2.** Newly added data collected in China after the outbreak of COVID-19 from government, commercial and public welfare sources and websites, academic papers, public reports, institutional reports, and fieldwork.

---

Figure 1 sets out a diagrammatic representation of the conceptual basis of big data technology for COVID-19 prevention and control on four levels: application, analysis, data, and collection.

In the next section, we discuss the key elements within each collection, data, analysis, and application layer of Figure 1.

**Figure 1.** Conceptual structure chart of prevention and control of COVID-19 with big data technology.

## Results

### Location Data and Travel Data

Turning to the collection, data, analysis, and application layers in Figure 1, the scale of population migration is crucial for disease space propagation predictions, risk area identification, and control measure decisions to control infectious diseases [34]. Studies have shown that there is a close relationship between the number of train trips and the number of COVID-19 cases [35]. Before Wuhan was quarantined on January 23, 2020, more than 5 million people left Wuhan for other parts of China [36]. Internet companies used ticket purchase information and toll booth information to create population migration maps. The maps show the movement of population between cities in specific time ranges. For January 22, 2020, the day before the closure of Wuhan, the data found that 74.77% of the total number of people who moved out of Wuhan migrated to other parts of Hubei Province including 14.56% in Xiaogan City, 14.08% in Huanggang City, and 7.65% in Jingzhou City; 5.67% moved to Henan Province; and 3.24% moved to Hunan Province [37]. In the early stage of the epidemic, the travel data identified cities and regions susceptible to potential future outbreaks, allowing government organizations to make timely preparations for epidemic prevention and control.

According to the patient information data provided by the National Health Commission, internet companies and government official websites produced epidemic maps showing the number of patients diagnosed with COVID-19, the number of suspected patients, and the number of cured patients in each province and city [38]. The death toll allowed the public to keep abreast of the epidemic's development. For example, based on a unified geographic framework, research institutions quickly

absorbed and integrated geographic big data including internationally published World Health Organization data, daily family health and disease control data, professional population health platform data, Tencent site selection request data, Baidu migration data, patient spatial-temporal trajectory data, international airline data, census data, remote sensing images, and other multisource data. Multi-scale comprehensive spatial-temporal dynamic visualization technology allowed provinces, cities, counties, communities, and individual epidemic data to be unified in a spatial-temporal data visualized on a multidimensional "one map." The map service provider identified the residential areas with confirmed or suspected cases on the map, and the map users can interrogate the information around their specific locations on the map. Individuals can avoid activities in high-risk areas, and hospitals that can receive suspected cases are highlighted on the map so that people can find COVID-19 treatment hospitals. Map service providers also used mobile phone signaling data to measure the density of people in specific areas and differentiate the display on the map through red, yellow, and green color differences to remind the public of areas to avoid to reduce the risk of infection.

Based on the card swipe information data, systems developed by the public transportation management departments allowed passenger flow and full load of subways and buses data to be queried in a timely manner to select the best travel arrangements and times, to avoid congestion, and to reduce the risk of infection. The epidemic prevention department can quickly confirm the flight, train, or bus information of travelers infected with COVID-19 within the past 2 weeks and inform fellow travelers who have been in close proximity to be tested and take self-isolation measures. To inform the traveling public about high-risk travel, internet companies entered the information of

flights, trains, or buses used by patients with COVID-19 into a tracking system and developed a “close contact measurement instrument.” By entering their ID number and name, a traveler can immediately check whether they have taken the same flight, train, or bus as a patient with COVID-19.

Through epidemiological surveys based on questionnaires, the staff of the epidemic prevention department can identify the areas and the specific times patients with COVID-19 visited before becoming sick and can promptly notify others who were active at the same time and place to pay attention to their health. For example, if a confirmed case occurs in a hospital, the hospital can notify other patients and people entering the hospital to isolate themselves through their mobile phone number. The operator’s mobile phone signaling data can timely and accurately identify the country where the user stayed in the previous 14 days and the domestic city where the user stayed for more than 4 hours to determine whether the user has been in a key epidemic area or country.

Most provinces and cities in China have established a big data health code system. When travelers scan their official Quick Response (QR) code, register, and fill in personal relevant information (including name; ID number; mobile phone number; body temperature; cities and travels in the past 14 days; and whether they have symptoms such as fever, coughing, and fatigue), the system will automatically generate a personal “health QR code,” which is divided into three color levels of red, yellow, and green [39]. Green means that the person did not appear in the virus-infected area during the quarantine period and can carry out cross-regional movement. When people with green codes have been to high-risk areas and in contact with high-risk people, their code will turn red. People with red or yellow codes will be quarantined, and the codes will turn green when certain conditions are met.

The digital epidemic prevention system, jointly developed by Alibaba’s Bodhidharma, Dingding, Alipay, and Alibaba Cloud, summarizes information from the hospital’s diagnosed cases and identifies people who have purchased fever-reducing drugs in pharmacies within the past month. Big data technology is then used to analyze the activity trajectories of confirmed cases and close contacts, and an epidemic spread model is constructed in combination with the positioning system. Based on the mobile phone positioning system of the diagnosed cases and close contacts, the expert team can find other mobile phone numbers within a 3-meter transmission range and more than a specified contact time based on the physical distance between the mobile phones to analyze the infection risks between parties. The big data positioning information can identify a large number of close contacts and quickly establish a province-wide big data outbreak early warning mechanism. For example, major epidemic transmission centers have been identified, including the Baodi Mall, a Tianjin hospital, the Tulong shopping mall in Harbin, and the Yintaidao shopping mall in Wenzhou [30].

## Medical and Health Data

For epidemic prevention and control, big data in health care can promote the timely detection and reporting of cases, improve the probability of finding diagnosis and treatment methods quickly, and improve the efficiency of hospital management in

a pressure environment. There were initial failures in fully identifying and reporting COVID-19 cases in the EMRS disease reporting system. EMRS information should be complete and accurate. In the early stages of the epidemic, frontline doctors were not efficient in collecting patient data, identifying patients’ conditions, and reporting infectious diseases. One way of addressing this problem was to link EMRS data to epidemic decision making through China’s Center for Disease Control and Prevention (CDC), the government’s public welfare institution responsible for the technical management of disease control and public health [40]. By connecting the CDC’s monitoring and early warning system to hospitals’ EMRS, big data technology was applied in a timely manner to extract and analyze medical big data. First, through automatic matching, CDC’s AI knowledge base interrogated EMRS for keywords such as pneumonia. When suspected hospitals cases were identified, the EMRS immediately monitored front-end doctors’ computers, prompting doctors to verify the completeness and accuracy of the EMRS information and generate an infectious disease report. Such monitoring systems attenuate concealing or underreporting infections. Second, CDC monitoring improved the discovery and testing of EMRS big data to ensure the effective transmitting of health data and to avoid late or underreporting. For example, the CDC monitoring system reduced the average time required for doctors to report a COVID-19 case from the previous 5-8 minutes to within 40 seconds and the time required for online reporting via the CDC web-based infectious disease reporting system from 2-3 minutes to a few seconds [41]. CDC monitoring also supported COVID-19 diagnosis both within China and worldwide. One example was the successful isolation of the first COVID-19 virus strain in China, with the publication of the virus’ scientific information, electron micrographs, specific primers, and probes for global use. In the early stages of COVID-19 in China, the failure to provide timely data allowed the virus to spread both locally and worldwide. In the middle stages of the disease, timely release of scientific resources and data provided COVID-19 genes and gene sets, and big data information for COVID-19 research platforms for Chinese and international researchers [42]. CDC monitoring also supported hospital management. For example, the CDC promoted the integration of EMRS, HIS, and LIS data, and the hospital operations data to manage protective supplies, health status reports, epidemic developments, and telecommuting. By analytically and visually processing the integrated data, managers made decisions and assessments, which supported hospital treatment regimens [40]. When medical resources were overwhelmed by patients, big data technology helped develop a hierarchical diagnosis and treatment system, which allocated scarce health resources efficiently. In epidemic prevention and control, big data predictive analytics were mainly applied to predicting the impact of epidemic developments on medical resources. Based on big data models such as communication dynamics and risk level distribution of the incidence rate and close contacts, predictive analytics estimated epidemic peaks and inflection points, which allowed the differential allocation of resources to regional hospitals. Big data searches on internet platforms and susceptible-exposed-infectious-removed (SEIR) transmission modeling can predict COVID-19 transmission trends [43]. Using

population migration data to fill in the dynamic propagation SEIR model combined with AI methods trained with SARS data, Yang et al [44] predicted a COVID-19 pandemic curve. The authors showed that if the Chinese authorities had postponed the implementation of strict public health measures for 5 days, the scale of the epidemic would have tripled. A loosening or removal of lockdown interventions would have caused Hubei Province to peak again from mid-March to late April [44].

Based on the predicted epidemic trends and risk level information, health departments deployed prevention resources in advance of the epidemic in specific areas to contain the spread of the virus and avoid second outbreaks. Relevant government departments also used big data predictive analytics to identify the epidemic's peak and inflection point to determine the approximate time to resume normal work. Finally, big data predictive analytics was applied to integrate HIS medical costs and insurance information to estimate epidemic trends, proportion of patients of different histology types, the cost of diagnosis and treatment, and the allocation of health resources.

Further, big data diagnostic analytics can screen existing clinical pneumonia drugs to treat patients with COVID-19. For example, big data on patients prescribed traditional Chinese medicine were used to explore the efficacy of Chinese medicinal materials and their composition to treat COVID-19. Zhang et al [45] systematically screened natural compounds used in Chinese treatment and found 13 of them to exert potential anti-COVID-19 benefits in terms of the regulation of viral replication, modulation of immune and inflammatory pathways, and hypoxia cascade.

### News Media and Social Data

During the outbreak, there were inaccurate statements and misleading information on the internet, such as rumors that high alcohol content drinks and gargling with salt water could resist COVID-19, drinking Banlangen and smoked vinegar could prevent COVID-19, and that children could not be infected with COVID-19 [46]. Such false information will lead the public to relax their vigilance and take incorrect COVID-19 epidemic prevention measures. After identifying this type of false COVID-19 information, internet companies alerted epidemic prevention experts and national authoritative epidemic prevention organizations to take action to correct such false or inaccurate information. China took action to correct false information through authoritative national media, short films, and live broadcasts [47].

When a major epidemic occurs, the negative impact of uncertainty and panic on social activities may exceed the negative impact of viral diseases. Social media data can track and evaluate the spatial spread of public sentiment. By tracking topics and sentiments that appeared in microblog users' timelines in response to COVID-19, a user semantic behavior evolution model was introduced to measure and analyze changes in public opinion [30,43]. The results indicated that from January 9 to February 10, 2020, more than 60% of posts related to science popularization of disease prevention and government COVID-19 announcements were positive and stable. For example, the posts with the topic of "help-seeking" were concentrated in the key epidemic area of Wuhan, and the posts

related to "donation information" were widely distributed throughout the country [30].

Through real-time monitoring of keyword information searched by users, such as the frequency of the words "fever," "epidemic," "cough," "pneumonia," and "infection" on internet platforms, health officials assessed the health status of people in various regions. When the frequency of such keyword searches increased rapidly in a certain area, the risk of a large-scale outbreak in that area was increased accordingly [5]. Such tracking allowed relevant health departments to formulate epidemic prevention and treatment measures in advance. For example, Qin et al [43] used big data to predict the number of suspicious or confirmed new cases of COVID-19. Using a series of lagging "social media search indexes" for various keywords including clinical symptoms of COVID-19 (such as dry cough, fever, chest pain, and pneumonia), the authors found that COVID-19 outbreaks could be found 6-9 days in advance.

### Data Collected by Intelligent Equipment

Using thermal imaging human body temperature measurement equipment in public places such as train stations, airports, shopping malls, hospitals, and pharmacies to automatically collect data, individuals with an abnormal body temperature in a large number of passing people can be identified using face recognition technology [48]. Once identified, people with COVID-19 can be isolated, containing the spread of the virus. This big data early warning system can automatically collect and analyze information to diagnose people with COVID-19 in real time.

### Data on Epidemic Prevention Materials

The spatial distribution of medical resources is usually balanced according to factors such as population density, but the uneven spatial outbreak and spread of COVID-19 creates large regional imbalances in the supply and demand for medical resources. The key to epidemic prevention and control is to understand the spatial and temporal dynamics of the supply and demand of medical resources to optimize the distribution of materials, resources, and medicine. Sharing data with emergency suppliers and public resource national trading institutions underpins a system that provides information on supply and demand for resources and maintains unified prices to minimize unfair competition, ensure material security, and guarantee material quality [49]. Through telephone and online inquiries, the dynamic status of medical protection equipment in China was analyzed. Data analytics on material needs identified the demand from multiple locations and allowed health organizations to coordinate the release and tracking of medical supplies by their name and quantity of required materials, contact information, and transport mode [50]. By stopping the release of material supplies through scattered, uncoordinated channels, big data allowed the managed allocation of supplies to hospitals and cities with the greatest need, balanced supply and demand, and ensured the efficient allocation of medical resources.

A stable and efficient national material supply and transportation system provides important support for successful epidemic prevention work. For example, using provincial epidemiological data, online consumption data and postal service data identifies

each provinces' supply and demand status for necessities and food, preventing shortages and price changes [51]. At the same time, by tracking the transportation of materials, highly sensitive nodes that may cause virus transmission during transportation were identified, and early warning and decision support were provided to prevent and control the regional spread of COVID-19.

### Online Consumer Data

Big data can help enterprises to target production, marketing, logistics, and safe work resumption. Amid the epidemic, enterprises producing medical products and basic necessities can assess public demand using big data to ensure supply and demand equilibrium by scheduling optimal production and efficient distribution of products. Big data, for example, identified electric pressure cookers as one of the most talked about products during the epidemic, which allowed firms to target the production and distribution of pressure cookers [52].

### Government Data

During the epidemic, the use of big data technology for population information management and decision making was a fundamental approach by government service departments [53]. Tax data, especially value-added tax invoice data, have the unique advantages of wide coverage, strong timeliness, and fine granularity, helping to schedule the resumption of work, production, and the operation of enterprises [54]. Gathering data on industry, region, scale, and economic type, national and local governments analyzed the dynamics of the economy's operation, planned the resumption of work, determined the production levels and sales of enterprises, identified and solved problems along the industrial supply chain, and provided targeted assistance to individual business and business sectors. For example, the Shandong Provincial Taxation Administration used big data to help a local pharmaceutical glass company to distribute their epidemic prevention supplies by screening logistics companies that had a high degree of credibility and carrier capacity, ensuring the smooth delivery of their supplies [55].

Through big data analysis, governments can assess the impact of the epidemic on socioeconomic operations in the near and long term; establish economic emergency response systems; implement various incentive measures such as tax cuts, fee reductions, and special subsidies; mitigate the risk of financial chain breakage; and promote the continuous operation of small- and medium-sized enterprises. For example, the Shanghai Municipal Tax Administration used tax data to identify potential targets for tax incentives and subsequently launched more than 30 tax incentive programs, covering more than 200,000 tax companies [56].

### Deep Learning Data

Used in a variety of fields, deep learning is a machine learning analytic method frequently used to interrogate big data, performing tasks that are difficult for conventional analysis methods [57-60]. Mobilizing big data, deep learning offers a method to better forecast disease trends, including COVID-19. For Hong Kong, Xu et al [61] showed deep learning yielded better prediction performance for flu-like diseases than the

generalized linear model, the least absolute shrinkage and selection operator model, and the autoregressive integrated moving average (ARIMA) model. Wang et al [62] found deep learning provided a convenient tool for fast screening COVID-19 and finding potential high-risk patients, which may be helpful for medical resource optimization and early prevention before patients show severe COVID-19 symptoms. Various non-China studies indicate that infectious disease can be predicted more effectively when large amounts of data including weather variables and internet big data are used to predict infectious diseases. Using deep learning, Chae et al [63] found that deep neural network and long-short term memory learning models outperformed ARIMA approaches when predicting for three infectious diseases in Korea 1 week into the future. Using data mining algorithms to predict COVID-19 outbreak trends, Ayyoubzadeh et al [8] showed that the most effective predictive factors, besides the previous day incidence, was the search frequency of handwashing, hand sanitizer, and antiseptic topics. Togacar et al [64] found a deep learning model using data on COVID-19, pneumonia, and normal x-ray imaging could detect COVID-19 efficiently.

## Discussion

### Issues and Challenges in COVID-19 Big Data

#### Data Collection and Access

During a pandemic, the way data are collected and the quality of the collected data pose challenges. When data were collected by government workers exposed to disease environments, causing physical and mental dangers, data standards were not uniform. For organizations, different information reporting systems and data reporting formats were adopted, resulting in inconsistent standards, unreliable structures, and untimely reporting, especially in the process of statistical aggregation [65]. Frequently, data were not updated in a timely manner. Against the backdrop of the rapid spread of the COVID-19 virus, immediate data updates were essential to assess the state of the epidemic and its dangers, and to avoid panic among the public. However, due to insufficient awareness of the epidemic's risk in the early stages, the lack of advanced means of data collection, the large number of subjects involved in data collection and release, and the inevitable "fragmentation" of big data platforms, much of the data were not updated timely or optimally.

#### Data Use

Data use depends heavily on visualization, and data mining techniques were found inadequate. Data source, quality, and scale all influence data integration, and raw data collection issues contribute to the difficulty of data integration. Converting low-value density big data into high-value density knowledge through data integration is the purpose of big data management applications [66]. Given existing data development capabilities, there has been a general lack of effective integration of data sources. This has been complicated by the rapid development of internet and information technology, and the rapidly expanding types and volume of data resources. Data quality and degree of data analysis determines big data's role in epidemic

prevention and control. Much of the data used for epidemic prevention and control were available through official channels or accumulated by enterprises during their operations but were of widely varying quantity, quality, and variety. It is often the case that data holders do not have sufficient skills to exploit good data, or those with good data development skills do not have sufficient data.

The visual presentation of spatial, temporal, and quantitative features of epidemic data in the form of maps is the most common means of using epidemic big data. Epidemic surveillance is about spatial governance through spatial-temporal modeling and analysis, including the control of people flow, logistics, information flow, and technology flow. Although geographic information technology has unique advantages in data collection, processing, and management, most visualization products simply present, rather than analyze, information about the epidemic. In the immediate COVID-19 period, there were insufficient data on transportation networks, service facilities, public opinion, prevention and control effects, and the information on their mutual relationship. More importantly, there was inadequate innovation in the way the data were used.

### **Data Sharing**

The key to the role of digital government and smart cities in managing major public emergencies is to enable data sharing. In 2015, China's State Council issued the *Action to Promote the Development of Big Data* [67], which proposed that big data should be used as an important means to enhance the government's governance capacity, improve the level of government decision making, and manage risk prevention through efficient collection and integration of government and social data. By the end of 2017, China had introduced a series of policies to promote effective government data sharing and completed the construction of a national data sharing platform to promote the sharing of data resources at the provincial and ministerial levels. In practice, data sharing has displayed a silo effect. Data sharing among Chinese departments and regional governments remains inadequate, and the phenomenon of "block islands" still exists. For example, the health code is a two-dimensional risk assessment code generated from personal travel information and health status information. During the use of these health codes, some regions did not recognize the health codes generated by other regions [39]. Partly, this is due to inadequate infrastructure for urban data collection, lack of community data resources, and lack of big data management expertise, which led to a disconnect between spatial and social governance. However, there was a continuing unwillingness to share data across provinces and municipalities, and insufficient means of information interaction, resulting in inaccurate data analysis and weak regional joint prevention capacity. Only by fully realizing data flow across regions, levels, and sectors can data be efficiently integrated and better applied to epidemic management.

### **Data Protection**

In terms of data protection, there is inadequate privacy protection and undisclosed compliance risks. The value of big data lies in its disclosure and concrete application. In the age of the internet and electronic information, people's lifestyles

generate big data on all aspects of their life, but privacy may be compromised. In the face of the rapidly spreading epidemic, government investigates and closely monitors the health of individuals, collecting a large amount of personal information on COVID-19 confirmed, suspected, and potential cases and their close contacts. Information on people leaving Wuhan to visit their home villages and cities have been exposed on the internet, which caused a serious negative impact on individuals and families who were subjected to unwarranted harassment, discrimination, and physical threats [68].

## **Strategies and Recommendations**

### **Data Collection and Access**

From China's big data experience during the first stages of the COVID-19 pandemic, data collection should have been more timely, comprehensive, and accurate. To improve data collection and access, electronic questionnaires should be promoted to conduct information surveys, including the use of the WeChat applet or Alipay applet. For COVID-19 tracking, after scanning their QR code, individuals can efficiently input their information such as ID card number, household registration, residential address, and itinerary of the past 2 weeks, and then update their body temperature every day. Of course, manual collection of data can lead to delays, concealment, inaccuracies, and underreporting. One solution is to collect these data automatically by apps, which will improve data accuracy and use. Accurate tracking data can be collected using portable electronic equipment, cameras, access control, license plates, and other information.

To conduct more in-depth scientific analyses, data on weather, news, transportation, business, and health are currently collected in addition to collecting accurate personal information data. The credibility of these data is important. For example, when the mobile phone number registered according to an individual's ID card information is used by others, there will be errors in predicting a person's movements. In addition, individuals deliberately concealing their own information or falsely reporting their own information leads to data errors. Data sharing will allow cross-comparisons of different data sources, including mutual authentication of government, operator, traffic, public security, network, and other information. For example, the National Health Commission and the national information security department could work together to formulate common standards of data structure, format, attributes, content, and scope for individuals, and release these data to the institutions or departments with investigation rights to ensure the quality of the data. Cross-comparisons of data raise issues of privacy and whether intentionally concealing or falsely reporting data should be legally punished.

### **Data Use and Sharing**

Data use and sharing require the integration of data sets and the strengthening of data sharing. One way to integrate data is to give full play to the technical advantages of scientific research institutions or commercial units. For example, the functions of the Guiyang big data exchange center, Shanghai Data Trading Center, and commercial data package trading platforms (such as COFCO, Youyi, Yaxin, and shuduoduo) can integrate, use,

and share data. In addition, one way to innovate data use is to use blockchain technology to build a neutral third-party security housing platform to realize the separation of ownership and use rights [69]. Secure house platforms allow the demand side to use data that it does not own. For the data supplier, secure house platforms provide massive data access to multiple data sources. For the data demander, it uses data fusion technology to provide multiparty high-quality data resources that the data demander did not have previously. In addition, it supports the third-party algorithm and user-defined algorithms. For example, AI companies can carry out AI analysis and algorithm modeling for pathological sections of patients in the secure house, which not only ensures patients' privacy and prevents the leakage of medical data but also optimizes the use of the AI. To fully realize big data sharing in a secure way, governments can set an identity for big data assets and establish a data query mechanism to realize cross-platform data tracing and extraction.

### **Data Innovation**

The value and efficiency of big data use can be improved by making full use of big data mining and data analysis methods. Based on big data resources and big data analysis methods such as machine learning and data simulation, a more comprehensive and rapid assessment of the risk and impact of the epidemic could be carried out. Strengthening data collaboration, for example, between data owners and big data technology platforms, and integrating multidisciplinary knowledge and analysis methods will yield innovative big data solutions. The health code is a successful example. Information on individuals' ID, residential address, health status, whether they have been to the infected area, and contact history of key personnel were entered into the applet and a QR code generated. Spatially, the risk level of the epidemic in defined areas were assessed temporally by the number of visits, length of stay, and interpersonal relations between individuals in epidemic areas, allowing three risk states (red, green, and yellow) to be measured, analyzed, and assessed [39].

A further innovation would be the expanded use of the QR code, where individuals would be required to scan their QR code to show their health code status before entering public places. At the same time, the health code would also record the current position of the individual. When their QR code is red or yellow, they would be denied entry to public areas. In addition, when there are COVID-19 cases in specific public areas, the health department can quickly inform individuals not to enter or to isolate through information automatically reported by their health code. In addition to obtaining basic health information of residents during the epidemic, the health code can obtain medical insurance information and other disease information, realize a series of digital services in the hospital system from registering appointments to picking up medicines, and fully exploit new opportunities for online appointments and online consultations while accumulating data assets for the analysis of medical and health big data intelligence applications.

### **Data Security and Privacy**

Attention should be paid to big data privacy issues [70]. Privacy issues are fundamentally country-specific legal requirements, where China's privacy framework will vary from that of other

countries. Guarantees of nondisclosure and proper use of personal privacy information are the most basic requirements for data collection and use. Statistical processes involving the collection, aggregation, sharing, and disclosure of personal information should require the protection of personal information to prevent data leakage, loss, and abuse. Governments should establish institutional safeguards, listing situations that require the public to declare private information data. The government should also specify the list of institutions that can request personal privacy information and the requirements allowing third-party access to personal data. In China, the law on the prevention and control of infectious diseases stipulates that "any unit or individual within the territory of China must accept the prevention and control measures such as the investigation, inspection, collection of samples, isolation and treatment of infectious diseases by the Department of Disease Prevention and Control, and truthfully report the relevant information" [71]. On February 9, 2020, China issued a notice protecting personal information and regulating the use of big data to support joint prevention and control of diseases, specifying that personal information collected for epidemic and disease prevention and control should not be used for other purposes. No unit or individual may disclose information such as name, age, ID card number, telephone number, or home address without the consent of the collector, except for those who have been desensitized due to the need for epidemic prevention and control [72]. Government departments only release information of public concern, such as "digitizing" individual patients. Each confirmed patient has a code, which only shows their gender, age, disease severity, and frequent activity area. There are legal penalties for failing to follow the legal requirements on data handling.

Privacy concerns might be further addressed by enhancing big data's privacy framework, including setting access and use permissions for the encrypted data collected, making the data available only to institutions or organizations with a clear purpose, ensuring only the minimum personal information for epidemic prevention and disease control is collected, and setting retention periods that limit the time collected personal information is retained.

Big data helped contain, suppress, and control COVID-19. The main lesson is that COVID-19 big data technology can be applied to epidemic alerts, tracking the spread of viruses in real time, planning public health interventions, monitoring the effectiveness of treatment regimens, identifying potential vaccine candidates, strengthening community and regional government responses to epidemics, and guiding social and economic recovery in the postepidemic period. In the long run, big data technology helps build smart, healthy, and resilient cities and countries.

### **Conclusion**

In China, big data technology displayed its potential in containing, suppressing, and controlling COVID-19, with the Chinese government and nongovernmental organizations making full use of big data information from the major areas of medical institutions, telecommunication operators, internet companies, government departments, commercial companies, and AI

equipment. Through the analysis of big data technology to prevent and control COVID-19, we found that big data technology played an important role in epidemic surveillance and early warning, tracing of virus sources and personal tracking, planning public health interventions, monitoring drug screening and medical treatment, strengthening community and regional government responses to epidemics, and guiding social and economic recovery in the postepidemic period. These big data applications were central for the public, enterprises, and governments in their response to COVID-19.

We also identified gaps in the use of big data technology to prevent and control COVID-19, including problems in data acquisition, data use, data circulation, and data protection. The application of big data technology in the prevention and control of infectious diseases like COVID-19 requires further development in the collection, analysis, distribution, and privacy around personal and public information. Although China's big data application to fighting the COVID-19 epidemic was a success story, it also provides lessons for the continuous improvement in the application of big data technology to epidemics in China and for other countries managing the COVID-19 pandemic.

## Abstract

**Background:** Hereditary angioedema is a rare genetic condition caused by C1 esterase inhibitor deficiency, dysfunction, or kinin cascade dysregulation, leading to an increased bradykinin plasma concentration. Hereditary angioedema is a poorly recognized clinical entity and is very often misdiagnosed as a histaminergic angioedema. Despite its genetic nature, first-line genetic screening is not integrated in routine diagnosis. Consequently, a delay in the diagnosis, and inaccurate or incomplete diagnosis and treatment of hereditary angioedema are common.

**Objective:** In agreement with recent recommendations from the International Consensus on the Use of Genetics in the Management of Hereditary Angioedema, to facilitate the clinical diagnosis and adapt it to the paradigm of precision medicine and next-generation sequencing-based genetic tests, we aimed to develop a genetic annotation tool, termed Hereditary Angioedema Database Annotation (HADA).

**Methods:** HADA is built on top of a database of known variants affecting function, including precomputed pathogenic assessment of each variant and a ranked classification according to the current guidelines from the American College of Medical Genetics and Genomics.

**Results:** HADA is provided as a freely accessible, user-friendly web-based interface with versatility for the entry of genetic information. The underlying database can also be incorporated into automated command-line stand-alone annotation tools.

**Conclusions:** HADA can achieve the rapid detection of variants affecting function for different hereditary angioedema types, and further integrates useful information to reduce the diagnosis odyssey and improve its delay.

## Introduction

Hereditary angioedema (HAE) is a rare genetic disease caused by an increase of vascular permeability, generating recurrent acute swelling episodes commonly localized on the face, trunk, and extremities. HAE can also be life-threatening when the upper airways or the tissues from the oral cavity are affected [1,2]. Because of its nonspecific clinical signs, HAE is poorly recognized by physicians. Therefore, delayed or ambiguous diagnoses are common, increasing the risk of patient morbidity and mortality [3]. With exceptions for particular subtypes, the recent international consensus guidelines recommend the use of genetic testing to reach a definitive HAE diagnosis in clinical practice [4]. However, with increasing recognition that the genetic cause of HAE is more complex than previously anticipated [5], the tasks involved in the identification of the genetic defect in each patient are increasingly demanding [6].

With the decreasing cost and increasing sequencing throughput of next-generation sequencing (NGS), the screens for gene defects can now be accomplished through a simultaneous evaluation of gene sets, the exome, or the whole genome as indicated [7]. However, access to either high-performance computational equipment and trained bioinformatics personnel or, alternatively, to paywalled cloud-based all-inclusive solutions is the most limiting factor for NGS to be efficiently used in clinical settings [5]. To facilitate the identification of pathogenic variants in HAE patients, Kalmár et al [8] developed HAEdb, an online locus-specific database to centralize the information of the genetic alterations, which allows researchers to retrieve mutation information and contribute new detected variants. However, HAEdb focuses only on the most frequently affected gene (*SERPING1*, encoding the C1 esterase inhibitor [C1-INH]) and uses a data retrieval scheme based on matching with the existing records, requiring the user to prioritize the most likely variant affecting function. Besides, HAEdb has not been updated to include the pathogenic classification according to the standard guidelines established by the American College of Medical

Genetics and Genomics (ACMG) [9], which would allow for standardization between laboratories and studies, while guiding global efforts for improving NGS-based diagnosis to move toward the precision medicine paradigm. More recent efforts such as that of Ponard et al [10] have aimed to fill this gap and updated the mutational spectrum in two of the known HAE genes (*SERPING1* and *F12*) based on the Leiden Open Variant Database (LOVD) v3.0, a platform-independent framework for the maintenance and curation of a web-based database of genetic variants [11]. Nevertheless, these resources are ill-adapted to current NGS technologies and to the evolving knowledge of the genetic causes of HAE.

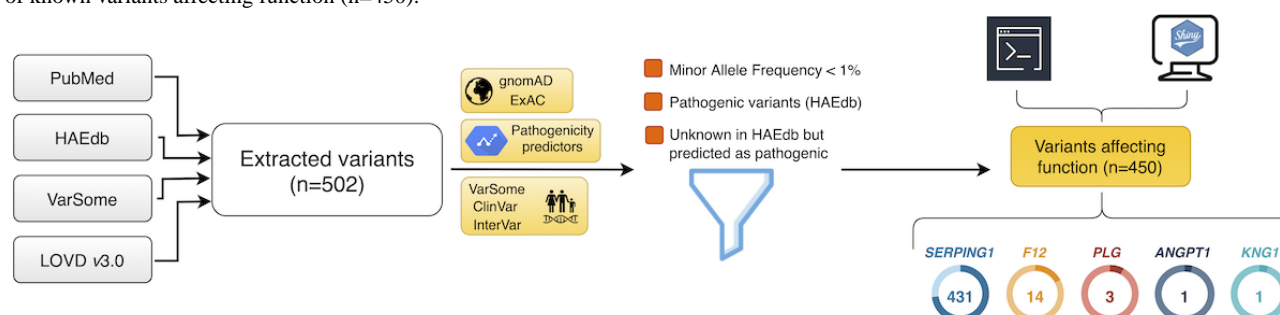

To fill this gap, we here present the Hereditary Angioedema Database Annotation (HADA) tool, a freely accessible, user-friendly, and versatile web-based interface to facilitate the identification of the genetic variants causing HAE.

## Methods

### Gene and Variant Extraction to Build the Database

We retrieved the variants found among HAE cases and relatives from HAEdb [8] (accessed June 18, 2020) and LOVD v3.09 (Figure 1). These databases contain hundreds of records for variants in the *SERPING1* or *F12* genes detected in clinical studies of families with one or more members affected by HAE. Additionally, a search was performed on January 1, 2020 in PubMed for the terms “angioedema” and “mutation” with the aim of retrieving other HAE genes from the literature. From this search, studies focusing on acquired forms of angioedema were ruled out, and an in-depth analysis of each prioritized study was performed. The VarSome database [12] was also screened to retrieve variants, as well as to update the genetic nomenclature of variant descriptors. The information described in the corresponding articles where each variant was described was manually inspected to verify that the original descriptions were accurate.

**Figure 1.** Schematic representation of the steps involved in gene and variant extraction, annotation, and database curation. All genetic variants reported in the articles studying hereditary angioedema (HAE) families in PubMed, HAEdb, VarSome, and the Leiden Open Variation Database (LOVD) were collected (n=502). ANNOVAR was used for annotation of frequencies, pathogenic predictors, and pathogenic classifications, among other information. Variants with a minor allele frequency below 1%, declared as pathogenic in HAEdb or as unknown but with a pathogenic prediction were kept as the set of known variants affecting function (n=450).

Given that a confident clinical interpretation of structural variants is challenging and that the standards for reporting those involving copy number variants have only recently been set [13], the criteria indicated above were only applied to single nucleotide variants (SNVs) and small insertion/deletions (indels). Therefore, the 45 gross mutations (ie, structural variants

in the *SERPING1* gene) from HAEdb that have been identified in HAE families were not integrated into HADA.

### Database Variant Annotation

According to their chromosomal coordinates, the selected variants were first adapted to the GRCh37/hg19 reference

genome, exonic locations, Human Genome Variation Society (HGVS) nomenclature, coding effect, and PubMed citation. ANNOVAR v18.04.16 [14] was used to annotate according to RefGene, the allele frequency in gnomAD v2.1.1 [15] and ExAC [16] (November 29, 2015 release), dbSNP build 150 information, and precalculated pathogenicity predictors (SIFT, PolyPhen2, MutationTaster, CADD, DANN, MetaSVM, LRT, and phastCons mammalian). Pathogenic probabilities according to ClinPred [17] and the ACMG pathogenic classification as determined by ClinVar [18] (March 5, 2019 release), InterVar [19] (January 18, release), and VarSome (accessed June 13, 2020) were also annotated (Figure 1).

### Database Curation

Many original descriptions of the genetic studies in HAE did not clearly declare the causality of the reported variants, thereby increasing the difficulty to identify variants with effects on the disease as opposed to variants without a disease effect [4]. To facilitate the interpretation of HADA results, we imposed the following filters for a variant to be designated as a variant affecting function (Figure 1): (1) variants described as pathogenic in HAEdb; (2) variants with unknown effects in HAEdb but predicted as pathogenic, likely pathogenic, or of uncertain significance (VUS) by VarSome, ClinVar, or InterVar (a flag will advise users in the case that contradictory classification information is reported for a variant); and (3) a reported minor allele frequency <1% in gnomAD, either on the

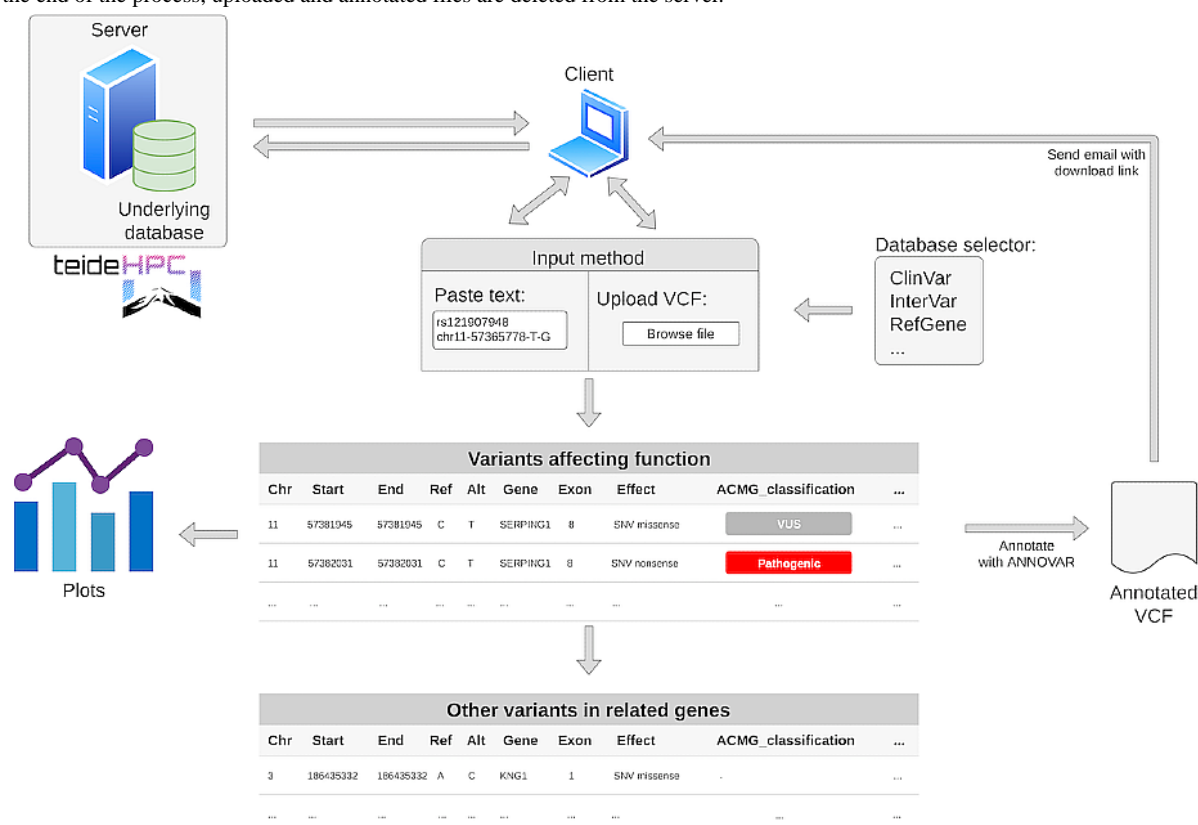

overall sample or for non-Finish Europeans (because most of the genetic studies in HAE to date have focused on European families).

Finally, to facilitate the identification of potentially novel variants in the user's uploaded data, HADA also includes all SNVs and small indels that were not classified as a variant affecting function using the criteria indicated above from dbSNP build 150, ClinVar, and InterVar located within 50-bp flanking regions of all exons from known HAE genes.

### Implementation of HADA

The database is built on MongoDB v4.2.1, a NoSQL query engine, to speed up database user queries and the variant calling file (VCF)-oriented analysis (Figure 2). HADA is built in Shiny v1.3.2, an R v3.6.1 package (R Foundation for Statistical Computing, Vienna, Austria) for building web apps. Specifically, we used ShinyJS v1.0 to run JavaScript code within the web app frontend and Plotly v4.9.0 to generate interactive plots. ANNOVAR v18.04.16 is used to provide annotations from the database in the uploads. To preserve potentially sensitive information included in the uploaded VCFs, HADA uses an encrypting code based on Cryfa [20] that automatically secures the access to the file and decrypts it once returned to the user. This provides a high level of security and transfers the data control to the user. No sensitive sample information is stored or maintained in the server.

**Figure 2.** Schematic representation of the HADA architecture and user interface. HADA is hosted on a server at TeideHPC, through a UI-based on Shiny. When the user sends a query to the server, it is encrypted and interrogates the HADA database, and returns matched variants affecting function associated with hereditary angioedema. The app also searches the data for other variants located within known hereditary angioedema genes to facilitate the identification of potentially novel variants. Once finished, an email with the link to download the annotated variant calling file (VCF) is sent to the user. At the end of the process, uploaded and annotated files are deleted from the server.

The curated database used by HADA is also available as a separate download at github [21] and it has been configured to annotate VCFs using ANNOVAR from the command line interface tool so that it can be easily incorporated into routine standalone NGS bioinformatics workflows. The HADA web interface is publicly accessible [22] hosted on TeideHPC premises [23].

### Validation in an HAE Family

To validate HADA with comprehensive NGS data, we generated whole-exome sequencing (WES) data from a patient with HAE and his two family members recruited by the Allergy Service from the Hospital Universitario Nuestra Señora de Candelaria (HUNSC), Santa Cruz de Tenerife, Spain. The study was approved by the HUNSC Ethics Committee and written informed consent was obtained from the patients. The index patient was a 31-year-old male who visited the emergency department more than 5 times due to acute angioedema attacks with facial and cutaneous symptoms, manifesting as episodes affecting the upper airways from the age of 23 years. His biochemical blood test showed normal levels of C1-INH (47 mg/dL) based on the N Antisera to Human Coagulation Factors and C1 Inhibitor kit (Siemens Healthcare Diagnostics, Marburg) and reduced C1-INH activity (10%) (Berichrom C1 inhibitor, Siemens Healthcare Diagnostics, Marburg, Germany), suggesting HAE type II. His mother (60 years old) and a sister (23 years old) reported no symptoms of HAE, and also consented to participate in the study.

Briefly, sequencing libraries were prepared from DNA extracted using a commercial column-based kit (GFX kit, GE Healthcare, Little Chalfont, UK) using Nextera DNA Exome Kit (Illumina Inc, San Francisco, CA). The TapeStation 4200 system (Agilent Technologies, Santa Clara, CA) was used for library size estimation and the concentration was determined by the Qubit dsDNA HS Assay (Thermo Fisher Scientific, Waltham, MA). Libraries were sequenced on a HiSeq 4000 Sequencing System (Illumina Inc) with paired-end 75-base reads. Libraries were sequenced along with 1% of PhiX control V3 to an average depth of 50X after removal of duplicate reads. Sequencing reads were preprocessed with bcl2fastq v2.18 and mapped to hg19/GRCh37 with the Burrows-Wheeler Aligner 0.7.15-r1140 [24]. Resulting BAM files were processed with Qualimap v2.2.1

[25], SAMtools v1.3 [26], and Picard v2.10.10 [27]. Variant calling was performed using HaploTypeCaller following the Best Practices workflow recommendations for germline variant calling in GATK (v3.8) [28], obtaining one VCF for each sequenced individual. A high confidence set of variants was obtained after applying the following filters: variants with PASS, read depth $\geq$ 20, genotype quality $\geq$ 100, mapping quality $\geq$ 50. The transition-to-transversion nucleotide substitution ratio was also obtained as a quality control for the refined set of variants. Sequencing data and variant identification were obtained by the Instituto Tecnológico y de Energías Renovables (Santa Cruz de Tenerife, Spain).

## Results

### Overall Characteristics of the Database

A total of 502 variants from 5 genes causally linked to HAE were retrieved from PubMed, HAEdb, VarSome, and LOVD. A subset of 450 variants was designated as variants affecting function, including variants reported in the following 5 genes: *SERPING1* (n=431), *F12* (n=14), *PLG* (n=3), *ANGPT1* (n=1), and *KN1* (n=1) (Figure 1). Three of these genes were discovered in the last 2 years based on WES approaches in HAE patients without C1-INH defects but not carrying *F12* variants affecting function [29-31]. ClinVar offered very limited information on this set of variants affecting function, as only 34 of them (7.6%) had corresponding ACMG class assignment: 2 are reported as benign or likely benign, 6 are indicated as VUS, and 26 are classified as pathogenic and likely pathogenic. InterVar included information for half of the set (226/450, 50.2%). However, 171 (75.7%) of these were classified as VUS. VarSome was the only resource that allowed assigning ACMG classes to all retrieved variants affecting function. According to VarSome, most of the HAE variants affecting function are classified as pathogenic (183/450, 40.6%) or likely pathogenic (171/450, 38.0%) (Figure 3). Although VarSome did not classify any of the HAE variants affecting function as benign or likely benign, 96 of them (21.3%) were still reported as VUS. Besides, precalculated pathogenicity predictors were available for a mean of 243 of the variants affecting function in the database. Taken together, these results highlight the existing gap in current interpretations of variant pathogenicity [32,33].

**Figure 3.** Precalculated pathogenic scores by the American College of Medical Genetics and Genomics (ACMG) pathogenic class for variants affecting function recorded in HADA. Panel A: VarSome proportions of ACMG classes among the hereditary angioedema variants affecting function. Panels B–F: pathogenicity prediction scores by ACMG pathogenic classes as provided by VarSome.

## HADA Interface and Usage

HADA has been developed as a user-friendly graphical web-interface tool. It is designed with the objective of enabling the analysis of genetic variants regardless of the detection approach used for the screening of the genetic causes of HAE (Figure 4). As such, HADA is compatible with individual VCFs that have been obtained at any scale (gene panel, exome, or whole genome) and by any NGS technology. Alternatively, the user could opt to provide hg19 chromosome coordinates of the variant(s) of interest as the rsID number, HGVS coordinate, or amino acid change, among others. The latter is still a common standard in laboratories relying on Sanger sequencing results. All of the annotation information used to construct the underlying database can be selected by the user to extract the available information. To facilitate a prospective analysis of each query variant, references to the corresponding articles reporting the variant are also offered (in chronological order). Direct links to external tools (ie, VarSome), which allows accessing graphical information of gene transcripts, complement the possibilities of HADA. Despite the fact that sensitive patient information is not necessary for HADA to provide results, HADA integrates an automatic data encryption algorithm for the queries based on VCF data, ensuring a password-secured encryption of the input data while uploaded and of the decryption when results are downloaded. Furthermore, the information provided by the user is not stored permanently by the server.

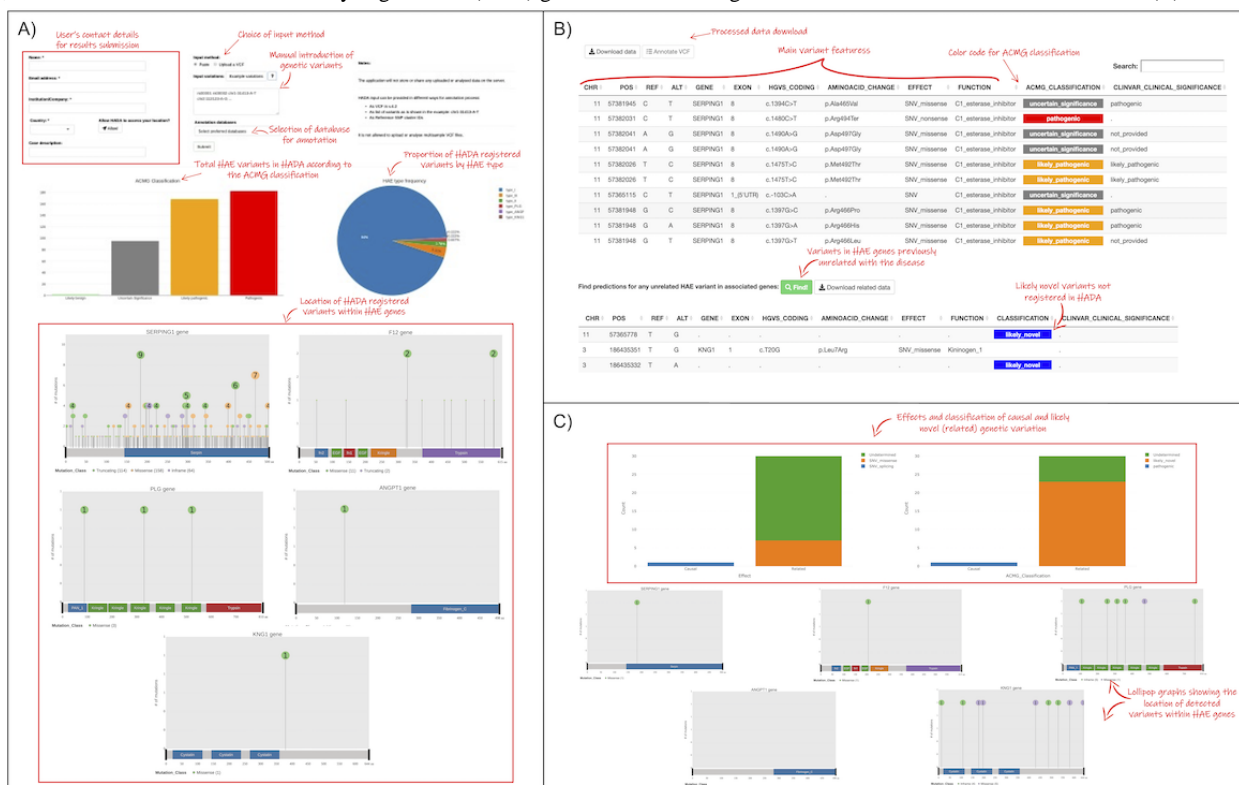

The data processing workflow is shown in Multimedia Appendix 1. Once the data are uploaded, the variants contained in the VCF

or that were provided by the user in chromosomal coordinates are matched against HADA. Automated detection and information extraction occur on the fly. Matched variants are subsequently shown in tabular format, accompanied by information previously selected by the user. HADA provides the ACMG classifications for each variant according to a color key to facilitate the identification of the HAE variants affecting function in the queries. HADA also suggests the subtype of HAE for which the variant affecting function is involved.

We anticipate that a user query might involve variants that have not yet been described among HAE genes (ie, novel HAE-related variants) or that have not been described in the scientific literature as an affecting functional variant to date. HADA integrates a genomic coordinates file that allows for the retrieval of predictions for any variant with any reference/alternative allele combination in any exonic region (plus a 50-bp flanking region on both ends of each locus) of the known HAE genes. Query results provided by HADA can be downloaded by the user in plain-text format in a comma-separated file, or as an annotated VCF in cases in which a VCF was uploaded by the user.

Finally, publication-ready plot generation and downloading are also incorporated in HADA. These functions plot graphs that summarize the information obtained from input data (ie, a VCF), as well as charts summarizing the proportions of the ACMG pathogenic classes predicted by VarSome, ClinVar, and InterVar separately, and the subtype of HAE that is associated with a variant affecting function that is identified in the query.

**Figure 4.** Selected snapshots of the HADA graphical interface with step-by-step instructions. Users can query variants of interest or alternatively upload an individual variant calling file (VCF) in the home page (A). The detected variants tab (B) shows the existence of variants affecting function in the query, as well as other variants in hereditary angioedema (HAE) genes. Plots are also generated and available for users to download (C).

### Validation of HADA in an HAE-Affected Family

To demonstrate the utility of HADA for the NGS-based identification of the variant affecting function involved in an HAE type II family, WES data (45 Mb) from the index patient, and the unaffected mother and sister were obtained. This detected a mean of 16,650 high-confidence variants per

individual. Sequencing metrics and variant calling results are shown in [Table 1](#). Resulting individual VCFs were processed with HADA, which reported a variant c.1396C>A (rs28940870) within *SERPING1* both in the index case and the sister that was heterozygous in both cases (compatible with an autosomal dominant inheritance pattern). The depth of coverage at this locus was 72X and 69X, respectively.

**Table 1.** Summary of the sequencing results in the validation study.

Feature	Index	Sister	Mother
Median insert size (bp <sup>a</sup> )	297	268	268
Total reads (millions)	130.4	100.5	148.7
Aligned reads (%)	99.5	100	100
Mean coverage (%)	49.3	44.3	54.2
Targeted fraction ≥ 30X (%)	66	55	76
Ti/Tv <sup>b</sup>	3.16	3.19	3.22
<b>Number of variants<sup>c</sup></b>	16,394	16,231	17,325
SNVs <sup>d</sup>	16,087	15,917	16,984
Indels <sup>e</sup>	307	314	341

<sup>a</sup>bp: base pairs.

<sup>b</sup>Ti/Tv: ratio of transitions to transversions.

<sup>c</sup>High confidence variants (FILTER=PASS; total depth≥20; genotype quality≥100; and mapping quality ≥ 50).

<sup>d</sup>SNVs: single nucleotide variants.

<sup>e</sup>Indels: insertion/deletion.

Most pathogenic prediction scores provided by HADA supported the variant as deleterious/damaging, and ACMG class predictors classified it either as a pathogenic/likely pathogenic variant or VUS ([Table 2](#)). This variant predicts an amino acid change (p.Arg466Ser) affecting the catalytic center of the protein, which has been previously described in independent HAE type II cases and was shown to be responsible for reduced C1-INH activity [34-36]. These observations are fully compatible with the

clinical and biochemical findings supporting a diagnosis of HAE type II in the index case. Surprisingly, the sister was asymptomatic and had never experienced angioedema attacks, which further exemplifies the incomplete penetrance of HAE or that disease onset has not yet occurred. In any case, the provided genetic information could be used to anticipate potential clinical symptoms.

**Table 2.** American College of Medical Genetics and Genomics (ACMG) class predictions and pathogenic scores provided by HADA for the c.1396C>A variant found in a hereditary angioedema-affected family.

Predictor	Estimation
<b>ACMG class prediction</b>	
VarSome	VUS <sup>a</sup>
ClinVar	Pathogenic
InterVar	Likely pathogenic
<b>Pathogenic predictors</b>	
SIFT <sup>b</sup>	Damaging
Polyphen2 <sup>c</sup>	Benign
MutationTaster	Disease-causing
CADD <sup>d</sup>	31
DANN <sup>e</sup> score	0.997
DANN rankscore	0.798
LRT <sup>f</sup>	Deleterious
MetaSVM	Damaging

<sup>a</sup>VUS: variant of uncertain significance.<sup>b</sup>SIFT: Sorting Intolerant From Tolerant.<sup>c</sup>PolyPhen2: Polymorphism Phenotyping v2.<sup>d</sup>CADD: Combined Annotation Dependent Depletion.<sup>e</sup>DANN: Deleterious Annotation of genetic variants using Neural Networks.<sup>f</sup>LRT: likelihood ratio test.<sup>g</sup>MetaSVM: meta-analytic support vector machine.

## Discussion

### Principal Findings

Here, we present HADA, a web-based analysis tool to facilitate the identification of the genetic variants causing HAE. With HADA, we aimed to provide a user-friendly tool to assist in the diagnosis of HAE that is adapted to NGS technologies and to the evolving knowledge of the causes of HAE. HADA has potential to reduce the time to interpret the detected variants in the NGS era by aggregating data from multiple sources, a process that commonly takes several hours to complete if it is handled manually [37,38]. At the moment, HADA integrates information from 450 SNVs and indels from 5 genes (*SERPING1*, *F12*, *PLG*, *ANGPT1*, and *KNG1*) that we classified as variants likely affecting function. While curating this information, we found that variant descriptions in HAE cases did not follow a standard [4], and many of the studies did not clearly declare the causality of the reported variants [35,39]. This situation helps to explain why up to 21.3% (n=96) of the simple bona fide variants affecting function continue to be reported as VUS in the best case. Finally, we demonstrated the utility of HADA for explaining HAE type II in a family that was assessed by WES in three family members, and offered conclusive information about the existence of the previously described variant c.1396C>A (p.Arg466Ser) in *SERPING1*.

As is the case for many other rare diseases, genetic testing in HAE has become an important step to reduce the diagnostic

odyssey [40], increase the diagnostic yield, and tailor treatments [4,5]. The widespread adoption of NGS technology in clinical settings has led to the emergence of a wide variety of bioinformatics tools to assist and accelerate the detection and interpretation of associated genetic variants and their impact on disease risks. In recent years, an array of variant prioritizers and interpreters have been developed to obtain optimal rankings for the variants causing the disease. However, NGS-based solutions have not been adopted in the HAE community until recently [29-31]. Part of the explanation may reside in the fact that only two causal genes were known until 2018, and therefore most clinical diagnoses could only be made based on clinical symptoms and the biochemical measurements of C4 and C1-INH levels in plasma, along with C1-INH activity [5]. Importantly, public resource updates to assist in variant interpretation lag behind the pace of genetic discoveries. This is the case of Simply-ClinVar [41] or ClinVar, which are still outdated with respect to the genetic causes of HAE, reporting information for only two of the associated genes (*SERPING1* and *F12*). Simply-ClinVar also suggests *SLC34A1* as another HAE gene, although this evidence is unsupported by the current literature. This situation is changing currently, and the benefits of using NGS technologies to assess multiple genes simultaneously for HAE diagnosis are now clearer [5]. In fact, in patients with normal levels and activity of C1-INH, genetic testing is recommended for the routine diagnosis of many HAE subtypes. Furthermore, according to Germenis et al [4] and the international consensus on genetic aspects of HAE, it is widely

recognized that C4 and C1-INH plasma measurements can generate inconclusive results even in patients with genetic defects in C1-INH. Based on this, HADA will surely help practitioners to adapt to the NGS-based genetic screens of HAE cases.

HADA has some strengths and limitations for the interpretation of genetic variants involved in the causes of HAE. Among the limitations, the tool does not currently assess VCFs from families or trios and does not allow inferring whether a variant affecting function has a de novo origin from the patient's data. Similarly, HADA uses GRCh37/hg19 coordinates, which is still considered to be the gold standard in clinical settings [42]. Despite the fact that HADA can report the existence of variants residing in introns near the key elements for splicing, as has been recently found for a type I HAE case [43,44], novel variants affecting function residing deep within intron positions will remain undetected. The main reason is the limited capacity of current algorithms to predict the pathogenic potential of deep intronic variants [45]. Similarly, a variable proportion of information remains unavailable for many of the variants affecting function collected in the underlying database. For example, allelic frequencies are currently available from gnomAD and ExAC for as few as 11 to 20 (2%-4%) of the variants affecting function in HAE. As an example, the variant detected in the family analyzed in this study is a bona-fide causal variant of HAE. However, there are no records of this variant in the gnomAD or ExAC databases. Similarly, not all variants affecting function in HAE are described in current ClinVar or InterVar versions. Collectively, this situation adds to the challenge of better predicting disease effects of many of the variants that are declared as VUS.

Structural variants have an important role in HAE due to the presence of Alu element-related reorganizations affecting function in *SERPING1*, potentially causing HAE type I [46,47]. However, structural variants will not be interpreted by HADA at the moment as they have not been collected in the database. One of the main reasons for this is that, unlike the case for SNVs and small indels, current locus-oriented databases such as HAEdb do not provide the chromosomal coordinates of recorded structural variants from HAE families, making it difficult to integrate in HADA.

Among the strengths of HADA, we highlight the versatility of the tool to allow performing simple queries or to directly upload

VCFs. This offers the possibility of analyzing a variant detected at any throughput scale, using either NGS technologies or Sanger sequencing. This feature is a great advantage compared to HAEdb or LOVD, which are not adapted for the automated analysis of NGS data (eg, from a VCF), serving only for single-variant queries, and neither of these previous tools has been subjected to a curation process or the inclusion of novel HAE genes. In addition to the imposed filters to construct the curated database of HADA, allele frequencies are also provided for all populations that are currently collected in the gnomAD and ExAC population databases. To cover the possibility of new discoveries, HADA also includes information from all other described variants in the coding regions, the 5' and 3' untranslated regions, and the 50-bp flanking regions (where most splicing variants affecting function are located) to easily flag novel variants in the uploaded data. Finally, despite the fact that its use does not require sensitive information for the analysis, HADA automatically conducts a password-secured encryption of the data and does not permanently store any data on the server.

We anticipate that HADA will be constantly updated to register new variants affecting function and associated information, changes in the pathogenic classification, and the possibility to assess structural variants, and GRCh38/hg38 coordinate and reference sequence number conversions. This will be based on third-party requests and internal updates according to novel discoveries and standards.

## Conclusions

To adapt the genetic diagnosis of HAE to the era of NGS-based genomic medicine, we have developed HADA as a free and publicly available tool for simplifying the identification of simple variants affecting function in HAE. HADA will allow users to focus on biologically relevant questions instead of having to learn to install software dependencies, variant annotation tools, and become familiar with the UNIX command line. The main advantages of HADA are that it is focused on a disease, its ease of use, the ability to display specific and curated information of HAE either from individual or VCF queries, and that it is freely available. By combining these features into a single graphical and interactive tool, we expect that variant prioritization in HAE will become easier, faster, and standardized.

## Acknowledgments

We would like to thank the patients and nurses involved in the validation study. This work was supported by the Ministerio de Ciencia e Innovación (RTC-2017-6471-1; AEI/FEDER, UE) and the Instituto de Salud Carlos III (CD19/00231), which were cofinanced by the European Regional Development Funds "A way of making Europe" from the European Union; Cabildo Insular de Tenerife (CGIEU0000219140); and by agreement OA17/008 with the Instituto Tecnológico y de Energías Renovables (ITER) to strengthen scientific and technological education, training, research, development, and innovation in genomics, personalized medicine, and biotechnology. AA was supported by a fellowship from ULL-Cajasierte. The content of this publication is solely the responsibility of the authors and does not necessarily reflect the views or policies of the funding agencies.

## Authors' Contributions

AA, AB, and CF wrote the manuscript and designed the figures. AA, LR, IR, and CF built and curated the database. ArC and JR contributed information for HAE clinical aspects and sample collection of the tested family. AIC, RM, AC, JS, and AA managed and sequenced the DNA samples of the family tested and performed the variant calling. AB, JS, and AA developed the front end. CF designed the project and obtained funding. All the authors revised and approved the final version of the manuscript.

## Conflicts of Interest

Takeda Pharmaceutical Company funded a travel grant to AA. The rest of the authors declare no conflicts of interest.

## Multimedia Appendix 1

Schematic representation of the variant calling file (VCF) variant matching against the curated database and data downloading in HADA.

**KEYWORDS**

patient satisfaction; modeling; method; scale level; measurement theory

In a paper published in the *Journal of Medical Internet Research*, Bidmon et al [1] investigated the relationships between 24 attributes of the service provided by physicians and 4 features of patient satisfaction with these physicians. The service attributes were assessed via 4-category rating scales coded from 1 for “strongly disagree” to 4 for “strongly agree” and the satisfaction features via 5-category rating scales from 1 for “bad” to 5 for “excellent.” The latter measures were rescaled to range from 1 to 4.

The authors stated that their measures “have to be assumed at ratio scale level.” Ratio scale level is a concept defined in the representational theory of measurement [2]. According to this theory, measurement means assigning numbers to objects so that the numerical relations reflect the empirical relations between objects. Examples of empirical relations are the relations that emerge when a double pan balance is used. When two objects *A* and *B* are compared, the relations “*A* is heavier than *B*,” “*B* is heavier than *A*,” or “*A* is as heavy as *B*” might emerge. When, for all objects, “*A* is heavier than *B*” and “*B* is heavier than *C*” imply that “*A* is heavier than *C*,” then these relations can be represented numerically by always assigning

the higher number to the heavier object. This is the prototypical example of an ordinal scale. When two objects *A* and *B* are placed together on one pan of the scale and an individual object *C* on the other, empirical relations between pairs of objects and individual objects emerge that are analogous to those for comparing individual objects. When, for these relations, the same regularities hold as for the addition of numbers, these relations can be represented by assigning numbers so that  $\text{number}(A) + \text{number}(B) = \text{number}(C)$ , if and only if *A* and *B* together are as heavy as *C*. Such an assignment is empirically determined except for the arbitrary choice of the measurement unit. The position of the zero-point is empirically determined. This is, by definition, a ratio scale.

In the measurements presented by Bidmon et al [1], the basic objects are statements regarding attributes or, respectively, physician practices. The relevant empirical relations are results of comparative judgments regarding these objects. Presently, there is no evidence that, for such judgments, empirical structures exist that permit the position of the zero-point to be determined. Hence, the zero-points for the rating scales analyzed by Bidmon et al [1] cannot be determined empirically. In fact,

these zero-points are determined by arbitrary settings established by convention. Therefore, these scales are definitely not ratio scales.

In the absence of empirically determined zero-points, the analyses performed by Bidmon et al [1] are questionable. The authors estimated parameters for the model

$$\ln(Y) = b_0 + b_1 \ln(X) \quad (1)$$

where  $Y$  represents satisfaction with a specific feature and  $X$  is an agreement with a statement regarding a service attribute. The estimations for these parameters change when the locations of the zero-points are changed. Consequently, what these parameters tell us about the actual relationships between satisfaction and service attributes is unclear.

**KEYWORDS**

online physician ratings; patient satisfaction; multiattribute models; health care management

We appreciate the comments made by Konerding [1] and are thankful for the opportunity to take part in this research dialogue. Konerding [1] states that "the zero-points for the rating scales analyzed by Bidmon et al [2] cannot be determined empirically" and "what these parameters tell us about the actual relationships between satisfaction and service attributes is unclear." It is obvious that the arguments of Konerding [1] rely solely on the paradigm of representational theory of measurement. However, the academic literature acknowledges three theories in this domain: the representational, the operational, and the classical (we refer to Michell [3] for an excellent discussion on this topic, which has already been cited in our paper [2]). Consequently, we understand the point of view conveyed by Konerding [1], but perceive it as too narrow in the spirit of empirical research. We are pleased to clarify as follows.

First, our assumption for the scale level of the satisfaction ratings draws from a well-known conceptual framework: the 3-factor model of customer satisfaction [4-6]. This model includes the concept of linear and nonlinear relationships between satisfaction ratings of a service attribute and the overall

satisfaction rating with the service (describing diminishing, constant, or increasing returns).

Second, the methodological assumptions to empirically identify the 3-factor model of customer satisfaction are clearly spelled out in our methods section (see our paper [2], subsection *Statistical Analysis*), and the approach using the log-log regression model to estimate elasticities is well established in the literature of econometric models of demand [7]. Elasticities allow the interpretation of slope coefficients in terms of diminishing, constant, and increasing returns.

Third, in our work [2], we emphasize the range and conditions where our results can be interpreted: the empirical meaning of our nonlinear slope coefficients and the prediction of changes in patient satisfaction apply to the range of publicly available ratings on the physician rating website. Explicitly assuming ratio-scale level within our specific range of satisfaction ratings is a helpful and valid assumption to empirically identify the 3-factor model of customer satisfaction (which has only been implicitly assumed in previous research). Our choice of numerical coding for the ratings (which follows common

practice in empirical research) ensures that the diminishing, constant, and increasing returns are correctly identified within the relevant range of our satisfaction ratings.

Fourth, we provide a robustness check in our paper [2] to show that our empirical findings do not rely on the log-log regression model or the elasticities (this robustness check was explicitly suggested by the author of the comments [1] during the review process of our paper [2]). The most important finding from applying the alternative approach is that it leads to results that are identical to those from our main approach for the classification of the service attributes to the 3-factor model of customer satisfaction. We would like to take the opportunity to

emphasize that this alternative approach (leading to the same results) should not be preferred to our main approach because it violates the principle of sparse parametrization and lacks straightforward hypothesis testing.

Taken together, we are thankful for the fruitful discussion concerning our main approach, which has led us to clearly spell out the assumptions under which our results are valid, and to emphasize the robustness check that supports the validity of our main approach. We advise researchers to bear these assumptions in mind when interpreting our results and especially when adopting our main approach to empirically identify nonlinear slopes from rating data.

**KEYWORDS**

internet-based intervention; education; spin bias

We read the article “Facebook as a Novel Tool for Continuous Professional Education on Dementia: Pilot Randomized Controlled Trial” by Chan et al [1] with great interest. The idea that face to face education is difficult and education via the internet or social networking systems is necessary is intriguing; this is an important perspective in the midst of the COVID-19 pandemic. In the article, the editor wrote, “readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness”; hence, we would like to discuss some perspectives.

First, the primary outcome was measured using the differences in the scores of the pre- and postintervention knowledge assessments, which comprised the 25-item Dementia Knowledge Assessment Scale (DKAS) and a formative evaluation of 20 multiple-choice questions. However, the authors’ conclusion is

focused on the outcome of improving participants’ knowledge concerning a single subscale in DKAS. This interpretation might be a spin that could warp the interpretation of results and mislead readers [2].

Second, the article has issues with multiple testing. When tests are divided into subscales, some of them may have significant differences. To show a significant difference in the effect, corrections to the multiple tests are required [3].

Finally, this study is a pre and post study; therefore, a paired *t* test should be used instead of a two-sample *t* test. The two-sample *t* test estimates the treatment effect using only the responses at follow-up, and it does not use any information at baseline, which may be useful for increasing efficiency if the baseline and follow-up outcomes are correlated [4].

**KEYWORDS**

dementia care; social network sites; Facebook

We would like to thank Dr Saishoji and colleagues [1] for the opportunity to respond to the issues raised in their letter and to clarify aspects of our study design in relation to these concerns. We would also like to thank Dr Saishoji and colleagues for their interest in our paper [2] and for taking the time to express their concerns.

Our study, a pilot randomized controlled trial, adopted mixed-research methods (quantitative and qualitative) to evaluate the feasibility and acceptability of utilizing Facebook to deliver a continuous professional education (CPE) program to health care professionals. We believe that it is important to explore different effects of the intervention on participants' own provision of care. Therefore, we focused on measuring the knowledge relevant for the practical care of people with dementia rather than a high level of scientific knowledge related to dementia [3].

In addition to the primary outcome (knowledge about dementia, via the Dementia Knowledge Assessment Scale), we also evaluated participants' compliance, participants' engagement in the intervention, participants' satisfaction, and participants'

attitudes toward using Facebook for professional education from a quantitative perspective. Although significant differences between the intervention group and the control group were not observed in the primary outcomes, we found that the Facebook intervention did well in offering gains to participants' knowledge and enhanced their engagement and compliance. For that reason, we tried to elaborate on all the outcomes to bring readers a comprehensive picture of the actual application of Facebook for future CPE programs.

We agree that there may be an increased risk of type 1 error when applying multiple statistical tests, and in some cases, correction, such as the Bonferroni correction, can be used. However, we understand that adopting this kind of correction is not a must; it depends on the rationale of the study [4]. Our study was exploratory, involving a few posthoc comparisons, which were regarded as hypotheses for further investigation. Thus, we believe that no correction would be needed in our pilot study.

We appreciate the comment on how our statistical analysis was reported. Hence, we would like to take this opportunity to

provide additional details pertaining to our analysis. In measuring the primary outcomes, an independent sample *t* test was used to compare the changes in the mean knowledge gain scores between the two groups at the postintervention assessments.

We agree with Dr Saishoji and colleagues [1] that online education is intriguing and important during the current COVID-19 pandemic. We would be glad to keep communicating with investigators on research in this area.

(*J Med Internet Res* 2020;22(10):e24891) doi:[10.2196/24891](https://doi.org/10.2196/24891)

In “Building a Digital Tool for the Adoption of the World Health Organization's Antenatal Care Recommendations: Methodological Intersection of Evidence, Clinical Logic, and Digital Technology” (*J Med Internet Res* 2020;22(10):e16355) the authors noted three errors.

The name of author Tigest Tamrat was incorrectly listed as “Tigist Tamrat”. This has now been changed to the correct spelling.

Under the section “Structured Documentation”, one instance of the phrase “business process mapping (BPM)” has been corrected to “business process mapping notation (BPMN)”.

Figure 6 has been replaced with a new version of subsection B (seen below), as the authors did not have permission to use images displayed in the originally published version of subsection B. Figure 6 subsections A, C, and D have not been changed from the originally published version.

**Figure 6.** Screenshots of the World Health Organization Digital Antenatal Care (WHO digital ANC) module. A: List of patients; B: Individual patient record summary; C: Home screen; D: Patient contact summary.

The correction will appear in the online version of the paper on the JMIR Publications website on October 13, 2020, together with the publication of this correction notice. Because this was

made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

## Abstract

As the demand for telepsychiatry increases during the COVID-19 pandemic, the strengths and challenges of telepsychiatry implementation must be articulated to improve clinical practices in the long term. Currently, observations within US contexts are lacking; therefore, we report on the rapid implementation of telepsychiatry and workflow experiences in a psychiatric practice based within a large health care system in southeast Texas with a national catchment area. We discuss the logistics of the implementation, including modes of communication, scheduling, coordination, and capacity; the psychological effects of web-based services, including both the loss of the physical therapeutic environment and the unique interpersonal dynamics experienced in the virtual environment; and postadoption patterns of engagement with our services and with other clinical functions affected by the rapid adaptation to telemedicine. Our art therapy group programming serves as an applied case study, demonstrating the value of a well-managed web-based program (eg, patients were receptive and well-engaged, and they appreciated the continuity of accessible service) as well as the challenges (eg, the need for backup plans and technological fallbacks, managing interruptions and telecommunication learning curves, and working around the difference in resources for art and music therapy between a well-stocked clinical setting versus clients' home spaces). We conclude from our experience that the overall strengths of telepsychiatry include receptive and well-engaged responses from patients as well as the expansion of boundaries, which provides a directly contextualized view into patients' home lives. Challenges and corresponding recommendations include the need for more careful safety planning for high-risk patients; maintaining professional boundaries in the newly informal virtual setting; designing the physical space to both frame the patient encounter and maintain work-life balance for the therapist; allowing for delays and interruptions (including an initial acclimation session); and preserving interprofessional care team collaboration when the physical locations that normally facilitate such encounters are not accessible. We believe that careful observations of the strengths and challenges of telepsychiatry during this pandemic will better inform practices that are considering telepsychiatry adoption both within pandemic contexts and more broadly thereafter.

## Introduction

The spread of COVID-19 and wide-scale self-quarantine and shelter-in-place orders have led many nonemergency practices

to adopt telehealth solutions to continue serving their patients [1], and psychiatry is no exception. While some cases will still warrant inpatient psychiatric admissions, including coordinated care for psychiatric inpatients who test positive for COVID-19

[2], telepsychiatry is a viable option for handling outpatient scenarios. Best practices are already in place [3], and there is a supportive evidence base for telepsychiatry [4-6], particularly for web-based therapy for depression [7] and posttraumatic stress disorder [8]. However, the forced adoption of and mass transition to telehealth during the COVID-19 pandemic has resulted in significant challenges for the implementation of telehealth for psychiatric services [9,10]. While guidelines exist for postpandemic telepsychiatry [11,12], given the unique characteristics of this COVID-19 pandemic, lessons learned from these transitions as well as implementation-specific guidelines would be highly applicable to other practices. To date, clinical implementations and lessons learned (and with largely positive results) have been reported largely from settings outside the United States, such as China [13,14], Europe [15-23], Turkey [24], and Australia [10,25-28], with only some US coverage (notably [9], [29], and [30]). In this paper, we document our experience with telehealth adoption at a psychiatry practice embedded in a large health system in the United States and summarize several important successful improvisations and challenges to support broader and more diverse adoption efforts.

Established in January 2018, the psychiatric outpatient clinic at Houston Methodist Hospital offers programs of care to address gaps in the current mental health treatment continuum. The therapeutic outpatient assessment services span approximately 10 business days (2 to 4 hours per day) and are tailored to patients with complex and persistent psychiatric conditions, including depression, anxiety-related disorders, trauma, psychosis, interpersonal dysfunction, chronic pain, sleep disorders, emotional regulation problems, and suicidality. The team-based, multidisciplinary assessment is designed to optimize insight, produce maximal diagnostic clarity, and create a roadmap for future treatment.

The clinic offers access to mental health care through a >5-week Functional Rehabilitation Program that includes morning group therapy sessions and individual sessions in the afternoon. The program proceeds on an outpatient basis, enabling patients to complete treatment while remaining engaged with their lives. The approach to treating patients incorporates an understanding of broader contexts, such as medical comorbidities and social determinants of health. The clinic also offers services to meet the varied and dynamic needs of our patients, including an intensive outpatient program, a modified functional rehabilitation program, individual psychotherapy, couples counseling, psychotropic medication management, and art and music therapies.

In some ways, our clinic had a “head start” on the COVID-19 pandemic compared to most other clinics, as it was already transitioning to digital platforms before the pandemic [31]. The system-wide support for innovative technologies in our health system had resulted in early adoption of and significant investments in telehealth, including secure and integrated technology to facilitate virtual visits embedded within our electronic health record (EHR), a virtual intensive care unit [32], and adoption of telemedicine postoperative follow-up [33]. We had already vested and integrated a platform called CareSense (MedTrak, Inc) for previsit and postvisit care coordination and patient-reported outcomes (see [31] and Fowler

et al, forthcoming). Hence, frequently cited sources of provider hesitation to adopt telemedicine, including workflow integration and infrastructure-related logistics [4,34-37], did not apply to our practice or to our overall culture. However, the COVID-19 pandemic still necessitated rapid adoption of changes to go live before full testing.

## Implementation and Experiences

On March 18, 2020, our outpatient clinic transitioned to a 100% telehealth platform, and it is continuing with this approach as of this writing. Our complete transition and continued use of telehealth technologies contrasts with many other outpatient practices, where clinics have followed suit with local businesses and have opened to provide at least some in-person treatment. We chose a more conservative approach to the ongoing use of telehealth technologies for many reasons. Hospital-wide policies require face masks and six feet of social distancing for all outpatient visits for both patients and providers. These safety requirements reduce the risk of COVID-19 transmission but come at a significant cost to the daily practice of outpatient psychiatric care. Our assessments and interventions rely heavily on nonverbal and verbal communication. Masks cover well over half of patients' faces, limiting providers' assessment of patient affect. Additionally, masks muffle voices. This facet of mask-wearing has the potential to negatively affect the content of verbal output and subsequently affect comprehension for patients and providers alike. Verbal communication from at least six feet away only worsens the potential negative consequences of muffled voices.

### Diversifying Modes of Communication: One Size Does Not Fit All

In our practice, we found it essential to leverage multiple platforms and modalities (eg, Cisco Webex, Microsoft Teams, email, telephone calls, the EHR, patient portal communications) to facilitate the initial transition. While such an inclusive strategy may increase the logistical complexity of care for the providers, our clients found the backup options and redundant systems to be essential. For instance, one client became anxious and frustrated by initial difficulties downloading Webex; therefore, we pivoted to using FaceTime (Apple Inc), which did not require an additional tool and was familiar to the client. Another client, who was feeling lonely and disconnected but struggled to find time for sessions because of childcare demands, was able to feel connected by occasionally texting her therapist. The texts included YouTube links to humorous videos on shared pandemic struggles. In addition to serving a wide range of client preferences, this flexibility was key to help us maintain the availability of service even when one modality lagged or became unresponsive. In addition, having different levels of fidelity on hand (eg, from high-tech Webex to low-tech telephone calls) created a scaffold for backup options and platforms that can be used in tandem. Of course, a list of both COVID-19-provisional approved applications and technology that is more generally compliant with the Health Insurance Portability and Accountability Act (HIPAA) should be consulted to ensure digital security and privacy [38].

Conversely, diversifying the modes of communication also carries efficiency costs (both within the care team and in team-client interactions). These include logging in to platforms and waiting for others to do the same; pausing for deliberate transition between speakers; and reporting the same information in different forms and in multiple places (eg, rapid switches between sessions on Microsoft Teams and formal documentation of the same in the EHR).

### Special Logistical Concerns

Handoff procedures were particularly transformed in the new process. Using the gaps between sessions for quick handoffs results in moving from meeting to meeting without a break and then ending the day with more in-depth documentation. We experienced an increased need for communication between team members; casual hallway or “water-cooler” handoffs frequently occur in physical clinic settings, but these could not occur when the care team shifted to telecommuting. Some team members adapted to the loss of this natural and implicit means of coordination by more explicit efforts, while others “went silent.” We learned that staff should consciously expect and prepare for these easily underestimated differences in communication dynamics.

Management of schedules and appointment times was also more stressful and demanding, as tardiness or absence from appointments became ambiguous. An office no-show can occur for many reasons but at least is always counted as an absence. Web-based absence can result from an otherwise ready client experiencing technical difficulties, a broken or misdirected link, or an adjacent appointment; other no-show reasons include forgetfulness or distractions due to other turmoil (quarantine-related or otherwise). In addition, team members’ and clients’ free time has been transformed, limited or expanded, and distributed differently due to lockdown. Factors such as childcare, other caregiver needs, or the presence or absence of other adults in the home have become factors that affect schedules.

Finally, we found that team members and clients had variable capacity to formulate their communication behaviors and subsequently adapt them to the virtual leap. Technological comfort, literacy, and fluency also played roles. When finally online, users experienced differences in the conversational flow in the web-based environment and had to adjust their interviewing styles, such as avoiding talking over the patient. Video exists in a liminal space between in-person interaction and nonvisual interaction. When face-to-face, interlocutors experience familiar nonverbal cues to signal when a speaker is finished or when a listener is still attentive or becoming unsettled, which informs the turn order of speaking as needed; in radio communications, there is a clear expectation that these cues will be absent (hence, conventions are in place such as saying “over” to replace the cues). Web-based video lacks the fidelity to retain the cues but “teases” users with at least some visual context; therefore, we may not properly reset our expectations (nods are missed in choppy video feeds, pitch cues are missed in the audio transmission, eye contact is disrupted by the offset camera eye, etc.). Delays in communication as speakers are confused by the turn order affect the length and

efficiency of the session, and more time is required to build rapport and trust with new patients.

### Psychological Effects of Web-Based Audiovisual Chat

Our clinic emphasizes differentiation through “time and team” to produce a therapeutic effect. With telehealth, we need to be more mindful of the “time” aspect, which as noted above has been transformed. Web-based chat fatigue (also referred to as “Zoom fatigue” during the COVID-19 pandemic) of patients and team members has sometimes motivated us to limit the duration and frequency of sessions to spread out the mental effort required. Patients still receive the time that our clinic promises; however, they may need to be more flexible with the duration of our programs. As a team, we do not have as much time to talk about patients together because we are confined to team meetings and have strict cutoff times and schedules before the next Webex meeting begins. We also miss the in-person consultations between staff, which have social and not purely logistical benefits. For both our clients and health care workers, a well-established period of reflective *time* can be as therapeutic and rejuvenating as any sacred or holy *space* [39]; therefore, the fragmentation of that time into asynchronous processes such as emails is felt. We have used other technology formats and call or text providers as needed to communicate. The needed information is communicated; however, these consultations are quick and detailed information is lost.

Time and space coalesce to form a therapeutic environment for mental health. Space is now virtual, with sessions taking place in the patient’s home or home office in a manner contiguous with the rest of their day. Thus, they can lose the effect of relocating to a separate and unique space, such as the psychiatrist’s office. In this new space, team members and clients have needed to work harder to generate and sustain interpersonal connection. Social signals and efforts must be amplified to overcome the loss of intimacy and belonging derived from physical proximity. This is difficult when new relationships begin in the virtual environment, in contrast to existing clients, with whom rapport was already established before the transition to virtual sessions. Conversely, video chat garners some closeness because of the virtual invitation into normally private spaces (eg, the therapist’s and client’s home office or kitchen table). Viewers obtain unintended but inevitable glimpses into each other’s home lives (children, pets, spouses roaming in the visual or audio background) [40], and even dress tends to be less formal.

### Services and Service Lines Under Telehealth

We carefully scrutinized which services can transition without an unacceptable loss of integrity and which cannot. Individual therapy is an easy and established service for telehealth [5,7]; group therapy has been received well by providers and clients alike, perhaps because the program is small. Art and music therapy programs had precedents; however, the success of transition was uncertain, and exploratory efforts were required to establish workability, as in our case study below. Neuropsychological services had to be limited to simple screening. These choices were determined by individual workplaces but should not arise in a vacuum.

Some programs may thrive more during quarantine than they otherwise would via telemedicine or other modes. Namely, we suspect that people are currently happy to connect in group programs because they are not seeing anyone else due to quarantine. Although there are still some technological challenges, patients are glad to have a social space. Once clients re-engage with their normal social supports and are not quarantined, participation in group sessions may decrease.

Specific functions of our psychiatric practice have also been transformed. Some psychological testing can now be completed through vendor-supplied web-based portals. Other tests require a physical presence, such as medical tests, genetic testing, and magnetic resonance imaging (MRI), and therefore present a challenge. More time is needed to order these tests and to receive results. We no longer have the luxury of ordering and coordinating care within our system. We must rely on external facilities, and relevant information is not always readily available in our EHR. Releases of information and other paper forms must be completed by hand, scanned by patients, and then emailed to us. Fillable forms (eg, smart PDFs) are more efficient and easier for patients who may lack access to technology or suitable home office supplies.

### Case Study: Art/Music Therapy Group

Art and music therapies are integral components of our uniquely structured Functional Rehabilitation Program; all patients participate in these forms of therapy in both individual and group settings. While more common forms of psychotherapy are also features of the core clinical programming (eg, acceptance and commitment therapy, dialectical behavioral therapy skills training, process-oriented group therapy), we chose to highlight art and music therapy because of the additional logistical challenges these therapies required in transitioning from in-person sessions to a telehealth platform—namely, the need for therapy-specific equipment, such as painting supplies and musical instruments.

The first tele-art therapy group was held by telephone rather than video due to technical difficulties. While it was difficult to conduct an art therapy group session without being able to see anything, the planned session included a writing prompt, and patients were able to share what they had written along with a description of what they had started to create (demonstrating the *importance of backup plans and backup technologies* noted above). The timing was a challenge as well because the session took a long time to get started due to technical issues; however, the patients were open to continuing to work on the art pieces on their own, and they brought their pieces to the next session (*anticipating in-session time spent on technology; managing interruptions*). By the second session, the video was functional, and the patients were able to show their images. The idea of using the group session as the time to start a piece and then continuing to work on the piece or create additional images during the week was well received, with mixed participation (*patients as receptive and well-engaged*). Availability of art materials is another challenge; some people have plentiful supplies at home, while others have more limited supplies. Ordering items for delivery now faces delays in shipping for

many items and low stock due to the increase in the numbers of people who are quarantined or sheltering in place who are ordering art supplies (*setting the in-home therapeutic space*).

Our providers observed that the patients seemed grateful to have the groups as a way to create structure in their days and to connect with others. Pre-existing rapport noticeably helped in this case: while similar online offerings are available, there is a sense of community for existing patients that they would not find by selecting a different offering, such as an online support group or art class. At the same time, our staff served as an anchor that enabled the patients to reach out to other support groups and engage in more opportunities during this time than they might normally have done because they knew they could check in with us about the other things they were trying.

Despite positive outcomes, the applied and physical nature of art and music therapy poses unique challenges, largely revolving around the resources necessary for traditional session plans. The therapist and patient do not have equal and shared access to instruments. If a patient wants to use music education in their therapy, such as learning guitar skills, they do not have access to the music therapist's instruments to achieve this. Time lags in internet video conferencing also make joint music-making difficult. This removes real-time improvisation and some re-creative approaches from the therapist's repertoire until technological adjustments or advancements are made; for example, music-making interventions such as group drumming are removed from the music therapist's toolbox.

In this type of therapy, there is also an increased burden on the patient to learn technological skills to participate in telemedicine. Even if the therapist has the resources to provide high-quality video and audio, that quality can be lost if the patients' technological resources are not equivalent. Higher-quality technology resources are needed to ensure quality experiences more than in conversation-based interventions (which, as we've seen, can default to mechanisms as simple as the telephone). USB microphones and high-speed home internet are not ubiquitous even among fairly privileged patients, raising additional concerns of potentially exacerbating disparities for lower-income patients and their care access to telemedicine programs of this nature. For patients who can obtain the necessary resources, technical literacy may still present a barrier; therefore, the therapist serves a dual role as the patient's information technology support in troubleshooting not only the teleconferencing method in general but also the audiovisual equipment required.

Although not ideal for re-creative or improvisational models, the internet and its associated technologies are rich in opportunities for receptive and compositional methods of music therapy. Most technology platforms (which are free but also require a certain amount of internet bandwidth) enable screen sharing and high-quality video for receptive music therapy interventions. This includes screen sharing for collaboration on lyrics or looking up chord charts on the internet. These web-based techniques take time to learn; therefore, the therapist should budget extra time accordingly for self-orientation and patient orientation. It is important for the therapist to test their new technology skills before entering sessions. The therapist

should practice their new skills with a fellow therapist or family member. Free and easy-to-learn software programs are available for music production and composition, such as GarageBand and Audacity. Granted, “easy-to-learn” is relative to the more complex software available as well as the patient’s or therapist’s baseline technological skills, although learning and improving one’s self-efficacy can have benefits and rewards as well.

## **Summary of Strengths, Challenges, and Recommendations**

Our clinical team identified several strengths and key challenges when moving forward with our rapidly implemented telemedicine program; these may be instructive both to other psychiatric practices that are thinking of adopting telemedicine and to practices seeking to improve currently implemented programs.

### **Strengths**

#### ***Patients Are Receptive and Well-Engaged***

All our prepandemic established patients continued to engage in some degree of programming when we transitioned from an in-person platform to telehealth. We were mindful of individual differences in the extent to which patients were willing to transition to telehealth programming and in their preferred platforms. Patients and providers engaged in a shared decision-making process, and we tailored our programming and mode of service delivery based on patient preferences. Postpandemic patients generally chose a reduced intensity of treatment from the beginning of their treatment with us. Overall, most patients seemed relieved that in the midst of the pandemic, therapeutic structures and support were still accessible. Rapport is enhanced by a sense that both providers and patients are going through a crisis together; this humanizes the providers to the patients while also giving providers an opportunity to model intentional coping, balanced responses to the crisis (on most occasions), and active anxiety regulation in real time. Our experience is corroborated by other US sites that implemented telemedicine rapidly [9] as well as by generally positive reviews showing patient satisfaction with telepsychiatry [5,6].

#### ***Virtual Groups Have Been Well-Attended, and Engagement in Some Respects Has Increased***

The relative isolation that group members are feeling has spurred them out of their comfort zones to engage more actively and depend more on their peers. For some group members, especially those with more avoidance and social anxiety, the current circumstances are leading them by necessity to experience their peers as a new and positive source of support.

#### ***Telepsychiatry Expands the Boundaries of Psychological Intervention Into the Real World***

By necessity, telehealth visits take providers out of the one-on-one environment of traditional brick-and-mortar practice and into their patients’ everyday lives, living rooms, and backyards. In one session, we were actually able to see one patient relate with her son in real time instead of just talking with her about their interaction and interpreting it as filtered

through her perception. This direct and contextualized interaction increases the ecological validity and relevance of therapy and opens opportunities for more flexible service delivery models in future practice that are more effective and helpful for patients and less restrained by antiquated “red tape.”

### **Challenges and Recommendations**

#### ***High-Risk Patients***

High-risk patients require more active safety planning, case management, and tolerance of anxiety and uncertainty related to unknown aspects due to lack of in-person visits. For our established chronically suicidal patients, we made emergency contact details readily available prior to scheduled sessions, expressed the ability and willingness to engage emergency medical services if necessary, and provided direct access to our inpatient psychiatric unit should the need arise. Fortunately, we did not need to mobilize any of these contingencies for prepandemic established patients. However, for patients who were admitted to our practice after we transitioned to an exclusively virtual platform, risk management created significant logistical challenges. We did facilitate inpatient psychiatric admissions with significant assistance from family members, who needed to bring their loved ones to the hospital emergency department, were not allowed to accompany them past that point, and were required to communicate with the inpatient care team almost exclusively by telephone. Additionally, we supplemented our outpatient programming with home health aides out of medical necessity. Management of risk in a virtual setting requires considerably more time, effort, and creative problem-solving than in-person clinical care [20]. To date, we have managed risk without adverse events. In this area, further research on the process, patient and provider experience, and outcomes is warranted.

#### ***Establish a Provider Culture of Telemedicine Adoption***

One observed strength was not a strength of our telemedicine program per se but of provider willingness to adopt telemedicine as a solution; 100% of providers transitioned to telemedicine platforms with varying degrees of fluency and need for ongoing logistical support. Studies have reported provider hesitation to adopt telemedicine based on concerns about workload [34], usability [35,36], EHR and systems integration [36], other logistics related to time and staff [37], and incentives, reimbursements, and regulations [35,36], especially in the case of telepsychiatry, which deserves special consideration when COVID-19–based federal policy changes and leniencies expire [4,41]. Hence, the success of telemedicine adoption is greatly facilitated by investing in the cultural, logistical, and infrastructural factors to enable success (see also Kalin et al [29], who likewise credit their successful COVID-19–related telepsychiatry adoption to organizational culture and prior technological readiness). However, “from-scratch” implementation is also possible, as in the case reported by Yellowlees et al [9], who impressively planned a complete program to adapt in-person sessions to telepsychiatry in one day and had fully implemented it for all patients within three working days. Other attempts were more encumbered by technical and training difficulties; however, it was found, as in

our study, that use of multiple platforms had a mitigating effect [30].

### ***Set the Therapeutic Frame With Intentionality to Manage Risk***

The transition to a virtual frame risks blurring normal therapeutic boundaries by decreasing the formality of the encounter. For example, there is a need to demarcate a telephone-based therapy appointment from a telephone call with a friend or a fellow citizen in the midst of a pandemic. In an office, this frame is set through physical elements, including the office, furniture, and waiting room. In virtual space, this frame must be instituted verbally, though not rigidly, through maintaining intentionality about how the conversation relates to the patient's overall goals. Mindfulness and management of the professional practitioner-patient relationship remains as important as ever. It is also worth noting that most web platforms allow for anonymous telephone calls or web-calling using a web-based profile, which allows the therapist to avoid disclosing their own personal account or telephone number when checking in with the patient.

### ***Setting the Physical and Visual Backdrop Requires Forethought and Design***

Setting the frame requires more than verbal and behavioral monitoring. Although it can be humanizing for the patient to see the therapist in their natural habitat, it may be necessary to hide unattractive objects in the therapist's home. A foldable standing blind can be useful for hiding items such as laundry baskets, beds, and the kitchen counter. The blind also provides a consistent, professional, and aesthetically pleasing therapeutic environment. Lighting is also a consideration; for webcasting, it is better to be lit from the front than from the back. To avoid additional glare from the ceiling fan, the laptop computer or camera should be positioned so that the ceiling fan is not in view.

### ***Maintain Work-Life Balance by Separation of Space and Time***

The blinds and other physical rearrangements needed for the therapeutic space can also benefit the therapist as a transitory demarcation of work versus home spaces. Home is a refuge from work, and working from home blurs the roles of the home and work environments. Using a blind to "set up" the office changes the environment from home to work and vice versa at the end of the day. This transition helps to "give back" the space to the therapist and acts as an affordance to return to normal use of the space. If the therapist's floor plan allows for a permanent home office space, this can also demarcate a work zone from a home zone; however, the lack of physical actions and motions for setup and breakdown in this case should be replaced by disciplined scheduling to signal work time and free time in some other way. It is worth noting that health care workers, including psychiatrists and mental health workers, can also benefit from receiving telepsychiatry services [24].

### ***Introduce the Client to the Virtual Space and Expect to Take Up Initial Session Time***

When beginning initial sessions, it is important to allow time for orientation to the technology [9]. In the same way a new patient may need help to find their way into the building and park their car, they may need our help to orient to the technology. It is important for the therapist to take a "walking with" stance with the patient and express that the therapist and the patient are "in this together." Allowing time for technology and normalizing it as part of the orientation to therapy can help assuage a new patient's anxiety about their first session. The therapist should aside a generous 10 or 15 minutes simply to help the patient with the technology. This also has the effect of building trust between the patient and the therapist. Provider-guided orientation may thus be uniquely warranted in telepsychiatry in contrast to other forms of telemedicine, in which the provider and patient may both prefer to save time by using pre-session tutorials or medical assistant-led guidance to use the technology instead.

### ***Interruptions May Disrupt Session Plans and Will Require Management***

Potential interruptions naturally arise as the patient's family or pets enter the picture, particularly if home childcare is an issue for either the patient or the therapist. These interruptions are inevitable and must be managed. In group sessions, this may cause patients to miss key discussions. Interruption recovery techniques include video replay (if sessions are recorded) or history logs (if time-stamped real-time notes are taken) [42]. Privacy issues can be mitigated through sound localization. Headphones are fairly essential, as they prevent family members from overhearing confidential session details or comments by therapy group members. Headphones also signal to others that the patient is absorbed in a task. If a meditative or focused exercise is planned, such as guided imagery or progressive muscle relaxation, it is important to let patients know this ahead of time so that they can take steps to help their family understand that they cannot be disturbed (and establish a backup plan in case of internet connectivity disruptions). Therapists and patients alike can also look into any affordable or employer-provided childcare options they feel safe with during the pandemic to mitigate childcare-related interruptions while remaining consistent with their household's social distancing plan.

### ***Shelter-in-Place Restrictions Challenge Active Interprofessional Collaboration***

Clinical isolation highlights the value of in-person informal consultation and colocation of a multidisciplinary team, both to preserve benefits to the patient derived from such team support [20,24] and for the morale of the team itself. Having short conversations in the hall, dropping by a colleague's office for a minute, and eating lunch with colleagues keep providers apprised of shared clinical work. Without these channels, more active time and participation are needed. We have implemented additional scheduled consultation meetings to account for the loss of informal consultation.

## Conclusion

The circumstances of the COVID-19 pandemic have created unprecedented challenges that are taxing the physical and mental

health of the populace; however, the pandemic has also created unprecedented opportunities to learn, teach, innovate, and evaluate telepsychiatry strategies as necessity spurs their adoption.

## Conflicts of Interest

None declared.
