Clinical decision support (CDS) systems have been discussed to enhance evidence-based practice and support cost-effectiveness [1-10]. On the basis of the three-level classification by Shortliffe, clinical predictive tools, referred to as predictive tools in this paper, belong to the highest CDS level, providing patient-specific recommendations based on clinical scenarios, which usually follow clinical rules and algorithms, a cost-benefit analysis, or clinical pathways [11,12]. Such tools include various applications, ranging from the simplest manual clinical prediction rules to the most sophisticated machine learning algorithms [13,14]. These research-based applications provide diagnostic, prognostic, or therapeutic decision support. They quantify the contributions of relevant patient characteristics to derive the likelihood of diseases, predict their courses and possible outcomes, or support decision making on their management [15,16].

When selecting predictive tools for implementation in clinical practice or for recommendation in clinical guidelines, clinicians and health care professionals, referred to as *professionals* in this paper, involved in decision making are challenged with an overwhelming and ever-growing number of tools. Many of these tools have never been implemented or evaluated for comparative effectiveness [17-19]. By definition, health care professionals include all clinicians who provide direct care to patients, in addition to professionals who work in laboratories, researchers, and public health experts [20]. Professionals usually rely on previous experience, subjective evaluation, or recent exposure to predictive tools in making selection decisions. Objective methods and evidence-based approaches are rarely used in such decisions [21,22]. When developing clinical guidelines, some professionals search the literature for studies that describe the development, implementation, or evaluation of predictive tools. Others look for systematic reviews comparing the tools' performance or development methods. However, there are no available approaches to objectively summarize or interpret such evidence [23,24]. In addition, predictive tool selection decisions are time-consuming as they seek a consensus of subjective expert views [25]. Furthermore, when experts make their decisions subjectively, they face much decisional conflict; they are less confident in the decisions they make and sometimes less satisfied with them [26].

To overcome this major challenge, the authors developed and published a new evidence-based framework for grading and assessment of predictive tools (the GRASP framework) [27]. The authors have also validated and updated the GRASP framework through the feedback of a wide group of international experts [28]. Furthermore, the authors applied the GRASP

framework to evaluate and compare 14 pediatric head injury clinical predictive tools. This study is now published [29]. The GRASP framework aims to provide standardized objective information on predictive tools to support the search for and selection of effective tools. On the basis of the critical appraisal of published evidence, GRASP uses 3 dimensions to grade clinical predictive tools: (1) phase of evaluation, (2) level of evidence, and (3) direction of evidence.

Phase of Evaluation

Predictive tools are assigned the letters A, B, or C based on the highest phase of evaluation: before implementation, during planning for implementation, or after implementation respectively. If a tool's predictive performance, as reported in the literature, has been tested retrospectively for validity using observational data, it is assigned phase C. If a tool's usability or potential effect have been tested prospectively using small pilots, which may or may not reflect routine practice, it is assigned phase B. Potential effect of a tool is the expected, estimated, or calculated impact of using the tool, assuming it has been successfully implemented and used in clinical practice. Finally, if a tool has been implemented in clinical practice and there is published evidence evaluating its achieved postimplementation impact prospectively, it is assigned phase A.

Level of Evidence

A numerical score within each phase is assigned based on the level of evidence associated with each tool. A tool is assigned grade C1 if it has been tested for external validity multiple times, grade C2 if it has been tested for external validity only once, and grade C3 if it has been tested only for internal validity. Grade C0 means that the tool did not show sufficient internal validity to be used in clinical practice. Grade B1 is assigned to a predictive tool that has been evaluated during the planning for implementation, for both of its potential effect, on clinical effectiveness, patient safety, or health care efficiency, and for its usability. Grade B2 is assigned to a predictive tool that has been evaluated only for its potential effect, while if it has been studied only for its usability, it is assigned grade B3. Finally, if a predictive tool had been implemented and evaluated for its postimplementation impact on clinical effectiveness, patient safety, or health care efficiency, then it is assigned grade A1 if there is at least one experimental study of good quality evaluating its postimplementation impact, grade A2 if there are observational studies evaluating its impact, and grade A3 if the postimplementation impact has been evaluated only through subjective studies, such as expert panel reports.

Direction of Evidence

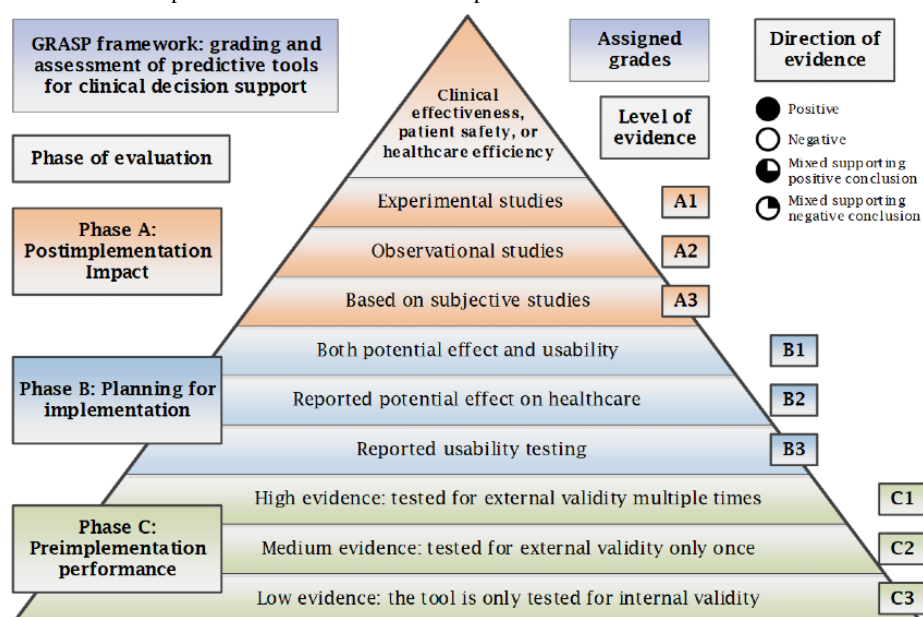

For each phase and level of evidence, a direction of evidence is assigned based on the collective conclusions reported in the

studies. The evidence is considered positive if all studies about a predictive tool reported positive conclusions and negative if all studies reported negative or equivocal conclusions. The evidence is considered mixed if some studies reported positive results, while others reported either negative or equivocal conclusions. To determine the overall direction of evidence, a protocol is used to sort the mixed evidence to support an overall positive or negative conclusion. The protocol is based on 2 main criteria: (1) degree of matching between the evaluation study conditions and the original tool specifications and (2) quality of the evaluation study. Studies evaluating tools in closely matching conditions to the tools' specifications and providing high-quality evidence are considered first for their conclusions in deciding the overall direction of evidence.

The final grade assigned to a predictive tool is based on the highest phase of evaluation, supported by the highest level of positive evidence, or mixed evidence that supports a positive conclusion. More details on the process of critical appraisal of published evidence, summarizing the evidence, and assigning grades to predictive tools are discussed in a published study that describes the development of the GRASP framework [27]. The GRASP framework concept is shown in Figure 1, and a detailed report of the GRASP framework is presented in Multimedia Appendix 1.

The aim of this study was to evaluate the impact of using GRASP on the decisions made by professionals in selecting predictive tools for CDS. The objective was to explore whether the GRASP framework positively supports professionals' evidence-based decision making and improves their accuracy and efficiency in selecting clinical predictive tools. To explore this impact, a group of hypotheses have been proposed including that using the GRASP framework by professionals is going to (1) make their decisions more accurate, that is, selecting the best predictive tools; (2) make their decisions more objective, informed, and evidence-based, that is, decisions are based on the information provided by the framework; (3) make their decisions less subjective, that is, decisions are less based on guessing, prior knowledge, or experience; (4) make their decisions more efficient, that is, decisions are made in less time; and (5) make them face less decisional conflict, that is, become more confident in their decisions and more satisfied with them. We also proposed that using GRASP can move professionals who have less knowledge, less experience, and are less familiar with predictive tools to an equal or even higher accuracy of decision making than professionals who have more knowledge, have more experience, and are more familiar with tools when they do not use GRASP.

Figure 1. The grading and assessment of predictive tools framework concept.

Methods

The Study Design

This study was based on experimental methods. It aimed to examine the performance and outcomes of professionals' decisions in selecting predictive tools with and without using the GRASP framework. Through a web-based survey, the experiment involved asking participants to select the best predictive tool for implementation in clinical practice or for recommendation in clinical practice guidelines from a group of 5 similar tools doing the same predictive task, one time with and another time without using the GRASP framework. In

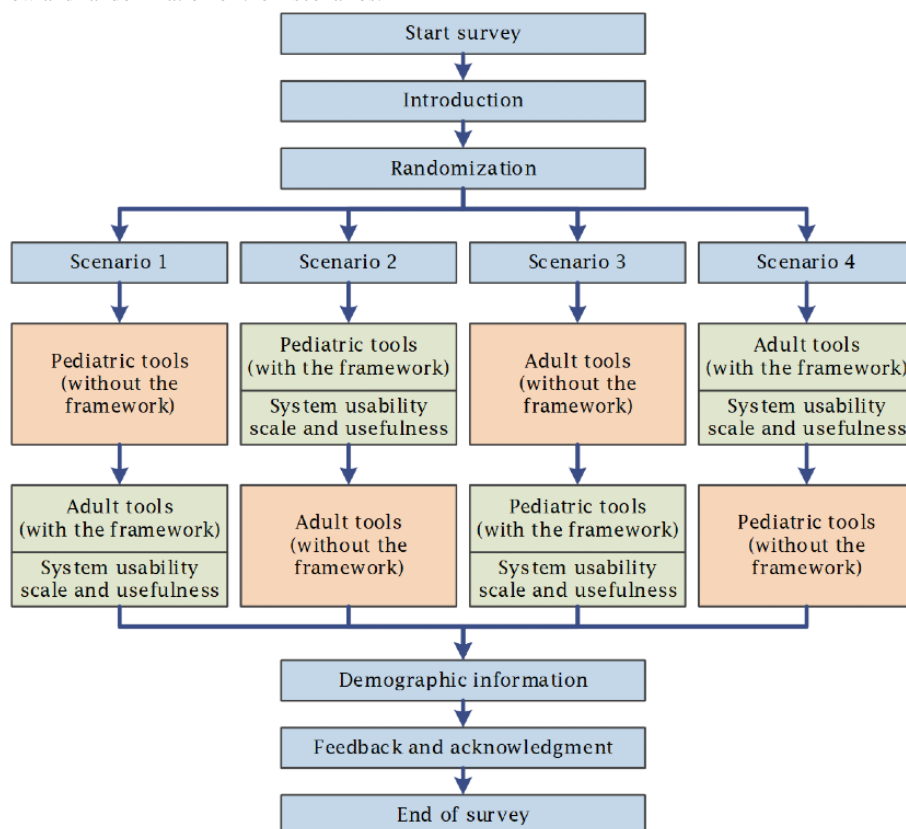

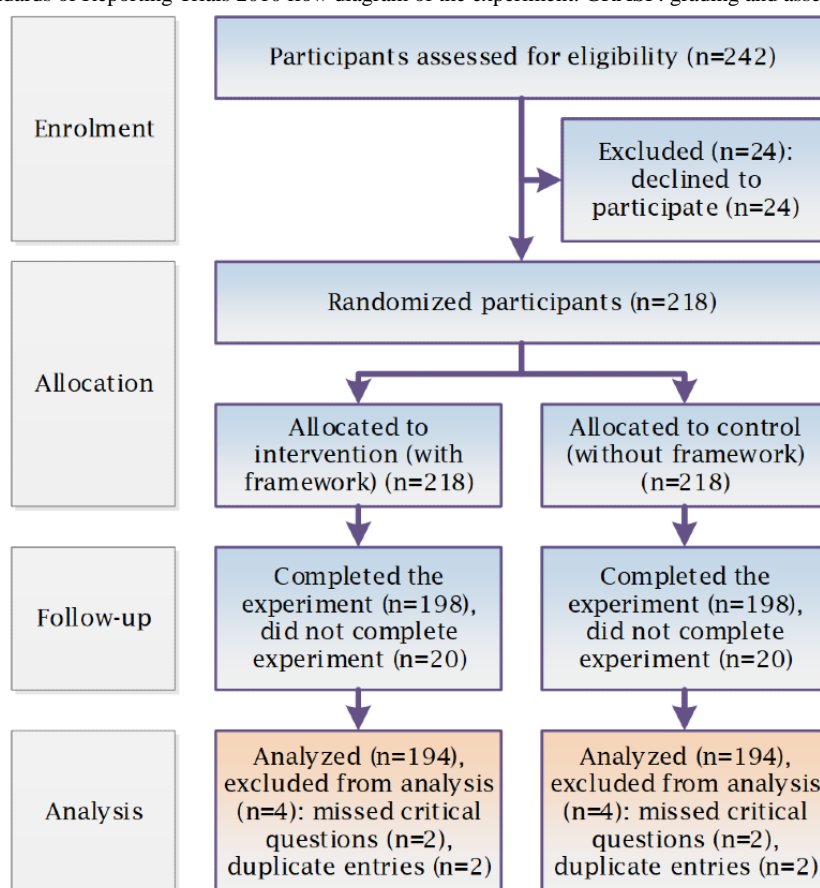

addition, participants were asked a few questions regarding the process of making their decisions through the 2 scenarios. Participants were also requested to provide their feedback on the perceived usability and usefulness of the evidence-based summary of the GRASP framework. This experiment does not include registration of the randomized controlled trial as it does not involve any patients, medications, or treatments.

The emergency department (ED) is among the top health care specialties that are increasingly utilizing predictive tools, especially in the area of managing traumatic brain injury (TBI), which is the leading cause of death and disability among trauma patients [30-33]. Two groups of predictive tools designed to

exclude TBI in the ED were prepared. The first group included 5 tools for predicting TBI in pediatrics: Paediatric Emergency Care Applied Research Network (PECARN) head injury rule, Children's Head injury ALgorithm for the prediction of Important Clinical Events, Canadian Assessment of Tomography for Childhood Head injury rule, Palchak head injury rule, and Atabaki head injury rule [34-38]. The PECARN, being the most validated and the only tool that has been implemented in clinical practice and discussed to have a positive postimplementation impact, is the best tool among the 5 [39,40]. The second group includes 5 tools for predicting TBI in adults: the Canadian CT Head Rule (CCHR), New Orleans Criteria (NOC), Miller criteria for head computed tomography, Kimberley Hospital Rule, and Ibanez model for head computed tomography [41-45]. The CCHR and NOC, being the only tools that have been implemented in clinical practice and are the most validated, showing high predictive performance, are the best tools among the 5 [46-48]. Two scenarios were prepared for this experiment. The first is the control scenario, which includes providing participants with basic information about each tool, the full text of the original studies describing the tools, and allowing them to search the internet for information. The second is the experiment scenario, including providing participants with the main component of the GRASP framework, which is an evidence-based summary of the predictive tools and the full GRASP report on each tool, in addition to allowing them to search the internet for information. To minimize bias, eliminate the pre-exposure effect, and improve the robustness, the experiment includes randomizing the 2 groups of predictive tools and the 2 scenarios. Accordingly, the participants go randomly through 1 of 4 scenarios: (1) pediatric tools without GRASP and then adult tools with GRASP, (2) pediatric tools with GRASP and then adult tools without GRASP, (3) adult

tools without GRASP and then pediatric tools with GRASP, and (4) adult tools with GRASP and then pediatric tools without GRASP. [Figure 2](#) shows the survey workflow and the randomization of participants.

The authors recruited a wide group of international professionals to participate in this experiment through a web-based survey. To identify potential participants who work at the ED and those who have knowledge or experience about CDS tools, published studies were used to retrieve the authors' emails and invite them. To retrieve studies on CDS systems, tools, models, algorithms, and pathways or rules used in the ED, emergency service, or emergency medicine published over the last 5 years by professionals who work in the EDs or services of their health care organizations or those who conducted emergency medicine, EDs, or emergency services research, 4 databases were used: MEDLINE, EMBASE, CINAHL, and Google Scholar. The authors expected a response rate of approximately 10%. Before the deployment of the survey, a pilot test was conducted by 10 expert professionals. The feedback of the pilot test was used to improve the survey. Professionals who participated in the pilot test were excluded from participation in the final survey. An invitation email, introducing details about the study objectives, the GRASP framework, the experiment task, the survey completion time, which was estimated at 20 min, and a participation consent was submitted to the identified potential participants with the link to the web-based survey. A reminder email, in 2 weeks, was sent to the potential participants who did not respond or complete the survey. [Figure 3](#) shows the CONSORT 2010 flow diagram of the progress of the randomized trial of the 2 groups: intervention group (GRASP) and control group (No GRASP), showing the enrollment, intervention allocation, follow-up, and data analysis [49,50].

Figure 2. Survey workflow and randomization of the 4 scenarios.**Figure 3.** Consolidated Standards of Reporting Trials 2010 flow diagram of the experiment. GRASP: grading and assessment of predictive tools.

The Study Survey

The web-based survey was developed using the Qualtrics Experience Management Solutions Platform [51]. The survey, illustrated through screenshots in the [Multimedia Appendix 1](#), includes 5 sections. The first section includes an introduction to the study objectives, the GRASP framework, and the experiment task. In addition, participants are provided with contacts to request further information or submit complaints. The second section includes randomizing the 2 scenarios and the 2 groups of predictive tools to create the 4 scenarios described above.

In this section, participants are asked to assume that they are the heads of busy EDs and are responsible for selecting the best tool, the most validated in the literature or implemented in clinical practice, out of the 5 diagnostic head injury predictive tools. The PECARN is the correct answer among the 5 pediatric tools, and both the CCHR and the NOC are correct answers among the 5 adult tools. On a 5-point Likert scale, participants were asked to show how much they agreed to the following: (1) they made their decisions based on guessing, (2) they made their decisions based on prior knowledge or experience, (3) they made their decisions based on the information provided in the survey, (4) they were confident in their decisions, and (5) they were satisfied with their decisions. The third section includes asking participants to provide their feedback on the usability of the evidence-based summary of the GRASP framework through a standard set of System Usability Scale (SUS) questions. The SUS is a simple, 10-item attitude Likert scale that provides a global view of subjective assessments of usability. It was developed by John Brooke in 1986 as a tool to be used in the engineering of electronic systems. It is now widely accepted as a tool for the evaluation of system usability [52,53]. Participants were also asked to provide free-text feedback on whether they think the framework is useful or not and why they think so. The fourth section includes participants' demographics, such as their clinical or health care role, specialty, gender, age group, years of experience, and how much they are familiar with head injury predictive tools.

The Study Sample Size

As an initial estimate of the required sample size for this study, and based on similar studies, evaluating the impact of using information systems on professionals' objective, informed, and evidence-based decisions, the authors aimed to recruit a sample of 40 to 60 participants [54-56]. More specifically, it was estimated that a sample size of 46 participants would be sufficient to test for at least a 10% difference, between the 2 arms of the experiment, in the measured outcomes, when using a paired two-tailed *t* test with a significance level of 0.05 and power of 0.95. Calculations were conducted using G*Power software [57].

Analysis and Outcomes

To test the 5 proposed hypotheses, the study was designed to compare the 2 scenarios, making decisions with and without using the GRASP framework, based on a group of 7 measures: (1) time needed for tool selection decision making; (2) accuracy of tool selection decisions; (3) making decisions subjectively based on guessing; (4) making decisions subjectively based on prior knowledge or experience; (5) making decisions objectively based on the information and evidence provided; (6) levels of participants' confidence in their decisions; and (7) levels of participants' satisfaction with their decisions. The accuracy of making decisions, with and without GRASP, was also compared along with knowledge, experience, and familiarity with predictive tools. [Table 1](#) shows the 5 proposed hypotheses and their related 7 outcome measures. To avoid an inflated Type I error and account for the 5 tested hypotheses and the 7 compared measures, the Bonferroni correction was used, by setting the alpha value of the paired samples *t* test to .007 instead of .05. The sample size was re-estimated to 96 participants. In addition, the SUS was calculated for the average rate and distribution of scores. The perceived usefulness and free-text feedback were analyzed. The demographic variables were analyzed for possible correlations or differences.

As this randomized controlled experiment was conducted via a web-based survey of clinicians and health care professions, [Table 2](#) shows the checklist for reporting results from the internet surveys (checklist for reporting results from the internet surveys).

Table 1. Proposed hypotheses and related outcome measures.

Proposed hypotheses	Related outcome measures
Using GRASP ^a will make predictive tools' selection decisions more accurate, that is, selecting the best predictive tools	Accuracy of tools' selection decisions
Using GRASP will make decisions more objective, informed, and evidence-based, that is, decisions are based on the information provided by the framework	Making decisions objectively based on the information and evidence provided in the experiment
Using GRASP will make decisions less subjective, that is, less based on guessing, prior knowledge, or experience	Making decisions subjectively based on guessing and making decisions subjectively based on prior knowledge or experience
Using GRASP will make decisions more efficient, that is, decisions are made in less time	The time needed for tools' selection decision making
Using GRASP will make participants face less decisional conflict, that is, be more confident and satisfied with decisions	Levels of participants' confidence in their decisions and levels of participants' satisfaction with their decisions

^aGRASP: grading and assessment of predictive tools.

Table 2. The checklist for reporting results from the internet surveys checklist.

Item category and checklist item	Explanation
Design	
Describe survey design	A randomized controlled trial experiment testing the impact of using the GRASP framework on clinicians and health care professionals' decisions in selecting predictive tools for CDS ^a , using a convenience invited sample to participate in the experiment
IRB^b approval and informed consent process	
IRB approval	The experiment was approved by the Human Research Ethics Committee, Faculty of Medicine and Health Sciences, Macquarie University, Sydney, Australia
Informed consent	Informed consent was introduced at the beginning of the survey for participants to agree before they take the survey, including the length of time of the survey, types of data collected and its storage, investigators, and the purpose of the study
Data protection	Collected personal information was protected through Macquarie University account on Qualtrics survey system
Development and pretesting	
Development and testing	The first author (MK) developed the survey and pilot tested the questions and its usability before deploying the survey to the participants
Recruitment process and description of the sample having access to the questionnaire	
Open survey versus closed survey	This was a closed survey; only invited participants had access to complete the survey
Contact mode	An initial contact, via email, was sent to all invited participants. Only those who agreed to participate completed the web-based survey
Advertising the survey	The survey was not advertised. Only invited participants were informed of the study and completed the survey
Survey administration	
Web or email	The survey was developed using the Qualtrics survey platform, and the link to the web-based survey was sent to invited participants via email. Responses were automatically collected through the Qualtrics survey platform then retrieved by the investigators for analysis
Context	Only invited participants were informed of the study via email
Mandatory/voluntary	The survey was not mandatory for invited participants
Incentives	The only incentive was that participants could request to be acknowledged in the published study. Participants were also informed of the results of the survey after the analysis is complete
Time/date	Data were collected over 6 weeks, from March 11 to April 21, 2019
Randomization of items or questionnaires	To prevent biases, items were randomized. Figure 2 shows the survey workflow and randomization of 4 scenarios
Adaptive questioning	Four scenarios were used and randomized, but they were not conditionally displayed
Number of items	From 5 to 8 items per page
Number of screens (pages)	The questionnaire was distributed over 5 pages
Completeness check	Completeness checks were used after the questionnaire was submitted, and mandatory items were highlighted. Items provided a nonresponse option "not applicable" or "don't know"
Review step	Respondents were able to review and change their answers before submitting their answers
Response rates	
Unique site visitor	We used the IP ^c addresses to check for unique survey visitors

Item category and checklist item	Explanation
View rate (ratio of unique survey visitors/unique site visitors)	Only invited participants had access to the survey. Survey visitors included those who completed the survey and those who started the survey but did not complete it or gave incomplete answers
Participation rate (ratio of unique visitors who agreed to participate/unique first survey page visitors)	The recruitment rate was 90% (218 participants agreed to participate out of 242 invited participants who visited the first page)
Completion rate (ratio of users who finished the survey/users who agreed to participate)	The completion rate was 91% (198 participants completed the survey out of 218 participants who agreed to participate)
Preventing multiple entries from the same individual	
Cookies used	Cookies were not used to assign a unique user identifier; instead, we used users' computer IP to identify unique users
IP address check	The IP addresses of participants' computers were used to identify potential duplicate entries from the same user. Only 2 duplicate entries were captured and were eliminated before analysis
Log file analysis	We also checked the provided demographic information, of all participants, to make sure the 2 identified duplicates were the only incidents
Registration	Data were collected and the user IP and other demographic data were used later on to eliminate duplicate entries before analysis. Most recent entries were used in the analysis
Analysis	
Handling of incomplete questionnaires	Only completed surveys were used in the analysis
Questionnaires submitted with an atypical timestamp	The task completion time was captured. However, no specific timeframe was used. In the analysis, we excluded statistical outliers, since the survey allowed users to re-enter after a while, for example, the next day. This is discussed in the paper
Statistical correction	No statistical correction was required

^aCDS: clinical decision support.

^bIRB: institutional review board.

^cIP: internet protocol.

Results

Descriptive Analysis

Out of 5857 relevant publications retrieved, 3282 professionals were identified and invited to participate in the survey. Over the survey duration of 6 weeks, from March 11 to April 21, 2019, we received a total of 194 valid responses, with a response rate of 5.9%. Valid responses were identified as those who completed the survey until the end and answered questions in all the survey sections, with no missing sections. Six participants missed answering one or more questions in one or more of the survey sections, 5 participants did not provide their demographics, and 57 participants did not wish to be acknowledged in the study. The detailed distributions of participants based on gender, age group, years of experience, clinical and health care role, clinical specialty, familiarity with head injury predictive tools, and their countries are illustrated in [Multimedia Appendix 1, Figures 4-10](#).

The GRASP Impact on Participants' Decisions

Using the GRASP framework, an evidence-based summary of predictive tools and a detailed report on each predictive tool, along with allowing participants to search the internet for further information, made them select the correct tools 88.1% of the time. Without GRASP, that is, using the basic information about the predictive tools, the full text of the studies describing each

tool, along with allowing participants to search the internet for further information, they selected the correct tools 53.7% of the time. This shows a statistically significant improvement of 64% ($88.1/53.7=1.64$; $P<.001$). On a 5-point Likert scale, where strongly agree is considered equal to 5 and strongly disagree is considered equal to 1, the participants reported that they made their tools' selection decisions based on guessing with an average of 1.98 (SD 1.22), when they used GRASP, compared with an average of 2.48 (SD 1.37), when they did not use GRASP. This shows a statistically significant reduction of 20% ($P<.001$). Participants reported that they made their tools' selection decisions based on their prior knowledge or experience with an average of 3.27 (SD 1.44) when they used GRASP, compared with an average of 3.55 (SD 1.31), when they did not use GRASP. This shows a statistically significant reduction of 8% ($P=.004$).

Participants reported that they made their tools' selection decisions based on the information provided in the survey with an average of 4.10 (SD 1.10) when they used GRASP, compared with an average of 3.11 (SD 1.42), when they did not use GRASP. This shows a statistically significant increase of 32% ($P<.001$). Participants reported that they were confident in their decisions, with an average of 3.96 (SD 0.87), when they used GRASP, compared with an average of 3.55 (SD 1.15), when they did not use GRASP. This shows a statistically significant increase of 11% ($P<.001$). Participants reported that they were

satisfied with their decisions with an average of 3.99 (SD 0.89), when they used GRASP, compared with an average of 3.54 (SD 1.20), when they did not use GRASP. This shows a statistically significant increase of 13% ($P<.001$). The duration of completing the task of selecting predictive tools showed high variability, with many statistical outliers. In addition to the average, the authors used the percentiles to avoid the effect of extreme outliers. The average duration of making the selection decisions showed a statistically insignificant reduction of 52% from 14.5 7 min ($P=.39$). There is also a reduction of 18.9% from 2.2 to 1.8 min on the 50th percentile, 37.3% from 5.3 to 3.3 min on the 75th percentile, 48% from 12.4 to 6.4 min on the 90th percentile, and 30.6% from 19.2 to 13.3 min on the 95th percentile. [Table 3](#) shows the impact of using GRASP on the 7 measures: decision accuracy, guessing, subjective

decisions, objective decisions, confidence in decisions, satisfaction with decisions, and task completion duration 90th percentile in minutes.

Using a paired samples t test, [Table 4](#) shows the estimation for the paired difference of the 7 measures and the effect size, calculating and interpreting the eta-squared statistic, based on the guidelines proposed by Cohen [58].

[Table 5](#) compares physicians to nonphysicians, emergency medicine to other specialties, familiar with tools to nonfamiliar, male to female, younger to older, and less experienced to more experienced participants. The GRASP detailed report is shown in [Multimedia Appendix 1](#). The GRASP evidence-based summaries of the 2 groups of pediatric and adult predictive tools are shown in [Multimedia Appendix 1](#).

^aGRASP: grading and assessment of predictive tools.

The GRASP Usability and Usefulness

The overall SUS rate of the GRASP framework and evidence-based summary, considering the responses of all 194 participants, was 72.5%, which represents a very good level of usability [59,60]. Examining the influence of demographics on the SUS rates, only 2 factors showed significant influence: the gender of participants and their familiarity with predictive tools. The female participants reported a statistically significant higher SUS rate (76.2%) in comparison with the male participants (70.8%), showing that female participants, more than male participants, thought GRASP is easy to use. Using the statistical Spearman correlation test, the degree of familiarity with head injury predictive tools showed a weak negative statistically significant correlation with the GRASP SUS score ($P=.03$). This indicates that participants who were less familiar with predictive tools thought that the GRASP framework was easy to use more than participants who were more familiar with the tools.

Among the 194 valid responses of participants, almost two-third (122) provided free-text feedback on the GRASP evidence-based summary usefulness and explained their feedback. The qualitative analysis of the open-ended question was conducted using the NVivo Version 12.3 software package [61]. Most respondents (88%, 108/122) reported that they found the GRASP evidence-based summary useful. They explained their responses with various reasons, mainly that the evidence-based summary was simple, clear, and logical. Some reported that the visual presentation was attractive, intuitive, and self-explanatory. Others reported that it concisely and comprehensively provided a summary of extensive information, and some reported that the presented information was consistent, easily comparable, making it easy to make informed decisions. A smaller group of 12% of participants reported that they found the GRASP evidence-based summary useless. They reported that it did not provide enough information to make informed decisions. Some reported that it was not clear enough, or simple enough, to understand and use to select predictive tools. One health care professional reported that “it is too complicated and needs to be simplified further,” while another reported that “it is oversimplified and missing some important parameters.” One health care professional reported “it might be more helpful when

the decision is less clear” and added, “I would like to see more info on the strengths/weaknesses of each tool.”

Discussion

Brief Summary

The use of GRASP has positively supported, and significantly improved, evidence-based decision making and increased the accuracy and efficiency of selecting predictive tools. Using the GRASP framework has significantly increased correct decisions and objective decision making, and significantly decreased subjective decision making based on guessing, prior knowledge, or experience. Moreover, using the GRASP framework significantly decreased decisional conflict, increasing the confidence and satisfaction of participants with their decisions. Furthermore, using the GRASP framework decreased the task completion time for selecting predictive tools. In addition, the average SUS of the GRASP framework was very good, and most participants found the GRASP framework useful.

It is a challenging task for most health care professionals to critically evaluate a growing number of predictive tools, proposed in the literature, to select effective tools for implementation in clinical practice or for recommendation in clinical guidelines, to be used by other professionals. Although most of these predictive tools have been assessed for predictive performance, only a few have been implemented and evaluated for comparative effectiveness or postimplementation impact. Professionals need an evidence-based approach to provide them with standardized objective information on predictive tools to support their search for and selection of effective tools for clinical tasks. On the basis of the critical appraisal of the published evidence, the GRASP framework uses 3 dimensions to grade predictive tools: (1) phase of evaluation, (2) level of evidence, and (3) direction of evidence. The final grade assigned to a tool is based on the highest phase of evaluation, supported by the highest level of positive evidence, or mixed evidence that supports a positive conclusion. In this study, we present an evaluation of the impact of the GRASP framework on professionals' decisions in selecting predictive tools for CDS.

The Impact of GRASP on Participants' Decisions

The GRASP framework provides a systematic and transparent approach for professionals to make objective, well-informed,

and evidence-based decisions regarding the selection of predictive tools. This is very similar to the findings of using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) framework in evaluating the quality of evidence and strength of recommendations regarding treatment methods and decisions endorsed in clinical guidelines [62,63]. The quality of decision making, while developing clinical guidelines, depends significantly on the quality of the evidence-informed analysis and advice provided [64]. Similarly, supporting professionals with evidence improves their accuracy and helps them make better clinical decisions and better organizational decisions [65,66]. Similarly, using GRASP and providing professionals with evidence-based information on predictive tools significantly improved professionals' accuracy of decisions in selecting the best predictive tools.

Providing professionals with GRASP evidence-based information also enabled them to minimize subjective decision making, such as guessing, prior knowledge, or previous experience. This has been discussed in other studies investigating the role of utilizing evidence-based resources in decreasing subjective bias in making clinical, population-related, and health policy decisions [67,68]. Evidence-based information on GRASP was associated with a decrease in professionals' decisional conflict by increasing their confidence in their decisions and their satisfaction with them. This has been discussed in similar studies reporting the impact of evidence-based information on decreasing decisional conflicts faced by both professionals and patients when they make clinical decisions [69-71]. When time is a sensitive factor for critical clinical and population decisions, efficient decision making becomes important [72]. Here comes the role of evidence-based decision making, which is discussed to be not only more accurate, objective, and of higher quality but also much more efficient [73,74]. Similarly, providing professionals with GRASP evidence-based information improved their efficiency in making predictive tools' selection decisions.

Using GRASP made nurses and other professionals make more accurate decisions than physicians when they are not using GRASP. Using GRASP, clinicians of specialties other than emergency medicine make better decisions than emergency medicine clinicians without GRASP. Furthermore, using GRASP, professionals who were not familiar with head injury predictive tools made better decisions than professionals who were familiar with the tools without GRASP. Furthermore, the use of GRASP made decisions more efficient. Accordingly, using GRASP has moved professionals with less knowledge, less experience, and less familiarity with predictive tools to higher accuracy, higher efficiency, and better decision-making levels than professionals who had more knowledge, had more experience, and were more familiar with tools, but did not use GRASP.

The Usability and Usefulness of GRASP

The usability of systems is an important foundation for successful implementation and utilization [75]. Usability can be evaluated by measuring the effectiveness of task management with accuracy and completeness, measuring the efficiency of utilizing resources in completing tasks and measuring users'

satisfaction, comfort with, and positive attitudes toward, the use of the tools [76,77]. One of the validated and simply applicable methods of measuring usability is the SUS [52,53]. When users have more experience with a system, they tend to provide higher, more favorable SUS scores for the system usability over users with either no or limited experience [78]. On the other hand, when users have less experience with a system, they tend to see new tools illustrating the system, or new approaches to understanding it, more usable than users who have extensive experience with the system itself [79]. This explains why the degree of familiarity with the tools was negatively correlated with the GRASP SUS score, where participants less familiar with tools provided higher SUS scores for GRASP than participants who were more familiar. It is reported in the literature that gender does not influence the perceived usability or usefulness of systems [80,81]. This was not the case with GRASP, where female participants provided higher SUS scores than males. Furthermore, female participants also thought that GRASP is more useful than males. Both findings could be explained by the greater improvement in female participants' confidence and satisfaction with their decisions when they used GRASP compared with male participants. Some participants' suggestions, reported in the free-text feedback, can be used in the future to add more information to the GRASP detailed report on each tool.

Study Conclusions

Through this study, the GRASP framework is presented as an effective evidence-based approach to support professionals' decisions when selecting predictive tools for implementation in clinical practice or for recommendation in clinical practice guidelines. Using the GRASP framework and the evidence-based summary improved the accuracy of selecting the best predictive tools, with an increased objective, informed, and evidence-based decision making and decreased subjective decision making based on guessing, prior knowledge, or experience. Using GRASP also decreased the decisional conflict faced by professionals by improving their confidence and satisfaction with their decisions. Using GRASP has also improved the efficiency of professionals in making their selection decisions by decreasing the time needed to complete the decision-making task.

The GRASP framework represents a high-level approach to provide professionals with an evidence-based and comprehensive, yet simple and feasible method to evaluate and select predictive tools. However, when professionals need further information, the detailed framework report provides them with the required details to support their decision making. The GRASP framework is designed for 2 levels of users:

- (1) Expert users, such as health care researchers, experienced in evidence-based evaluation methods. They will use the framework to critically evaluate published evidence, assign grades to predictive tools, and report their details.
- (2) End users, such as clinicians and health care professionals, responsible for selecting tools for implementation in clinical practice or for recommendation in clinical guidelines. They will use the GRASP framework detailed reports on tools and their

assigned grades, produced by expert users, to compare existing predictive tools and select the most suitable tools [27].

The GRASP framework is not meant to be absolutely prescriptive. A lower grade tool could be preferred by a health care professional to improve clinical outcomes that are not supported by a higher grade one. For example, a practicing clinician may prefer an A2 tool showing improved patient safety in 2 observational studies rather than an A1 tool showing reduced health care costs in three experimental studies because they are now trying to improve patient safety to avoid reducing health care costs. It all depends on the objectives and priorities that the clinicians and health care professionals are trying to achieve. In addition, sometimes, more than one predictive tool should be endorsed in clinical practice guidelines, each supported by its requirements for application, conditions of use, and recommended for its most prominent outcomes of predictive performance or postimplementation impact on health care and clinical outcomes. Furthermore, even when GRASP assigns high grades to predictive tools, some of these tools may not be simply recommended for use in a different country or population than the ones that were used to develop and validate the tools in the first place. This might happen because of the population-related differences in the risks associated with the incidence of certain medical conditions, outcomes, or prognoses. This necessitates adjustment of the tools to the local context, thereby producing new versions of the tools, which requires re-evaluation by GRASP.

Although the GRASP framework has been developed to assess and grade predictive tools and other similar CDS systems, the application of the framework concept of grading tools and systems based on the published evidence is not limited to predictive tools or CDS systems. The GRASP framework concept can be applied to assess and grade many other types of clinical tools, systems, and methods.

Study Limitations and Future Work

Although we received a large and sufficient number of 194 valid responses, the very low response rate of 5.9% could have been improved if potential participants were motivated by some incentives. They could have also been motivated if more support was provided through their organizations, which need more

resources to synchronize such efforts. For the sake of keeping the survey feasible, for most busy professionals, the number of questions was kept limited and the time required to complete the survey was kept in the range of 20 min. However, some of the participants showed their willingness to provide more detailed feedback, which could have been done through interviews, for example, but this was out of the scope of the study and was not initially possible with the huge number of invited participants. The reduction in the decision-making duration of selecting predictive tools, while using GRASP, was statistically insignificant, because of the high variability and extreme statistical outliers, with and without GRASP. This could be explained by the fact that the Qualtrics platform of the survey measures the task completion duration by subtracting the time of loading the page from the time of pushing the Next button after completing the task and not the actual time the participants spent active on the page, which is currently under development [82].

To enable a wider global audience of clinicians, health care professionals, and clinical guideline developers to access detailed information, reported evidence, and assigned grades of different predictive tools, it is essential to implement the GRASP framework into a web-based platform. However, maintaining such a grading system up to date is a challenging task, as this requires continuous updating of the predictive tools grading and assessments when newly published evidence becomes available. In addition, the entire process is currently conducted manually, which represents a large burden on assessing and grading the huge number of existing predictive tools and those continuously emerging. Accordingly, it is essential to use automated or semiautomated methods for searching and processing new information to keep the GRASP framework information, grades, and assessments updated. Finally, we recommend that the GRASP framework be utilized by working groups of professional organizations to grade predictive tools to provide consistent results and increase reliability and credibility for end users. These professional organizations should also support disseminating such evidence-based information on predictive tools, similar to announcing and disseminating new updates of clinical practice guidelines.

Acknowledgments

The authors would like to thank Peter Petocz, Professor of Statistics at Macquarie University, for his guidance and support in the statistical analysis. They would also like to thank all the professors, doctors, and researchers who participated in evaluating the impact of the GRASP framework, including Aaron Brody, Adam Rose, Adel Hamed Elbaih, Aleix Martínez-Pérez, Alireza Razzaghi, Amanda Montalbano, Andreas Huefner, Andreas Sundermeyer, Andres M Rubiano, Andrew MacCormick, Andrew Miller, Antoinette Conca, Ashraf Bedaewi, Asit Misra, Ausra Snipaitiene, Azadeh Tafakori, Başak Bayram, Bedia Gulen, Bhagavatula Indira Devi, Brent Becker, Brian Rowe, Chad Cannon, Chen-June Seak, Chimwemwe Mula, Christian Waydhas, Christophe Marti, Christopher R Carpenter, Claire Vajdic, Claudine Blum, Clermont E Dionne, Corrado Tagliati, David R Vinson, Dawn Moeller, Deepak Batura, Deepika Mohan, DJ Choi, Duane Steward, Dustin Ballard, Edward Baker, Elise Gane, Elizabeth Manias, Elizabeth Powell, Ellen Weber, Emanuele Gilardi, Eveline Hitti, Ewout W Steyerberg, Eva Bitzer, Fawaz Abdullah Alharbi, Fayza Haider, Fernanda Bellolio, Fleur Lorton, Francesco Fleres, Gabriel Rodrigues, Gerry Lee, Giacomo Veronese, Gianfranco Sinagra, Giovanni de Simone, Guillaume Foldes-Busque, Gulten Sucu, Guo XH, Gwendolyn Vuurberg, Herbert J Fernandes, Hon Lon Tam, Hsu Teh-Fu, Ibrahim Jatau Abubakar, Ilias Galanopoulos, Iqra Manzoor, Jennifer Hoffmann, JM Ferreras, Joel Noutakdie Tochie, John Kellett, Jonathan Elmer, Jorge Acosta-Reyes, Juan Del Castillo-Calcaño, Julia Lappin,

Abstract

Background: Suboptimal use of antibiotics is a driver of antimicrobial resistance (AMR). Clinical decision support systems (CDSS) can assist prescribers with rapid access to up-to-date information. In low- and middle-income countries (LMIC), the introduction of CDSS for antibiotic prescribing could have a measurable impact. However, interventions to implement them are challenging because of cultural and structural constraints, and their adoption and sustainability in routine clinical care are often limited. Preimplementation research is needed to ensure relevant adaptation and fit within the context of primary care in West Africa.

Objective: This study examined the requirements for a CDSS adapted to the context of primary care in West Africa, to analyze the barriers and facilitators of its implementation and adaptation, and to ensure co-designed solutions for its adaptation and sustainable use.

Methods: We organized a workshop in Burkina Faso in June 2019 with 47 health care professionals representing 9 West African countries and 6 medical specialties. The workshop began with a presentation of Antibioclac, a publicly funded CDSS for antibiotic

prescribing in primary care that provides personalized antibiotic recommendations for 37 infectious diseases. AntibioClic is freely available on the web and as a smartphone app (iOS, Android). The presentation was followed by a roundtable discussion and completion of a questionnaire with open-ended questions by participants. Qualitative data were analyzed using thematic analysis.

Results: Most of the participants had access to a smartphone during their clinical consultations (35/47, 74%), but only 49% (23/47) had access to a computer and none used CDSS for antibiotic prescribing. The participants considered that CDSS could have a number of benefits including updating the knowledge of practitioners on antibiotic prescribing, improving clinical care and reducing AMR, encouraging the establishment of national guidelines, and developing surveillance capabilities in primary care. The most frequently mentioned contextual barrier to implementing a CDSS was the potential risk of increasing self-medication in West Africa, where antibiotics can be bought without a prescription. The need for the CDSS to be tailored to the local epidemiology of infectious diseases and AMR was highlighted along with the availability of diagnostic tests and antibiotics using national guidelines where available. Participants endorsed co-design involving all stakeholders, including nurses, midwives, and pharmacists, as central to any introduction of CDSS. A phased approach was suggested by initiating and evaluating CDSS at a pilot site, followed by dissemination using professional networks and social media. The lack of widespread internet access and computers could be circumvented by a mobile app with an offline mode.

Conclusions: Our study provides valuable information for the development and implementation of a CDSS for antibiotic prescribing among primary care prescribers in LMICs and may, in turn, contribute to improving antibiotic use, clinical outcomes and decreasing AMR.

Introduction

Antimicrobial Resistance

Antimicrobial resistance (AMR) is a global threat that affects both high-income countries (HIC) and low- and middle-income countries (LMIC). The drivers of AMR, including antibiotic misuse, lack of infection prevention and control, and poor sanitation, particularly affect LMICs [1,2]. Data suggest that 80% to 90% of all antibiotics used in humans are prescribed in primary care [3]. Although antibiotic use has been increasing over the last decade in LMICs [2,4], antibiotic prescribing indicators in primary care for the African region deviate significantly from the World Health Organization's (WHO) reference targets [5]. Deviations from existing guidelines on antibiotic use, including delays and overuse, are linked both to patients' behavior and that of health care professionals [6,7]. There is thus a need to find interventions that could improve antibiotic prescribing in primary care to respond to the global threat of AMR.

Electronic Clinical Decision Support Systems

Electronic clinical decision support systems (CDSS) have been devised to provide prescribers with rapid access to updated information, which is required to make appropriate therapeutic decisions [8]. CDSS can be split into CDSS providing unsolicited information (eg, alerts for drug interactions) and CDSS providing solicited information (eg, diagnostic support systems). Computer representations of patient care guidelines are among commonly used CDSS [9,10]. They allow the prescriber to enter basic clinical information of a patient and access the diagnostic or therapeutic guidelines adapted to the patient's unique situation. Machine learning CDSS that find their own decision rules from the data are increasingly being developed and may replace knowledge-based CDSS in which

human experts define the decision rules in the future [11]. CDSS adapted in primary care have the potential to reduce overall antibiotic use and improve the appropriateness of antibiotic prescribing [12,13]. In LMICs, the introduction of such aids is in the early stages of development [14], but it could have a measurable impact within the context of sparse infectious diseases specialists. Primary care prescribers in LMICs often lack clinical practice guidelines adapted to their setting and do not have access to antimicrobial stewardship programs [15]. Although they may not have access to health care information systems, CDSS providing diagnostic guidance or easy access to therapeutic guidelines may help them make the right decision at the point-of-care [16]. Improving the adequacy of antibiotic prescribing might, in turn, lead to better clinical outcomes and decreased AMR. Moreover, CDSS have the potential to be implemented in multiple health facilities without recruiting new prescribers [17] and could optimize the utilization of resources that are scarce in LMICs.

Implementation of Clinical Decisions Support System in West Africa

Consequently, the development and implementation of CDSS that fit into clinical work might be part of interventions to mitigate against drivers of AMR in LMICs. However, the adaptation of CDSS for antibiotic prescribing in routine clinical care and their sustainability are often limited [10,18]. As is the case with many innovations in health care, multiple CDSS have been abandoned after their development and initial evaluation because of multiple factors, including the lack of preimplementation work [19]. Indeed, at the global level, the situation analysis for AMR in human health often lack the assessment of technological innovations [20]. Moreover, many CDSS failed to demonstrate a clinical impact because of the low uptake of the CDSS and poor adherence to the generated advice [21,22]. According to the WHO, the adaptation of

electronic CDSS is particularly low in LMICs [23]. Interventions to implement CDSS are challenging because of cultural and structural constraints, and these challenges are even more pronounced in primary care where prescribing can be done by a variety of health care professionals or when resources are limited [14,24]. West Africa hosts about 381 million people and includes 16 countries, among them some of the lowest income countries in the world [25,26]. French-speaking West African countries, including Benin, Burkina Faso, Cameroon, Chad, Ivory Coast, Republic of Congo, Guinea, Mali, Niger, Senegal, and Togo, were among the LMICs with the highest increase in global antibiotic consumption between 2000 and 2015 [2]. As highlighted by the WHO, countries in the African region are the least advanced regarding electronic and mobile health [23].

Objectives

Before developing or implementing a CDSS for antibiotic prescribing in West Africa, we need to understand the contextual, structural, and behavioral determinants that will facilitate or prevent the use of CDSS for antibiotic prescribing. Our study aimed to examine the requirements for a CDSS adapted to the context of primary care in West Africa and to analyze the barriers and facilitators of its implementation and adaptation by prescribers using qualitative methods during a preimplementation workshop.

Methods

Study Design

Our aims were (1) to understand the potential benefits and risks of a CDSS for antibiotic prescribing in primary care in West Africa, (2) to analyze the barriers and facilitators of its implementation, and (3) to ensure co-designed solutions for its adaptation and sustainable use. To this end, we organized a workshop with West African antibiotic prescribers that began with a presentation of Antibiocllic, a CDSS for antibiotic prescribing currently widely used in France and freely available on the web and as a smartphone app (further details below). We chose to begin the workshop with an example of an existing CDSS rather than with a theoretical description of a CDSS for antibiotic prescribing. This strategy was considered by the organizing team as the most promising to elicit reactions among the participants. The main characteristics of a CDSS were presented, and the organizers went through a number of clinical scenarios on infectious diseases using Antibiocllic. Then, the organizers moderated a roundtable discussion with all the participants. During this first-of-its-kind workshop, the participants generated barriers and facilitators to the use of a CDSS such as Antibiocllic in West Africa and were asked to hypothesize if its use could lead to benefits or risks, including unexpected events. Participants were specifically asked to debate the challenges in the implementation and adaptation of a CDSS for antibiotic prescribing in West Africa and to co-design solutions.

Antibiocllic—An Example of a Clinical Decision Support System for Antibiotic Prescribing

Antibiocllic is a French CDSS for antibiotic prescribing in primary care, [27] targeting 37 common infectious diseases, freely available on the web and as a smartphone app on iOS and Android. It was codeveloped by general practitioners, specialists of infectious diseases, and engineers in 2011. Clinicians can enter the diagnosis of a patient on the website or app, they are then asked a few targeted questions (age group, comorbidities, renal function, breastfeeding, and pregnancy). Finally, they receive a tailored recommendation of antibiotic regimen, dose, and duration according to French national guidelines. [Multimedia Appendices 1 and 2](#) describe how to use Antibiocllic respectively with slides or video in English. Antibiocllic was developed using a systematic method to transform clinical practice guidelines from the French National Authority for Health and the French Infectious Diseases Society (SPILF) into decision trees in Antibiocllic. Antibiocllic is updated frequently and modified as soon as a new guideline is published. The number of Antibiocllic users in France has steadily increased over the past years from a median (IQR) of 414 (245-494) a day in 2012 to 5365 (2891-5769) a day in 2018, without any saturation to date ([Multimedia Appendix 3](#)). The smartphone app has been downloaded 22,970 times on Android and 15,200 times on iOS. More details are described in a recent study [27].

Workshop Location and Participants

The 3-hour workshop to discuss the implementation and adaptation of a CDSS for antibiotic prescribing in West Africa was organized in Burkina Faso by 2 professors of infectious diseases, 1 from Burkina Faso (AP) and 1 from France (FL). To maximize participation and cost efficiency, the workshop took place during the French-speaking university course *Antibiologie et Antibiothérapie en Afrique Subsaharienne* (*Antibiotic therapy in Sub-Saharan Africa*) organized in Bobo-Dioulasso, Burkina Faso, on June 2019. This course lasts 5 weeks and is organized every year by the University Nazi Boni of Bobo-Dioulasso and the University of Montpellier. The course is open to West African health professionals working on AMR or antibiotic therapy, whether in primary, secondary, or tertiary care, with no selection among participants. Attendance to the workshop was voluntary for the participants of the course.

Electronic Questionnaire

After the roundtable discussion, an electronic questionnaire with closed- and open-ended questions was given to each participant ([Multimedia Appendix 4](#)). The questionnaire allowed the collection of in-depth individual data on the implementation and adaptation of a CDSS for antibiotic prescribing. The questionnaire was codeveloped by a multidisciplinary team including 6 members of the Antibiocllic study team: infectious diseases clinicians (AP and FL), a microbiologist (AO), public health specialists (JB and GS) with experience in the West African context, and an implementation science and knowledge mobilization lecturer (RA). The first part collected demographic characteristics and information regarding the use of electronic tools for antibiotic prescribing. The second part displayed open-ended questions about potential outcomes and users of a

CDSS for antibiotic prescribing in West Africa and the challenges of its implementation and adaptation.

Data Analysis

Data from the closed-ended questions of the questionnaire were imported into R software version 3.2.4 (R Foundation for Statistical Computing). Numerical data are presented as absolute numbers, proportions, and median (IQR). The entire roundtable discussion was audio recorded and transcribed verbatim by the AMK France professional company. Data from the roundtable discussion and open-ended questions were analyzed using thematic analysis and were coded to identify key categories, which were developed into themes using NVivo 12 software (QSR International). The analysis of questionnaires and the roundtable discussion supported cross-validation and triangulation of the findings.

Ethical Considerations

Written consent was obtained from each participant. No distinguishable personal information was recorded, and all the data were analyzed anonymously. This survey was approved by the research ethics committee of Centre Muraz (Health Research Institute, Bobo-Dioulasso, Burkina Faso) and was compliant with the European General Data Protection Regulation.

Results

Participants

All 47 participants of the course, 19 women and 38 men with a median (IQR) age of 31 (30-38) years, participated in the workshop and completed the questionnaire (Table 1). Most of the participants (35/47, 74%) were from Burkina Faso, but 8 other West African countries were represented. Approximately half of the participants (24/47, 51%) worked in a university hospital, whereas the others worked in general hospitals (14/47, 30%), public health institutes (4/47, 9%), dispensary (1/47, 2%), private hospital (1/47, 2%), or pharmacies (1/47, 2%). The low number of participants working as primary care prescribers may be related to a more difficult access to university degrees. The specialty of the participants was general practice (21/47, 45%), microbiology (13/47, 28%), pharmacy (4/47, 9%), anesthesiology and intensive care (3/47, 6%), infectious diseases (2/47, 4%), and neurosurgery (2/47, 4%). Only 26% (12/47) of participants, all in Burkina Faso, stated that they used national guidelines to prescribe antibiotics. The others used French guidelines (20/47, 43%), WHO guidelines (20/47, 43%), or local hospital guidelines (4/47, 9%).

^aCentral Africa.^bThe 12 participants were from Burkina Faso.

Current Use of Technology and Clinical Decision Support Systems

Most of the participants (35/47, 74%) had a smartphone with internet access during their clinical consultations, but less than half (23/47, 49%) of the participants had access to a computer, and 15% (7/47) of the participants had no access to any electronic tools during their consultations. Most of the clinicians

did not use an electronic health record system (39/47, 83%) or CDSS (36/47, 77%) for any clinical decision making during their clinical consultations. The only CDSS mentioned by the participants was a tool for basic medical calculations and a tool that displays medical cards. No CDSS for antibiotic prescribing (nor for any antimicrobial drug) was used by the participants (Figure 1).

Figure 1. Current use of technology during consultation among participants. CDSS: clinical decision support systems.

Potential of a Clinical Decision Support Systems for Antibiotic Prescribing

Most of the participants expected favorable outcomes from the implementation of a CDSS for antibiotic prescribing in primary care in their countries (Figure 2). They thought a CDSS was likely to improve the quality of antibiotic prescribing (47/47, 100%), improve adherence to guidelines (47/47, 100%), improve the management and care of patients (44/47, 94%), decrease the number of medical errors (44/47, 94%), improve the volume

of antibiotic use (44/47, 94%), improve the duration of antibiotic therapy (43/47, 91%), fight against AMR (43/47, 91%), increase the medical knowledge of users (43/47, 91%), and save time during consultation (38/47, 81%). Participants disagreed on the fact that such a tool could strengthen the physician-patient relationship (20/47, 43% judged it likely; 11/47, 23% unlikely; and 16/47, 34% were neutral) or could lead to blind obedience to electronic tools from prescribers (16/47, 34% judged it likely; 16/47, 34% unlikely; and 15/47, 32% were neutral).

Figure 2. Expected outcomes of a clinical decision support system for antibiotic prescribing. CDSS: clinical decision support systems.

During the roundtable discussion and through the open-ended questions, the participants identified a number of consequences of a CDSS on a wider scale. Participants underlined the lack of antimicrobial stewardship teams in West Africa. They hypothesized that a CDSS could help many isolated structures to have access to antibiotic prescribing recommendations and could relieve existing antimicrobial stewardship teams of simple antibiotic prescribing advice and let them focus on complex cases. One participant noted that a CDSS could be used to increase surveillance capability in primary care. Indeed, its use could be monitored and lead to reports on the incidence of infectious diseases and the rate of antibiotic prescriptions. The participants agreed that this is particularly important in West African countries where epidemiological data are scarce. The use of French guidelines was not seen as a barrier to a CDSS. Indeed, most of the participants declared that they did not have national guidelines to prescribe antibiotics in their country. However, the participants pointed out that a successful CDSS could have a positive impact in encouraging national societies to develop guidelines that could then be integrated into the CDSS. More broadly, they agreed that this CDSS could help to increase the awareness of health professionals on the importance of appropriate prescribing and the risks of AMR. The

participants also agreed that a CDSS could be used in the initial training and continuous medical education of health professionals by updating antibiotic prescribing knowledge:

If you use it continually, you certainly update your knowledge. [General practitioner in Burkina Faso]

Regarding the scope of a CDSS for antibiotic prescribing, the participants stated that it could have a positive impact on the management of urinary tract infections (84%); skin and soft tissue infections (84%); gastrointestinal tract infections (83%); genital infections (80%); pneumonia (77%); meningitis (70%); ear, nose, and throat infections (70%); dental infections (67%); and surgical site infections (61%). The participants identified a wide diversity of potential users of a CDSS for antibiotic prescribing in West Africa, including general practitioners, infectious diseases specialists, physicians in other specialties, pharmacists, nurses, clinical microbiologists, and midwives.

Challenges

The participants identified a number of challenges and proposed a number of solutions for the adaptation of a CDSS for antibiotic prescribing in a West African setting (Table 2), and these are grouped by system level.

Table 2. Challenges and potential solutions for the development and implementation of a clinical decision support system in the West African context.

^cWHO: World Health Organization.

Country Level

At the country level, the participants pointed out the scarcity of epidemiological data in West African countries, the difference between epidemiology of diseases in HICs and LMICs, the lack of national guidelines, and the limited availability of diagnostic tests and antibiotics. To produce computer-interpretable clinical guidelines, CDSS developers need to have access to clinical practice guidelines. For countries where national guidelines for infectious diseases management do not exist, the participants first suggested the development of a CDSS based on French or WHO guidelines to encourage the establishment of national guidelines. To address the specific needs of primary care prescribers in West Africa, the CDSS should not only target the management of common bacterial diseases but also the management of parasitic diseases and tuberculosis. Participants stressed the importance of tailoring the CDSS to local capacity and infrastructure, such as resource availability and antibiotics, with the help of national scientific societies.

Health Care Structure Level

The first challenge at the organization level was the lack of internet access and information technology (IT) infrastructure. Taking into account the wide availability of smartphones with internet access, the participants highlighted major opportunities through the development of mobile phone versions of CDSS (on iOS and Android) with an offline mode. The second challenge was the important number of independently operating and geographically isolated health structures, such as dispensaries, in the West African health system. To reach these structures, participants suggested the involvement of relevant stakeholders, including health authorities, the Ministry of Health, scientific societies, the media, and opinion leaders, using traditional and social media:

It is important to use the traditional networks of the Ministry of Health where information goes down hierarchically but also social media that are more and more used. [Physician in a university hospital, Burkina Faso]

The organization of a phased approach was suggested by initiating and evaluating CDSS in a pilot primary care structure linked to an academic hospital followed by dissemination to other health structures:

You have to show people that it's used by people like them starting with a pilot test site. [Physician in a general hospital, Burkina Faso]

Individual Level: Clinicians and Patients

The diversity of primary care prescribers who have different levels of decision support needs was identified as a challenge to developing effective CDSS. A physician working in a general hospital stated that in West Africa “nurses see a lot of patients, certainly more than physicians” highlighting the need to codevelop the CDSS with primary care health care professionals who frequently prescribe antibiotics, such as general practitioners, nurses, midwives, microbiologists, dentists, and pharmacists. The implementation of a CDSS in West Africa should take into account the lack of widespread knowledge on the use of CDSS by organizing training sessions with primary care prescribers. One participant said that some health care professionals or patients could be refractory to new technologies, but this was not considered a major barrier by the other participants. The participants identified a number of facilitators for the adaptation of a CDSS by primary care prescribers and patients, including the independence of the tool from pharmaceutical companies, codevelopment with users, free access to the CDSS, and good usability.

The most discussed unexpected consequence was that an open access CDSS such as Antibioclic could amplify self-medication of antibiotics due to availability without prescription:

My point of view is really mixed. This represents an undeniable progress for antibiotic prescribing but in the context of our country, there is a non-negligible risk of self-medication by non-healthcare professionals. [General practitioner, Burkina Faso]

A very good tool for the treatment of infections but which could be dangerous in the southern countries because of self-medication and the accessibility of antibiotics without prescription. [Physician in a university hospital, Burkina Faso]

In this context, the CDSS may be used as a substitute for expert health care opinion. However, some participants highlighted the fact that much information is already available on the web and that Antibioclic is already available, including in Burkina Faso, with no reported use by patients. In fact, there was uncertainty regarding if implementing a CDSS in West Africa would amplify the phenomenon of self-medication or would help by providing a reliable source to patients who would want to self-medicate anyway:

Some patients will buy antibiotics without prescription, with or without the tool. [General practitioner, Burkina Faso]

On the contrary, if patients have access to national recommendations, this reinforces and this even facilitates your message. [Professor in a university hospital, Burkina Faso]

A consensus emerged that the best solution is to increase efforts to limit access to antibiotics without prescription.

Discussion

Principal Findings

We conducted a preimplementation workshop with West African health professionals to examine the requirements for a CDSS adapted to the context of primary care in their countries. The use of CDSS for antibiotic prescribing (and other clinical decisions, in fact) is currently missing, but the importance and need for such tools to support antibiotic prescribing in primary care were stressed by all participants. Regarding the

implementation of a CDSS in primary care, the participants encouraged a procedure of co-designing the tool with health professionals and stakeholders involved in antibiotic prescribing and initiation via a primary care pilot site, which is linked to an academic hospital (Figure 3). The diffusion of the CDSS would be more successful if supported by networks of medical specialists and the Ministry of Health but should also take advantage of social media because of its high use among health care professionals. The lack of widespread internet access and computers during consultation was a barrier to the use of the CDSS, but it could be circumvented by the development of a mobile app with an offline mode. The CDSS should be tailored to the local epidemiology of infectious diseases and AMR, and the high prevalence of malaria, tuberculosis, and HIV in West Africa should be taken into account when developing the CDSS [28]. The availability of diagnostic tests and antibiotics may differ between West African countries and may vary over time, requiring frequent updates of the CDSS.

Figure 3. Key steps for the development and implementation of a clinical decision support systems for antibiotic prescription in low- and middle-income countries. AMR: antimicrobial resistance; CDSS: clinical decision support systems.

The participants pointed out the potential risk of self-medication in countries in which antibiotics can be bought with no

prescription. Such a risk should certainly be anticipated and monitored, but most of the participants did not think that the

CDSS should have restricted access. On the contrary, some participants thought that a CDSS could provide an opportunity to strengthen the education of the general public about antibiotic prescribing and AMR. Development and implementation of a CDSS was seen to be associated with a number of benefits related to improving clinical care and reducing AMR and also to strengthening and updating practitioners' knowledge of antibiotic prescribing recommendations, encouraging the development of national guidelines, and developing surveillance capabilities in primary care. Indeed, the implementation of a CDSS for antibiotic prescribing could be coupled with measures that allow an increase in the capability of surveillance of antibiotic use. Examples include real-time monitoring of requests expressed on the platform and extracting reports about antibiotic use [27,29]. Moreover, the implementation of a CDSS in the community could have implications beyond antibiotic prescribing in primary care. Indeed, primary care is the gateway to secondary and tertiary care, and AMR in primary care circulates in the whole health system [30].

Comparison With Prior Work

The lack of preimplementation and co-design work concerning the assessment of CDSS for antibiotic prescribing has been reported in recent reviews [10,31]. More broadly, research on the implementation strategies for CDSS in primary care is lacking [32]. A qualitative design involving 33 face-to-face interviews with general practitioners has been used to codevelop computer-delivered interventions to promote guidelines for antibiotic prescribing in the United Kingdom. The authors focused on the technical development of prompts and the determinants of their acceptability but did not study the implementation of the CDSS in clinical practice [33]. Postimplementation research found that the key factor for the use of this CDSS by general practitioners in primary care was their awareness of the implementation of the system within their practice [22]. The lack of end-user engagement with implementation and the rigidity of the guidelines incorporated in the prompts were barriers to the effective adaptation of the system, stressing the importance of a systematic and theoretically informed process of implementation for CDSS [34]. The nonadaptation, abandonment, scale-up, spread, and sustainability framework has been developed to support the implementation of technological innovations in health and social care [19]. It lists challenges in 7 domains: the condition or illness, the technology, the value proposition, the adopter system (comprising professional staff, patient, and lay caregivers), the organization(s), the wider (institutional and societal) context, and the interaction and mutual adaptation between all these domains over time.

Few studies have focused on CDSS for the management of infectious diseases in LMICs and in particular in West Africa. A recent review identified 6 CDSS for the management of febrile children in primary care in LMICs [35]. In a pilot cluster-randomized controlled study, the clinical algorithm for management of childhood illness available on smartphones (e-ALMANACH) increased the number of children screened for red flags and decreased antibiotic prescription in Tanzania [36]. This result was confirmed in another controlled study in which the use of e-ALMANACH to manage children improved

clinical outcomes and reduced antibiotic prescription by 80% [37]. Electronic point-of-care tool, an electronic algorithm using point-of-care testing results including C-reactive protein and procalcitonin, was shown to improve the clinical outcomes of children with febrile illnesses as compared with the e-ALMANACH CDSS [38,39]. Another study described a protocol for the implementation on a large scale in Burkina Faso of an electronic tool for integrated management of childhood illnesses [40]. The results of this trial have not been published yet. In general, few data are available on the adaptation and sustainability of such interventions. One team analyzed the implementation cost of a CDSS for antenatal and delivery care and found that most of the cost resulted from the recruitment and training of nurses and midwives using the CDSS and from buying laptops [41]. A CDSS that is easily used by health care professionals and is available as a free mobile app could lead to a decreased implementation cost. A study in Burkina Faso confirmed a positive attitude toward electronic decision support systems and the need for simplicity and good usability of the tool. They found similar barriers, such as the lack of infrastructure and IT systems and the limited availability of drugs and diagnostic tests [42]. The development of CDSS in LMICs could be facilitated by the development of mobile health [43] and by sharing open-source codes [44]; however, other challenges remain: countries often have to buy a back-office or another hosting solution and have to pay for the maintenance of the server [45,46]. These costs, if not anticipated, can limit the sustainability of CDSS.

Limitations

The participants stressed the diversity of prescribers and health structures in West Africa that must be taken into account when codeveloping the CDSS. However, most of the participants in our workshop were physicians specialized in general practice working in Burkina Faso university hospitals. This bias was related to our recruitment of participants via a university degree organized by French and Burkina Faso universities. We, thus, need to involve more primary care prescribers such as nurse prescribers, midwives, and physicians working in dispensaries to allow for a broader view of primary care antibiotic prescribing. Indeed, prescribing habits may vary between professional groups [47,48], and we would like to capture potential differences among prescribers concerning the use, needs, and expectations regarding CDSS for antibiotic prescribing.

To open the discussion, we decided to provide an example of a currently used CDSS. Indeed, as we anticipated that most of the participants had no experience using electronic decision support systems for antibiotic prescribing, we wanted to show them an existing CDSS and collect opinions. This approach was likely to influence the answers of participants and the discussion during the roundtable discussions. However, we think that the barriers and facilitators identified in the study are not limited to Antibioclic. Indeed, the contextual barriers that have been found have been described in other studies. Nonprescription dispensing of antibiotics in the community has been widely described both in LMICs [49,50] and in HICs [51]. In a recent review, the authors did not find any clinical practice guideline applicable to prehospital care in LMICs among 276 guidelines

[15]. For countries where national guidelines for the management of infectious diseases do not exist, the participants suggested the development of a CDSS first based on French or WHO guidelines to encourage the establishment of national guidelines.

The governance system and public health priorities could be important additional factors that need to be studied in West Africa before the implementation of a CDSS. Work has been done in European countries about governance to address AMR [52], and relevant frameworks for assessing this important factor exist [20,53]. However, the analysis and governance frameworks for antibiotic prescribing often lack the assessment of technological innovation, such as electronic decision support. Including CDSS in the national action plan as in the United Kingdom's 2019-2024 national plan that targets to "be able to report on the percentage of prescriptions supported by a diagnostic test or decision support tool by 2024" is probably an

important step toward the development and implementation of support systems [54]. We are not aware of Western African national action plans mentioning the development and use of CDSS.

Conclusions

Preimplementation research is needed to ensure that CDSS are adapted to the context in which they are deployed. Our study provided valuable information to develop and implement a CDSS for antibiotic prescribing among primary care prescribers in LMICs. We plan to organize workshops to co-design a CDSS tailored to the context of primary care in West Africa. Optimizing the use of antibiotics in primary care may have beneficial consequences for the entire health system and can contribute to limiting the spread of AMR. Most of the barriers and facilitators that we identified may easily relate to a broad spectrum of CDSS, including systems for clinical decisions other than antibiotic prescribing.

Acknowledgments

The authors thank all the participants in the workshop and the team of the university course *Antibiologie et Antibiothérapie en Afrique Subsaharienne* organized by the University Nazi Boni of Bobo-Dioulasso and the University of Montpellier and supported by the WHO, West African Health Organization, and SPILF. RA acknowledges the support of the National Institute for Health Research Fellowship in knowledge mobilization at the National Institute of Health Research Health Protection Research Unit in Healthcare-Associated Infection and Antimicrobial Resistance at Imperial College and of the Economic and Social Research Council as part of the Antimicrobial Cross Council initiative supported by the 7 UK research councils, and the authors also acknowledge the support of the Global Challenges Research Fund. This study was funded by a PhD studentship from Île-de-France Regional Health Agency, Paris, France, granted to NP and by a grant from the French Association de Chimiothérapie Anti-Infectieuse via SPILF awarded to NP.

Abstract

Background: Asthma exacerbation is an acute or subacute episode of progressive worsening of asthma symptoms and can have a significant impact on patients' quality of life. However, efficient methods that can help *identify personalized risk factors and make early predictions* are lacking.

Objective: This study aims to use advanced deep learning models to better predict the risk of asthma exacerbations and to explore potential risk factors involved in progressive asthma.

Methods: We proposed a novel time-sensitive, attentive neural network to predict asthma exacerbation using clinical variables from large electronic health records. The clinical variables were collected from the Cerner Health Facts database between 1992 and 2015, including 31,433 adult patients with asthma. Interpretations on both patient and cohort levels were investigated based on the model parameters.

Results: The proposed model obtained an area under the curve value of 0.7003 through a five-fold cross-validation, which outperformed the baseline methods. The results also demonstrated that the addition of elapsed time embeddings considerably improved the prediction performance. Further analysis observed diverse distributions of contributing factors across patients as well as some possible cohort-level risk factors, which could be found supporting evidence from peer-reviewed literature such as respiratory diseases and esophageal reflux.

Conclusions: The proposed neural network model performed better than previous methods for the prediction of asthma exacerbation. We believe that personalized risk scores and analyses of contributing factors can help clinicians better assess the individual's level of disease progression and afford the opportunity to adjust treatment, prevent exacerbation, and improve outcomes.

KEYWORDS

asthma; deep learning; electronic health records; health risk appraisal

Introduction

Background

Asthma is a common and serious health problem that affects 235 million people worldwide [1] and an estimated 26.5 million

people (8.3% of the US population) in the United States [2]. Asthma takes a significant toll on the population, which imposes an unacceptable burden on health care systems. In 2013, the total annual cost of asthma was US \$81.9 billion in the United States [3]. If not well controlled or stimulated by specific risk

factors, asthma may develop into exacerbations (asthma attacks), which are acute or subacute episodes characterized by a progressive increase in one or more typical symptoms of asthma (dyspnea, coughing, wheezing, and chest tightness) [4]. In 2016, 12.4 million current asthmatics (46.9%) in the United States had at least one asthma exacerbation in the previous year [2]. Exacerbations of asthma can be severe and require immediate medical interventions, either as an emergency department (ED) visit or admission to the hospital [5]. Serious asthma exacerbations may even result in death [6]. Therefore, it is of practical significance to make early predictions such that interventions can be carried out in advance to reduce the probability of an exacerbation.

Investigations on risk factor analysis or prediction for asthma exacerbation have been respectable, in which the mainstream adopts traditional statistical methods, such as logistic regression [7-10], proportional hazards regression [11], and generalized linear mixed models [12]. However, most of them have only explored a small group of candidate risk factors and are usually hard to extend to other data sets and make personalized predictions difficult [13,14]. With the explosion of health care data in recent years, machine learning methods have taken a nontrivial place in this domain, benefiting from their general superiority over statistical methods in processing larger numbers of variables and flexibility in modeling more complex correlations [15]. Typical models include naïve Bayes [16], Bayesian networks [16-19], artificial neural networks [17], Gaussian process [17], and support vector machines [16,17]. However, although different attempts have been made, there are still several deficiencies in traditional machine learning methods. For example, ignoring temporal dependencies between variables might not provide a meaningful risk estimation of future exacerbations for individual patients [14]. Furthermore, most approaches only concentrate on the quantitative evaluation of prediction performance, but lack further attention to personalized risk factors [20].

Recent revolutions in health artificial intelligence started from deep learning, which has an upper hand on health care predictions because of its flexibility in dealing with longitudinal data [21], powerful learning capabilities [22], and ability to alleviate the problem of data irregularity [23]. One of the most popular architectures is recurrent neural networks (RNNs), which make predictions according to the sequence of historical events. Dozens of successes have been achieved in applying deep learning to disease predictions [24], mostly using variants of RNNs with distinct network components, for example, by adding an attention mechanism to evaluate the weights of each variable [25-29] or by using special configurations to tackle the problem of time decays [23,25,27,30-32]. Typical prediction tasks include the prediction of diabetes mellitus [23], Parkinson disease [29,33], chronic heart failure [26], sepsis [34], mortality, and readmission [25]. However, deep learning-based studies on the prediction of asthma exacerbation remain lacking. Do et al [35] proposed a protocol for the prediction based on RNNs and reinforcement learning but did not test the method on real-world data.

Objectives

Inspired by previous studies, we applied long short-term memory (LSTM) [33], a popular RNN variant commonly used by previous predictive models [23-25,29,34] as the main framework for asthma exacerbation prediction, which can mitigate the gradient vanishing problem in RNNs. We proposed the time-sensitive, attentive neural network (TSANN), which employs a self-attention mechanism [36] to help model the context of both visit-level and code-level variables. Meanwhile, to incorporate the impact of elapsed time, we projected the relative time of each clinical variable into a low-dimensional space and combined it with the code representations. Using the attention weights of the TSANN, data analysis was then conducted to investigate personalized and cohort-level risk factors.

There are major differences between TSANN and recent state-of-the-art deep learning-based clinical predictive models such as time-aware LSTM (TLSTM) [23], Reverse Time Attention model (RETAIN) [27], and Attention-based Time-aware Disease Progression (ATTAIN) [32]. First, the model structures are different. Compared with TLSTM and ATTAIN, which only include 1 layer of RNN, our two-layer architecture enables us to analyze the relative importance of each event within each visit. Although RETAIN also has 2 layers of attention, it does not have explicit hierarchical structures as TSANN. Instead, an additional inference step is required to obtain the contribution of each variable. Second, TSANN uses a different approach to model the elapsed time. RETAIN, TLSTM, and ATTAIN feed the time elapsed into a decay function as a single value and multiply it with the network memory. In comparison, the elapsed time embeddings in TSANN are more analogous to position embeddings in natural language processing, which were introduced to model the relative distance between words by learning multidimensional and semantic representations to facilitate certain tasks such as relation classification [37] and neural language modeling [36,38,39]. By using time embeddings, we assume that time is no longer a single value as it was used in previous methods, but it can represent more complex patterns together with clinical variables such as varying lengths of correlations between variables.

The primary aims of this study were (1) to propose a novel predictive model with better performance and (2) to add the transparency of the model by visualizing contributing factors at both the individual and cohort levels. Furthermore, the proposed model can potentially be applied to other clinical problems. Deep learning models are usually scalable. Although focusing on asthma exacerbation for this specific project, the proposed approach can also be adopted in risk predictions for other chronic diseases. We hope that the associated pipeline of deep learning-based predictive modeling, including data collection, model training, model evaluation, and risk factor analysis, can help the clinical community better understand the underlying mechanisms of disease progression and assist in decision making.

Methods

Problem Statement

Given a sequence of historical clinical variables in patients with asthma, we aimed to evaluate the risk of developing asthma exacerbation in the designated time window. Meanwhile, personalized contributing factors are to be identified to facilitate the evaluation of disease progression and make early interventions.

Database

The study used Cerner Health Facts, a Health Insurance Portability and Accountability Act–compliant database collected from multiple enrolled clinical facilities, containing mostly inpatient data. Data in Health Facts were extracted directly from the electronic health records (EHRs) from hospitals with which Cerner has a data use agreement. Encounters may include the pharmacy, clinical and microbiology laboratory, admission, and billing information from affiliated patient care locations. All personal identifying information of the patients was anonymized. In this study, we primarily focused on the impact of clinical factors on asthma exacerbation; therefore, we extracted diagnoses, medications, and demographic characteristics such as gender, race, and age from the database as clinical variables or clinical events. The University of Texas Health Science Center (UTHealth) had agreements with Cerner to use these data for research purposes. The institutional review board at the UTHealth approved the study protocol.

Study Design

We conducted a retrospective study to predict the risk of asthma exacerbation. Patients' records between 1992 and 2015 were

extracted from the Cerner database. For clarity, we defined several terms in advance (Table 1).

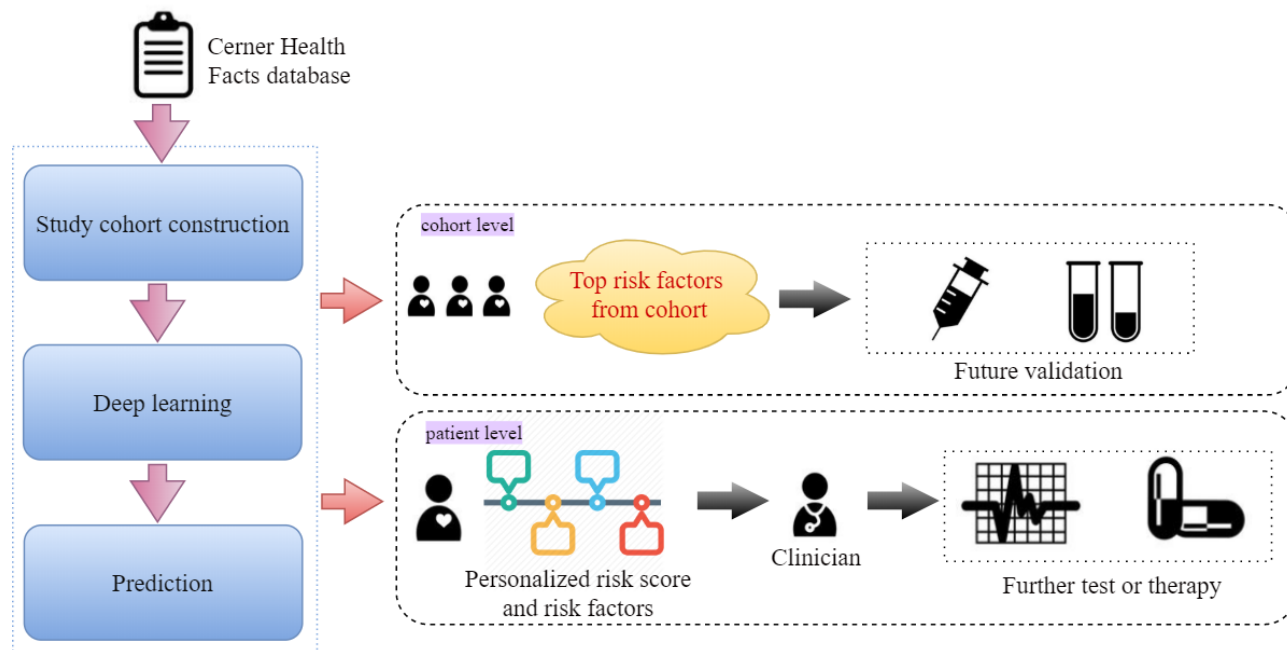

We built 2 cohorts as simulations for both the real-world application scenario (*early prediction*) and the model evaluation (called *next-visit prediction* in many previous studies [27,32]). In early prediction, we could not foresee when the exacerbation would happen but could only evaluate the future risk at each visit. In our study, we selected the fifth visit from the asthma index as the prediction date (*testing set A*) according to the average number of visits (5.78, SD 6.04) between asthma index and exacerbation among the patients. The detailed steps for the cohort selection are listed in Multimedia Appendix 1 [4,25,40-55]. In next-visit prediction, we simply set the penultimate visit as the prediction date (*testing set B*). We set testing set A as our primary evaluation set as it was much closer to the realistic diagnostic situation.

The TSANN model was trained to evaluate the risk of asthma exacerbation given the observed time window. The main outcomes of the proposed method are (1) a score that measures the risk of asthma exacerbation for each patient and (2) visualization of the results, including a personalized heatmap identifying the importance of each clinical variable in the observed time window, cohort-level risk factors, and their temporal distributions among patients. On the basis of the outcomes, further data mining or clinical trials can be carried out for validation. For example, cohort-level factors will help data scientists reduce labor and expertise in collecting candidate risk factors from the literature before conducting a regression analysis. Patient-level factors will facilitate physicians and patients in better understanding disease progression. The workflow of this research is shown in Figure 1.

Table 1. Defined terms for asthma exacerbation prediction.

Term	Definition
Index date	The date of the first diagnosis of asthma in a patient's EHR ^a
Exacerbation date	The date of the first diagnosis of asthma exacerbation after the index date
Case group	Patients with asthma and later asthma exacerbations within 365 days and satisfying the inclusion and exclusion criteria
Control group	Patients with asthma but without exacerbations within 365 days and satisfying the inclusion and exclusion criteria
Prediction date	Training set: for the case group, the visit date before the exacerbation date; for the control group, the penultimate visit date within 365 days: <ul style="list-style-type: none"> • Testing set A: the fifth visit starting from the index date • Testing set B: defined analogously to the training set
Observed time window	The time window between the index date and the prediction date

^aEHR: electronic health record.

Figure 1. The workflow of the prediction and risk analysis of asthma exacerbation.

Selection of Study Subjects

The subjects in the study were patients with a diagnosis of asthma. The inclusion and exclusion criteria derived from previous studies [4,56] were as follows.

Inclusion Criteria

The subjects in the study were patients with at least one record of asthma diagnosis. The definitions of asthma and exacerbation are as follows.

Asthma

1. Asthma diagnosis codes were provided according to the International Classification of Disease Code (ICD; ICD-9 code 493.xx or ICD-10 code J45.xx). This is the first occurrence of asthma in the patient's EHR.
2. At least one of the asthma medications was prescribed on the asthma diagnosis date (the index date). Asthma medications include short-acting beta agonists, inhaled corticosteroids (ICS), long-acting beta agonists (LABA), leukotriene receptor antagonists, anticholinergics, and ICS/LABA combinations.

Asthma Exacerbation

1. Asthma (ICD-9 code 493.xx or ICD-10 code J45.xx) was given as a primary diagnosis for an ED visit or hospitalization.
2. At least one oral corticosteroid treatment was received.

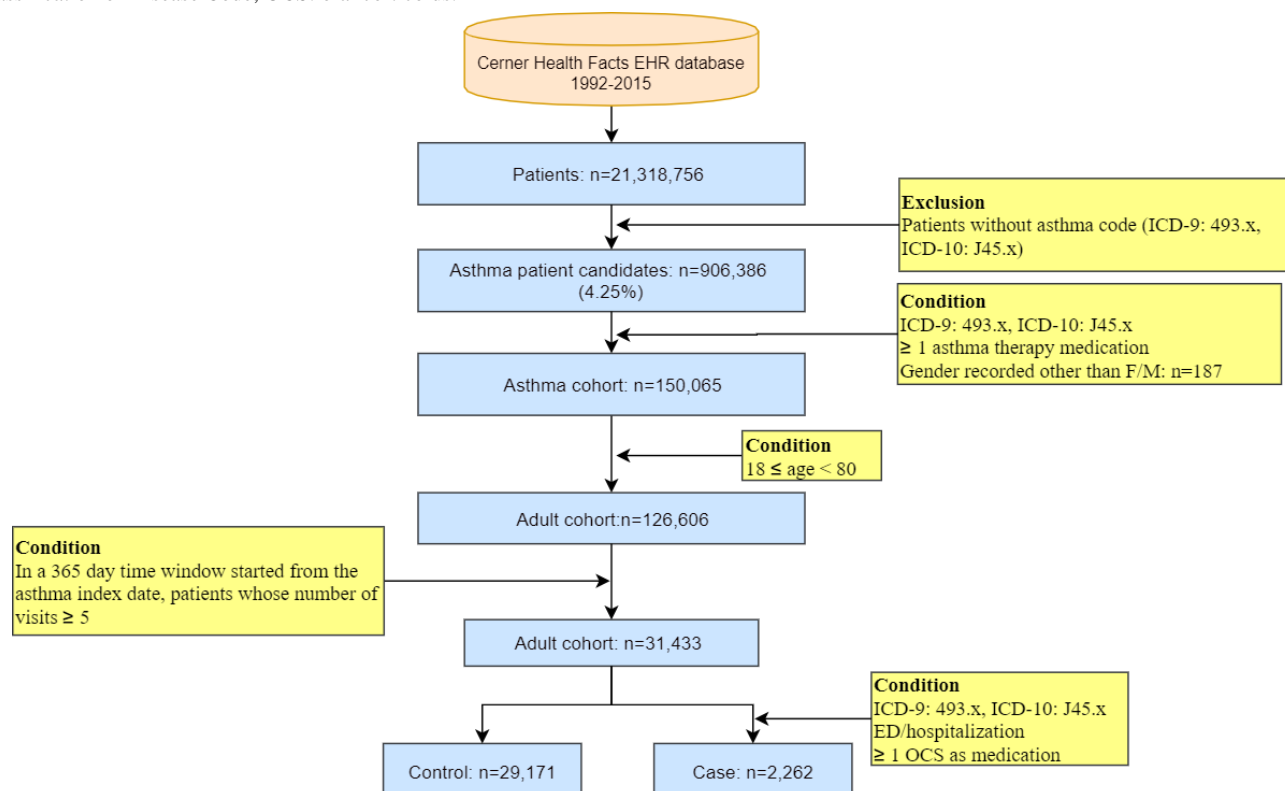

Exclusion Criteria

To allow the data to better fit for machine learning models, we excluded the following patients:

1. Those with missing or unclear time information (eg, with a wrongly recorded format of time stamps)
2. Those with a gender other than male or female
3. Those whose number of visits is <5 in the observed time window

This study only focused on adult patients aged between 18 and 80 years. In the end, 31,433 individuals remained, including 2262 cases and 29,171 controls (case by control ratio approximately 1:13). The cohort selection process is shown in [Figure 2](#). A detailed descriptive analysis of the cohort is shown in [Multimedia Appendix 1](#).

Figure 2. Cohort selection process for the study of asthma exacerbation. ED: emergency department; EHR: electronic health record; ICD: International Classification of Disease Code; OCS: oral corticoids.

Time-Sensitive Attention Neural Network

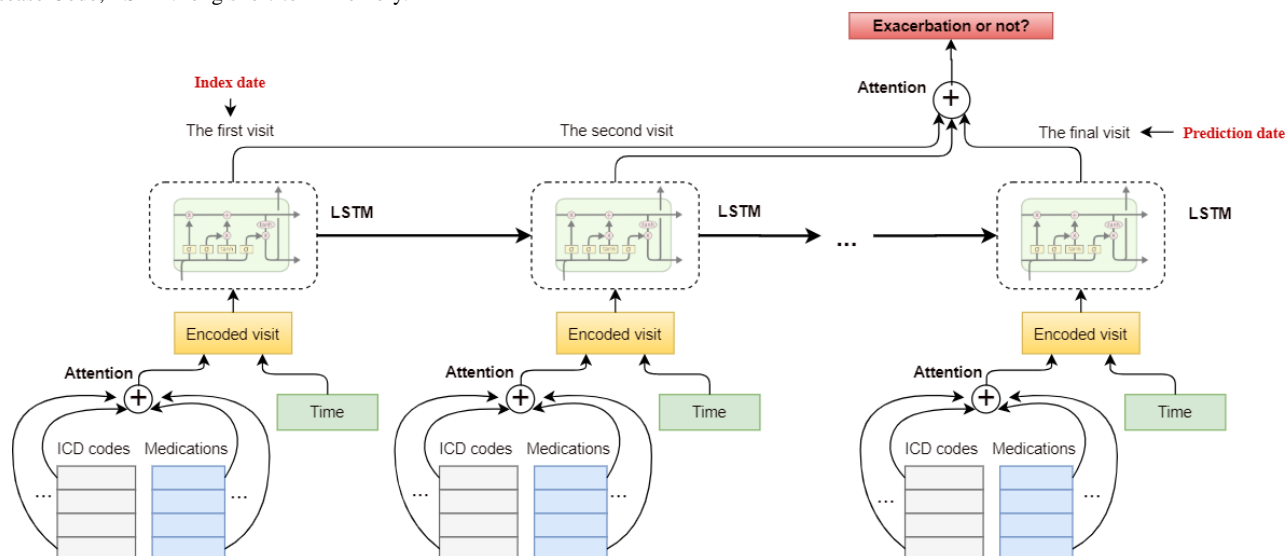

Model Overview

TSANN takes the whole sequence of clinical variables in the observed time window as inputs and outputs the probability of asthma exacerbation (Figure 3). The architecture of TSANN is based on LSTM and strengthened by the addition of hierarchical attention and elapsed time embeddings.

For each visit, multiple clinical variables were encoded in the input layer and averaged through the code-level attention

mechanism. The elapsed time embedding is attached to each visit as complementary information to indicate the time interval between the date of each visit and the prediction date. LSTM then accepts the sequence of encoded visits as inputs and outputs further encodings for each visit. The visit-level attention layer is then applied to the outputs of the LSTM to summarize all the visits for each patient. Finally, by feeding the output of visit-level attention into the Softmax function, a probability indicating the risk of disease onset is generated.

Figure 3. Overview of the time-sensitive attentive neural network model for asthma exacerbation prediction. ICD: International Classification of Disease Code; LSTM: long short-term memory.

Input

The inputs of the model consist of 2 types of features. One type is clinical concepts (we use *clinical concepts* and *clinical variables* interchangeably), including ICD codes, medications, and demographic features. All ICD-10 codes were converted into ICD-9 based on predefined mappings [57] because very few diagnosis codes in our data set were encoded by ICD-10 as the data collection time range is between 1992 and 2015, but the implementation of ICD-10 started in October 2015. All medications were normalized to their generic names. The demographic features included age, gender, and race, which were only taken as inputs on the prediction date. Using a projection matrix \mathbf{C} (V_c : concept vocabulary size and D_c : concept embedding dimension), we mapped each clinical concept into a concept-embedding vector:

$$\mathbf{C}_{ij}$$

where \mathbf{C}_{ij} is the generated concept-embedding vector and \mathbf{C}_{ij} is the one-hot vector denoting the existence of clinical concept j in visit i .

The other feature type is time features, which indicates the occurrence time for each clinical variable. Intuitively, variables with different time stamps would behave differently in prediction. For instance, in many cases, a clinical event that happened several days ago would play a more important role than one that happened several months ago. Meanwhile, due to the nature of data irregularity and deficiency of EHRs, successive visits always have diverse time intervals [23], which makes it indispensable to consider the time elapsed when conducting predictive modeling.

Elapsed time embeddings were introduced to represent the relative time gap for each clinical concept. Specifically, taking the time of the prediction date T_0 as a pivot, the time attribute of each clinical concept is the absolute difference between its occurrence time T_i and T_0 , that is, the relative time gap $T_0 - T_i$. As the observed time window has an upper bound of 365 days, the vocabulary size V_t of the time embeddings was set as 365.

We applied a matrix \mathbf{W}_t to project each time value to an m -dimension vector. Unlike the clinical concept embeddings, elapsed time embeddings are fed into the model after the code-level attention and assigned to each visit. The equation to obtain the elapsed time embedding for each visit is analogous to that for concept embeddings, where:

$$\mathbf{W}_t$$

Specifically, the minimum time unit in this study was set as day.

Code-Level Attention

Attention is a mechanism specifically designed for deep neural networks that acts as an information filter; meanwhile, it can alleviate information loss when dealing with long sequences. It selects important sequence steps by assigning them different weights [58,59]. Through attention, each clinical concept is

assigned a weight such that important concepts would have larger weights than the others. We adopted the attention mechanism from Yang et al [60], in which the weight of each variable is generated according to the sequence and context vector. Specifically, given the set of codes \mathbf{C}_{ij} in the i th visit, the encoded representation for visit v_i can be generated by:

$$\mathbf{W}_v$$

$$\mathbf{b}_v$$

$$\mathbf{u}_{ij}$$

where \mathbf{W}_v and \mathbf{b}_v are the weight and bias for matrix transformation, \mathbf{u}_{ij} is the attention vector for each code j in v_i , \mathbf{u}_v is the context vector for v_i , which is randomly initialized and updated during training, and α_{ij} is the attention weight for the concept V_{ij} based on which we can generate its final weight. By assigning time embeddings to the i th visit v_i , the representation of each visit is updated as \mathbf{C}_{ij} , where \mathbf{C}_{ij} denotes the matrix concatenation.

Visit-Level Attentive LSTM Layer

Taking the encoded representation of each visit as input, LSTM models the sequential information in the observed time window and obtains the summarization at the final step (the prediction date). The advantage of LSTMs over traditional RNNs is that they can alleviate the gradient vanishing problem and are thus able to retain longer *memories* from prior time stamps [61,62]. LSTMs are implemented by several matrix multiplications and nonlinear transformations that aim to mimic the memory mechanism of human brains, which are called *gates*, signifying that the network can select effective information and abandon useless information. The equations of the LSTMs are as follows:

$$\mathbf{W}_f$$

$$\mathbf{b}_f$$

$$\mathbf{W}_i$$

$$\mathbf{b}_i$$

$$\mathbf{W}_c$$

$$\mathbf{b}_c$$

$$\mathbf{W}_o$$

$$\mathbf{b}_o$$

where \mathbf{W}_s and \mathbf{b}_s are the weights and biases for different gates or cells (f_i : forget gate, i_i : input gate, C_i : memory cell, o_i : output gate, and h_i : hidden cell) and σ is the activation function, such as *Tanh* or *sigmoid*.

By assigning attention weights to the outputs of LSTM from each step, we can weight each visit in the observed time window and obtain a summary of these visits as r_p :

where W_p and b_p are the weight and bias for matrix transformation, u_i is the attention vector for each visit i given v_i , u_p is the context vector, and j is the attention weight for each visit v_j . This process can be seen as a simulation of the diagnosis procedure of a clinic visit, during which a physician would look back into a patient's EHR, measure the impacts of each historical clinical event, and make the final decision.

Output

The visit-level attention layer compresses all the information in the observed time window into a fixed-length vector r_p . The

output of attention goes through a fully connected layer with nonlinear activation. Finally, a Softmax function is applied to generate the prediction probability, P :

where P is used as the score to evaluate the risk of developing asthma exacerbation.

Evaluation

Area under the receiver operating curve (AUC) is widely used as an evaluation metric for predictive models, which reflects a balance between sensitivity and specificity [63]. According to the prediction probability P (between 0 and 1) for each instance, the AUC value is generated by setting different cutoffs. The methods listed in Table 2 were compared in our experiments.

Table 2. The methods used for comparisons.

Method	Note
LR ^a	A popular conventional machine learning algorithm [64], usually serving as a strong baseline in predictive modeling [27]. The input of LR is a fixed-length feature vector that denotes the frequencies of each variable. For LR considering time, we associate each variable with its time stamp and expand the vocabulary. We did not use <i>day</i> as the time unit as it would have introduced a greater number of variables (ie, 12,390×365 [the code vocabulary size×the maximum number of days]), which would have been too sparse and difficult for computation. Instead, we set month as the time unit, and finally, 148,680 distinct clinical variables were generated. We employed the Synthetic Minority Oversampling Technique [65] to help alleviate the problem of data imbalance
MLP ^b	The MLP model used in this study contains 1 input layer and 1 Softmax layer [66]. The representations of all the codes were averaged on each dimension after being projected to the embedding space for each patient
LSTM ^c	The basic LSTM algorithm, taking the sequence of the clinical variables as input ordered by time. The variables in each visit are averaged
ALSTM ^d	Comprising 1 layer of LSTM and 1 layer of attention
TLSTM ^e [23]	The time-aware LSTM model, which is one of the state-of-the-art predictive models. In TLSTM, the time gap is used to compute the information decay in the LSTM unit
RETAIN ^f [27]	A two-layer attention model, which is another state-of-the-art model for the prediction of disease onset. In RETAIN, the time features are not embedded as vectors but real values denoting the gaps from the first visit
ATTAIN ^g [32]	A modification of TLSTM with special types of attention mechanisms added (flexible attention). It also uses a similar time decay function as RETAIN. We implemented it ourselves using TensorFlow
TSANN ^h -I	The proposed TSANN model but with the second attention layer removed. Prediction is based on the final state of LSTM
TSANN-I-step	Apply the time-encoding method from Song et al [39] on TSANN-I. In TSANN-I-step, although time was also encoded using a vector, it only showed the order of each visit, for example, 1, 2, 3 for consecutive visits, but not the actual elapsed time
TSANN-II	A complete version of the proposed TSANN model

^aLR: logistic regression.

^bMLP: multilayer perceptron.

^cLSTM: long short-term memory.

^dALSTM: attention long short-term memory.

^eTLSTM: time-aware long short-term memory.

^fRETAIN: Reverse Time Attention model.

^gATTAIN: Attention-based Time-Aware Disease Progression.

^hTSANN: time-sensitive attentive neural network.

For evaluation, we first split the data into a training set and a held-out testing set with a ratio of 8:2. Furthermore, five-fold cross-validation was performed on the training data set for parameter tuning. During cross-validation, a grid search was

applied to tune the hyperparameters including learning rate (0.0005, 0.001, 0.005, 0.01), l2 penalty (0.0001, 0.0005, 0.001), batch size (32, 64, 128), activation function for LSTM (ReLU [40] and Leaky_ReLU [41]), whether to add batch normalization

[45], and the optimizer selection between RMSprop [42] and Adam [43]. We then averaged the AUCs of each epoch (up to 30 epochs) across five folds to obtain the best training epoch. The optimal hyperparameters were adopted to retrain the model on the entire training set and produce the AUC on the testing set. Finally, the hyperparameters for the model TSANN-I, which has the best AUC value, were as follows: batch size=32, concept embedding dimension=100, time embedding dimension=20, Adam as the optimizer with learning rate=0.001, l2 penalty=0.0001 for all parameters, Leaky_ReLU as the activation function, and adding batch normalization before Softmax. The codes for RETAIN and TLSTM were reused from the respective studies. All other deep learning models were implemented with TensorFlow [44] and trained on Nvidia Tesla

V100, Quadro P6000, and Titan XP GPUs. We shared our code on GitHub to facilitate other researchers [67].

Results

AUC Values

AUC values with (+time) and without the consideration of time (–time) on testing set A (the primary evaluation set) are shown in Table 3. In the table, for TLSTM, we only considered a +time version as it is defined as a time-aware variant of LSTM, and for multilayer perceptron (MLP), LSTM, attention long short-term memory (ALSTM), TSANN-I, TSANN-I-step, and TSANN-II, we used the elapsed time embeddings introduced in this study to include time.

Table 3. Area under the curve (AUC) values by different models (–time: time information was excluded and +time: time information was included).

Method	AUC ^a –time	AUC+time
LR ^b	0.6447	0.6773
MLP ^c	0.6545	0.6753
LSTM ^d	0.6045	0.6567
ALSTM ^e	0.6346	0.6714
TLSTM ^f	—	0.6548
ATTAIN ^g	0.6119	0.6597
RETAIN ^h	0.6455	0.6882
TSANN ⁱ -I	0.6692	<i>0.7003^j</i>
TSANN-I-step	0.6463	—
TSANN-II	<i>0.6827</i>	0.6855

^aAUC: area under the receiver operating curve.

^bLR: logistic regression.

^cMLP: multilayer perceptron.

^dLSTM: long short-term memory.

^eALSTM: attention long short-term memory.

^fTLSTM: time-aware long short-term memory.

^gATTAIN: Attention-based Time-aware Disease Progression.

^hRETAIN: Reverse Time Attention model.

ⁱTSANN: time-sensitive attentive neural network.

^jThe optimal value for each column is italicized.

When comparing vertically (different rows) and considering time information, we noticed that TSANN-I achieved the optimal AUC value, improving the strongest baseline (RETAIN) by 1.21% (the difference was significant according to the Wilcoxon test with $P=.03$). Among other methods, TSANN-II achieved a performance comparable with that of RETAIN. The conventional machine learning method logistic regression (LR) behaved better than some deep learning methods but was worse than RETAIN, TSANN-I, and TSANN-II. TSANN-I-step, which only used time embeddings to denote the relative position of each visit, did not produce good results. Although TLSTM and ATTAIN performed well on other tasks, they did not obtain satisfactory results on our data. For results without time,

TSANN-I and -II performed much better than others, with a maximum improvement of 2.82%.

When comparing the results horizontally (–/+ time), considerable improvements were observed after adding time information on most methods; for example, TSANN-I obtained a 3.11% improvement. Surprisingly, TSANN-II, when integrating time embeddings, did not improve considerably.

Better performances by TSANN models and considerable improvements after adding the time information could also be observed on testing set B (we did not list the results here but showed them in Multimedia Appendix 1 as it is not our primary evaluation set). As expected, the general results on testing set

patient's status of hypoxemia worsened the condition of asthma following symptoms in the breath, and asthma exacerbation was then diagnosed.

These highly associated variables can either be signs of asthma worsening or be triggers for exacerbation, which requires further confirmation by domain experts. Signs including symptoms and treated medications may convey important clues for disease progression and will help clinicians in making final diagnoses, whereas the triggers behaving as personalized risk factors will potentially benefit early interventions. In addition, each heatmap is associated with a probability score derived from equation 15, indicating the risk of the patient in developing an exacerbation (the top row in [Figure 4](#), *predicting 1* indicates *predicting exacerbation*).

behave distinctly among individuals with different action times or different incidences. [Figures 5](#) and [6](#) present 2 examples in which the time distributions for the clinical variables are displayed through scatters. In these scatters, each circle represents a patient where its size and color depth denote the importance of the corresponding variable. In the figures, the x-axis represents the time gap between the occurrence date of the variable and the prediction date, whereas the y-axis is employed merely for cosmesis. We randomly selected a maximum of 2000 patients to plot this figure.

Figures 5 and 6 were derived from an ICD code (530.81) and a medication (fentanyl), respectively. We observed different effective time ranges for these 2 factors, where the first factor tends to distribute more intensively between the previous 250 to 50 days, whereas the second factor focuses more intensively on the previous 100 days. We hope that these visualizations can help determine the temporal distributions of highly associated factors to aid asthma control.

Table 4. Clinical variables with the top-ranked weights (/N stands for the clinical variable presented in N months before the prediction date).

Sr. No.	ICD ^a -9/occurrence time	Medication/occurrence time
1	493.9×asthma/0-5 ^b (meaning diagnosed with asthma multiple times before exacerbation)	Methylprednisolone/0, 1 ^c
2	786.07 wheezing/0-2 ^d	Prednisone/0, 1, 2 ^c

^aICD: International Classification of Disease Code.

^bIdentified possible risk factors of asthma exacerbations by the domain expert. The authors regard these as containing valuable information.

^cThese medications can be used to treat asthma or control the symptoms of asthma. In this study, it was difficult to determine whether these medications are risk factors as we were unable to investigate the dosage of these medications in the current study. Inappropriate medication use, short-acting beta agonists/inhaled corticosteroids, could also lead to asthma exacerbations.

^dThese factors were symptoms, comorbidities, or combined medications. We believe they were not risk factors for asthma exacerbations.

^eIt could hardly be determined whether these factors caused asthma exacerbations, but they demonstrated high associations. The authors regard these as containing valuable information.

Figure 6. The time distribution of the contribution of the clinical variable fentanyl.

Discussion

Principal Findings

Our proposed method obtains the optimal AUC value on the prediction task, with hierarchical attention and elapsed time embeddings as its booster. The visualization also provides useful tracks for a better understanding of disease progression. The primary outcomes of this study are as follows: (1) a new state-of-the-art predictive model for asthma exacerbation prediction was proposed and validated and (2) a reasonable pipeline of disease risk prediction and factor analysis was

introduced. Some of the identified risk factors can be validated from the literature, which shows the effectiveness of the method, whereas some other factors, although supportive shreds of evidence were seldom reported in previous studies, offer meaningful insights for further research. The discussions in this section are primarily based on the results of testing set A without additional comments.

Model Performance

TSANN-I and TSANN-II have the capacity to capture nonlinearities and learn more complex dependency relationships between variables, benefiting from the structure of hierarchical

attention and the addition of elapsed time embeddings. It is difficult for LR and MLP to learn temporal dependencies between variables according to their natural structures, which makes them perform worse than TSANNs. However, they obtained better AUCs than LSTM and ALSTM on testing set A, partly because the truncation of EHRs by 5 visits weakens their advantages in modeling longer sequences. Although TLSTM and ATTAIN also integrated the time information, they did not obtain satisfactory results as other methods. It is likely that the combination of the single-layer deep learning structure and the numerical time decay function is insufficient in dealing with more complex temporal patterns on this data set and even confuses the classifiers. RETAIN also has a hierarchical attention structure, as introduced in the Introduction section. However, one of its attention mechanisms is applied to each code-embedding dimension, which is different from ours and requires an additional inference step for interpretation. In addition, our addition of time embeddings enhanced the flexibility of modeling the time information, which contributed considerably to the performance.

A typical characteristic of the EHR data is irregularity, which means that the time gaps between clinic visits are irregular and the visits are often sparsely distributed along the timeline and sometimes are even missing. Thus, the predictive model is responsible for serializing the visits for each patient with consideration of time elapses between continuous visits and reduces the effect of missing data. The comparisons between results with and without time information in Table 3 demonstrate the effectiveness of considering time elapses in this cohort. It might be inferred that the prediction of asthma exacerbation is quite time sensitive and most of the critical risk factors should have been time stamped. For instance, even for a visit just before the prediction date, if its occurrence is several months earlier, its impact would be reduced. Similar cases can also be found in Baytas et al [23], who reported an improvement of 6% from LSTM to TLSTM. In comparison, for TSANN-I-step, although time embeddings were also used, they were only used to denote the relative position of each visit in the sequence but lacked the ability to represent time decays, which can hardly obtain satisfying results here. However, adding time to TSANN-II did not improve much as in other methods, a possible reason might be that the addition of visit-level attention weakens the contribution of time embeddings.

Risk Factors

As mentioned earlier, the factors identified by this method can be roughly divided into possible risk factors and highly associated factors, for which some pieces of evidence can be found in the literature. Besides, there were still several candidate factors proposed by our model that were seldom reported, for example, HIV infection, or we could not confirm their associations, for example, abdominal pain. One possible reason is that we only considered structured data but not textual information (ie, clinical notes); therefore, that disease or symptom may not be detailed enough to understand given only a code (ie, we know abdominal pain but do not know in which part). Furthermore, according to the AUC values of the model, the results may not be precise enough and still need to be improved. Overall, our method is completely data driven,

without any predefined candidate risk factors by experts, which is different from most studies based on regression analysis [7]. We expect that our method can provide compensational information and some new findings can be further validated by clinicians or researchers.

Error Analysis

We analyzed patient samples that are likely to be false-positives or false-negatives according to the prediction probability (as we did not require an output label but only a probability indicating the risk of each patient). One possible reason for the likely false-negatives (ground truth is case, but the predicted probability for case is quite low) is the data missing problem. For example, patient A had some respiratory symptoms such as asthma, shortness of breath, and chronic airway obstruction about 6 months before the prediction date; however, all the diagnosis codes were related to heart disease and hypertension. Therefore, it is likely that some symptoms that might serve as better indications were missing. On the other hand, one explanation for some false-positives (ground truth is control, but the predicted probability for control is quite low) is the difficulty in evaluating the severity of certain diseases or symptoms. For example, patient B had continuous respiratory symptoms such as chronic airway obstruction, but without any laboratory test values or knowledge of the drugs, it is difficult to determine whether these symptoms worsened or were already well controlled. To mitigate these factors, it is desirable to integrate more variables and background knowledge into the model in the future.

Comparison With Prior Work

One of the advantages of machine learning over statistical analysis is that it can make predictions on unseen samples [15], and it might be much easier to be deployed in real-world applications. Although many studies have focused on asthma exacerbation prediction, the majority of them belong to statistics, as they did not test their model on held-out data sets [68,69]. Among other machine learning studies, multiple conventional models have been explored, such as classification and regression tree [11,70], random forest [71], LR [72], and support vector machines [16]. However, none of these previous studies used deep learning as we know. Compared with these conventional machine learning methods, our deep learning-based method has multiple advantages. First, no feature engineering is needed, which will extremely reduce the laborious cost and expertise at the first step, for example, in comparison, Luo et al [20] included 235 features designed by multiple clinical experts as inputs that might cost a lot, but we input all the clinical codes to the model and kept their original formats without any feature selection. Second, LSTM structures can integrate any temporal patterns; thus, dependencies between variables can be easily modeled. Third, deep learning methods usually obtain better performances compared with conventional machine learning methods because of their capacities in modeling complex data structures [22,23,27], which was also proved in our experiments (compared with LR).

Furthermore, compared with previous studies, we are the first to make comprehensive visualization and personalization over the associated factors. One paper mentioned *personalize*, but it

only discussed it as a future possibility [16]. In comparison, our method showed not only cohort-level factors but also temporal-based personalized risks and factors, which would greatly facilitate precise medicine. Meanwhile, as we did not limit our input to the predefined factors, we were able to find new potential risk factors. However, one drawback of deep learning-based methods compared with the previous shallow methods is the lack of interpretability from some perspectives, for example, they can hardly report statistical evaluation measures such as *P* values and CIs, which might need further exploration.

Limitations and Future Work

Using deep learning, we offered a novel means of identifying possible risk factors and predicting the risk of asthma exacerbation. However, this study has some limitations. First, for the model interpretation part, how multiple clinical variables interact with each other needs further exploration; simply considering each variable independently but ignoring the dependency patterns between them might be insufficient for interpretation, for example, the prescription of a drug might be closely associated with a disease or symptom. Second, structured EHRs have their own drawbacks, such as data irregularity, sparsity, and noise. Thus, some potential risk factors for asthma exacerbations might not be recorded or might even be incorrectly recorded in EHRs. As a result, information integrity cannot be

guaranteed. We may need to find ways to make the data complete and more reliable, such as including information from textual reports or patient surveys. Third, it is still difficult for computer programs alone to distinguish between asthma symptoms and risk factors, and knowledge injection is needed in the future. Finally, the performance of the model still has room for improvement. It might be boosted further by designing more powerful structures or including background knowledge.

Conclusions

In this paper, we proposed an attentive deep learning-based model for asthma exacerbation prediction and employed elapsed time embeddings to model the time decays. By leveraging the weights of the model, we not only generated personalized heatmaps and specific risk scores at the individual level but also identified possible risk factors at the cohort level. Compared with previous studies, our model is effective in modeling time information and obtains better overall AUCs. As the model is completely data driven and relies little on feature engineering, it can easily be generalized to other prediction tasks. To the best of our knowledge, this is the first study to predict asthma exacerbation risks using a deep learning model that includes elapsed time embeddings. Some of the top-ranked risk factors identified have gained supporting evidence from previous medical studies, which proved that our method has good reliability and accuracy.

Acknowledgments

The authors thank Dr Irmgard Willcockson for proofreading. In addition, the authors thank Cerner for providing the valuable Health Facts electronic medical record data. The authors gratefully acknowledge the support of Nvidia Corporation with the donation of the Quadro P6000 and Titan XP GPUs used for this research.

This research was partially supported by the National Library of Medicine of the National Institutes of Health under award number R01LM011829, the National Institute of Allergy and Infectious Diseases of the National Institutes of Health under award number 1R01AI130460, National Center for Advancing Translational Sciences of the National Institutes of Health under award number U01TR02062, and the Cancer Prevention Research Institute of Texas Training Grant #RP160015.

Authors' Contributions

CT conceived the research project. YX, HJ, and CT designed the pipeline and method. YX implemented the deep learning model of the study and prepared the manuscript. HJ completed the clinical part of the manuscript. WZ and HX provided valuable suggestions on cohort selection and experimental design. Y Zhou and Y Zhang extracted, cleaned the data, and performed statistics. LR helped to reorganize the data and performed normalizations for the revised version. FL, JD, SW, DZ, and CT proofread the paper and provided valuable suggestions. All the authors have read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Childhood cancers previously considered to be incurable now have 5-year survival rates up to 84%. Nevertheless, these patients remain at risk of morbidity and mortality from therapy-related complications. Thus, patient education and self-management strategies for promoting a healthy lifestyle are of tantamount importance for improving short- and long-term health outcomes. A Facebook-based “Healthy Teens for Soaam” (a Korean term for childhood cancers) program was developed to help improve knowledge and self-management practices of teens with cancer related to their disease and treatment.

Objective: The two-fold purpose of this usability study was (1) to describe the process of developing an 8-week Facebook-based intervention program for teens with cancer, and (2) to evaluate its usability to refine the program.

Methods: Multiple phases and methods were employed to develop and evaluate the usability of the program. Study phases included: (1) needs assessment through focus group interviews and qualitative content analysis, (2) development of module content, (3) expert review and feedback on module content, (4) Facebook-based program development, (5) usability evaluation by heuristic evaluation, (6) usability evaluation by targeted end-user testing, and (7) modification and final version of the program. Usability of the final version was confirmed through feedback loops of these phases.

Results: Based on 6 focus group discussion sessions, it was determined that teens with cancer were interested in seeing stories of successful childhood cancer cases and self-management after discharge, and preferred multimedia content over text. Therefore, each Facebook module was redesigned to include multimedia materials such as relevant video clips tailored for teens. Usability assessed by heuristic evaluation and user testing revealed several critical usability issues, which were then revised. Potential end users tested the final program and perceived it to be usable and useful for teens with cancer.

Conclusions: To our knowledge, “Healthy Teens for Soaam” is the first Facebook-based intervention program for teens with cancer. We actively worked with current childhood cancer patients and survivors to develop and improve this program, achieved good usability, and met the expressed needs and preferences of target end users. This 8-week Facebook-based educational program for teens with cancer, developed as the first step of an upcoming intervention study, will be useful for improving knowledge and self-management strategies of teens.

pediatric cancer patients; childhood cancer; social network site; Facebook; usability

Introduction

Survival rates associated with childhood cancers continue to improve, partly due to advances in diagnostic techniques and treatment modalities along with clinical research [1]. According to the Surveillance, Epidemiology, and End Results Cancer Statistics Review, the 5-year survival rate of children with leukemia 0-19 years of age in the United States is 84.1% and the 5-year survival rate of patients with childhood brain and central nervous system cancers is 74.8% [2]. In South Korea, the 5-year survival rate among patients with childhood cancers overall was 81.7% in 2014 [3].

Despite improvements in survival, childhood cancer survivors still face a high risk of therapy-related complications or adverse effects that persist or arise after completion of treatment [4]. Childhood cancer survivors are at significantly increased risk of relapse, second malignancy, and long-term late effects, including cardiovascular and pulmonary dysfunction, endocrine disorders such as metabolic syndrome, and others [5,6]. Specifically, childhood cancer survivors of 5 years or greater have at least one chronic health condition [7]. A study on the late effects of childhood cancer treatment found that the cumulative incidence of a chronic health condition among long-term childhood cancer survivors was 99.9% by 50 years of age, with a nearly 2-fold greater cumulative burden among survivors compared to matched community controls [5].

Some morbidities are modifiable through preventive healthy behaviors such as physical activity, good nutrition, obesity prevention, and avoidance or cessation of smoking, as well as identification of characteristics that may modify morbidities or adherence to healthy behaviors to better target interventions [8,9]. For example, one study showed that childhood cancer survivors of older age and lower socioeconomic status were less frequently engaged in preventive healthy behaviors [10]. Another study reported that a greater proportion of female survivors smoked compared to teens without cancer [11]. Although childhood cancer survivors have been found to engage in unhealthy behaviors (eg, tobacco, alcohol, drug use, and sexual behaviors) and to be nonadherent to national health behavior guidelines at rates similar to those of their healthy siblings and teens without cancer [12,13], these behaviors are likely to be more consequential for individuals with organ damage secondary to cancer treatment. Moreover, late effects of treatment such as obesity, cancer-related pain, and sensory impairments have been significantly associated with increased risk of comorbid symptoms [14]. Increased comorbidities are associated with decreased quality of life, and with an increased risk of hospitalization and mortality [15]. Thus, the importance of patient education and promoting self-care for a healthy lifestyle for teens with cancer is increasingly becoming recognized to help mitigate complications of cancer and its treatment.

Children currently undergoing cancer treatment, as well as survivors, require follow-up care for the rest of their lives; thus, the Children's Oncology Group (COG) has emphasized the importance of regular medical follow-up and has developed the "COG long-term follow-up guidelines for survivors of

childhood, adolescent, and young adult cancers" [16]. In addition, various interventions to improve long-term outcomes for teens with cancer have been developed worldwide. For example, the Nursing Discipline of the COG has developed key principles and recommendations for patient and family education practices [17] as well as interventions for teens with cancer, such as nutrition and cooking workshops [18], nutrition and body weight changes [19], systematic intervention for psychological preparation for radiotherapy treatment [20], mobile health intervention to improve adherence and quality of life [21], and a web-based physical activity intervention [22]. However, few intervention studies involving teens with cancer have been conducted in Korea. Existing examples include web-based patient safety education [23], an art intervention for siblings of children with cancers [24], and educational interventions to enhance adherence to prophylactic treatment [25]. Intervention programs for preventing long-term late effects of childhood cancers and their treatment are glaringly absent. In particular, there is a crucial need for interventions that promote self-management strategies for achieving a healthy lifestyle among teens with cancer. This is important, as they will likely survive into adulthood and need to develop the knowledge and skills necessary to prevent or mitigate the late effects of cancers, and thereby improve their health-related quality of life.

Knowledge about their disease, the importance of treatment adherence, and strategies to improve adherence could be improved through innovative health interventions designed specifically for teens [21]. Among teens with cancer, inadequate information was identified as one of the barriers to compliance with chemotherapy [26]. Adult survivors of childhood cancers were found to lack detailed knowledge of their treatment history and risk for late effects [27]. Therefore, further efforts are needed to educate and empower teens with cancer to gain appropriate knowledge and assume responsibility for their health management [28].

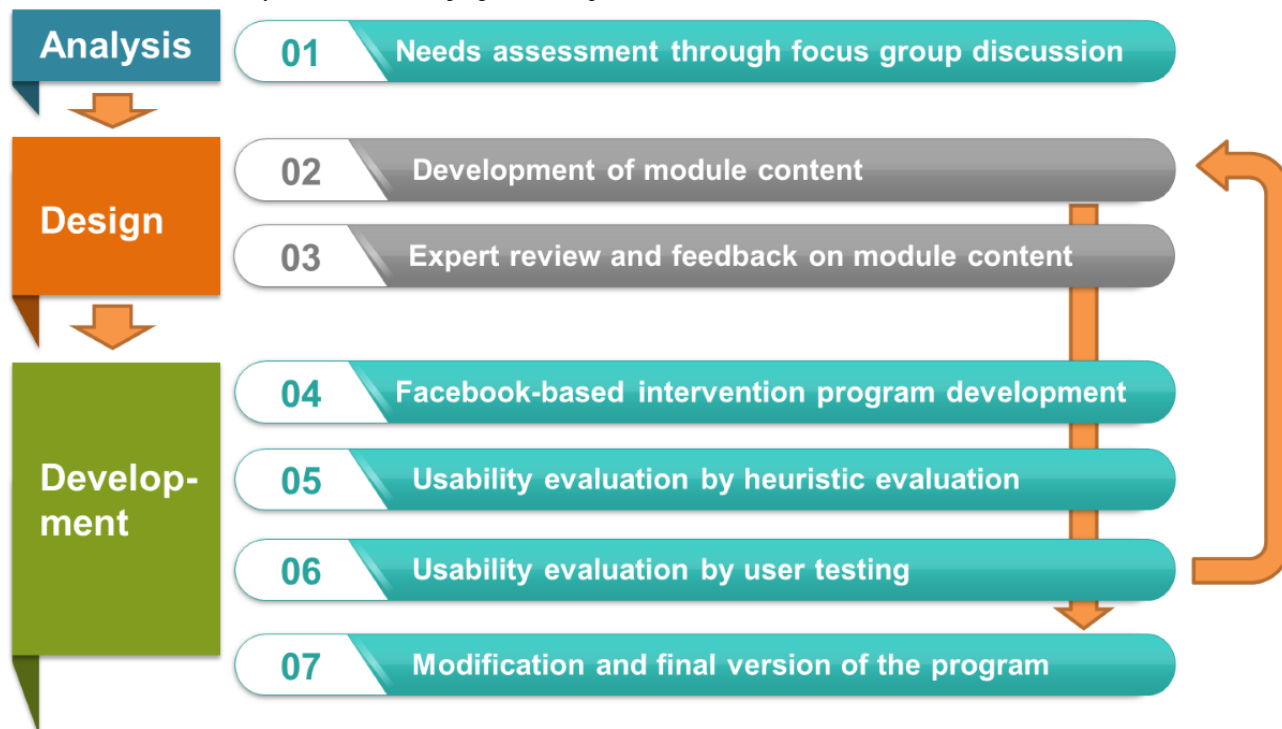

Social media has been increasingly utilized as a platform for delivering health interventions in childhood cancer care. For example, Watson [29] reported that oncology health care professionals utilized social media to listen, learn, engage, and cocreate to advance cancer care. Teens with cancer have also turned to social media for information about cancer or to interact with peers and others about their diagnosis and its impact [30]. Importantly, the effectiveness of using social media platforms such as Facebook has been reported for this tech-savvy generation. For example, a previous study [31] found that a randomized trial of a Facebook-based physical activity intervention among young adult cancer survivors significantly increased their physical activity. Therefore, we developed an educational program for teens with cancer on Facebook called "Healthy Teens for Soaam" (*soaam* is the word for pediatric cancers in Korean), as the first step of an intervention that will deliver educational materials with the aim of increasing knowledge and improving self-care practices related to their disease and treatment. The purpose of this usability study was (1) to describe the process of developing this 8-week modular intervention program for teens with cancer and (2) to evaluate its usability to refine the program.

Methods

Study Design

This study was reviewed and approved by the principal investigator's institutional review boards

Figure 1. Flow chart of "Healthy Teens for Soaam" program development.

Phase 1: Needs Assessment Through Focus Group Discussion and Qualitative Content Analysis

Semistructured focus group discussions were conducted with 12 teens with cancer. Participants were recruited from childhood cancer self-support groups in Korea using convenience and snowball sampling methods. A flyer was posted to the online platforms of self-support groups on popular Korean online platforms (Naver Café, KakaoTalk, and Band), and interested volunteers contacted the researchers by phone or email. Interested participants also suggested other potential participants to the researcher.

A total of 6 in-person focus group discussion sessions were conducted, during which participants were accompanied by their parent or legal guardian. Each session included 2 to 5 participants, and each lasted for about 60 to 90 minutes. Focus group discussions were facilitated by the principal investigator (BP) and a research assistant. First, the principal investigator explained the overview of the program, distributed handout materials detailing program contents, and asked participants and parents to provide their opinions regarding the contents. For example, they were explicitly prompted to provide suggestions regarding the addition, removal, or emphasis of content. Besides answering questions, participants and parents were encouraged to share their personal experiences with childhood cancer using prompts such as "If you have anything you want to share with us even though it is not directly related to the contents, don't hesitate to tell us." Focus group

(1041078-201606-HRSB-122-01 and 20200026). The study was conducted in 7 phases (Figure 1) and was guided by the Analysis, Design, Development, Implementation, and Evaluation (ADDIE) instructional design approach [32]. This article describes the first 3 phases of the ADDIE approach.

discussions were recorded and transcribed verbatim for qualitative content analysis using NVivo 11 (QRS International, Burlington, MA, USA).

Focus Group Discussion Data Analysis

Qualitative content analysis was conducted using a combination of the content analysis method suggested by Krippendorff [33] and the inductive coding approach suggested by Elo and Kyngäs [34]. Coders read the transcripts and freely generated themes. They then developed categories from similar themes as the coding progressed. Major coding rules included the following: (1) a category was created if a list of at least three themes was generated under that category, and (2) multiple sentences from the same participant that referred to the same content were coded as one unit.

Qualitative content analysis was conducted by the two coders (the principal investigator [BP] with a PhD in nursing and the research assistant with a master's degree in nursing) to ensure reliability of the analysis. Coders independently analyzed the transcripts. Questions or disagreements regarding the themes or categories were discussed. Revision and refinement of themes and categories continued until content analysis was completed.

Based on results from focus group discussions, the program module content was organized using the following usability design methods. First, we used group information together (also known as card sorting) after the focus group discussions. We defined the important themes from the focus group discussions

and grouped them into several categories such as diagnosis, examination, treatment, social support, and return to society/school. Second, we developed a structure for 8 weekly modules. Third, we developed low-fidelity module prototypes such as paper prototypes. Finally, we established high-fidelity mockups using PowerPoint slides.

Phase 2: Development of Module Content

Main topics for the program module content were developed based on the results from the focus group discussion “needs assessment.” Module content was written at a sixth-grade reading level using the Flesch–Kincaid readability test guidelines [35,36]. Content was developed with guidance from published research articles, medical and nursing textbooks, information available from health professional organization websites (eg, Korean Association for Children with Leukemia [37]), patient education materials in hospitals, and consultations with a panel of experts.

We incorporated usability principles for teen-friendly websites [38] into the program prototype in terms of content, appearance, and navigation. For example, we developed the content using PowerPoint 2016 (Microsoft Corp, Redmond, WA, USA) slides visualized on a single page without scrolling [38,39]. To improve appearance, we used large font sizes and avoided garish color schemes [38,39]. Moreover, slides for each module had their own theme to distinguish them from other modules. Although Facebook posts appear in reverse chronological order (ie, the most recent post appears on the top of users’ News Feeds), this was not considered a potential problem for participants because the module content was designed to be updated weekly and potential target participants were familiar with Facebook navigation.

Each module included specific learning objectives, structured learning material for fundamentally important content with external web links for further information, multimedia such as video clips or games relevant to the topics, and discussion topics at the end of the modules. Participants were asked to respond to discussion topics by adding comments on Facebook. This served to monitor module participation and sharing of personal experiences for social support. Although not done during testing, in the implementation study, a program moderator (researcher) will provide feedback and encourage interactions among participants on discussion boards. Discussions included the following topics: “Let’s talk about blood transfusion experiences. Have you ever received a blood transfusion? If yes, please tell us about the specific blood product you received, your feelings, and side effects,” and “Have you had any pain while getting treatment in the hospital? Which one was the most painful, and how did you overcome the pain—pain medication, massage, and ice bag?”

Phase 3: Expert Review and Feedback on Module Content

The module content was reviewed by four experts currently working in pediatric hematology and oncology units in tertiary hospitals, who each had more than 10 years of experience: two nurses with master’s degrees in pediatric nursing and two pediatric hematology and oncology physicians with PhDs.

Reviewers were knowledgeable about the most recent evidence in this highly specialized field and reviewed the module contents for accuracy. They were asked to rate the ease of understanding and appropriateness of information for teens with cancer (1=strongly disagree; 2=disagree; 3=agree; 4=strongly agree). Based on their feedback, module contents were revised and finalized for mockups of the Facebook-based program.

Phase 4: Facebook-Based Intervention Program Development

Facebook Group was used to develop the 8-week intervention program, with the “private group” functionality utilized to protect participants’ privacy. With a private group, only people who are invited by the group creator (principal investigator of this study) can join and see who is in the group and what they post [40]. We chose the private group option because, as established by the focus group discussions, many participants did not want to be widely known as cancer patients. Additionally, we customized the group’s privacy options [41], for example, by selecting the “hide group” and “membership approval” options so that only members could find the group and that only the group creator could approve new members.

To deliver module content, we composed PowerPoint slides and then uploaded each slide to the group’s Photos section. Participants could easily navigate the slides by clicking the “next” and “back” buttons. Considering that the purpose of this program is to deliver accurate and reliable educational content, only group administrators were granted posting permission, but participants were allowed to add comments to each post to share their opinions or contribute to discussions.

Phase 5: Usability Evaluation by Heuristic Evaluation

Two experts in the field of usability and human-computer interactions reviewed the Facebook-based program using Nielsen’s heuristics [42,43] adapted and tailored for children’s electronic learning (eLearning) program evaluation [44]. The two usability experts have PhDs in health care informatics and were currently teaching and conducting research on health care informatics in universities, one for 17 years and the other for 5 years. The criteria of Nielsen’s heuristics tailored for eLearning in children were: (1) visibility of system status; (2) match between system and the real world; (3) user control and freedom; (4) consistent and standards; (5) error prevention; (6) recognition rather than recall; (7) flexibility and efficiency of use; (8) esthetic and minimalist design; (9) help users recognize, diagnose, and recover from errors; (10) help and documentation; (11) design attractive screen layout; (12) use appropriate hardware devices; (13) challenge the child; (14) evoke child mental imagery; and (15) support child curiosity [44]. Comments from the heuristic evaluation were analyzed employing content analysis using the inductive coding approach described in Phase 1. The program was revised according to feedback from the heuristic evaluation.

Phase 6: Usability Evaluation by User Testing

User testing was conducted using observation, the think-aloud method, voice and screen activity capture using Camtasia 9 (TechSmith, Okemos, MI, USA), and surveys. Participants for this phase were recruited through parents of teens belonging to

a childhood cancer self-support group in Korea using convenience and snowball sampling. A flyer was posted to the online platforms of self-support groups on KakaoTalk and Band, and interested volunteers contacted researchers by phone or email. Inclusion criteria were teens with cancer who were (1) aged 13 to 18 years old, (2) diagnosed with any type of childhood cancer, (3) received any type of cancer treatment (eg, radiation therapy, chemotherapy, stem cell transplant), and (4) at any stage of treatment (newly diagnosed through completed treatment). Participants arranged appointments for screening, consenting, and user testing. As the participants were adolescents, both informed consent from their parents or guardians and assent from the teens were obtained prior to participation.

Procedures

A total of 11 face-to-face, 1:1 user testing sessions were conducted. Testing was facilitated by the principal investigator in a private room at the study site. Before conducting user testing, the researcher gave instructions about the program and usability evaluation methods such as the think-aloud method and Camtasia screen-capture software. Participants were then provided with an information page that included the Facebook program link, user ID, and password. They were assigned a user testing task to review 2 out of the 8 modules, including logging in, navigating through instructions on the first page to modules, reading content, watching video clips, and adding comments. They were assured that they could stop at any time for any reason. Each session lasted 30 to 40 minutes.

During evaluation of the program, participants were encouraged to think out loud while their voices were recorded using Camtasia. During pauses from thought verbalization, participants were probed with the following prompts: “What do you think about this? What features do you think need improvement?” At the same time, the researcher documented comments from participants and her own observations using the user testing worksheet.

Measures

Before user testing, participants’ demographic characteristics as well as their internet and Facebook usage habits were queried and documented. After user testing, participants filled out a short survey that evaluated electronic health (eHealth) literacy and perceived usability. The eHealth literacy was assessed using the eHealth Literacy Scale (eHEALS) [45], which has 8 items and assesses an individual’s knowledge, comfort, and perceived skills for locating, evaluating, and applying eHealth information for health issues. The Korean version of eHEALS, known as K-eHEALS, was previously tested for reliability and validity [46]. Total eHEALS scores range from 8 to 40, with a higher score indicating better health information literacy. Cronbach α of the original scale was .88 [45] and was also .88 for the Korean version [46]. Cronbach α for this study was .71.

Perceived usability of the program was assessed using the Perceived Health Website Usability Questionnaire (PHWSUQ)

[47]. This questionnaire has 12 items scored using a 7-point Likert scale. It measures three dimensions of usability: satisfaction, ease of use, and usefulness. Cronbach α values for the subscales ranged from .64 to .93, and was .85 for this study.

Data Analysis

Quantitative data from the questionnaires were analyzed with descriptive statistics using SPSS Statistics for Windows, version 25.0 (IBM Corp, Armonk, NY, USA). Audio recordings from user testing sessions were transcribed verbatim and analyzed employing the content analysis method described in Phase 1. Qualitative data, collected throughout observation and screen activity and recorded by Camtasia, provided a rich contextual background and a strong source of triangulation for developing themes and generating a comprehensive review of the program’s usability. Thus, screen recordings were reviewed when the transcript did not capture enough usable detail, which improved the accuracy of content analysis.

Phase 7: Modification and Final Version of the Program

Modifications regarding content and appearance issues were made on the PowerPoint slides, and the revised slides were uploaded to Facebook (the process was conducted in the order phase 2 to phase 4 to phase 7). If content revisions required expert opinions, relevant experts were contacted to confirm the accuracy of the new content (the process was conducted in the order phase 2 to phase 3 to phase 4 to phase 7).

Results

Phase 1: Summary of Focus Group Discussions

Participant characteristics are summarized in Table 1 [48].

Participant feedback regarding the outline of the program (Table 2) included (1) a desire for stories of successful cases and self-management at home, (2) a preference for multimedia content (eg, video clips) rather than text, (3) requests for more patient safety-related material, (4) an expressed need for detailed program objectives and instructions, and (5) appeals for more information on treatment, prognosis, and medical terminology. One teen expressed their support for the program as follows:

This is the big problem. The reason I’m so supportive of this education program (Healthy Teens for Soaam) is that there’s a limitation of internet and you narrow down the range a little bit..... I hope the contents go on in the future.

Additionally, participants freely described and shared their experiences with cancer treatments, and the emerging themes and categories dealt with information needs, support systems, barriers to treatment, facilitators to treatment, return to social life, and health care system issues. Other representative comments from the focus group discussions are provided in Multimedia Appendix 1.

Table 1. Characteristics of focus group discussion participants (N=12).

Characteristic	Value
Age (years), mean (SD)	15.2 (5.3)
Sex, n (%)	
Male	6 (50)
Female	6 (50)
Diagnosis, n (%)	
Leukemia	6 (50)
Brain tumor	2 (17)
Aplastic Anemia	2 (17)
Other	2 (17)
Treatment, n (%)	
Completed with ongoing outpatient follow up	9 (75)
Ongoing chemotherapy	3 (25)

Table 2. Content analysis of focus group discussion transcriptions (N=12).

Theme	Frequency of units
Feedback on the program	
Add story of successful cases and self-management after discharge	9
Prefer multimedia (video clips) than text	10
Add patient safety issues	11
Need detailed program objectives and instructions	13
Add information on treatment, prognosis, medical terms	20
Information needs	
Lack of information or inaccurate information	7
Current sources of information (eg, other patients, hospital handout, searching the internet)	19
Useful information during treatment (personal experience)	20
Support system	
Current support from hospital, school, pediatric cancer associations, self-support groups, etc	10
Need systematic supporting system for patients and families	13
Useful support during treatment (personal experience)	15
Barriers to treatment	
Economic problems	5
Hospital-related issues (eg, lack of available beds for admission, manpower shortage, miscommunications between health care providers)	8
Side effects of treatment (eg, chemotherapy, transfusion, infection)	25
Emotional reactions at the time of diagnosis and during treatment	28
Facilitators to treatment	
Patients' insight on diagnosis	4
Empathy of health care providers	6
Social support from friends, other patients, family members	13
Return to social life	
School life	4
Lack of physical activity	6
Concerns related to infection prevention, weak immunity	10
Health care system issues	
Disabled child registration and welfare benefits	2
Inadequate and poor social welfare system	4
Health insurance	5

Phases 2 and 3: Facebook-Based 8-Week Intervention Program

An overview of the final version of the program is provided in [Table 3](#). Content was revised and updated according to focus group discussion feedback. Participants and parents were interested, for example, in the topics of returning to school and the effects of chemotherapy on the adolescent's fertility; therefore, we added these topics to the modules. Additionally, as participants preferred multimedia over reading text, we searched for movies and Korean dramas depicting stories involving teens with cancer and included links to short video clips in the relevant module content. Animations explaining

cancers and their treatment tailored for teenagers were also added for a better understanding of how treatment proceeds.

Four childhood cancer experts reviewed the content and provided feedback on whether the information was accurate and current, including the pictures and video clips from movies and Korean dramas. Two nurses reviewed relevant medical terminology from academic journals and textbooks, and noted that it differed from the terminology commonly used by participants and parents. For example, granulocyte colony-stimulating factor injections for neutropenia were usually referred to as "count shots" (ie, a shot given when the absolute neutrophil count is low) or "Grasin" among participants and

parents. Thus, we also used these words in the program content. Two physicians contributed information on the most recent treatment practices for childhood cancers in tertiary hospitals.

For example, a previous version contained only bone marrow transplantation, but we added information about cord blood transplantation and peripheral blood stem cell transplantation.

Table 3. Overview of the Facebook-based Healthy Teens for Soaam program.

Module (Week)	Contents
Introduction	Program purpose, program schedule, how-to-use tutorial video clip
Module 1 (Week 1)	Pediatric cancers characteristics <ul style="list-style-type: none"> -Pediatric cancers statistics (risks and causes of pediatric cancers) -Pediatric cancers symptoms, early signs -International Childhood Cancer Day (February 15) -Psychosocial services and support for children and families
Module 2 (Week 2)	Types of pediatric cancers and their characteristics <ul style="list-style-type: none"> -Bone cancers, brain cancers, leukemia, hepatoblastoma, lymphoma, neuroblastoma, rhabdomyosarcoma, retinoblastoma, Wilms tumor, etc
Module 3 (Week 3)	Diagnostic tests <ul style="list-style-type: none"> -Imaging tests, CT^a scans, MRI^b, ultrasound, blood tests -Bone marrow aspiration and biopsy
Module 4 (Week 4)	Pediatric cancers treatments 1 <ul style="list-style-type: none"> -Hickman catheter insertion and management -Chemo-port insertion and management -Radiation treatment and chemotherapy
Module 5 (Week 5)	Pediatric cancers treatment 2 <ul style="list-style-type: none"> -Treatment team and frequently used medical terminology -Caring tips for mouth care and oral mucositis -Caring tips for infection and bleeding -Symptoms of infection, ANC^c
Module 6 (Week 6)	Pediatric cancers treatment 3 <ul style="list-style-type: none"> -Managing side effects of radiation and chemotherapy -Pain, transfusion -Growth and development, fertility -Stem cell transplantation (BMT^d, CBT^e, PBSCT^f)
Module 7 (Week 7)	Back to school and society <ul style="list-style-type: none"> -Follow-up care after cancers treatment -Facilitating school reentry guide -Nutrition and daily activity
Module 8 (Week 8)	People around me: family and friends Review and summary

^aCT: computed tomography.

^bMRI: magnetic resonance imaging.

^cANC: absolute neutrophil count.

^dBMT: bone marrow transplantation.

^eCBT: cord blood transplantation.

^fPBSCT: peripheral blood stem cell transplantation.

Phases 4 and 5: Revision After Heuristic Evaluation

Usability experts pointed out usability problems of the program among three categories of Nielsen's heuristics tailored for children's eLearning [44]: (3) user control and freedom, (7) flexibility and efficiency of use, and (10) help and documentation. For example, even though Facebook has a Help menu for user support, the experts suggested that there should

be a Help section specific to the program. Therefore, we added a "Help and FAQs" section for dealing with problems encountered while using the program. However, some usability issues were not changeable on the ready-made Facebook platform; these included Facebook advertisements and the reverse chronological order of posts.

All four childhood cancer experts rated the content highly for its ease of understanding (4=strongly agree) and appropriateness for teens with cancer (4=strongly agree). They also commended the detailed instructions and the neat and consistent overall design of the PowerPoint slides.

Phases 6 and 7: Revisions After User Testing

User testing participant characteristics (Table 4) included a mean age of 16.7 years, and the majority had leukemia and were

Facebook users (91%). Their mean K-eHEALS score suggested good eHealth literacy. The mean PHWSUQ score (reflecting the program's perceived usability) indicated that the program was perceived as usable. All 11 participants completed the user testing tasks and 9 participants were able to navigate through the program with little or no guidance. The mean testing time was 38.8 (SD 3.1) minutes. Representative quotes from user testing are shown in Multimedia Appendix 1.

Table 4. Characteristics of user testing participants (N=11).

Characteristic	Value
Age (years), mean (SD)	16.7 (1.1)
Sex	
Male	7 (64)
Female	4 (36)
Diagnosis	
Leukemia	8 (73)
Other	3 (27)
Facebook user	
Yes	10 (91)
No	1 (9)
K-eHEALS ^a , mean (SD)	27.6 (1.3)
PHWSUQ^b, mean (SD)	
Total PHWSUQ	60.1 (2.8)
Satisfaction	32.9 (4.8)
Ease of use	15.4 (2.9)
Usefulness	17.8 (3.4)
Preferred frequency of content update, n (%)	
Every day	1 (9)
2-3 times per week	4 (6)
Once per week	6 (55)

^aK-eHEALS: Korean version of the eHealth Literacy Scale (range 8-40).

^bPHWSUQ: Perceived Health Website Usability Questionnaire (range 12-84 total; 6-42 satisfaction; 3-21 ease-of-use and usefulness).

The transcript of user testing content analysis identified 20 themes under four categories: program content, program appearance, navigation, and others, which mainly included feedback about the strengths of the program (Table 5). Participants mentioned that they gained some new knowledge from this program, but some perceived the content as difficult to understand or as having low readability because of the medical terminology. Regarding the appearance of the program, participants generally liked the layout, but three users noted, for example, that some text was hidden behind images or that low-resolution figures were difficult to decipher. Nine participants had no issues with navigation of Facebook, but two participants needed help from the researcher. Seven participants expressed their impressions about the discussion section, where they could share personal experiences with participants who had similar experiences. For example, one teen said: "Then if

I don't know the details right now, I think it would be helpful for patients to learn this by Facebook myself."

Critical usability issues reported during user testing were reviewed, and, where necessary, revisions were made and confirmed through feedback loop of the phases (Figure 1). Regarding usability issues with "program content," one participant suggested a movie on a pediatric patient, which was not in our movie list. She mentioned that it had helped her a lot when she underwent treatment. In this case, childhood cancer experts reviewed the movie and included relevant video clips to the module. Some video clips and pictures that were not working or had low graphic resolution were replaced with other video clips and pictures. Usability issues with "program appearance" were mostly minor revisions such as typos, font size, or picture location issues, which were corrected directly on the PowerPoint slides, and then the revised slides were

reuploaded on Facebook. There were few usability issues with “navigation.” Participants easily recovered from failed paths, with brief help from the researcher. However, for first-time users of Facebook, we added a short video tutorial of the

program navigation. [Multimedia Appendix 2](#) shows a screenshot of the final version of the “Healthy Teens for *Soaam*” program on Facebook.

Table 5. Content analysis of user testing transcriptions (N=11).^a

Category, Themes	Type of feedback	Frequency of units
Program Content		
Reading level of elementary or middle school	Positive	2
Explanations on medical terminologies are useful	Positive	7
Video clips and pictures were helpful	Positive	14
Easy to understand, good readability	Positive	28
Helpful and useful educational content	Positive	34
Knowledge/information first learned from this program	Positive	35
Need revisions or irrelevant information	Negative	2
Some video clips and pictures were not working or had low graphic resolution	Negative	3
Need more information on specific topics	Negative	5
Content was not easy to understand, low readability (use of difficult medical terminology)	Negative	7
Program Appearance		
Liked layout (eg, font style, font size, sentence length, location of pictures and paragraphs)	Positive	23
Suggestions	Negative	3
Issues with layout (eg, picture sizes and locations)	Negative	6
Navigation		
Familiar with Facebook navigation	Positive	6
Got lost or failed path (needed help from the researcher)	Negative	2
Others (strengths of program)		
Reasons for not doing or following self-management at home	Positive	3
Provide online social support	Positive	4
Good sources of information: from health care professionals, school, the internet, family, self-experience	Positive	14
Improved intention (attention) to know about their disease	Positive	15
Can share personal experiences on treatment	Positive	17

^aRepresentative comments from user testing are shown in [Multimedia Appendix 1](#) (quotations from focus group discussions and user testing).

Discussion

Principal Findings

The aim of this study was to develop a Facebook-based intervention program for childhood cancer participants and to evaluate its usability to guide program refinements. Overall, the evaluation of “Healthy Teens for *Soaam*” revealed that the program was perceived as usable by our participants, who were representative of our target audience (teens with cancer). Seven phases of development and usability evaluation uncovered usability issues as well as areas to enhance user satisfaction, which were then modified accordingly.

Childhood cancer participants and families wanted a comprehensive online information source where they could find

childhood cancers–related information. Preexisting sources of information (eg, other patients, hospital handouts, searching the internet) were not reliable and potentially provided limited or outdated information. Therefore, focus group discussion participants greatly valued the objectives and content of this program. Moreover, participants supported the discussion topics at the end of each module. Considering the characteristics of adolescence, peer groups are important for their socialization; however, hospital admissions and principles to prevent infection limit their opportunities to participate in peer group activities. Online interactions among teenagers with similar diagnoses provide the next-best opportunity for social support.

User testing by potential end users revealed that the program content was comprehensive. Previous research has found the two main predictors of noncompliance to chemotherapy to be

child resistance and inadequate information [26]. To overcome these barriers, this program provided tailored information to teens with the goals of improving their knowledge and reducing their resistance to treatment by explaining the rationale behind treatments and procedures, and may therefore improve treatment compliance among teens with cancers.

By adapting the Facebook platform to this program, we took advantage of the following key points: (1) potential end users are familiar with navigation of the program, (2) researchers can reduce costs for developing new online platforms, and (3) researchers may be able to improve treatment fidelity, as teenagers access Facebook almost every day and are continuously connected via the smartphone app. By contrast, the limitations of using Facebook [49] include: (1) design-related limitations (eg, limited freedom and options for text editing and background color schemes) and (2) the inability to control certain features such as advertisements and chronology of posts.

Next Steps

The next step of this “Health Teens for Soaam” program will be delivering this 8-week Facebook-based intervention for teens with cancer in South Korea. The purpose will be to increase knowledge and provide accurate, up-to-date information about self-management strategies for improving health and wellness. Through this intervention, we will be able to determine the effectiveness and efficiency of the Facebook-based intervention program.

A previous Facebook-based intervention program for young adult cancer survivors found that engagement with the Facebook program was variable, and investigators recommended that future research should explore how to promote sustained engagement in online social networking [31,50]. Our program includes discussion sections similar to the previous intervention [31,50], in that relevant discussion topics are included in each module. To foster interaction and social support between participants, a moderator will encourage and remind users of discussion sections. A review of the use of social media for teens with childhood cancer [30] reported that health care providers are increasingly integrating social media into their professional life, and that it provides several advantages for both patients and health care providers. For example, the presence of health care providers presents an opportunity for

direct interaction with patients and the ability to provide them with reliable, data-based health information. In turn, the health care providers also learn about the experiences and concerns of teens with cancer in real time. Thus, we will consider inviting pediatric oncology health care providers to serve as additional moderators who can provide expert opinions in response to participant queries. This option will improve our study, promote better participant engagement, and enhance treatment fidelity.

Strengths and Limitations

This study had several strengths. We used rigorous qualitative analysis methods, including focus group discussions and user testing transcriptions. Additionally, the use of multiple methods provided a strong source of triangulation and enhanced the reliability of our results, which were informed by both qualitative and quantitative data. We described all development and usability evaluation processes conducted in 7 phases to provide guidance to researchers who want to use Facebook as an intervention platform. According to a recent systematic review of the use of Facebook, only 10 studies have investigated this platform for such interventions [51]. This could be partly because there is no guide on how to utilize this platform, and the task could seem daunting without guidance. Lastly, we used multiple usability evaluation methods. For example, we relied on expert reviews of our content by health care professionals, heuristics evaluation of the Facebook program by human-computer interaction experts, and user testing of the Facebook program by potential end users. Feedback comments from the different evaluation methods guided different aspects of usability issues and improved various facets of our program.

Our study also had several limitations. Regarding participant recruitment, focus group discussions and user testing employed convenience and snowball sampling methods. Sample sizes were relatively small and participants were from one metropolitan area. We did not apply strict inclusion criteria for user testing participants, instead including participants with any type of cancer and at any stage of treatment (ranging from newly diagnosed to completed chemotherapy). Additionally, the current health status of participants was biased toward teens who were in good health. These limitations could decrease the generalizability of the study findings. In addition, our findings may reflect a response bias, as participants who were already interested in Facebook may have been more likely to participate.

Acknowledgments

This study was supported by a National Research Foundation of Korea (NRF) grant funded by the Korean government (MISP and MSIT; 2016R1C1B2013649 and 2020R1C1C1010602).

Authors' Contributions

BP was the lead investigator and oversaw implementation of the project. JK contributed to the content development and implementation of the study. VR contributed to the formulation of this manuscript. All authors reviewed and approved the manuscript for publication.

Abstract

Background: An established and well-known method for usability assessment of various human-computer interaction technologies is called heuristic evaluation (HE). HE has been adopted for evaluations in a wide variety of specialized contexts and with objectives that go beyond usability. A set of heuristics to evaluate how health information technologies (HITs) incorporate features that enable effective patient use of person-generated health data (PGHD) is needed in an era where there is a growing demand and variety of PGHD-enabled technologies in health care and where a number of remote patient-monitoring technologies do not yet enable patient use of PGHD. Such a set of heuristics would improve the likelihood of positive effects from patients' use of PGHD and lower the risk of negative effects.

Objective: This study aims to describe the development of a set of heuristics for the design and evaluation of how well remote patient therapeutic technologies enable patients to use PGHD (PGHD enablement). We used the case of Kinect-based stroke rehabilitation systems (K-SRS) in this study.

Methods: The development of a set of heuristics to enable better use of PGHD was primarily guided by the R3C methodology. Closer inspection of the methodology reveals that neither its development nor its application to a case study were described in detail. Thus, where relevant, each step was grounded through best practice activities in the literature and by using Nielsen's heuristics as a basis for determining the new set of heuristics. As such, this study builds on the R3C methodology, and the implementation of a mixed process is intended to result in a robust and credible set of heuristics.

Results: A total of 8 new heuristics for PGHD enablement in K-SRS were created. A systematic and detailed process was applied in each step of heuristic development, which bridged the gaps described earlier. It is hoped that this would aid future developers of specialized heuristics, who could apply the detailed process of heuristic development for other domains of technology, and additionally for the case of PGHD enablement for other health conditions. The R3C methodology was also augmented through the use of qualitative studies with target users and domain experts, and it is intended to result in a robust and credible set of heuristics, before validation and refinement.

Conclusions: This study is the first to develop a new set of specialized heuristics to evaluate how HITs incorporate features that enable effective patient use of PGHD, with K-SRS as a key case study. In addition, it is the first to describe how the identification of initial HIT features and concepts to enable PGHD could lead to the development of a specialized set of heuristics.

Introduction

Varying Effects of Person-Generated Health Data

Person-generated health data (PGHD) are produced from technologies that allow people to access and utilize health data that they themselves generate outside of a health clinic setting, and to share these data with health care providers and others, typically via the internet. These technologies are designed to generate data about a range of health conditions and in pursuit of a range of health outcomes for remote patient monitoring [1,2]. Example technologies include home-based, web-based, mobile, and wearable apps, which cater to a range of health conditions such as irritable bowel syndrome [3], diabetes [4,5], and bipolar disorder [6]; text reminders for asthma management [7]; and social networking sites for the mental well-being of cancer patients [8].

It is possible for PGHD utilization to have positive, negative, or nil effects on patients who use these technologies. PGHD use has been reported to provide patients with a range of benefits, such as increasing interest in their own health care processes [5,9,10], allowing them to monitor and manage their own health status [11], and motivating them to undergo positive behavior change [1,12]. However, PGHD utilization can also cause patients to feel frustrated and discouraged [1], and some patients may feel excluded from the benefits of PGHD [11]. This highlights the need to consider patients' perspective in the design and development of health technologies [13], particularly those that generate PGHD [14].

Measuring PGHD Effects

The varying effects of PGHD use on patients necessitates the development of a patient-reported outcome measure (PROM) of utilizing PGHD, or PROM-PGHD [15], to provide a standardized way of measuring PGHD outcomes and build empirical evidence about PGHD [16]. PROMs are used to assess the health status or experience of health services and interventions by patients themselves [17-19] and have been shown to improve the precision of evaluating health information technologies (HITs) [20]. Similarly, PROMs-PGHD would measure patients' health outcomes or status as a result of accessing and using PGHD. Moreover, they could complement other clinical health outcome indicators, similar to how PROMs are used alongside other biometric measurements of patient health [21].

The authors previously developed a PROM-PGHD that entailed establishing health outcomes that should be measured for a specific technology category and a health condition [15,22]. The process identified some features that a domain or type of PGHD-enabled technology, that is, stroke rehabilitation systems, should have to evaluate their effectiveness in producing positive effects on patients who use PGHD to self-monitor or manage a specific health condition. For example, simulated stroke rehabilitation technologies should provide patients with real time information on the remaining exercise repetitions they need to do for them to self-manage their limited energy [1].

Evaluation of Technologies Using Heuristics

Using a list of features based on predetermined criteria to assess technology categories is called heuristic evaluation (HE). First introduced by Nielsen and Molich [23], HE is an established and well-known method for the usability assessment of various human-computer interaction technologies [24]. Using a set of guidelines, called heuristics, expert evaluators are able to quickly and efficiently identify issues that could affect the usability of technology artifacts [25]. In practice, it could also be conducted during the design process to identify potential problems before launch [24,25].

HE has since been adopted for evaluations in a wide variety of specialized contexts and with objectives that go beyond usability. This has resulted in specialized heuristics, which could be used to direct evaluators to focus on assessing technologies according to specific concepts of interest [24]. Nielsen's original set of heuristics has been adopted or augmented to assess the quality of novice programming systems [26], identify common mistakes caused by novice and experienced users of a web-based health record system for nurses [27], and assess the safety of a HIT [28]. Such specialized heuristic evaluations have identified problems beyond the original scope of the original heuristics [29] and could therefore increase the effectiveness of evaluations in varied contexts [30] and improve the quality of insights gained [26].

Heuristics for PGHD Enablement

Developing a set of heuristics for use in the formative stages of development of patient and consumer health technologies could ensure more deliberate PGHD-enabling designs. This would improve the likelihood of positive effects from patients' use of PGHD and lower the risk of negative effects. Such heuristics would also offer health care providers a standard way to evaluate technologies as part of selecting and implementing PGHD programs with their patients [11]. HE would complement other in-depth PGHD evaluation methods [2,15] to explore PGHD outcomes [14,16], integration with clinical tools [2], and assessment of quality management [31]. A set of heuristics to evaluate how HITs incorporate features that enable effective patient use of PGHD is needed in an era where there is a growing demand and variety of PGHD-enabled technologies in health care and where a number of remote patient-monitoring technologies do not yet enable patient use of their PGHD. Furthermore, research into the outcomes and benefits of PGHD has not kept up [2,11,14]. Specifically, methods are only emerging for systematic measurement of patient-reported health outcomes from accessing and utilizing PGHD [11,15]. In contrast to the already strong standardization of PROMs in many aspects of health care [21], PGHD outcome evaluation methods are idiosyncratic and reported research is fragmented [11].

Objective

In this study, we describe the development of a set of heuristics for the design and evaluation of how well remote patient therapeutic technologies enable patients to use PGHD (PGHD enablement). We used the case of Kinect-based stroke

rehabilitation systems (K-SRS) to illustrate how the development of PROM-PGHD has led to the creation of these heuristics.

Methods

Case Study

An important use case for evaluating PGHD effects is in simulated rehabilitation technologies for stroke, in particular those using body-tracking technology Kinect (Microsoft) [15]. Key considerations within the context of stroke rehabilitation include the inherent complexity of care necessary to improve health outcomes [32,33], the requirement for stroke survivors to frequently conduct repetitive movement exercises [34,35], and the difficulty of accessing therapy accompanied by the high cost of care over an extended period [36].

K-SRS offer a more convenient and cost-effective option [14]. They allow stroke survivors to undertake prescribed movement exercises simulating activities of daily living (ADL) [37-40]. As survivors use these systems, they produce PGHD in the form of data indicating their therapeutic progress. These data, generally designed to be used by clinicians, have the potential to be used by stroke survivors themselves for health self-monitoring [14,38,39].

Methodology to Develop Specialized Heuristics

A number of heuristic development processes have been employed in the literature. This includes literature reviews, analysis of usability problems, mixed processes, use of guidelines, interviews, and analysis of theories related to a specific domain [41]. Of these, only one methodology known as the R3C [42] has been used extensively (14 times) [41,43,44]. The authors have since improved it [45]. Another widespread approach is to point out the limitations of existing heuristics, in particular [23], and build on these by exploring other aspects that need to be considered for the target domain. The original set of usability heuristics did not detail the steps taken to develop them [23,46]. Subsequently reported processes for developing heuristics for specific application domains have varied.

Procedure to Develop Heuristics for PGHD Enablement

The development of a set of heuristics for PGHD enablement was primarily guided by the R3C methodology most utilized and applied in the literature [45]. However, a closer inspection of the methodology reveals that neither its development [44] nor its application to a case study [47] were described in explicit detail, leaving room for flexibility and interpretation for future implementations. There are also overlaps between its steps and the other heuristic development processes described earlier [41]. For instance, step 1 explores and describes the target technology domain, followed by step 2, where the meaning of usability is reexamined within the context of the target technology domain. Thus, a literature review may be conducted for these steps [47]. Moreover, although those steps do not specify conducting qualitative activities such as interviews and focus groups, their goals may indeed be augmented by such activities.

Thus, the development of a specialized set of heuristics for K-SRS technologies was guided by the R3C [45]. Where relevant, each step was grounded through the best practice activities in the literature, that is, analysis of the context of use through a literature review, interviews, and focus groups, and by using the original heuristics [23] as a basis for determining the new set of heuristics. As such, this study builds on the R3C methodology, and the implementation of a mixed process is intended to result in a robust and credible set of heuristics. Moreover, the detailed implementation of each step is intended to aid future developers of specialized heuristics for PGHD enablement within various contexts of health conditions and technology domains.

The steps of R3C are described in [Textbox 1](#). The objective of this study was to develop an initial set of heuristics for PGHD enablement; thus, only steps 1 to 4 are implemented in this study. Evaluation of the heuristic set (step 5) and further refinement (step 6) is an area for future research.

Textbox 1. Methodology to develop a specialized set of heuristics.

Steps of the R3C methodology to develop a specialized set of heuristics [44,45,47]

- Step 1: Exploratory stage
 - Examine literature related to the main topics or technology domain of the research.
- Step 2: Descriptive stage
 - Highlight key concepts from step 1. Connect the information, and assign weights.
- Step 3: Correlational stage
 - Identify the characteristics that the heuristics should have. Original heuristics [23] may be used as a basis. Clarify the need to consider the target technology domain.
- Step 4: Specification stage
 - Formally specify the set of proposed specialized heuristics, using a standard template. Prioritize heuristics, and report any missing elements that need to be added.
- Step 5: Validation or experimental stage
 - The new set of heuristics is tested on the target domain, and usability problems or issues found are compared with those that would be found using traditional heuristics.
- Step 6: Refinement stage
 - The new set of heuristics is refined or improved following analysis of the results of step 5. However, this occurs iteratively, that is, if no more changes are recommended after step 5 then the development ends there.

Results

Step 1: Exploratory Stage

A literature review was conducted as part of the PROM-PGHD development process to understand how K-SRS have been designed to enable PGHD and what benefits, if any, were recorded [14] using them. Similar to how this step was applied for this case [47], the review also analyzed features of this domain, such as the effectiveness of K-SRS. Moreover, the types of PGHD generated by K-SRS were reviewed as well as how people were able to access those PGHD, the intended users and uses of PGHD, and any effects on patients from using PGHD [14].

The literature review described the context under which PGHD is produced and used, relevant for step 4 when the heuristics are specified. As part of this step, factors that may influence the outcomes resulting from accessing and using PGHD were analyzed. The review has shown that PGHD was given to patients to guide them, for example, change movement behavior or actions to perform correct exercise movements. PGHD were also provided to help them achieve their short- and long-term goals [14]. However, although people were generally provided with some form of PGHD as feedback, they did not have access to all their PGHD, which clinicians have access to. Other uses of PGHD include clinicians analyzing them to tailor rehabilitation programs for patients; researchers analyzing the effects on patients when they use a K-SRS; and to assess a variety of K-SRS, for example, how effective and reliable they are, and even compare them with other domains of technologies [14]. The review also identified one study that reported that a

patient's daily access to her PGHD caused her to remember them over time and be motivated to improve [48].

The review also highlighted the lack of patient-centered design in the development of K-SRS, given that the focus of providing data back to patients was for prescribing tasks and not to allow patients to access and make sense of their PGHD themselves. This is a missed opportunity to encourage patients to be more involved in their own health care [14], as patients who have direct access to their PGHD may become more engaged and thus improve their health outcomes [5,9,10,49]. Indeed, the lack of patient participation in the design of such PGHD systems may undermine patients' rehabilitation experience [50]. This is indicative of the need for developers of technology-based rehabilitation systems to consider PGHD in their design, implementation, and evaluation and allow patients to access them [14].

Step 2: Descriptive Stage

This step is described as having 3 tasks: highlighting, connecting, and assigning weights to the concepts found in step 1. Step 2 is applied for this study as follows. First, concepts found through the literature review that could enable the effective patient use of PGHD were identified. Second, the concepts were categorized based on their inherent meaning according to 5 different reported effects of PGHD use thematically derived from the literature. Articles from a significant journal special issue on PGHD were inductively analyzed as an efficient and targeted way to identify reported effects of PGHD utilization from a range of HITs for different health conditions [15]. This process identified 5 different effects that may result from patients' use of their PGHD. PGHD may influence health-related behavioral or attitude changes, influence

patients' management of their own care owing to changes in how they feel about their health status, influence interest in their health care processes, facilitate their personal care goals, and influence their relationship with care providers. Concepts that did not match any of these effects were assigned a different category.

Table 1 shows the categorized concepts highlighted from the literature review. More example quotes are shown in [Multimedia Appendix 1](#). The *Weight* column is discussed in the following paragraphs.

In the third activity of this stage, the concepts were assigned weights through qualitative studies. As part of the PROM-PGHD development process, the input of target users (stroke survivors) and experts (physiotherapists) was elicited through focus groups and interviews [51]. On the basis of the health and technology case under consideration, stroke survivors with experience interacting with a leading K-SRS called Jintronix [14,52] were asked to respond to open-ended questions around the effects resulting from their access to and utilization of PGHD. Meanwhile, the clinicians were asked how they thought that access and utilization of PGHD would affect the stroke survivors they were working with. Participant recruitment was conducted in Australia at 3 different sites, with ethics approval granted by the Human Research Ethics Committees of Deakin University (2017-087), Austin Health (HREC/17/Austin/492), and the University of Melbourne (1852259.1). A total of 10 stroke survivors (7 females and 3 males) were recruited through Deakin University; 5 clinicians (4 females and 1 male) and 6 stroke survivors (1 female and 5 males) were recruited through the

Austin Health hospital; and 1 stroke survivor (female) was recruited through Headway ABI in Queensland, Australia.

The qualitative studies enabled the authors to receive direct feedback from PGHD users to assign weights to the concepts found from step 1. In addition, the studies also bridged any relevant gaps between the concepts described in the literature, those perceived by clinicians, and those reported as important by stroke survivors themselves [1]. New PGHD outcomes were documented that were not previously identified through the review and analysis of the literature described earlier [14], leading to the identification of new features that should be incorporated in technologies to enable effective patient use of PGHD.

Concepts identified through the literature review but not described by either stroke survivors or clinicians were assigned a weight of 0, concepts described by clinicians only were assigned a weight of 1, concepts described by stroke survivors only were assigned a weight of 2, and concepts described by both stroke survivors and clinicians were assigned a weight of 3. **Table 1** shows the key concepts identified through the literature review assigned with weights and example quotes describing the concept, if any. **Table 2** shows new concepts identified through the qualitative studies, also assigned with weights and listing example quotes.

The categories were initially applied by GD and then independently reviewed by the coauthors. Any disagreements in the categories applied were discussed in a meeting until agreement was reached for each concept. More example quotes are shown in [Multimedia Appendix 1](#).

Table 1. Weighted key concepts identified from step 1: exploratory stage.

Categories	Key concepts	Weight
Stroke survivor health-related behaviors	PGHD ^a can guide stroke survivors to make appropriate movement behavior or action changes to perform an exercise correctly	<ul style="list-style-type: none"> • 2—stroke survivors: <ul style="list-style-type: none"> • “I automatically adjust what I was doing, if I couldn't burst every balloon I, I had to adjust... To work out what I was doing wrong” (FG1_STC2-3)
Stroke survivor personal care goals	PGHD can help stroke survivors achieve their short- and long-term goals	0—Not described
Functional effectiveness of therapy	PGHD can help inform clinicians, to analyze the functional effects of simulated rehabilitation therapy, and tailor programs for stroke survivors	0—Not described
Evaluation of the PGHD-enabled K-SRS ^b	PGHD can be used to assess the effectiveness and reliability of a K-SRS, compared with other types of simulated rehabilitation technologies	0—Not described
Stroke survivor interest in care processes	<ul style="list-style-type: none"> • PGHD may be remembered by stroke survivors over time and can provide them with more motivation to improve their therapy performance • PGHD needs to be accessible to the stroke survivors who produce them to allow them to be more involved in their own health care 	<ul style="list-style-type: none"> • 3—stroke survivors and clinicians: <ul style="list-style-type: none"> • PGHD may provide “an extra percentage of motivation” (FG1_STC2-1) and an “incentive to do better” (FG1_STC2-3) • Clinician: “something to keep striving” (FG3_AHC1_3) • 3—stroke survivors and clinicians: <ul style="list-style-type: none"> • “it helped me understand my rehabilitation progress” (INT1_HWC1) • “quite often you learn more when you've done something wrong” (FG2_AHP_2) • Clinician: “[survivors] would understand better after a second session where they could compare their results...it's good for them to have a comparison, to see how they've changed from one session to another” (FG3_AHC1_5)

Table 2. Weighted new concepts identified from qualitative studies.

Categories	Key concepts	Weight
Stroke survivor health-related behaviors	<ul style="list-style-type: none"> PGHD^a can encourage stroke survivors to do more exercises related to their therapy PGHD can discourage stroke survivors from doing more exercises if it is negative or low 	<ul style="list-style-type: none"> 3—stroke survivors and clinicians: <ul style="list-style-type: none"> “if I can see the improvement I’m making then it would...encourage me to maybe have more of those sessions” (INT1_STC3) Clinician: “that might stimulate them to be more compliant” (FG3_AHC1_5) 3—stroke survivors and clinicians: <ul style="list-style-type: none"> “probably lose faith in the system” (INT2_AHP) [unless there is] “some explanation [...] that you need to consider looking” (INT2_AHP) Clinician: “They might get over it, or might not be willing to participate” (FG3_AHC1_3)
Stroke survivor personal care goals	<ul style="list-style-type: none"> PGHD can demotivate stroke survivors if it is negative 	<ul style="list-style-type: none"> 2—stroke survivors: <ul style="list-style-type: none"> “that can be a positive motivator, but can also (be) a negative one” (INT2_STC1) “I’m thinking well, are normal people at a hundred percent? And I’m only at 60?” (FG1_AHP_2)
Feelings about health status	<ul style="list-style-type: none"> PGHD can cause positive or negative emotions, correlated with whether their PGHD is positive or negative PGHD can make stroke survivors feel confused about their health progress PGHD can make stroke survivors feel more self-aware about their health care 	<ul style="list-style-type: none"> 3—stroke survivors and clinicians: <ul style="list-style-type: none"> “going backwards, that would be a little bit depressing” (INT1_AHP) seeing “yourself gradually making improvements, it just makes you feel so much better. Okay, I’m achieving something” (INT1_AHP) Clinician: “a score can motivate you or please you” (FG3_AHC1_5) 3—stroke survivors and clinicians: <ul style="list-style-type: none"> “the percentages to me is more difficult to understand [...] are we trying to be a hundred percent at these things?” (FG1_AHP_2) Clinician: “scope to put in something about, I didn’t really understand” (FG3_AHC1_4) 2—stroke survivors: <ul style="list-style-type: none"> “to measure your improvement...or measure your, deterioration...You could see it in cold hard figures.” (FG2_AHP_2)
Stroke survivor interest in care processes	<ul style="list-style-type: none"> PGHD can interest stroke survivors in how their exercises are contributing to their activities of daily living PGHD can help stroke survivors to self-manage their energy while undergoing therapy PGHD can affect stroke survivors’ perception about their therapy 	<ul style="list-style-type: none"> 1—clinicians: <ul style="list-style-type: none"> “any relevance to a functional activity. You know like washing the dishes, or hanging the washing out or...climbing a flight of stairs” (FG3_AHC1_4) 2—stroke survivors: <ul style="list-style-type: none"> “It was certainly something that I watched, to see where I was at. ‘Cause you need to think about this, we have some sort of a budget of energy that you have to manage yourself, and you can’t afford to get to empty” (FG1_STC2-3) 3—stroke survivors and clinicians: <ul style="list-style-type: none"> Mismatch between PGHD and feeling of performance: “you probably think oh, the system’s not doing its job” (INT2_AHP) “nothing going on in the background about anyone judging me...that there isn’t anything that’s being kept from me” (FG1_AHP_2) Clinician: if you just did the computer thing and they...just stopped without data they’d be like, why do I do it?” (FG3_AHC1_2)

Categories	Key concepts	Weight
Stroke survivor relationship with care provider(s)	<ul style="list-style-type: none"> PGHD can prompt stroke survivors to contact their therapists about their therapy performance PGHD can make stroke survivors be more conscious of the exercises prescribed by their clinicians 	<ul style="list-style-type: none"> 3—stroke survivors and clinicians: <ul style="list-style-type: none"> “If they were always bad then I would need more assistance and even if they [were] good, they [are] not perfect, right so I would want to have more, more assistance to improve” (INT2_STC3) Clinician: how can I get a better score...why did I...not do very well” (FG3_AHC1_4) 1—clinicians: <ul style="list-style-type: none"> “maybe if they're not being compliant, they might get a phone call from the therapist” (FG3_AHC1_5)
Relationship with family and carers	<ul style="list-style-type: none"> PGHD can assist stroke survivors in communicating their rehabilitation progress with their loved ones 	<ul style="list-style-type: none"> 3—stroke survivors and clinicians: <ul style="list-style-type: none"> “you could show them something, it's easier for them to visualize” (INT1_AHP) Clinician: “share it with family...it's that...bragging power as well, perhaps” (FG3_AHC1_4)

^aPGHD: person-generated health data.

Step 3: Correlational Stage

In this stage, the characteristics that the new set of heuristics should have are defined, which are later specified in step 4.

The key concepts identified through the first 2 steps are used as the basis to define the characteristics. As opposed to concepts, characteristics read as features that K-SRS should have to enable stroke survivors to use PGHD. These characteristics are also matched with the original heuristics [23] to identify any similarities. Some of the concepts were defined with similar characteristics and, therefore, combined. To further increase the credibility of the resulting heuristics, any characteristic matching an original heuristic is reworded using the original heuristic as a guide. Moreover, concepts with a weight of 0, that is, not described by stroke survivors or clinicians, were not

defined as a characteristic and correspondingly not specified as a heuristic.

The characteristics were initially defined by GD and then independently reviewed by the coauthors. Any disagreements were discussed in a meeting until agreement was reached for each characteristic.

Table 3 lists the characteristics defined from the concepts identified previously that match an original heuristic [23], and as we have reworded them. Textbox 2 lists the characteristics that did not have a matching original heuristic [23]. The numbering continues from Table 3 through to Textbox 2, to indicate which characteristics were combined in the next step. To see which concepts were defined as which characteristics, please see Multimedia Appendix 1.

Table 3. Characteristics defined from the key concepts identified from steps 1 and 2—that match an original heuristic.

Number	Characteristics	Reworded using the original heuristic as a guide
1	<ul style="list-style-type: none"> PGHD^a-enabled systems should assist users in performing more exercises or actions, in a correct way. Matched with original heuristic 9. 	<ul style="list-style-type: none"> Help stroke survivors in performing more exercises or actions and to recognize, understand, and recover from errors they make. Guidance or error messages should be expressed in plain language (no codes), precisely indicate the problem, and constructively suggest a solution.
2	<ul style="list-style-type: none"> PGHD-enabled systems should provide PGHD to stroke survivors for increased understanding about their rehabilitation or therapy process. Matched with original heuristic 1. 	<ul style="list-style-type: none"> PGHD-enabled systems should always provide PGHD to stroke survivors to keep them informed about what is going on with their health status, through appropriate feedback within reasonable time. This would increase their understanding about their rehabilitation or therapy process.
3	<ul style="list-style-type: none"> PGHD-enabled systems should avoid formatting PGHD through a scale that represents a completeness or an endpoint, for example, 100% as much as possible, as it would likely represent failure. Instead, PGHD should resemble the ongoing functional therapeutic progress of stroke survivors. Matched with original heuristic 2. 	<ul style="list-style-type: none"> PGHD-enabled systems should present PGHD in a format that matches the real-world context, therapy progress, and goals of the stroke survivors.
4	<ul style="list-style-type: none"> PGHD-enabled systems should ensure that PGHD is, or could be, presented in a way that is clearly understandable to a stroke survivor. Matched with original heuristic 2. 	<ul style="list-style-type: none"> PGHD-enabled systems should ensure that PGHD is clearly understandable to stroke survivors. The system should speak their language, with words, phrases, and concepts familiar to them, rather than system-oriented terms. PGHD-enabled systems should follow real-world conventions, making information appear in a natural and logical order.
5	<ul style="list-style-type: none"> PGHD-enabled systems should provide PGHD to stroke survivors for increased self-awareness about their health care. Matched with original heuristic 1. 	<ul style="list-style-type: none"> PGHD-enabled systems should always provide PGHD to stroke survivors to keep them informed about what is going on with their health status, through appropriate feedback within reasonable time. This would increase their self-awareness about their health care.
6	<ul style="list-style-type: none"> PGHD-enabled systems should provide patients real-time PGHD that allow them to self-manage their energy while performing therapy exercises. Matched with original heuristic 1. 	<ul style="list-style-type: none"> PGHD-enabled systems should always provide PGHD to stroke survivors to keep them informed about what is going on with their health status, through appropriate feedback within reasonable time. This would allow them to self-manage their energy while performing therapy exercises.
7	<ul style="list-style-type: none"> Notwithstanding the need for PGHD to be as accurate as possible, PGHD-enabled systems should inform the patients of its limitations or potential inaccuracies in the PGHD produced by stroke survivors. PGHD-enabled systems should also provide PGHD to stroke survivors to foster an increased sense of trust about their rehabilitation or therapy process. Matched with original heuristic 1. 	<ul style="list-style-type: none"> PGHD-enabled systems should always provide PGHD to stroke survivors to keep them informed about what is going on with their health status, through appropriate feedback within reasonable time. This would foster an increased sense of trust about their rehabilitation or therapy process.
8	<ul style="list-style-type: none"> PGHD-enabled systems should allow stroke survivors to contact their/a clinician about their PGHD or at least provide survivors with the option of viewing functional, action-based suggestions for them to improve their performance. Matched with original heuristic 10. 	<ul style="list-style-type: none"> Even though it is better if the system can be used without additional help or documentation, it may be necessary to provide them. PGHD-enabled systems should provide stroke survivors the option to contact a clinician about their PGHD and vice versa or at least provide survivors with the option of viewing functional, action-based suggestions for them to improve their performance. Any such information should be easy to search, focused on the survivors' exercises, list concrete steps to be carried out, and not be too lengthy.

Number	Characteristics	Reworded using the original heuristic as a guide
9	<ul style="list-style-type: none"> PGHD-enabled systems should provide stroke survivors the option of allowing their clinicians to contact them based on the progress of their PGHD. Matched with original heuristic 10. 	<ul style="list-style-type: none"> Even though it is better if the system can be used without additional help or documentation, it may be necessary to provide them. PGHD-enabled systems should provide stroke survivors the option to contact a clinician about their PGHD and vice versa or at least provide survivors with the option of viewing functional, action-based suggestions for them to improve their performance. Any such information should be easy to search, focused on the survivors' exercises, list concrete steps to be carried out, and not be too lengthy.

^aPGHD: person-generated health data.

Textbox 2. Characteristics defined from key concepts identified from steps 1 and 2, which do not have a matching original heuristic.

Characteristics
<ul style="list-style-type: none"> 10 <ul style="list-style-type: none"> Person-generated health data (PGHD)-enabled systems should present PGHD that indicate negative or decreasing therapy progress carefully and in a form that elicits a stroke survivors' competitiveness with the self. 11 <ul style="list-style-type: none"> PGHD-enabled systems should highlight PGHD indicating positive or improving therapy progress more and providing them with more frequency than negative or decreasing progress. 12 <ul style="list-style-type: none"> PGHD-enabled systems should provide PGHD to stroke survivors for increased understanding about how their rehabilitation is contributing to their functional ability. 13 <ul style="list-style-type: none"> PGHD-enabled systems should provide stroke survivors with the option to share their PGHD with loved ones in a secure manner.

Step 4: Specification Stage

In this stage, the characteristics defined in step 3 are specified as a heuristic, following a structured format: ID, name, definition, explanation of how the heuristic was developed, example(s) of when a system being evaluated complies with or violates the heuristic, expected benefits if the system complies with the heuristic, and anticipated problems of heuristic misunderstanding [45].

The ID applied to the heuristics was structured as [Number]-PGHD-W[Weight]. The weights were indicated to provide implementers an idea of the process that went through developing the heuristics. The heuristic names were written succinctly, in a similar fashion to the original heuristics [29]. The characteristics were written as the heuristic definition. The explanation of each heuristic described how they were developed from one or more heuristic and provided example descriptions of those concepts by stroke survivors, clinicians, or both. The example and benefits of each heuristic were described based on the literature review [14] and qualitative studies [1]. The anticipated problems indicated where heuristic definitions may be quite close and may be misunderstood.

A number of characteristics were either similar or tightly complemented each other and were therefore combined into one heuristic. Characteristics 3 and 12 described the need for K-SRS to match the health and therapy context of the stroke

survivors. Characteristics 5, 2, 6, and 7 described the need for K-SRS to always provide PGHD to stroke survivors. Finally, characteristics 8 and 9 both described the need for K-SRS to provide options for stroke survivors to seek more information, contact their clinicians, and allow their clinician to contact them.

A necessary augmentation is conducted in this step. In combining the characteristics, considerations had to be taken with the individual weights and the categories of those characteristics. Where the weights of the characteristics being combined were different, the highest weight was indicated for the resulting heuristic's ID. Meanwhile, the categories were added as tag(s) under each heuristic, and reworded to indicate how the heuristic informs implementers to enable PGHD use. This preserves the categories identified in step 2 as metadata that could aid implementers in understanding the concepts underlying each heuristic. Interestingly, the R3C methodology did not describe how the categories were relevant to the resulting heuristics [41].

The heuristics were initially specified by GD and then independently reviewed by the coauthors. Any disagreements were discussed in a meeting until agreement was reached for each specified heuristic. Moreover, steps 5 and 6 are expected to refine the example, expected benefits, and anticipated problems of each heuristic. Therefore, the heuristics presented here may still be revised later on [45].

The next section shows the new, initial set of heuristics for PGHD enablement.

Design Heuristics to Enable Better Use of PGHD for Testing

Eight new heuristics for PGHD enablement in K-SRS were created. Heuristics with higher weights are presented first, to highlight heuristics that should be prioritized. The first 6 heuristics have a weight of 3, and the last 2 heuristics have a weight of 2. There are 6 tags used: improve health-related behaviors, increase positive feelings about health status,

facilitate positive personal care goals, increase interest in care processes, improve relationships with care providers, and improve relationships with family and caregivers.

For brevity, only the ID, name, tag(s), definition, and explanation are presented in [Textbox 3](#). This could also be the short form that implementers may use when evaluating HITs, similar to how brief definitions are presented for the original heuristics [29]. However, as with the original heuristics, implementers ought to understand the underlying concepts and anticipated problems of each heuristic and should, therefore, view the full specifications in [Multimedia Appendix 1](#).

Textbox 3. Short form of the specified heuristics for person-generated health data enablement.

1-PGHD-W3: Encouraging person-generated health data (PGHD)

- Tag(s): Improve health-related behaviors; increase positive feelings about health status
- Definition: The system should highlight PGHD indicating positive or improving therapy progress and provide them with more frequency than negative or decreasing progress.
- Explanation: This heuristic was formed from 3 concepts identified through a literature review and confirmed by stroke survivors and clinicians. Stroke survivors and clinicians commented on how PGHD can cause positive or negative emotions, correlated with whether the PGHD is positive or negative, for example, when survivors frequently see their PGHD improve, it encourages them to do more of the exercises. A clinician described how seeing PGHD could help survivors be more compliant. On the other hand, if survivors see their PGHD decline, they might lose faith in the system and not perform their exercises.

2-PGHD-W3: Evoking competitiveness with self

- Tag(s): Facilitate positive personal care goals
- Definition: The system should present PGHD that indicates negative or decreasing therapy progress carefully and in a form that elicits a stroke survivors' competitiveness with the self.
- Explanation: This was a concept identified through a literature review and confirmed by stroke survivors and clinicians. Stroke survivors described how seeing their PGHD can motivate them to try harder, sometimes even when their PGHD indicates that they are not doing very well with their therapy exercises, because it can feel like a competition with themselves. Clinicians agree that it can give survivors something to keep them striving to be better.

3-PGHD-W3: Understandable health data

- Tag(s): Increase positive feelings about health status
- Definition: PGHD-enabled systems should ensure that PGHD is clearly understandable to stroke survivors. The system should speak their language, with words, phrases, and concepts familiar to them, rather than system-oriented terms. They should follow real-world conventions, making information appear in a natural and logical order.
- Explanation: This was a concept identified through a literature review and confirmed by stroke survivors and clinicians. A stroke survivor found that simply having percentages as feedback for performing an exercise could be confusing, as it could be misunderstood as being compared with people who have not had stroke. Clinicians also agreed that PGHD may not be understood by survivors.

4-PGHD-W3: Visibility of health progress

- Tags: Increase positive feelings about health status; increase interest in care processes
- Definition: PGHD-enabled systems should always provide PGHD to stroke survivors to keep them informed about what is going on with their health status, through appropriate feedback within reasonable time.
- Explanation: This heuristic was formed from 4 concepts identified through a literature review and confirmed by stroke survivors and clinicians. Stroke survivors described how PGHD could help them understand their rehabilitation progress, to determine whether their functional progress was headed in the right direction and learn when they have made a mistake. PGHD could also help them self-manage their energy as they perform their exercises and increase their trust in their therapy process.

5-PGHD-W3: Help and support

- Tag(s): Improve relationship with care providers
- Definition: Even though it is better if the system can be used without additional help or documentation, it may be necessary to provide them. PGHD-enabled systems should provide stroke survivors the option to contact a clinician about their PGHD; allow their clinicians to contact them; or at least provide survivors with the option of viewing functional, action-based suggestions for them to achieve their therapy goals. Any such information should be easy to search, focused on the survivors' exercises, list concrete steps to be carried out, and not be too lengthy.
- Explanation: This heuristic was formed from 2 concepts identified through a literature review and confirmed by stroke survivors and clinicians. Stroke survivors described how they would want to contact their therapists, particularly if they have not been doing well to ask for assistance and ask for advice on what they could do better. Clinicians also described how it would be good if therapists could contact survivors when they are not being compliant. They also described how stroke survivors would likely ask for more explanation and for advice on how they can do things differently to improve their PGHD.

6-PGHD-W3: Communication of health data

- Tag(s): Improve relationship with family and carers
- Definition: PGHD-enabled systems should provide stroke survivors with the option to share their PGHD with concerned parties, for example, loved ones, in a secure manner.
-

Explanation: This was a concept identified through a literature review and confirmed by stroke survivors and clinicians. Stroke survivors described how it could help them communicate their health status to people they would like to share it with, particularly when they are tired or when they “run out of words.” Clinicians described how survivors might want to share their PGHD with family, particularly with the younger generation who are more technologically inclined.

7-PGHD-W2: Guide for correct exercise movement or actions

- Tag(s): Improve health-related behaviors
- Definition: The system should help stroke survivors in performing more exercises or actions and to recognize, understand, and recover from errors they make. Guidance or error messages should be expressed in plain language (no codes), precisely indicate the problem, and constructively suggest a solution.
- Explanation: This was a concept identified through a literature review and confirmed by stroke survivors. A stroke survivor commented on how PGHD can help them work out what they were doing wrong and adjust accordingly.

8-PGHD-W2: Match between system PGHD and real-world context of stroke survivors

- Tag(s): Facilitate positive personal care goals; increase interest in care processes
- Definition: PGHD-enabled systems should present PGHD in a format that matches the real-world context, therapy progress, and goals of the stroke survivors. When presenting PGHD, for example, as a score, percentage, or a graph, they should be matched to the therapy goals of the survivors. These goals may change over the course of a survivors' therapy, from gaining functional progress in the first few months or years to maintaining function to perform ADL when their progress starts to plateau [1]. PGHD needs to be connected with the needs of the stroke survivors and where they are clinically.
- Explanation: This heuristic was formed from 2 concepts identified through a literature review and confirmed by stroke survivors and clinicians. Stroke survivors described how receiving a percent score that did not indicate a 100% could be a negative motivator. Achieving 100% given their condition could be very difficult or even impossible. Clinicians also described how PGHD should help survivors understand how their therapy is contributing to improved performance of ADL.

Discussion

Principal Findings

This study is the first to develop a new set of specialized heuristics to evaluate how HITs incorporate features that enable effective patient use of PGHD, with K-SRS as a key case study. In addition, it is the first to describe how the identification of initial HIT features and concepts to enable PGHD could lead to the development of a specialized set of heuristics. As such, it uncovers a valuable dimension to the PROM-PGHD development method, which considers the sociotechnical context of HITs [15,22]. This context is the complex nature of interactions between people's unique health conditions and behavior and that of the technologies and tools they use within their environment [53]. The prior development of a PROM-PGHD for the key case of K-SRS was guided by this context [15]. Although PROMs have long been known to support the evaluation of health interventions, which may be supported by HITs [20], they are developed to consider only the health condition of patients. Conversely, the nature of PGHD requires the development of a PROM-PGHD to consider the sociotechnical context of the patient experience, that is, both the health condition and technology category [15].

Subsequently, this study highlights the value of considering the sociotechnical context of HITs in their design and evaluation. Although unexpected consequences and even failures can occur from design flaws and technical limitations, they are also often the result of sociotechnical factors [54]. Thus, HIT usability testing and evaluation can benefit from frameworks, standards, and guidelines that consider the sociotechnical context of those technologies [53,55]. In particular, PROMs-PGHD [15], heuristics for PGHD enablement, and cognitive work analysis

[56] ensure that understanding of the complexities of care is incorporated in HIT design and implementation [56].

The R3C methodology [45] guided the heuristic development process; however, it was not applied without some difficulty. The methodology's development, description, and application to a case study [44,47] were not described in explicit detail, which left too much room for flexibility. More specifically, it did not specify how the concepts identified from step 1 were going to be connected in step 2; how weights were going to be determined and applied to those concepts, and what influence those weights would have on the succeeding steps; how the characteristics were going to be identified in step 3 and how they differed from the concepts previously identified; and how the original heuristics were going to be “used” as a basis, after matching them with the defined characteristics. Moreover, although R3C presented a structured template for the specification of the heuristics in step 4, the resulting case heuristics only presented summaries or abbreviated versions [47,57,58]. Subsequently, implementations of R3C's steps to develop other specialized heuristics have varied [59-61].

A step-by-step implementation of the R3C methodology was presented. A systematic and detailed process was applied in each step of heuristic development, which bridged the gaps described earlier. It is hoped that this would aid future developers of specialized heuristics, who could apply the detailed process of heuristic development for other domains of technology, and additionally for the case of PGHD enablement for other health conditions. Throughout the process, it was observed that the concepts and characteristics may need to be combined. This study presents a way to retain the weights and categories applied to them as heuristic metadata to aid implementers in understanding their underlying concepts.

Although the last 2 heuristics have a weight of 2, implementers should still aim to conduct the evaluation using all 8 heuristics. However, in case of any resource constraint, the first 6 heuristics should be prioritized.

The R3C methodology [44] was also augmented through the use of qualitative studies with target users (stroke survivors) and domain experts (physiotherapists) to determine the weights, discover new concepts, and ensure the defined characteristics and resulting heuristics were as close to the experiences of the users as possible. This is intended to result in a robust and credible set of heuristics, before the validation stage (step 5), after which the specified heuristics may be improved through the refinement stage (step 6). This is especially valuable, as the R3C methodology's recommended iteration of the process leads from step 6 back to step 4 [45], implying that steps 1 to 3 need to be rigorously implemented. Subsequently, the initial set of heuristics presented here will be validated and refined following steps 5 and 6.

Limitations

Data gathered from the qualitative studies were used as an important augmentation in the heuristic development process. However, as those studies were primarily meant to support the development of a PROM-PGHD, it is possible that participants were not asked all the relevant questions around PGHD enablement features. In the event, many concepts found through the literature review were supported by qualitative studies, and indeed, most of the resulting heuristics were formed from new concepts found in those studies. Therefore, although it might

appear to be a limiting factor, it actually indicates the robustness of the process followed and highlights the importance of this suggested augmentation. Moreover, the validation stage (step 5) still allows for possible additional heuristics to be identified.

The flexibility of the R3C methodology [44] meant that it is possible that the process followed in this study deviated from the original intent of the authors. However, we believe that the detailed, step-by-step implementation of R3C and the suggested augmentation have in effect modeled a way to build on and strengthen it.

Conclusions

The new set of heuristics for PGHD enablement, following a detailed, systematic development process augmented from best practice that we have presented, could serve as a guide for future developers of specialized heuristics in general and specifically for developers of heuristics for PGHD enablement of a variety of technology domains and health conditions. The new set of heuristics is needed in a period of rising demand for, supply of, and variety of PGHD-enabled technologies in health care. It offers health care providers a standard way to evaluate technologies as part of selecting and implementing PGHD programs with their patients [11], complementing other in-depth PGHD evaluation methods [2,15], and has a broader relevance for the design and implementation of HITs. In addition, an interesting dimension to the PROM-PGHD development process was discovered, and it highlights the value of considering the sociotechnical context of HITs in their design and evaluation.

Abstract

Background: The standard approach for evaluating the effects of population-level substance use prevention efforts on youth and young adult perceptions and behaviors has been to compare outcomes across states using national surveillance data. Novel surveillance methods that follow individuals over shorter time intervals and capture awareness of substance use prevention policy and communication efforts may provide a stronger basis for their evaluation than annual cross-sectional studies.

Objective: This study aimed to identify a combination of strategies to recruit a sample of youth and young adults sufficiently representative of the Vermont population and determine how best to retain a web-based panel of youth and young adults over a 6-month period.

Methods: Eligible participants were Vermont residents aged 12 to 25 years who were willing to complete three 10 to 15-minute web-based surveys over a 6-month period. Recruitment was conducted via the following three main mechanisms: (1) web-based recruitment (paid and unpaid), (2) community-based recruitment through partners, and (3) participant referrals via a personalized link. Upon completion of the baseline survey, participants were randomly assigned to one of the following three retention incentive conditions: (1) guaranteed incentive (US \$10), (2) lottery incentive (US \$50 weekly lottery drawing), and (3) preferred method (guaranteed or lottery). Analyses examined cost per survey start by recruitment source, distribution of demographic characteristics across incentive conditions, and retention by study condition at 3-month and 6-month follow-ups.

Results: Over a 10-week period in 2019, we recruited 480 eligible youth (aged 12-17 years) and 1037 eligible young adults (aged 18-25 years) to the Policy and Communication Evaluation (PACE) Vermont Study. Facebook and Instagram advertising produced the greatest number of survey starts (n=2013), followed by posts to a state-wide web-based neighborhood forum (n=822) and Google advertisements (n=749). Retention was 78.11% (1185/1517) at 3 months and 72.18% (1095/1517) at 6 months. Retention was equivalent across all incentive study conditions at both waves, despite a strong stated preference among study

participants for the guaranteed payment at baseline. Youth had greater retention than young adults at both waves (wave 2: 395/480, 82.3% vs 790/1037, 76.18%; wave 3: 366/480, 76.3% vs 729/1037, 70.30%). Substance use prevalence in this cohort was similar to national and state-level surveillance estimates for young adults, but was lower than state-level surveillance estimates for youth. Most participants retained at wave 3 provided positive qualitative feedback on their experience.

Conclusions: Our study supports the feasibility of recruiting a web-based cohort of youth and young adults with representation across an entire state to evaluate substance use prevention efforts. Findings suggest that a guaranteed payment immediately upon survey completion coupled with a bonus for completing all survey waves and weekly survey reminders may facilitate retention in a cohort of youth and young adults.

KEYWORDS

recruitment; retention; adolescents; young adults; prevention

Introduction

Adolescence and young adulthood are defined by developmental processes that mark increased susceptibility to risk-taking behaviors, including substance use [1-4]. In tobacco control, prevention efforts have shifted from individual and group-level interventions to population-based approaches, including policy and mass media efforts to reduce the appeal and accessibility of tobacco products to young people [5]. Concurrently, state-level cannabis policies in the United States have aimed to liberalize the accessibility of cannabis products, though there have been few state-level prevention campaigns. Using national surveillance data across states has been the standard approach to evaluate the effects of these policies on youth and young adult perceptions and behaviors [6,7]. These evaluations, which use cross-sectional data over time, may mask more nuanced trends in individual-level changes in harm perceptions and behavior and have largely failed to address spillover effects on other substance use. Novel surveillance methods that follow individuals over time and capture awareness of substance use prevention policy and communication efforts may provide a stronger basis for their evaluation.

Vermont represents a unique test case for the evaluation of population-level interventions for substance use for three reasons. First, the prevalence of substance use in young people from Vermont is higher than national estimates [8-10]. Second, Vermont has implemented a number of new policies related to substance use in the past 5 years, including a state-wide opioid drug disposal program, stronger prescribing guidelines, and requirements in the Vermont Prescription Monitoring System (2016); legalized possession of cannabis for adults aged 21 years or above [11] (2018); a ban on the web-based sale of e-cigarettes [12] and a 92% tax on e-cigarettes [13] (2019); and an increase in the legal age of tobacco sale to 21 years [14] (2019). In addition to policy efforts, the Governor's 2018 Opioid Coordination Council Report recommended development and implementation of school-based primary prevention programs for opioid use and a comprehensive drug prevention messaging campaign [15]. Third, while Vermont has a relatively homogeneous population in terms of race/ethnicity, it is the second most rural state in the country [16], with between 60% and 100% of the area classified as rural depending on the definition [17]. Thus, policy and communication interventions

may be implemented or experienced differently than in settings with greater population density.

In 2018, researchers and program staff at the University of Vermont and the Vermont Department of Health began discussing the development of a longitudinal cohort study of youth and young adults to evaluate responses to changes in tobacco, alcohol, and other substance use policies, communication, and interventions at the state level. The Policy and Communication Evaluation (PACE) Vermont Study was designed to complement existing evaluation efforts that rely on a combination of state-level surveillance and smaller convenience samples [18]. The PACE Vermont Study uses web-based data collection in a large sample of youth and young adults, with surveys at shorter intervals to capture changes over time. The survey instrument was also designed to be flexible, allowing for assessment of emerging issues and communication outcomes (eg, knowledge, attitudes, and beliefs) not typically captured in state surveillance systems.

Web-based data collection was proposed to reduce barriers to participation in research among rural people from Vermont, given that as of 2018, 98% of young adults aged 18 to 29 years use the internet, as do 78% of adults who live in rural communities [19]. Similarly, 94% of young adults aged 18 to 29 years and 65% of adults in rural communities own a smartphone [20]. Adoption of web-based surveys for data collection is likely to appeal to young people, who grew up with computers and use them in virtually all aspects of their lives, while reducing transportation and other costs that serve as barriers to engaging in traditional clinical trials [21-24]. With respect to retaining young people in longitudinal studies, there was no clear recommendation on incentives to maximize retention, as previous studies had identified multiple means, including increasing participant payments, conducting sweepstakes, providing bonuses, and sending reminder postcards [25-28].

This study had the following two primary goals: (1) to identify the combination of recruitment strategies that would provide a sample of youth and young adults sufficiently representative of the Vermont population and (2) to determine how best to retain a web-based panel of youth and young adults to be able to attribute changes in knowledge, attitudes, beliefs, and behaviors to specific interventions. Specifically, this study experimentally compared the effects of a lottery payment, a guaranteed

payment, and participant preference for a particular completion incentive on retention at 3-month and 6-month follow-ups. Our a priori hypothesis was that retention would be higher in the participant preference incentive condition than in the lottery or guaranteed payment incentive condition, as providing choice for some study-related decisions has been described as a means to improve retention in studies involving young adults [29].

Methods

Study Overview

The study consisted of three web-based surveys conducted from March 2019 through October 2019 and was approved by the Institutional Review Boards of the University of Vermont and Vermont Department of Health. This research also received a Certificate of Confidentiality from the National Institutes of Health.

Recruitment and Enrollment

Eligible participants were Vermont residents aged 12 to 25 years who were willing to complete three 10- to 15-minute web-based surveys over a 6-month period. Youth participants aged 12 to 17 years also had to report being a US citizen or permanent resident. Recruitment was conducted by Hark, a Vermont-based digital design and marketing firm [30], over a 10-week period (March 26-June 4, 2019). Participants were recruited via the following three main mechanisms: (1) web-based recruitment including both paid and unpaid advertising, (2) community recruitment through partner organizations, and (3) participant referrals via a personalized link. Each recruitment type contained a unique link to the study website to be automatically tracked via Google Analytics. Web-based recruitment occurred through paid Facebook, Instagram, and Google display and Gmail advertisements; free Craigslist Vermont advertisements; posts on PACE Vermont's social media accounts (Facebook, Instagram, and Twitter); paid posts on a state-wide online neighborhood forum (Front Porch Forum) [31]; and paid placement of advertisements in local web-based and print newspapers with relevant news stories. Community recruitment occurred through outreach from engaged partners to their constituents and via news media on the PACE Vermont Study. Partner organizations received a recruitment toolkit, with a tailored newsletter blurb, flyers, sample email language, and sample social media posts for print and digital promotion of the study, as well as a timeline for distribution of recruitment material to their networks. Participant referrals were requested at the end of baseline survey completion via a thank you email with a personalized referral link, a request to share the survey link with friends on social networks, and a direct link to the PACE Vermont Facebook page. Parents of youth participants were able to opt in to be considered for a small study incentive (US \$5) for referring another eligible family to the study using their unique link. The PACE research team met weekly to monitor representation by age, race, ethnicity, and county, and promotional strategies during this period were adjusted to focus on underrepresented areas of the state or sociodemographic groups.

Digital advertising channels, including Google display advertisements, Google Gmail advertisements, and Facebook

display advertisements, delivered content to the following three Vermont-based segments: youth (aged 12-17 years), young adults (aged 18-25 years), and parents (aged ≥ 18 years). In addition to age and geography, Google and Facebook's interest and lifestyle-based targeting enabled specific targeting of parents. Prior to recruitment, the PACE team integrated Google and Facebook advertisements with the study landing page and its web analytics tool. Google and Facebook campaigns for the PACE Vermont Study were set to optimize their targeting algorithms and advertisement variations to achieve a maximum number of survey starts rather than clicks or page views. The initial structure of both the Facebook and Google advertisement campaigns mirrored the audience segments (youth, young adults, and parents). Advertisements for each segment featured visual assets (ie, photographs, illustrations, and graphics) and text in the form of headlines, posts, email body, and call-to-action buttons. Advertisements directed at youth and young adults used the following message themes: (1) earn cash rewards and buy the things you really want and (2) be a leader in your community and share your opinion on important topics. Advertisement visuals took the following two approaches: (1) photographs of youth and young adults smiling and holding a mobile phone or gift card and (2) eye-catching illustrations and graphics with action-oriented phrases like "We want to hear from you." Advertisements directed at parents were designed to motivate parents to encourage their children to join the study. Parent-focused messages used the following themes: (1) your family can help improve the health of Vermont's youth for years to come and (2) your teen's participation will help Vermont create substance-abuse resources for other families. Advertisement visuals took the following two approaches: (1) humorous photography of toddlers and young children making messes and (2) sentimental photography of parents embracing their babies and young children. A separate wave of Facebook and Google advertisements ran close to the end of the recruitment window and highlighted the urgency of participation with messages like "Don't miss out on PACE VT" and "Time is running out." Other promotional channels like Front Porch Forum and Craigslist primarily targeted parents and older young adults. Because these channels do not allow for advanced targeting beyond geography, promotional messages mirrored those of parents in our paid campaigns.

All study advertisements and links directed participants to the PACE Vermont website, where there was a brief study description and link to an open web-based screener. In addition to direct advertising to youth, parents of eligible youth were also targeted via promotional efforts. They were asked to review an information sheet and provide informed consent prior to youth providing assent to complete the screener. Youth who initiated the screening survey without parental consent were asked to provide parent contact information, which triggered an email to the parents. Upon parental consent, youth received a unique link to the screener to provide assent. Youth and young adults underwent an electronic informed consent process and received an email link to contact study personnel to ask questions about the study. Eligible consenting youth and young adults were automatically forwarded to the baseline survey, where they completed demographic information and questions on substance use knowledge, attitudes, beliefs, and behaviors.

These included measures of ever and past 30-day use of cigarettes, alcohol, and marijuana, which served as benchmarks for comparison to prevalence estimates from state and national surveillance on substance use data. Participants were then automatically forwarded to a web-based version of the University of Vermont participant payment form required for internal tracking of study payments. All surveys were voluntary, deployed via Qualtrics [31], and optimized for completion via a computer or mobile phone.

During baseline data collection, we revised our survey delivery to ensure the eligibility of participants and the validity of study responses in several ways as follows: (1) adding automatic screening within our survey platform, Qualtrics [32], to exclude participants with an IP address outside Vermont; (2) conducting consistency checks between age and date of birth, as well as state of residence and location of IP address; (3) adding a CAPTCHA item in the screener to ensure that respondents were human and not bots; (4) conducting additional screening of respondents with suspicious email addresses (eg, common e-mail format across surveys completed within minutes of each other and email addresses including names that did not correspond to contact information) and out-of-state phone numbers; and (5) using information from the screening and payment forms (eg, consistency of name across forms and location of participant address) to verify eligibility. Potentially fraudulent participants were flagged and received an email from the study team offering an opportunity to confirm their contact information and remain in the study. Respondents who did not confirm that they were valid participants were removed from the study.

Intervention and Retention

At the end of the baseline survey, participants were asked “Which of the following would you like to receive for completing other web-based surveys like this?” with the following two response choices: “Receive a \$10 online gift card” or “Be entered into a lottery to receive \$50.” After responding to this question, participants were randomly assigned within the Qualtrics survey system to one of the following three study conditions: (1) guaranteed incentive (US \$10), (2) lottery incentive (US \$50 weekly lottery drawing), and (3) preferred method (guaranteed or lottery, based on the response to the question). Participants were informed of their study condition, and those in the guaranteed condition were automatically directed to a web interface [33] to confirm their email address and receive their US \$10 electronic gift card (wave 1 study payment). Gift cards were emailed to wave 1 participants once they were confirmed as participants with valid completion. Lottery drawings were conducted among those who had completed the survey in a given week ($n=3$ youth and $n=3$ young adult winners selected each week during each survey wave), and winners were notified by email. Participants were told that they would receive a bonus payment for completing all three surveys (lottery payment group: US \$50 bonus; guaranteed payment group: US \$20 bonus in addition to US \$10 per completed survey). Thus, all participants received US \$50 upon completing all three surveys and lottery participant winners could receive more.

Follow-up surveys were launched approximately 3 months (June 27-July 31, 2019) and 6 months (September 17-October 15, 2019) after the baseline survey. Each survey was distributed initially via email or text message, based on participant preference, with a message that notified participants about the dates of data collection, including the 1-month window during which the follow-up survey would be open for completion. Weekly reminder messages were sent to youth and young adults who had not completed the survey via both email and text message throughout the 1-month window, with additional reminders in the last 2 days of each window via email, text message, and social media. Incentive payments at each follow-up were dictated by the study condition, with those in the guaranteed condition automatically linked to Rybbon to confirm their email address and receive their US \$10 gift card immediately. As in the baseline survey, lottery drawings (US \$50) were conducted each week during data collection for the two follow-up surveys and winners were notified by email. At the completion of the final follow-up survey, participants who had completed all three waves received their bonus payment immediately via Rybbon.

Participant Feedback

At the end of the final survey, participants were asked the following two questions about their experience in the PACE Vermont Study: “What was your favorite part of participating in the PACE Vermont Research Study?” and “What could we improve in the PACE Vermont Research Study to make it easier for you to participate?” Responses were open-ended. Two coders (SEL and CM) reviewed the responses and created in vivo inductive categories from themes that arose during the course of data analysis, as described by Miles and Huberman [34]. Responses for each question were then coded in NVivo software (QSR International) independently by each coder, and responses were allowed to fall into more than one category. Reliability of the coders for each category ranged from a kappa value of 0.47 to 0.97, representing moderate to almost perfect agreement. For the question “What was your favorite part of participating in the PACE Vermont Research Study?” the coding category with the lowest level of agreement was “other” ($\kappa=0.47$) and the category with the highest level of agreement was “compensation” ($\kappa=0.97$). For the question “What could we improve in the PACE Vermont Research Study to make it easier for you to participate?” the coding category with the lowest level of agreement was “learning” ($\kappa=0.54$) and the category with the highest level of agreement was “compensation” ($\kappa=0.88$).

Statistical Analysis

This study used the following two sources of data: advertising metrics, and enrollment and follow-up data from our surveys. First, we estimated the cost per survey start according to the recruitment source by dividing the total amount spent on each source by the number of survey starts. Second, we developed a CONSORT diagram to track participants from enrollment through the three survey waves and estimated differences in retention by the intervention condition at each stage using chi-square tests. We conducted additional analyses to test whether retention differed by concordance between preference

and the intervention condition (ie, lottery vs guaranteed compensation). We also examined the distribution of sociodemographic characteristics (ie, county, sex, race/ethnicity, and employment status) and substance use (ever and past 30-day cigarette, alcohol, and marijuana use) by age and the intervention condition using chi-square tests and *t* tests and the differences in these characteristics among those retained at all three waves versus those lost to follow-up. Survey weights were developed post-hoc from population estimates of females and males between the ages of 12 and 25 years (year by year) residing in each of Vermont's 14 counties in 2017 [35]. The goal of survey weighting was to determine how closely the convenience sample matched other state surveillance, as well as correct for the higher response by females and those residing in Chittenden County. Each cell of the table was divided by the total number of individuals between the ages of 12 and 25 years residing in the 14 counties ($n=116,407$) to generate population-based proportions. A comparable table of survey respondents was created, totaling the number of individuals who completed the baseline survey by sex, age, and county of residence. Each subtotal was divided by the total number of respondents ($n=1517$) to generate sample-based proportions. Survey weights were then calculated by dividing population proportions by sample proportions, again by sex, age, and county. We compared the weighted prevalence of ever and past 30-day use of cigarettes, alcohol, and marijuana in our sample to national and state-level surveillance estimates from the National Survey on Drug Use and Health (NSDUH) [10,36]. Finally, we assessed the major categories of responses to two participant feedback items from qualitative coding.

Results

Recruitment and Enrollment

Table 1 presents information on new visitors to the study website; survey starts for parents, youth, and young adults; and cost per survey start by recruitment source. Survey starts by recruitment source were tracked using Google Analytics on the PACE Vermont study website. Survey completions by recruitment source could not be captured as surveys were conducted within Qualtrics. Overall, there were 9975 new visitors to the study website, with Facebook and Instagram advertisements accounting for 54.55% (5441/9975) of web traffic, with 2013 survey starts. Google display and Gmail advertisements accounted for 35.10% (3501/9975) of web traffic and 749 survey starts. Three postings in an email digest with state-wide coverage (Front Porch Forum) generated 9.75% (973/9975) of web traffic and 939 survey starts. Partner referrals, newspaper print advertisements, and Craigslist advertisements produced smaller numbers of new users and survey starts. The cost per conversion to a survey start was US \$382 considering all recruitment sources; when newspaper print advertisements

were excluded, the cost per conversion to a survey start was US \$11. Only four parents received the US \$5 referral incentive.

The best performing Google advertisements were Gmail advertisements run close to the end of the recruitment window highlighting the urgency of participation for parents, youth, and young adults; the top Facebook posts for youth and young adults highlighted urgency and the importance of youth and young adult feedback ("We want to hear from you.") The top performing Facebook post for parents cited how findings from the PACE Vermont Study would be used to guide resources for substance use prevention in Vermont. While advertisements targeting youth ran for the duration of the recruitment period, advertisements targeting parents were more effective at recruiting youth than youth-specific advertisements.

In addition to the 2723 youth and young adult survey starts from the study advertisements, participants referred others to the study, resulting in 2861 completed screenings (Figure 1). Of those assessed for eligibility, 1008 were deemed ineligible (eg, not aged 12-25 years and not Vermont residents) and 336 were excluded for other reasons, including being flagged as potentially fraudulent.

Overall, there were 480 youth respondents and 1037 young adult respondents included in the PACE Vermont Study sample (Table 2). The recruitment cost per eligible enrolled participant was US \$29 (US \$44,111/1517 participants). Participants represented each of the 14 counties in the state, with the distribution by county generally reflecting 2017 population estimates for Vermont youth and young adults [35]. The majority of the sample was female (1071/1517, 70.60%), was white (1318/1517, 86.88%), and reported working either part-time or full-time (898/1517, 59.20%).

Table 3 presents the number of responses and weighted prevalences of cigarette, alcohol, and marijuana use by age group in the PACE Vermont Study compared with estimates for the same measures in the NSDUH. Ever use estimates for each substance were provided in the 2018 NSDUH national report [36] and past 30-day measures were drawn from the 2016-2017 state-level report [10]. Prevalence of ever cigarette, alcohol, and marijuana use in PACE Vermont Study youth participants was generally similar to national estimates from the NSDUH, although past 30-day use estimates tended to be lower in PACE Vermont youth compared with state-level estimates from the NSDUH. Ever and past 30-day use in young adult PACE Vermont participants tracked closely with NSDUH estimates, with the following three exceptions: past 30-day cigarette use was lower in the PACE Vermont sample compared with the NSDUH estimate (18.78% vs 33.38%), and the PACE Vermont sample showed higher ever alcohol use (PACE vs NSDUH: 89.52% vs 79.70%) and ever marijuana use (70.57% vs 51.50%).

Table 1. Recruitment sources, costs, and conversions in the PACE Vermont Study 2019.

Source	Cost (total: US \$44,110.71)	New users (N=10,250)	Conversions, n				Cost per conversion ^a
			Parent survey starts (N=1026)	Young adult survey starts (N=1772)	Youth survey starts (N=951)	Total survey starts (N=3749)	
Facebook & Instagram advertising	US \$23,676.42	5441	443	1247	323	2013	US \$11.76
Google display & Gmail advertising	US \$9213.78	3501	331	233	185	749	US \$12.30

Intervention and Retention

Randomization of the 1517 eligible participants was generally equal across study conditions, with 34.08% (517/1517) allocated to the “guaranteed” incentive, 32.63% (495/1517) to the “lottery” incentive, and 33.29% (505/1517) to the “preferred” incentive. Proportions were similar when looking at youth and young adult subgroups separately. There were no differences in the distribution of participants to the study condition by age, county of residence, sex, race, ethnicity, or employment status (Table 2). Response to the question about incentives for completing similar web-based surveys indicated a strong preference for the guaranteed incentive (1304/1517, 85.96%), and 67.96% (1031/1517) of participants were assigned to an incentive condition concordant with their preference.

At wave 2, 78.11% (1185/1517) of the full sample completed the survey. Youth retention at wave 2 was 82.3% (395/480), while young adult retention was 76.18% (790/1037; $P=.007$). At wave 3, 72.18% (1095/1517) of the full sample completed the survey; again, youth had higher retention (366/480, 76.3%) than young adults (729/1037, 70.30%; $P=.02$). Overall, 70.20% (1,065/1517) completed all three waves of the study (74.0% [355/480] of youth and 68.47% [710/1037] of young adults; $P=.03$).

Retention did not differ by incentive condition at wave 2 ($P=.28$) or wave 3 ($P=.59$). Retention was also similar when examining concordance between preference and the intervention condition, with 77.98% (804/1031) retention at wave 2 among those with

concordant preference and an incentive condition compared with 78.4% (380/485) in the nonconcordant group ($P=.87$). Proportions were also similar at wave 3 (concordant: 751/1031, 72.84%; nonconcordant: 343/485, 70.7%; $P=.39$). Retention across all three waves did not differ by county, sex, race/ethnicity, or employment status. Retention was lower, however, among participants who had ever used a cigarette ($P=.005$) and those who reported past 30-day use of marijuana ($P=.001$; data available upon request).

Participant Feedback

Of the 1095 respondents in the wave 3 survey, 86.58% (948/1095) provided a response to the question regarding their favorite part of the survey and 81.55% (893/1095) provided a response to the question regarding potential improvements to the survey. Table 4 presents coded responses to each item. With some responses categorized into more than one code, there were 1049 responses to the item on the favorite part of participating in the study, with 28.60% (300/1049) noting financial compensation as their favorite part, followed by learning something new (192/1049, 18.30%) and making a meaningful contribution to science or to the community (184/1049, 17.54%). There were 910 responses to the item on potential improvements to the study, with the majority noting no changes needed (496/910, 54.5%), followed by specific recommendations related to ease of use (302/910, 33.2%). Recommendations included suggestions for improvements to survey structure, survey timing, and survey wording.

Table 4. Participant feedback at the end of the PACE Vermont Study.

Question, code, and subcode	Value, n (%)
What was your favorite part of participating in the PACE^a Vermont Research Study? (1049 responses)	
Survey task ($\kappa=0.50$) <i>Favorite part was the survey task itself.</i>	162 (15.4)
Learning ($\kappa=0.57$) <i>Favorite part was learning something new.</i>	192 (18.3)
Learning: self ($\kappa=0.91$) <i>Enjoyed learning something about themselves or having an opportunity to self-reflect.</i>	85 (8.1)
Learning: other ($\kappa=0.72$) <i>Enjoyed learning new information about policies, organizations, or substances.</i>	89 (8.5)
Ease of use ($\kappa=0.80$) <i>Favorite part was the ease of use and accessibility of the surveys.</i>	110 (10.5)
Contribution ($\kappa=0.83$) <i>Favorite part was making a meaningful contribution to something (eg, science and the community).</i>	184 (17.5)
Compensation ($\kappa=0.97$) <i>Favorite part was the financial compensation.</i>	300 (28.6)
Other ($\kappa=0.47$) <i>Response not otherwise categorized.</i>	80 (7.6)
None ($\kappa=0.71$) <i>Did not generate a response (eg, "I did not have a favorite part").</i>	21 (2.0)
What could we improve in the PACE Vermont Research Study to make it easier for you to participate? (910 responses)	
Learning ($\kappa=0.54$) <i>Requested more resources or opportunities to learn.</i>	16 (1.8)
Ease of use ($\kappa=0.88$) <i>Suggested improving survey's ease of use.</i>	302 (33.2)
Survey design ($\kappa=0.81$) <i>Suggested improvement to survey structure or design.</i>	119 (13.1)
Reminders & timing ($\kappa=0.87$) <i>Suggested improvement to timing of surveys or the reminder system.</i>	43 (4.7)
Question improvement ($\kappa=0.84$) <i>Suggested improvement to wording or content of survey questions.</i>	140 (15.4)
Compensation ($\kappa=0.88$) <i>Suggested improvement to the compensation system.</i>	53 (5.8)
Other ($\kappa=0.58$) <i>Not otherwise categorized.</i>	43 (4.7)
None ($\kappa=0.78$) <i>No response generated (eg, "nothing").</i>	496 (54.5)
None: positive ($\kappa=0.83$) <i>Response generated was wholly positive.</i>	244 (26.8)

^aPACE: Policy and Communication Evaluation.

Discussion

Principal Findings

This study identified successful recruitment strategies for a web-based cohort study of youth and young adults to inform and evaluate state-level substance use prevention efforts. It also

tested the effect of three incentive conditions (guaranteed, lottery, and preferred) on retention over a 6-month period. Over a 10-week period in 2019, we were able to recruit 480 eligible youth and 1037 eligible young adults to the PACE Vermont Study. Findings from this study indicated that Facebook and Instagram advertising produced the greatest number of survey starts, followed by posts to a state-wide online neighborhood

forum in Vermont (Front Porch Forum) and Google advertisements (display and Gmail). The integration of Google and Facebook advertisements with the study landing page and its web analytics tool was critical to evaluating survey starts as the advertising metric of interest in support of PACE's recruitment efforts. Validation of study responses was achieved through multiple methods, in line with other web-based studies [37]. Data collected on county supported the distribution of responses across the state, in line with the distribution of youth and young adults in the population. The success of the local online neighborhood forum in driving traffic to the study website highlights the potential importance of these venues in recruitment. While community partner sources did not drive the same level of traffic to the site, advertisement of the study via these community organizations and through the local web-based digest may have lent credibility to the study and increased awareness that improved recruitment. Substance use prevalence estimates in PACE Vermont youth and young adults generally tracked national estimates from the NSDUH, although youth reported lower prevalence of current cigarette, alcohol, and marijuana use than estimates from NSDUH's state-level surveillance.

Retention was 78.11% (1185/1517) at 3 months and 72.18% (1095/1517) at 6 months. Contrary to our hypothesis, retention was equivalent across all incentive study conditions. This may have been due to a strong stated preference among study participants for the guaranteed payment and assignment of approximately two-thirds of participants to an incentive condition that was concordant with their preference. Youth participants at both waves had greater retention than young adult participants. Participants retained at all three waves were less likely to be ever cigarette users or past 30-day marijuana users compared with those lost to follow-up. The majority of participants retained at wave 3 provided feedback on their experience of the study, with largely positive comments about compensation, learning something new, and making a difference. Participants also provided specific feedback to improve future surveys, such as requests for more resources or opportunities to learn and suggestions to improve timing and reminders for surveys.

Limitations

The PACE Vermont Study was limited to a small largely rural state, and thus, successful recruitment strategies may not be generalizable to other study contexts. Additionally, while the sample was generally aligned with population distribution by county, there were imbalances by sex in the study sample, with the majority of the sample being female (1071/1517, 70.60%) in contrast to 48% of the state population of youth and young adults. There was also one county (Chittenden) with a higher response than expected according to population distribution, but this county is both the most populous and home to the University of Vermont with the largest population of undergraduates in the state who would have been eligible for the study. Lower prevalence of past 30-day cigarette, alcohol, and marijuana use in the PACE Vermont youth compared with state estimates suggests that youth enrolled in this study may represent a lower risk sample. This may be due to the recruitment process for youth that required parental consent to

participate, thus attracting a lower risk pool of youth, or the smaller sample size of youth than young adults. Additional attrition by ever cigarette users and past 30-day marijuana users may have produced a sample with fewer risk behaviors at follow-up. Given the randomized nature of the incentive condition and balance in demographic characteristics across conditions, findings related to retention are likely to be generalizable to other web-based survey studies of youth and young adults.

Comparison With Prior Work

Similar to other web-based studies [28,38], Facebook and Instagram advertisements provided the greatest reach and lowest cost per survey start when considering parent, youth, and young adult screener surveys; these were followed by Google advertisements via display and Gmail. The success of these strategies may have been related to consistency with recommendations for Facebook recruitment, including having an attractive website [18] and existing social media accounts (@pace_vt) that identified the partner organizations involved in the study (ie, University of Vermont and Vermont Department of Health) and supported the credibility of the study [34].

Retention in our cohort of youth and young adults was higher at 6 months (72.18%) compared with a national cohort of young adults aged 15 to 21 years who also completed web-based surveys (63%) [27]. Our randomized experiment regarding incentive conditions showed, similar to previous studies [37-40], that multiple means of compensation produce equal retention when combined with providing completion bonuses and sending multiple reminders. However, our baseline item regarding incentive preference suggests that the majority of youth and young adults prefer a small guaranteed payment for responding to a web-based survey. Thus, providing guaranteed compensation could help to improve recruitment of youth and young adults in future studies. Our ongoing retention efforts draw on expertise gathered from in-person cohort studies of youth and young adults [25,29]; we send birthday postcards to participants at the start of each month and continue to post on our social media accounts to retain awareness of and engagement in the study.

Conclusions

Findings from the PACE Vermont Study demonstrated the feasibility of using traditional web-based advertising strategies (eg, Facebook and Google), in addition to web-based outreach through local community forums and organizations, to recruit a cohort of 1517 Vermont youth and young adults for a web-based study to evaluate state-level substance use prevention efforts. Participants were well distributed by age and county according to state population estimates and reported substance use prevalence comparable to national estimates in these age groups. Youth participants generally reported lower prevalence of risk behaviors compared with state-level estimates [10]. The higher proportion of female participants enrolled in the PACE Vermont Study is consistent with other studies, documenting higher recruitment of women to health studies via web-based advertising [38,40,41]. Retention in this web-based cohort study was over 70% at a 6-month follow-up and did not differ by the incentive condition, as seen in other studies of young adults

[27]. Participant feedback on the study experience was positive. Results from our study suggest that providing a guaranteed payment immediately upon survey completion coupled with a bonus for completing all survey waves and weekly survey reminders may facilitate retention in a cohort of youth and young adults. Future work in our cohort will assess the impact of other

means of retaining participants, including ongoing cohort engagement via regular contact (eg, birthday postcards and social media posts), ongoing community engagement (eg, reporting to community partners on PACE Vermont Study outcomes), and nonfinancial incentives (eg, lottery for PACE-branded items).

Acknowledgments

The PACE Vermont Study was funded by the Vermont Department of Health, the University of Vermont Cancer Center, and the University of Vermont Larner College of Medicine. The effort of the author ACV was supported by the National Institute of General Medical Sciences of the National Institutes of Health under award number P20GM103644. Although this work was funded in whole or in part with monies provided by or through the State of Vermont, the State does not necessarily endorse the researchers' findings and/or conclusions. The findings and/or conclusions may be inconsistent with the State's policies, programs, and objectives. Additionally, the content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health.

Conflicts of Interest

None declared.

This randomized study was not registered as the authors state that it is a pilot study to determine best practices in recruitment and retention for other trials, which have been registered. The editor granted an exception. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: The prevalence of social media use among youth and young adults suggests it is an appropriate platform for study recruitment from this population. Previous studies have examined the use of social media for recruitment, but few have compared platforms, and none, to our knowledge, have attempted to recruit cigarillo users.

Objective: The purpose of this study was to examine the effectiveness of different social media platforms and advertisement images for recruiting cigarillo users aged 14-28 years to complete a cigarillo use survey.

Methods: We obtained objective data for advertisement impressions for a 39-week social media recruitment campaign. Advertisements were targeted to users based on their age, geography, and interests. Effectiveness was defined as the percentage of approved surveys per advertising impression. Chi-square tests were performed to compare the effectiveness of different advertisement images and platforms.

Results: Valid survey completers (n=1089) were predominately older (25-28 years old, n=839, 77%). Of the 1089 survey completers, 568 (52%) identified as male, 335 (31%) as African American, and 196 (18%) as Hispanic. Advertisements delivered via Facebook/Instagram were more effective than Twitter; 311/1,027,738 (0.03%) vs 661/2,998,715 (0.02%); $\chi^2_1=21.45$, N=4,026,453; $P<.001$. Across platforms, ads featuring exclusively an image of cigarillos were more effective (397/682,994, 0.06%) than ads with images of individuals smoking (254/1,308,675, 0.02%), individuals not smoking (239/1,393,134, .02%), and groups not smoking (82/641,650, 0.01%); $\chi^2_3=133.73$, N=4,026,453; $P<.001$.

Conclusions: The campaign was effective in recruiting a diverse sample representative of relevant racial/ethnic categories. Advertisements on Facebook were more effective than Twitter. Advertisements that featured an image of a cigarillo were consistently the most effective and should be considered by others recruiting cigarillo users via social media.

KEYWORDS

adolescent, young adult; tobacco products; social media; research subject recruitment

Introduction

Recent data on smoking prevalence indicates that a substantial proportion of youth in the US smoke cigar products, including cigarillos [1]. Like other tobacco products, cigarillo use increases the risk of cancer, cardiovascular disease, and mortality, and some early evidence suggests that cigarillos may be more harmful to organ systems than cigarettes [2]. Cigarillo use is also concentrated among young, urban, minority populations that have traditionally experienced health disparities related to tobacco use and may be more vulnerable to the long-term harmful effects of smoking [3]. Considering the public health risk presented by cigarillo use, understanding patterns of use and the addictive properties of these products via survey research could serve as the first step in reversing current trends in their adoption and use by youth and young adults.

Recruiting cigarillo users for survey research presents unique challenges using traditional methods. Youth and young adults are less likely to respond to survey recruitment via telephone and change their residency often, making mail-based recruitment less effective [4]. Youth and young adults may also feel more comfortable completing surveys addressing behaviors such as tobacco use, which may be illegal or stigmatized among these participants, online rather than in a school setting or other public venue [5]. Web-based recruitment may, therefore, be more appropriate given the increasing comfort and amount of time spent with digital platforms in this population and the relative anonymity of accessing and completing surveys online [6].

Web-based recruitment using social media may be particularly appropriate in reaching youth and young adult cigarillo users [7]. In addition to being delivered on the web, social media reaches a diverse group of users, including significant proportions of low-socioeconomic status, minority populations, especially among younger age groups [8]. Advertising on social media also allows for the specific targeting of these groups using demographic characteristics as well as specific behaviors associated with tobacco use [9]. There is also a seamless user recruitment experience as social media advertisements link participants directly to online screeners and surveys.

A growing body of research has examined the use of social media advertisements for tobacco research recruitment. Studies have found social media advertising recruitment to be more efficient for recruiting smokers when compared to specialized mailings [10], research databases, course-based recruitment [11], and online panels [12]. Conversely, school-based referrals, bus ads, participant referrals, and fliers were found to be more cost-effective than social media when recruiting adolescent smokers [13]. Other studies that did not compare social media to alternative recruitment methods describe social media as effective in recruiting young adult smokers for survey and intervention research [14,15].

Most studies examining social media advertising recruitment have used Facebook [7]. The few direct comparisons of Twitter and Facebook for study recruitment have yielded mixed results, primarily used interpersonal modes of social media recruitment vs paid advertising, and assessed effectiveness with nonmonetary outcomes [16,17]. Given the significant risk of

cigarillo use among youth and young adults, the growing evidence of the efficacy of social media in recruiting young adult smokers, and a lack of evidence supporting effective social media advertising strategies, the purpose of the current study was to examine the relative effectiveness of using Facebook, Instagram, and Twitter to recruit cigarillo users to complete an online nicotine dependence survey and provide guidance for future efforts using social media to study cigarillo use behavior.

Methods

Recruitment

Participants between 14 and 28 years old who smoked at least two cigarillos per week were considered eligible. Participants also had to read and understand English and have access to an internet-connected device. Study procedures were approved by the Case Western University Institutional Review Board, and participants provided informed consent. Our study did not collect individually identifiable data from social media platforms, reducing risks related to social media data privacy and anonymity recently raised in the research community [18]. Six social media advertisements were developed to run simultaneously on Facebook, Instagram, and Twitter platforms. Because advertisements were run together on a combined Facebook/Instagram campaign with the same URL, we were unable to separate the results for Facebook and Instagram at the survey completion level. We will refer to these combined platforms as “Facebook” when describing analyses for survey initiation and valid completion. To partially address this limitation, we analyzed advertising effectiveness between Facebook and Instagram at the level of advertisement clicks, which is available from the advertising management platform. Each advertisement contained identical wording that encouraged viewers to participate and featured a direct link to a brief eligibility screener administered via Qualtrics (Figure 1).

Advertisements featured planned images representing characteristics we intended to evaluate for advertising effectiveness (a cigar product, a smoking individual, a group of people, and gender). Advertisements were targeted to geographic areas reporting a high prevalence of cigarillo use (Cuyahoga County, OH; Baltimore, MD; Broward County, FL; Detroit, MI; DeKalb County, GA; Houston, TX; Philadelphia, PA; Washington, DC, Duval County, FL; and Fort Worth, TX) [1]. Advertisements were delivered daily for approximately 4 weeks in each location over 39 weeks beginning in June of 2017 and ending in March 2018. Advertisements were targeted using the age range most similar to our inclusion criteria that were an available option. We targeted Facebook advertisements to users 14–28 years old during the entire campaign and Twitter advertisements to users 13–34 years old, starting in November, once that feature became available. Advertisements were also targeted on relevant keywords such as “cigarillo” and “blunt” that were considered relevant to the target population. We did not encourage the sharing of social media advertisements through advertising messages or any other mechanism.

A budget of \$240/day was set, and advertisements were scheduled to run with identical budgets so that advertisements would be delivered with similar frequency by the advertising

platform algorithm. This method was essential to allow a fair comparison of advertisements as less effective advertisements may run for a brief time when using social media advertising optimization algorithms. We used the cost/click method of

payment traditionally used by advertisers wishing to direct users to a website whereby costs are based on an online auction for individual clicks on the advertisement.

6. Cigarillos

Survey

Individuals who completed the screener and met the eligibility criteria were invited to take the survey. Invitations were delivered via a brief email or text message, based on participant preference, and included a link to a survey administered via Qualtrics. Reminders were sent via the preferred method at 2, 5, and 8 days after initially sending the survey link. Respondents who submitted valid surveys were remunerated with a \$15 gift card.

The survey included questions assessing several dimensions relevant to cigarillo consumption, including demographic information, nicotine dependence, brand preference, group smoking behavior, psychosocial constructs, and the sequence of product initiation. Several sections of the survey used branching logic such that for each tobacco product endorsed, additional questions were assessed. Therefore, the number of survey items varied based on participants' reported product use.

Because nomenclature for tobacco products varies across audiences and geographically [19], several features were incorporated into the questions about tobacco products to ensure that items about tobacco products would be consistently understandable across participants with varying demographic and geographic characteristics. The questions referring to tobacco products used: the name of the product type (eg, "tipped cigarillo"), a familiar product brand (eg, "Black & Mild"), and a photograph of the product. Instructions and survey items were written at a 6th-grade literacy level. On average, the survey took about 30 minutes to complete.

Strategies to Ensure the Quality of the Survey Data

Multiple strategies were used to ensure the quality of online survey data, which can be adversely affected by respondents who falsely complete surveys for financial gain [20]. First, for the screener survey, we analyzed contact information items (email address and phone number) for validity and consistency and to identify possible repeat respondents [21]. Second, the screener survey included an open-answer item asking for a brief description of how participants got started smoking little cigars or cigarillos. This item required a multiple word response and was used to screen out responses generated by computer programs. This question was manually evaluated before a link to the survey was sent to the eligible participant. Third, a question about how the participant heard about the survey was used to ensure that participants came across the survey legitimately. If they claimed to hear about the survey through a channel that was not used by us, their responses were flagged and examined more carefully.

Completed surveys were manually assessed by study staff for validity before analysis. Validation was performed through the use of "trap" or "red herring" questions [22], checking for surveys completed abnormally fast or with poor response consistency [23], checking for unusually repetitive responses ("straight-lining") [24], and checking response sets with similar email addresses or IP addresses. Surveys that exhibited these characteristics were reviewed more carefully. Suspected repeat responders (based on emails or IP addresses) were rejected if there was sufficient evidence (based on the reviewer's judgment)

to do so. For example, if respondents with the same IP address gave similar answers, the surveys were completed one immediately after the other, or the respondents had emails sufficiently similar to suggest they were, in fact, the same person. Suspected satisficing cases were reviewed and either outright rejected or placed in a questionable category for further review. Multiple members of the study staff then reviewed these cases to make a final determination to accept or reject the survey.

Measures

Data on advertising effectiveness were obtained objectively from the Facebook/Instagram and Twitter advertising analytics platforms. Data included advertisement impressions (number of individuals to whom the advertisement was delivered), cost, number of times an advertisement was clicked, and number of times an advertisement was shared on the social media platform. The advertisement that generated each survey was identified by linking the response to a unique URL. Survey data included demographics and metadata related to survey and screener completion.

Statistical Analysis

Statistical analyses were conducted with SAS (Version 9.2) and SPSS (Version 25). Descriptive statistics were used to assess participant characteristics and sharing rates. Advertising effectiveness by platform and content is expressed as ratios. These included the number of screeners started per impression, the number of valid surveys per impression, and the cost per started screener and valid survey. We chose started screeners and valid surveys as the indicators of recruitment effectiveness except for the analyses of Facebook vs Instagram, where clicks were used as a metric of effectiveness. We also calculated the time in hours from when a participant started a screener to when they completed a survey. Differences between advertisement effectiveness were examined using Pearson chi-square tests. Analysis of which participant characteristics predicted recruitment advertising platform was performed using logistic regression models. Differences in survey time to completion were examined using *t* tests.

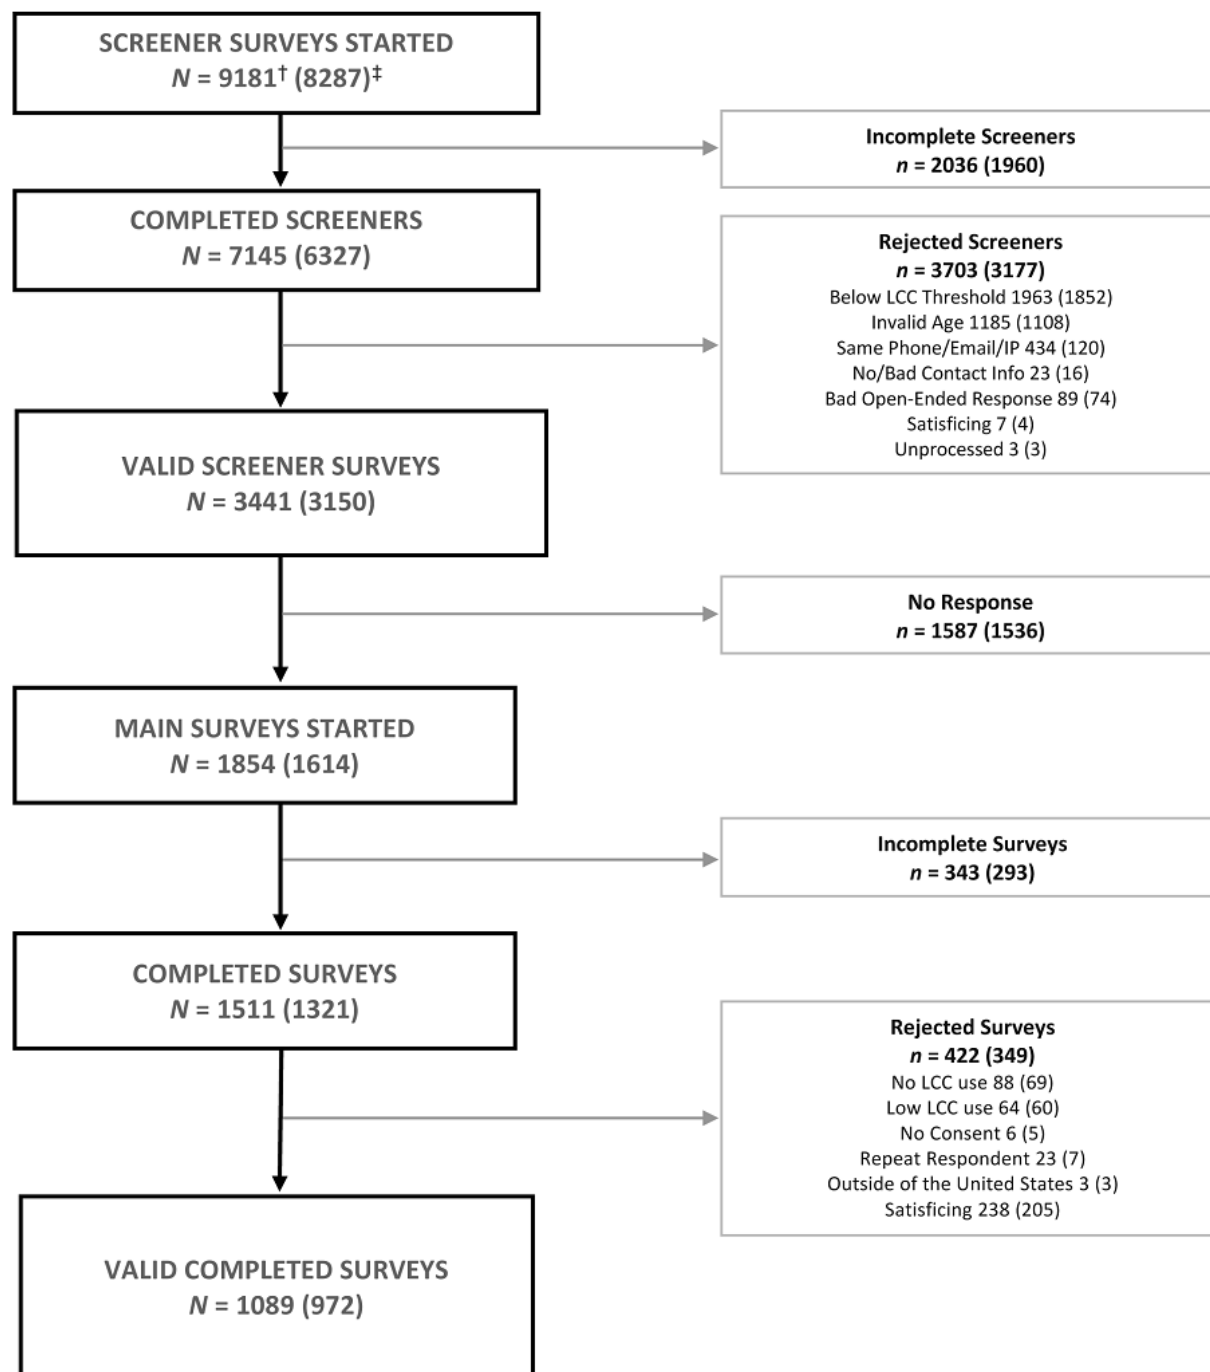

Results

The combined social media advertising campaign generated 4,026,453 impressions, and 8287 started screeners. Of 6327 completed screeners, 3150 (50%) were identified as eligible and were sent a link to the survey (Figure 2). Slightly more than half of the eligible participants started the survey (1614/3150, 51%), and 1321 of those completed it. Of the completed surveys, 349 were rejected due to a low level of cigarillo use, satisficing, or not meeting other review criteria. Table 1 shows the demographic characteristics of the total valid survey completers (n=1089) and valid survey completers who were recruited using social media (n=972). We found no significant differences in gender, age, race/ethnicity, and education between those who were recruited via Twitter or Facebook and subjects recruited by other methods (eg, palm cards, referral by another participant, n=117). Of note, 509 (47%) of the total sample were female, 839 (77%) were aged 25-28, 335 (31%) were African American, and 196 (18%) were Hispanic. The median number of cigarillos

per day for all valid survey completers was 0.93. In addition, 585 (53.7%) also smoked cigarettes, and 866 (79.5%) reported

using at least one other combustible tobacco product in the past 30 days.

Figure 2. Screener to survey completion flowchart.

[†] Total survey participants

[‡] Survey participants recruited by social media

Tables 2-3 describe advertisement effectiveness and cost comparisons. There was no significant difference between the percent of started screeners by impressions between Facebook and Twitter. Advertisements featuring a female image were more successful in generating started screeners than those with male images, and advertisements with a cigarillo image were more effective than those without. Facebook generated a greater percentage of valid surveys per impression than Twitter. There

was no significant difference by the gender of the advertising image, and advertisements with a cigarillo image again were markedly more effective. Facebook was less cost-effective for generating started screeners but more cost-effective for producing valid surveys. Facebook was significantly more effective in generating clicks on the study advertisement per impression than Instagram (n=8507, 1.76% vs n=1198, 1.16%,

$\chi^2_1=188.24$, $P<.001$, $N=585,648$). Instagram was also more expensive than Facebook per click obtained (\$1.32 US vs \$0.81 US). Facebook and Twitter significantly differed in the interval between respondents starting a screener and completing a survey (mean 66.63 h, SD 69.60 vs mean 80.03 h, SD 79.14; $t=2.55_{967}$, $P=.01$). Across platforms, advertisements were shared 310 times (79 on Facebook, 231 on Twitter).

Analysis of the predictors of social media recruitment platform is detailed in [Table 4](#).

Gender and race/ethnicity of survey completers did not predict through which social media platform a participant was recruited. The odds of being recruited by Facebook ($n=310$) versus Twitter ($n=659$) were 1.5-fold higher for those aged ≥ 21 years when compared to adolescents. Those recruited via Facebook were also more likely to report lower levels of education.

Table 1. Demographic characteristics and tobacco use of valid survey completers.

Characteristic	Total valid survey completers (N=1089), n (%)	Valid survey completers recruited via social media (N=972), n (%)

Discussion

This study was successful in recruiting a large sample of youth and young adult cigarillo users, supporting the use of social media-based advertising to reach this group, which traditionally presents a challenge to survey and study recruitment efforts. The recruited sample was diverse and representative of individuals most likely to use cigarillos, with over a third of our sample consisting of African Americans, a demographic group with the highest reported cigarillo use among adults [3].

Advertisements on Facebook were more effective than Twitter in producing valid surveys. Facebook was also a more cost-effective recruitment method. Differences observed in the cost per approved survey (approximately \$10 US) could represent a significant increase in the overall costs of recruitment in extensive studies. A limited number of previous studies have compared Facebook and Twitter research recruitment. A feasibility study examining the use of QR codes, Facebook, and Twitter for recruiting adolescents to take a health-related survey found Twitter to be marginally more cost-effective than Facebook [16]. That study, however, used student seeds to deliver Twitter recruitment as opposed to advertising. In another study that recruited focus groups about vaccination, Facebook was found to be more efficient than Twitter when comparing staff time spent per questionnaire received, but this study also used individual Facebook and Twitter accounts, not advertisements [17].

Our cost per valid survey of \$40 US falls within a broad range of previous findings related to the cost-effectiveness of social media recruitment of tobacco users. Ramo et al reported substantially lower Facebook costs of \$8.80 US per eligible, consented participant in a tobacco cessation intervention and \$4.28 per completed survey in a separate study, both targeting young adults [14,15]. Other recent studies recruiting tobacco-related survey participants reported a cost per completed survey of \$1.86 US (Facebook) [11], \$21.73 US (Twitter) [12], and a cost per enrolled smoker for randomized controlled trials ranging from \$41 to \$62 US (Facebook) [25,26]. Many factors affect social media advertising costs, including seasonality, industry type, and the specificity of the audience being targeted [27]. It might be the case that a more specific audience (eg, individuals who smoke cigarillos) reduces the cost-effectiveness of the advertisements. In addition, social media advertising costs have risen in recent years as more advertisers use the platform and as a result of recent changes to the advertising algorithm, which may account for some of the increase from previous studies [28]. When comparing social media costs in the current study to other modalities for recruiting tobacco users, Facebook and Twitter advertisements fall in the middle of the cost-effectiveness range. For instance, Brodar et al reported a cost per enrolled smoker in an experimental trial ranging from \$7 US using Craigslist to \$375 US for newspaper advertisements [25].

Our results also demonstrate that differences in effectiveness are a function of the metric used. Twitter was as effective in generating started screeners as Facebook but was less effective in generating approved surveys. Investigators should use the

measure of effectiveness most closely related to their recruitment goal as opposed to more distal measures such as advertising clicks that are more accessible via social media advertising platforms. Participants recruited via Facebook also completed the process of producing a valid survey more rapidly than those recruited via Twitter. For large studies or those on a short timeline, this measure of performance should be considered to ensure that the study goals are met. We observed minimal naturally occurring sharing of advertisements across platforms when compared to the reach of paid advertising. The viral nature of social media platforms, however, lends itself to this mode of recruitment, and researchers are beginning to use this strategy for a variety of recruitment and communications tasks [29,30]. Given the fact that sharing is a cost-free method of disseminating social media advertisements, future research should test methods for increasing the effectiveness of viral social media survey recruitment, such as nonmonetary rewards or small monetary incentives.

Regardless of the platform, the inclusion of a cigarillo image was consistently the most effective advertisement design. A similar result was found in a comparison of Facebook advertisement images used to recruit young smokers, where the advertisement with an image of a cigarillo had the lowest cost per unique click of 4 images used [15]. This strategy was also used in another successful Twitter recruitment campaign where all advertisements featured a prominent image of a tobacco product [12]. The impact of the image may be the result of having a strong visual cue similar to existing cigarillo marketing or the simplicity of the image given the limited space available for social media advertisements.

This study has several strengths. We had a large sample of advertising impressions on which to base our analysis. We created individual URLs for each advertisement on each platform linked to individual participants' screeners and surveys, allowing us to examine more relevant forms of effectiveness and assess demographic factors associated with social media platform advertising effectiveness. Limitations include our inability to examine Facebook and Instagram separately at the same level of effectiveness as our other analyses. The demographic profile of these social media platforms differs on several key demographic factors such as age and race, which may create differences in their effectiveness as suggested by our results comparing clicks per impression. In addition, over the past five years, Instagram use has consistently increased while Facebook has leveled off [31]. Understanding the effectiveness of Instagram should increase in importance if this trend continues. This study is not experimental, meaning that individuals were not randomized to the social media platform exposure. This limitation creates the possibility that participants may have been exposed to advertisements from Facebook and Twitter and responded only after being exposed to a specific dose. Additionally, the targeting features of social media platforms, such as geo-targeting, are inferred based on data collected in part through self-report, which may reduce their accuracy.

Social media platforms should be considered for tobacco-related research, especially in studies attempting to recruit hard-to-reach populations, such as youth, young adults, and minorities. This

method is cost-effective when compared to other modalities and provides a convenient means of digital recruitment on a nationwide basis. Although in the current study, Facebook was a more cost-effective platform, given the fact that we observed some differences in the likelihood of recruitment platform between age and education levels and our inability to determine

how many individuals in the sample use both, it may be that using multiple platforms remains the optimal recruitment strategy. Using multiple social media platforms may be less cost-effective, but by increasing the potential audience size, researchers may improve the ability to reach subgroups and recruit rapidly, if required.

Abstract

Background: Word embeddings are dense numeric vectors used to represent language in neural networks. Until recently, there had been no publicly released embeddings trained on clinical data. Our work is the first to study the privacy implications of releasing these models.

Objective: This paper aims to demonstrate that traditional word embeddings created on clinical corpora that have been deidentified by removing personal health information (PHI) can nonetheless be exploited to reveal sensitive patient information.

Methods: We used embeddings created from 400,000 doctor-written consultation notes and experimented with 3 common word embedding methods to explore the privacy-preserving properties of each.

Results: We found that if publicly released embeddings are trained from a corpus anonymized by PHI removal, it is possible to reconstruct up to 68.5% (n=411/600) of the full names that remain in the deidentified corpus and associated sensitive information to specific patients in the corpus from which the embeddings were created. We also found that the distance between the word vector representation of a patient's name and a diagnostic billing code is informative and differs significantly from the distance between the name and a code not billed for that patient.

Conclusions: Special care must be taken when sharing word embeddings created from clinical texts, as current approaches may compromise patient privacy. If PHI removal is used for anonymization before traditional word embeddings are trained, it is possible to attribute sensitive information to patients who have not been fully deidentified by the (necessarily imperfect) removal algorithms. A promising alternative (ie, anonymization by PHI replacement) may avoid these flaws. Our results are timely and critical, as an increasing number of researchers are pushing for publicly available health data.

privacy; data anonymization; natural language processing; personal health records

Introduction

Motivation

Natural language processing (NLP) is increasingly used to assist medical practitioners with various tasks, ranging from patient phenotyping to unplanned hospital readmission prediction [1-3]. Although a diverse range of approaches are used, a large number of NLP applications use algorithms, such as Continuous Bag of Words (CBOW), Skipgram, and Global Vectors (GloVe) [4,5], which represent tokens as dense numeric vectors termed as *word embeddings*. Most of these representations are computed from large corpora of text, such as clinical notes or narratives from health records, made available by health care providers (HCPs). Usually, before these data are provided to researchers, the HCPs apply anonymization algorithms to deidentify the personal health information (PHI) in the data. In this work, we adopted the terminology of the US Health Insurance Portability and Accountability Act (HIPAA), where *PHI* refers to *individually identifiable health information*, which includes personal identifiers ranging from names and phone numbers to fingerprints.

There is a wide variety of techniques to locate and deidentify PHI in clinical text, ranging from dictionaries [6] to recurrent neural networks [7]. Once the sensitive information is located within a record, anonymization can employ either *removal* or *replacement*, that is, the sensitive information is either simply deleted, changed to a data-type identification tag such as **NAME**, or replaced with another randomly chosen PHI of the same type. Many publicly available resources use PHI removal, for example, the Multiparameter Intelligence Monitoring in Intensive Care (MIMIC-III) dataset [8] used informative deidentification tags. However, in this paper, we showed that as no perfect PHI search algorithm exists, data *secured* this way can be exploited because traces of identities remain in the text and are detectable even in embeddings that are generated from it.

Specifically, we discussed the privacy concerns that arise from publicly releasing word embeddings that have been trained on clinical notes secured using the PHI removal paradigm. At first glance, it may seem that releasing word embeddings has low risk because of the unordered nature of these models; all that is released is a list of words, arbitrarily ordered, with dense numeric vectors associated with each word. However, through our experiments with three of the most popular embedding techniques, we showed that they can be leveraged to learn information presumed to be removed.

Our work relies on the assumption that some name tokens will inevitably be missed by the deidentification process. This is a realistic assumption as, to date, there is no deidentification algorithm that has perfect recall (ie, captures all PHI). This necessarily means that the word list of the embedding model will contain names that are not properly protected. We also assume that malicious actors will be able to successfully identify these tokens from a very large wordlist. Given these two assumptions, a publicly released traditional word embedding model then presents a small, but nontrivial, risk of patient identities being attacked. This risk is relative to the number of

patients in the data set and the particular deidentification and embedding algorithms used. Up to 0.6% of all patients may be at risk of having their full names detected in a data set (built from individual name tokens), and as many as 0.02% to 0.15% may have their full name associated with a diagnosis. Although these risks appear small, with the growing number of publicly available embeddings trained on clinical data, we aimed to draw attention to the possible critical mass of potential privacy exposure.

Specifically, we showed that (1) it is possible to associate name tokens together to form *true* name pairs, (2) there is a significant difference between the distances of diagnoses that have been associated with a patient and those of diagnoses not associated, and this is true both at the population level and at the patient level, and (3) it is possible for a malicious actor to determine diagnoses assigned to multiple patients, using only precomputed embeddings. In this work, we will refer to diagnostic codes and diagnoses interchangeably, although this is not, of course, a general equivalence. Here, we take the diagnostic code simply as an indication of the condition that the patient is suspected of having, which is sensitive information that must be protected. Finally, we replicate these results and perform further experiments with a synthetic data set that we make publicly available.

Our work is the first to study the privacy implications of releasing word embeddings. This demonstrates how anonymizing clinical notes using PHI removal is likely to leave sensitive patient information vulnerable. By methodically exploring a variety of algorithms and hyperparameters, we showed that our observation holds in the general case. Furthermore, we demonstrated that it is easier to reassociate sensitive information with rare names compared with common ones. Finally, we argue that, given our results, data holders and providers should explore whether other paradigms, such as PHI replacement, are more successful in securing sensitive information when compared with PHI removal.

Background

Clinical Word Embeddings

Word embeddings (ie, *word vectors* or *distributed representations*) are dense numeric vectors used to represent words. Many word embedding techniques fall into one of two categories: low-rank approximations of co-occurrence matrices [4,9] and those created using shallow neural networks using contextual information [10]. There is also a recent and growing body of embedding models employing deeper neural networks to create contextual word embeddings, which vary depending on the surrounding context [11,12].

Inspired by the distributional hypothesis [13], word embeddings trained on health care data are strongly correlated with human-annotated word similarity metrics for medical terms [2], although their performance on clinical classification tasks is strongly dependent on the quality, size, and type of data from which they are created [14]. In fact, embeddings created from clinically related data (eg, clinical notes and biomedical text, such as a collection of all PubMed Central articles and PubMed

abstracts), often performed better than, and never performed worse than, unspecialized corpora [2].

Until recently, there had been no publicly released embeddings trained on clinical data [15-18]. However, some newly released embeddings [15-18] are trained using contextual word embedding models on MIMIC, which itself uses PHI removal to abide by HIPAA regulations. Our work demonstrates how, if no additional security measures are taken, then traditional (noncontextual) models may be compromised. More work is required to assess whether our findings hold for the four new models as well (ie, contextual word embeddings) [15-18].

Privacy of Clinical Notes

There are 3 main approaches to protect the privacy of patients: dictionary-based, statistical, and hybrid approaches. Dictionary-based methods often use large wordlists or predefined regular expressions to locate private information in the text [6,19]. Statistical methods, often more robust than dictionary-based approaches [20], use models such as recurrent neural networks [7] to automatically detect private information. Hybrid methods combine the two approaches to compensate for their respective weaknesses [21]. No matter the method used to detect PHI, once it is detected, there are two ways to secure the data: PHI removal and PHI replacement.

Personal Health Information Removal

In PHI removal, sensitive information is located in text via a specialized search algorithm and then is either deleted or replaced with an informative deidentification tag (eg, all names are replaced with [**NAME**]). Although simple and common, this approach is not secure and can be easily exploited. Given that no PHI search algorithm is perfect, as a data set increases in size, it becomes increasingly certain that some PHI will be missed. Thus, if clinical notes are shared in a text format after this technique is used for deidentification, a malicious party can uncover names missed by the algorithm by manually inspecting the data. We demonstrate later that word embeddings created from such data are also vulnerable to similar exploits.

Personal Health Information Replacement

In PHI replacement, sensitive information, once located within the text by the search algorithm, is replaced with other information of the same type; for example, names can be randomly replaced with other names. This approach is more secure than PHI removal as it obscures instances where the PHI detection algorithm has failed and thus provides the data-curator with plausible deniability for any specific record.

We advocate that HCPs and data providers employ this paradigm because, if done correctly, it is much harder to exploit and thus reduces the risk to patient privacy. It is also a simple and

effective way to protect against the exploitation of word embeddings that we demonstrated in this work.

Methods

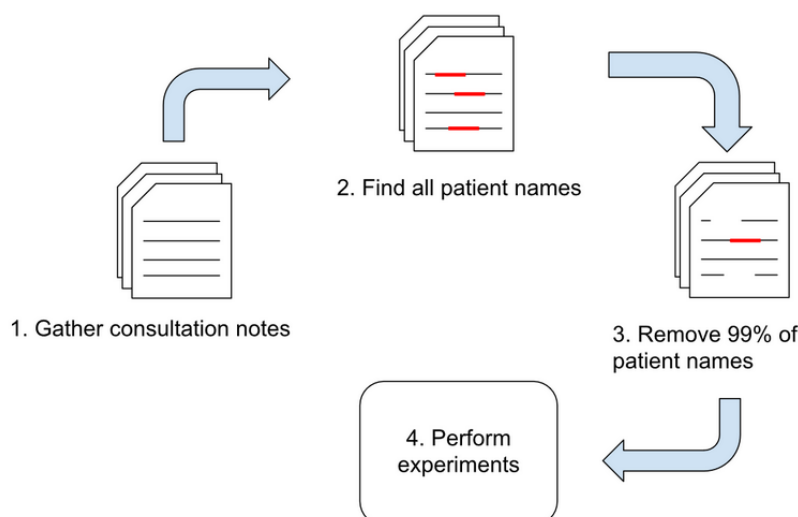

Data

In our experiments, we used consultation notes. In [Multimedia Appendix 1](#), we demonstrate how these findings are reproducible with an experiment performed with a selected subset of Wikipedia pages. We made the latter publicly available alongside the code. For all texts, we removed all punctuation and numeric characters, and we lowercased all text but performed no lemmatization, tokenization, or any other preprocessing.

We used consultation notes provided to the authors by ICES (formerly known as the Institute for Clinical Evaluative Sciences) under data sharing agreements with physicians for the purposes of evaluation and research. Consultation notes are written by specialist physicians and other health care consultants to a patient's family physician. They describe the tests performed, results observed, and other details that the specialist physician or health care consultant considers relevant. We compiled patients' consultation notes and all their prescribed diagnostic codes that are indicative of suspected diagnoses and ordered tests, and are therefore sensitive health information that must not be connected to patient identities. The billing codes table includes text fields describing each code in 1 to 3 words, for example, *colon screening*. These data sets are linked using unique encoded identifiers and analyzed using ICES.

Although this work is conducted at ICES, ICES does not grant its research affiliates (including the authors of this paper) access to *true* patient names, but replaces them in the manner described earlier (PHI replacement), using a semimanual, dictionary-based masking process to consistently replace each true name with a randomly chosen fake name. We used heuristics to detect names in the notes. More concretely, we looked for semistructured notes that have *Name: str1, ..., strN* (representing a series of alphabetical tokens separated by commas followed by a semicolon) to indicate the presence of a name. The heuristic is not 100% accurate, which is why, in [Multimedia Appendix 2](#), we can provide only an estimate of how many true names exist by manually analyzing a randomly sampled set.

We perform our experiments on clinical consultation notes for which we can locate the associated fake patient name. For our experiments, we treat the fake names as if they were the *true* names and removed 99% of them, thus emulating current PHI removal algorithms [7]. This protected data set is then used as the first step of our experiments, as shown in [Figure 1](#). Detailed information regarding the data is provided in [Multimedia Appendix 2](#).

Figure 1. Process flow for gathering and preparing the clinical notes for embedding generation and experimentation.

Experiments

Experimental Hypothesis

The intuition behind reidentifying patient information solely from word embeddings stems from the *distributional hypothesis* [13]—that words appearing in similar contexts tend to have similar meanings and therefore have closer vector representations than other words. Knowing this, we expect differences between both:

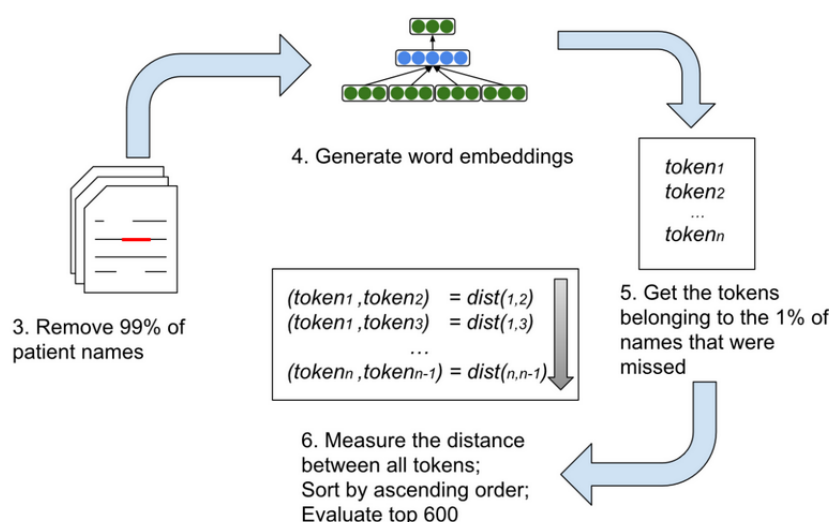

1. The average distance between the tokens that make up a person's name, compared with tokens from different names.
2. The average distance in vector space between a person's name and their diagnoses (referred to as the in-group),

compared with the average distance between their name and those diagnoses with which they are not associated (referred to as the out-group).

If there is a large enough distance between a person's in-group and out-group, then this observation could be used to extract sensitive information thought to have been hidden by the unordered nature of embeddings. In the following sections, we validated this hypothesis empirically.

Experiment 1: Name Reconstruction Experiment

In the first experiment, we tested whether it is possible to reconstruct true name pairs simply from a list of individual name tokens. Figure 2 presents the steps of this experiment, picking up from the last step of Figure 1.

Figure 2. Process flow for generating word embeddings and performing the name reconstruction experiment.

A list of individual name tokens, corresponding to the fifth step in Figure 2, is easily generated by manual exploration of the words. However, as we left 1% of the names, to emulate the imperfect deidentification algorithms, we knew all the tokens (ie, the 1% of name tokens purposefully left in place).

We performed this experiment on our consultation notes data set, where over 99% of names were removed to emulate a PHI

removal approach and only 1054 unique name tokens (from 650 full names) remained in the text.

We performed our experiment with 3 commonly used traditional word embedding algorithms (CBOW, Skipgram, and GloVe) for clinical prediction and modeling tasks. For each, we tested a variety of hyperparameters. Where a specific hyperparameter is not explicitly mentioned, we used the default hyperparameter

of the training model, which can be found in [Multimedia Appendix 2](#).

However, for the sixth step, an attacker would not know how many full names were in the data set. If we assume that each name is composed of 2 tokens and none of the names share any name tokens; we would expect the number of complete names to be half the number of name tokens (ie, 1052/2 complete names). Relaxing both assumptions increases the expected names. Given name tokens A and B , we considered a name to exist if either $\langle A, B \rangle$ or $\langle B, A \rangle$ exist as names (ie, ignoring ordering). On this data set, we created many word embedding models ($n=88$) with a wide set of hyperparameters (ie, model specifications) that included variations in the distance metric (cosine or cityblock) and context window size.

Experiment 2: Name-Diagnostic Code Association Experiment

In this section, we explored the second part of our hypothesis: is there a difference between the average distance in vector space between a person's name and their diagnoses (their *in-group*) compared with the average distance between their name and those diagnoses with which they are *not* associated (their *out-group*)?

For this experiment, we used the same data and tested the properties of the same word embedding algorithms for various hyperparameters, as in the last experiment. We first define a patient's name vector as the average of the vectors of its components (ie, first, last, and possibly middle names). Here, $numtoken$ is the number of space-separated tokens in a string and is the vector representation of the i th token of the name:

Second, we defined the in-group d_{in} as the set of diagnoses for *name* and the out-group d_{out} as all other diagnoses, with d_i representing any individual diagnosis. The average distance for each of these groups from their respective names are referred to as *in_group* and *out_group*, respectively:

We presented the results using the *cityblock* distance (ie, the Manhattan distance) instead of the cosine distance because it performs better at this task (by uncovering more information), and past work has shown that the vector magnitude (ie, the sum of all dimensions) is affected by the number of times that the word occurs in the corpus [22]. However, our experiments were performed using the cosine distance metric as well, and complete results can be found in [Multimedia Appendix 2](#).

Initially, we explored the raw data (ie, without any deidentification algorithm) by plotting the difference between the in- and out-groups for names that occur below different frequency thresholds. A name is below the threshold if the average counts of its components are below that threshold. For example, if “James” occurs 201 times in the corpus and “Qwerty” appears twice, then “James Qwerty” is below an arbitrary threshold of 200 ($101.5 < 200$).

[Figure 3](#) shows that the more frequently a name occurs, the smaller the difference between the in-groups and out-groups. Nonetheless, the difference is still pronounced when all names are considered, with the lowest value being just under 5. Surprisingly, against our intuition, the in-group is larger than the out-group. We saw this result consistently throughout our testing described in the following sections.

Figure 3. Relationship between frequency of name occurrence and the average difference between the in-group and out-group for patients. This graph is generated from an experiment run on a GloVe model with a dimension of 100, window of 10, learning rate of 0.05, minimum occurrence of 1, and alpha of .75.

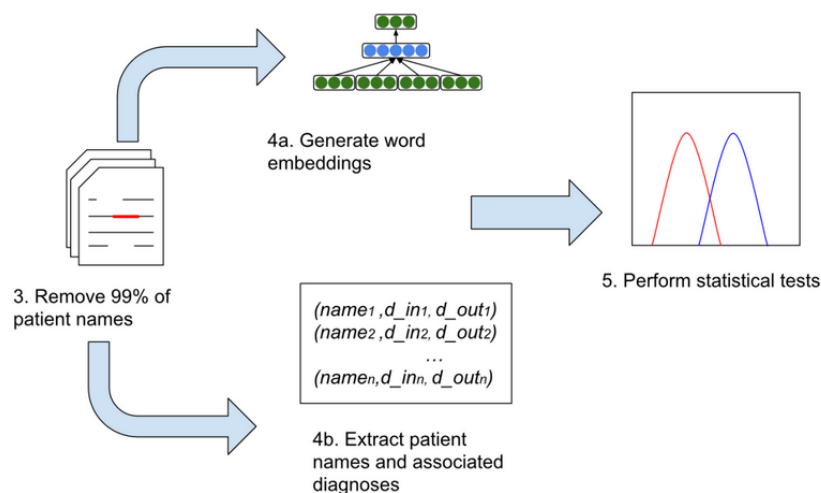

Statistical Testing

Given our initial observation that, on raw data, there is a difference between in- and out-groups on the population level on raw data, we now examine if the observed differences are

statistically significant at both the population and patient levels for various embedding algorithms and hyperparameters on the deidentified data set (ie, 99% of names have been removed to emulate an optimum real-life data sharing scenario). A diagram of the experimental process is shown in [Figure 4](#).

Figure 4. Process flow for generating word embeddings and performing statistical testing. For population-level statistical testing, we performed a Wilcoxon signed-rank test, and for patient-level statistical testing, we calculated empirical P values using 1000 randomly generated permutations.

Experiment 2a: Population-Level Statistical Testing

In this experiment, we aimed to determine whether the difference between the in- and out-groups on the population level is statistically significant.

Here, as with all the clinical text experiments, the embedding model is trained using all consultation notes after 99% of the names have been removed. Using the same setup as in the previous section to obtain distances between in- and out-groups, we used the Wilcoxon signed-rank test to compare the pairings of in- and out-groups for each name on the population level. The Wilcoxon signed-rank test is nonparametric and, unlike the paired Student two-tailed t test, makes no assumptions regarding normality.

This experiment is performed for various embedding algorithms, distance metrics, and hyperparameter ranges.

Experiment 2b: Patient-Level Statistical Testing

Here, we explored whether there is a statistically significant difference between the in- and out-groups for each patient, which would indicate that an individual patient is at risk of having their diagnostic code uncovered.

In this experiment, we compared the average difference between a patient's in-group and the out-group. Although each comparison will result in a P value for each patient, for brevity and privacy, we do not report the per patient analysis of the ICES data, but instead report the number of patients for which the difference is significant after correcting for multiple comparisons. To determine statistical significance at the patient level, we calculated empirical P values by randomly sampling in- and out-groups generated using 1000 permutations of the same size from the same data set.

We experimented with various embedding algorithms, distance metrics, and hyperparameter ranges.

Experiment 3: Scenario Simulation

In this experiment, we performed a hypothetical attack to examine whether the results of the previous 2 experiments demonstrate an actionable level of risk. Assuming the role of an attacker who has access only to released embeddings built from doctor-patient consultation notes that have been secured by using PHI removal, we showed how we are able to associate name tokens that were missed by PHI removal to arrive at a list of complete patient names and that we are able to associate these names with some target diagnoses.

For this hypothetical scenario, we used the same data and tested the properties of the same word embedding algorithms for various hyperparameters as in the last experiment.

The attack is as follows:

1. Identify a list of target diagnoses that we wish to attribute to patients. As an example, we considered the following set of diagnoses: constipation, diarrhea, vaginitis, sexual dysfunction, urinary infection, herpes genitalis, dementia, anorexia, alcoholism, threatened abortion, and AIDS.
2. For each name, calculate the 5 diagnoses that are farthest from the name.
3. Using these 5 diagnoses as the basis for prediction, we calculated Top-1 ($A@1$) and Top-5 ($A@5$) accuracy.

To ensure that our results are not an artifact of the selected diagnoses, we repeated the above experiment 1000 times for each tested hyperparameter, randomly selecting 30 target diagnoses. To be as stringent as possible, we chose from diagnoses that appeared at least 10 times in the data (which likely will result in a pessimistic bias, as demonstrated in [Multimedia Appendix 2](#)).

Results

Experiment 1: Name Reconstruction Experiment

The results of this experiment demonstrate that it is possible to reconstruct true name pairs simply from a list of individual name tokens and their respective embeddings.

In this section, we present the results for various context window sizes, an expected name list of size 600, and a cosine distance

metric. We observed that up to 68.5% (411/600) of the paired tokens come from true names, as shown in [Table 1](#) and [Figure 5](#). As there are over 170,000 name-pair combinations, these embeddings clearly carry patient information that can be identified, thus affirming our hypothesis. The complete results for other hyperparameters, the number of names expected, and the cityblock distance metric are presented in [Multimedia Appendix 2](#).

Table 1. The number and percentage of paired tokens that are part of true names as a function of context window size, using the cosine distance metric of the first 600 paired tokens sorted in ascending order.

Context window size	Skipgram names, n (%)	CBOW ^a names, n (%)	GLoVe ^b names, n (%)
1	51 (8.5)	17 (2.8)	8 (1.3) ^c
3	369 (61.5)	265 (44.2)	158 (26.3)
5	393 (65.6)	323 (53.8)	278 (46.3)
7	410 (68.3)	331 (55.2)	317 (52.8)
9	411 (68.5)	340 (56.7)	323 (53.8)

^aCBOW: Continuous Bag of Words.

^bGLoVe: Global Vectors.

^cResult not significant after correcting for multiple comparisons using the Holm-Bonferroni correction.

Figure 5. Visual representation of the percentage of paired names belonging to true names from the first 600 paired tokens when sorted in ascending order.

Experiment 2: Name-Diagnostic Code Association Experiment

Experiment 2a: Population-Level Statistical Testing

The results of this experiment indicate that, at the population level, the average difference between the in- and out-groups per

patient is statistically significant. [Table 2](#) and [Figure 6](#) show the results for various embedding algorithms, varying context window sizes, and a cityblock distance metric. The complete results for other hyperparameters, other distance measures, and absolute distances are shown in [Multimedia Appendix 2](#).

Table 2. Difference between the in-group and out-group as a function of context window size for various word embedding algorithms using the cityblock distance metric. The differences are relative distances between word embedding vectors in an n-dimensional space.

Context window size ^a	Skipgram difference	CBOW ^b difference	GLoVe ^c difference
1	3.91	7.59	4.85
3	2.88	28.53	5.69
5	2.33	39.55	5.45
7	1.84	47.10	5.12
9	1.51	51.61	5.54

^aAll differences were statistically significant after correcting for multiple comparisons.

^bCBOW: Continuous Bag of Words.

^cGLoVe: Global Vectors.

Figure 6. Visualization of the difference between the in-group and the out-group as a function of context window size for various word embedding algorithms using the cityblock distance metric.

Given our selected hyperparameters, we observed that for all sizes tested and for all embedding techniques, the difference between the in- and out-groups on the population level was statistically significant with $P < .001$ calculated using the Wilcoxon test, after correcting for multiple comparisons using the Holm-Bonferroni correction [23]. The Holm-Bonferroni correction is a sequentially rejective procedure for correcting multiple comparisons that keeps the family-wise type I error bounded. Figure 6 shows that the difference between the in-group and out-group decreases for embeddings created with the Skipgram algorithm as the context window increases. Conversely, the difference grows for CBOW, while it remains relatively stable for all GloVe models.

Experiment 2b: Patient-Level Statistical Testing

Building on our previous observations, the results of this experiment indicate that, at the patient level, for a percentage of examined patients (up to 449/638, 70.4%), the average difference between in- and out-groups per patient is statistically significant.

Table 3 and Figure 7 show the results for various embedding algorithms, varying context window sizes, and a cityblock distance metric. The complete results for other hyperparameters, other distance measures, and absolute distances are shown in Multimedia Appendix 2.

Table 3. The percentage of patients whose diagnoses are identifiable due to a statistically significant difference between the in-group and out-group as a function of context window size for various word embedding algorithms using the cityblock distance metric.

Size	Skipgram patients, %	CBOW ^a patients, %	GLoVe ^b patients, %
1	49 (7.7)	77 (12.1)	400 (62.7)
3	41 (6.4)	149 (23.4)	401 (62.8)
5	33 (5.2)	152 (23.8)	403 (63.2)
7	16 (2.5)	153 (24.0)	380 (59.6)
9	12 (1.9)	153 (24.0)	449 (70.4)

^aCBOW: Continuous Bag of Words.

^bGLoVe: Global Vectors.

Figure 7. Visualization of the percentage of patients who have a significant difference between their in- and out-groups as a function of context window size for multiple word embedding algorithms using the cityblock distance metric.

Table 3 presents the patient-level analysis for different context window sizes. As shown in Figure 7, using the CBOW algorithm, an increasing window size initially correlates positively with the number of vulnerable patients, defined as having a significant difference between the in-group and out-group. The opposite trend is observed for the Skipgram model. Context window size does not appear to have an effect on word embeddings created using GloVe, as the number of patients remains relatively stable.

Experiment 3: Scenario Simulation

Having demonstrated that the difference between in- and out-groups is statistically significant, in this section, we showed that our hypothetical attack results in an actionable level of risk, that is, an attacker who has access only to released embeddings built from doctor-patient consultation notes that have been secured by using PHI removal may be able to arrive at a list of complete patient names, and associate these names with target diagnoses.

We observed that for our chosen target diagnoses (ie, constipation, diarrhea, vaginitis, sexual dysfunction, urinary

infection, herpes genitalis, dementia, anorexia, alcoholism, threatened abortion, and AIDS) our approach outperforms the majority baseline for both top 1 (A@1) and top 5 (A@5) accuracy of 0.00 and 0.70, respectively, Multimedia Appendix 2 (top n rate is the fraction of examples for which the correct label is among the n labels considered most probable by the model). The complete results for all hyperparameters as well as both distance metrics are presented in Multimedia Appendix 2.

We observed similar results when the above experiment was repeated 1000 times for each tested hyperparameter, randomly selecting 30 target diagnoses. Table 4 shows how often our attacker's approach surpasses the baseline of choosing the majority diagnoses for both top-1 and top-5 accuracies. We show that we can consistently beat strong baselines, although the highest top-1 and top-5 accuracies are modest at 0.08 and 0.15, respectively. The complete results for all hyperparameters as well as both distance metrics are presented in Multimedia Appendix 2.

Table 4. The percentage of times using a word embedding–based attack beats the majority baseline for A@1 and A@5 for various context window sizes over 1000 random diagnosis selections.

Context window size ^a	Skipgram A@1, A@5	CBOW ^b A@1, A@5	GLoVe ^c A@1, A@5
1	55.8, 56.7	61.8, 61.8	55.4, 56.9
3	55.6, 53.1	51.2, 52.6	60.5, 59.5
5	57.4, 55.6	53.6, 54.5	59.4, 57.2
7	57.4, 53.5	54.6, 53.9	55.9, 54.0
9	57.2, 53.2	53.7, 51.2	60.6, 56.7

^aWe observed that the majority baseline is surpassed consistently and up to 60% of the time.

^bCBOW: Continuous Bag of Words.

^cGLoVe: Global Vectors.

Discussion

Principal Findings

In this work, we have shown the following:

- There is a statistically significant difference between the distance of patients' in- and out-groups at the population level.
- For many individual patients, the difference between their personal in-group and out-group is also statistically significant.
- A malicious actor working only with word embeddings may identify full names occurring in the training corpus of the embeddings as well as sensitive attributes associated with these names.

Limitations

We explored the induced privacy (or lack of privacy) of embeddings created from medical notes. We empirically highlighted the security risks of sharing clinically sourced word embeddings. Although their nature does serve to obfuscate information, we have shown that it is still possible to connect PHI to names from word embeddings secured using PHI removal. There is much variation in the risks observed in this work, which are dependent on imperfect deidentification algorithms and very skilled attackers. The actual risk to patient information, while nonzero, remains small and dependent on many variables such as the attack strategy, deidentification method, and embedding algorithm. We therefore advocate for more research to see whether the adoption of PHI replacement would better secure released embeddings. In addition to deidentification methods (where more research needs to be done), appropriate controls on who can access the anonymized data and oversight of these data are also recommended.

Conclusion

We have focused on the reidentification of names and their association with diagnostic codes, although other sensitive PHIs may also be vulnerable. We demonstrated how sharing word embeddings trained on clinical notes that have been protected using only PHI removal is not safe, as any PHI missed by the algorithm will remain in its original context. The risk of obtaining sensitive information from embeddings can be diminished by applying the anonymization methods of PHI replacement on the clinical notes before training the embedding,

that is, when all known PHIs have been randomly shuffled, it becomes much more difficult (but not impossible) to determine which names in the data set belong to true patients, as the names that are shuffled together will behave in a manner similar to true names that have been missed. Such embeddings can theoretically still be at risk if an attacker is able to determine how to differentiate between fake and true names. However, this would mitigate the methods of attack described in this work, thereby making the created embeddings more secure. Alternatively, noise can be added to the generated embedding model to induce privacy and reduce risk. This risk reduction is, naturally, relative to the amount of noise added, and determining the exact amount of noise without distorting the signal or degrading performance is the subject of future research.

Regarding reassociating name tokens or associating names with diagnostic codes, Skipgram is least effective at preserving privacy, followed by CBOW and GloVe. However, when examining the number of statistically significant differences, we observe the opposite ranking. Although many sentence- and text-classification tasks observe little difference in downstream performance between these 3 algorithms, past work [5] has demonstrated differences in the ability of these algorithms to represent words. For example, Skipgram can perform better than CBOW for more frequent words [5], possibly explaining the difference in modeling names (which are infrequent in our vocabulary).

As expected, tokens from the same complete name have closer vector representations. However, despite our intuition, we find that the in-group is surprisingly larger than the out-group. That is, the average distance between a name and a diagnosis is larger if the person with that name has a diagnosis. This was consistent among all parameters tested, and among all 3 embedding models. This was also observed in our novel data set. This was perplexing because our expectation of word embeddings informs us that words that occur in similar contexts should be closer together, and in-group diagnoses are often in the same note as the name, while out-group diagnoses are not in the note at all. Even though the name and diagnosis tokens may not co-occur directly, as they would gravitate to words that co-occur with both, this would result in the names and in-group diagnoses being closer. Although a deeper theoretical investigation remains to be conducted, we hypothesize that this may be due to interaction effects within the contexts; names are quite tightly

clustered together, and they rarely occur in the same context window of the diagnosis with which they are associated. It may be that these other names draw the *common* diagnoses closer, as they occur with more names, in turn leaving the less common, but relevant, diagnoses further from the *name* cluster. This requires further research.

Acknowledgments

The authors thank the helpful staff at ICES (Dr Liisa Jaakkimainen, Dr Therese Stukel, Elisa Candido, Daniella Barron) for granting us access to data and for their insight into our manuscript. This study was supported by ICES, which is funded by an annual grant from the Ontario Ministry of Health and Long-Term Care. Abstract

Background: Noncommunicable diseases (NCDs) have become the main public health concern worldwide. With rapid economic development and changes in lifestyles, the burden of NCDs in China is increasing dramatically every year. Monitoring is a critical measure for NCDs control and prevention. However, because of the lack of regional representativeness, unsatisfactory data quality, and inefficient data sharing and utilization, the existing surveillance systems and surveys in China cannot track the status and transition of NCDs epidemic.

Objective: To efficaciously track NCDs epidemic in China, this pilot program conducted in Ningbo city by the Chinese Center for Disease Control and Prevention (CDC) aimed to develop an innovative model for NCDs surveillance and management: the integrated noncommunicable disease collaborative management system (NCDCMS).

Methods: This Ningbo model was designed and developed through a 3-level (county/district, municipal, and provincial levels) direct reporting system based on the regional health information platform. The uniform data standards and interface specifications were established to connect different platforms and conduct data exchanges. The performance of the system was evaluated based on the 9 attributes of surveillance system evaluation framework recommended by the US CDC.

Results: NCDCMS allows automatic NCDs data exchanging and sharing via a 3-level public health data exchange platform in China. It currently covers 201 medical institutions throughout the city. Compared with previous systems, automatic popping up of the report card, automatic patient information extraction, and real-time data exchange process have highly improved the simplicity and timeliness of the system. The data quality meets the requirements to monitor the incidence trend of NCDs accurately, and the comprehensive data types obtained from the database (ie, directly from the 3-level platform on the data warehouse) also provide a useful information to conduct scientific studies. So far, 98.1% (201/205) of medical institutions across Ningbo having been involved in data exchanges with the model. Evaluations of the system performance showed that NCDCMS has high levels of simplicity, data quality, acceptability, representativeness, and timeliness.

Conclusions: NCDCMS completely reshaped the process of NCD surveillance reporting and had unique advantages, which include reducing the work burden of different stakeholders by data sharing and exchange, eliminating unnecessary redundancies,

reducing the amount of underreporting, and structuring population-based cohorts. The Ningbo model will be gradually promoted elsewhere following this success of the pilot project, and is expected to be a milestone in NCDs surveillance, control, and prevention in China.

KEYWORDS

surveillance; noncommunicable diseases; regional health information platform; electronic health records.

Introduction

With the rapid socioeconomic development and acceleration of population aging and urbanization, noncommunicable diseases (NCDs), such as cardiovascular diseases, cancers, chronic obstructive pulmonary diseases (COPDs), and diabetes, have become the main public health concerns worldwide. The WHO reported that NCDs kill around 40 million people every year, equivalent to 70% of all deaths globally [1]. China, as a developing country with the largest population, has been experiencing incremental prevalence of NCDs over the past decades; the proportional burden of NCDs increased by 37.27% from 60.21% in 1990 to 82.65% in 2016 [2]. Studies have shown that the prevalence of diabetes in adults was 9.7% in 2013, COPD among people aged 40 and above was 13.6% in 2015, and hypertension in adults aged 35-75 years was 44.7% in 2014-2017 in China [3-5]. Moreover, cardiovascular diseases, cancer, and chronic respiratory disease were the leading causes of death, accounting for approximately 79.4% of total deaths [6].

Monitoring is a critical and indispensable measure for NCDs control and prevention, including providing evidence for policy making and data support for evaluation of the global and regional targets [7]. As a cornerstone of public health practice in improving disease surveillance, the US Centers for Disease Control and Prevention (CDC) launched the CDC Surveillance Strategy in 2014 to achieve the targets of advancing the use of electronic health records (EHRs), retiring redundant systems, and maximizing performance of agency resources [8]. In China, the Chronic Disease and Risk Factor Surveillance Survey was introduced in 2004 using a multistage stratified cluster random sampling method to monitor NCD epidemics nationwide every 3 years [5,9-11]. However, due to the collection of NCD information by self-reports and the heavy workload involved in field survey, the monitoring data can only be obtained through selected surveillance points and their quality varies among regions. Several surveys and registries on specific chronic diseases are available in China, including those on stroke, hypertension, COPD, diabetes, and cancer, which provide valuable national epidemiological data on NCDs [3-5,12,13]. However, because these surveys and registries are independent from each other with inconsistent research methods and different population coverage, it is difficult to compare the varied results and obtain a whole picture of current situation of NCDs in China, which also reflects the shortcomings of traditional surveillance system in data sharing and utilization [14]. A population-based data with high quality generated from a

reliable surveillance system is crucial to detect the priorities to track and tackle NCDs and find the cost-effective interventions to reduce the burden of NCDs.

Ningbo is a prefecture-level city of Zhejiang province in eastern China, consists of 10 districts with a registered population of 5.93 million, and has the very advanced regional health information platform in China. In 2016, Ningbo successfully achieved the 3-level (county/district, municipal, and provincial level) direct reporting of infectious diseases through a data exchange platform, which shortened the reporting time to 2 minutes from uploading a report card in the hospital information system (HIS) to the national information system [15]. Two years later, a similar but improved reporting and management model for NCDs was successfully implemented, named integrated noncommunicable disease collaborative management system (NCDCMS). This pilot study was conducted in Ningbo by the Chinese CDC and aimed to develop an innovative model for NCDs surveillance and management in order to efficaciously tackle NCDs epidemic in China.

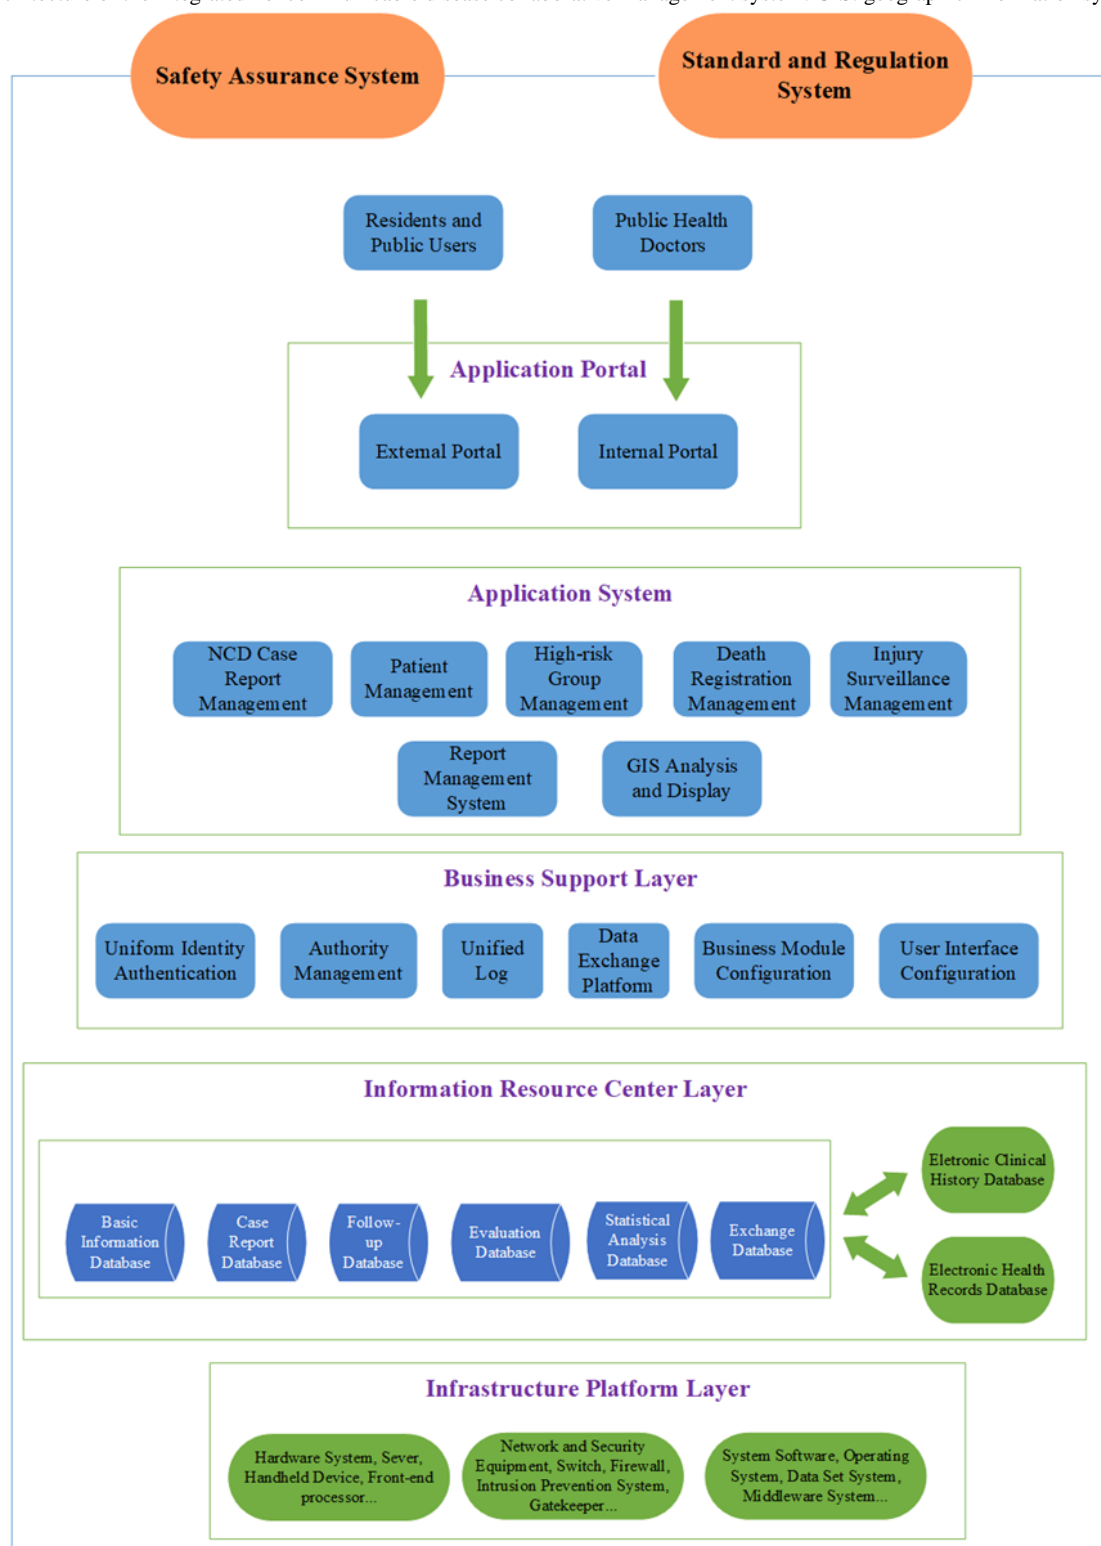

Methods

Ningbo Model

The Ningbo model was constructed through a 3-level direct reporting strategy based on the regional health information platform. The uniform data standards and interface specifications were developed to connect different platforms and conduct data exchanges. NCDs registration report and management standards were issued to clarify data quality evaluation indicators and data security management standards. 9 attributes of the surveillance system evaluation framework recommended by the US CDC were used for evaluating the performance of NCDCMS [16,17].

Architecture of the NCDCMS

With full consideration of the current situation of Ningbo and the potential requirements of system development, the SOA (service-oriented architecture) and ESB (enterprise service bus) technologies were used for building a multilayer architecture system based on the concept of integrated information system design. The architecture of NCDCMS is made up of 7 components: the infrastructure platform layer, the NCDs information resource center, the business support layer, the application system, the application portal, the safety assurance system, and the standard and regulation system. Figure 1 shows the architecture of the overall system.

Figure 1. Architecture of the integrated noncommunicable disease collaborative management system. GIS: geographic information system;

Process of Model Construction

To build an effective and reliable NCDs surveillance and management system, the NCDs 3-level direct reporting model was constructed by following these 4 aspects: (1) We completed the construction of the 3-level public health data exchange platform by connecting Ningbo Health Network (municipal level) with Zhejiang Provincial Health Network (province level) and County/District Health Network (county/district level).

Health Network is the special information network for health industry in China. On this basis, the Ningbo public health data exchange platform was organized to achieve the data exchange from the county/district platform to the municipal platform, and further to the provincial platform. (2) We developed uniform data standards and interface specifications. The interface specifications were used as regulations and standards to connect different platforms and conduct data collection, exchange, inquiry, and reconciliation. (3) To connect HIS with the data

exchange platform, all medical institutions were required to adjust their public health module in accordance with the uniform data standards and the interface specifications. After the adjustment, automatic popping up of report card, automatic extraction of patient information, and real-time data exchange among platforms can be achieved. (4) We finally issued the Ningbo NCDs Registration Report and Management Standards. It elaborated the standardized workflow and mechanisms for interdepartmental collaborations between different stakeholders. The indicators of data quality evaluation and data security management were also included and elaborated in detail in these standards.

Evaluations of the System Performance

Because NCDCMS is a public health surveillance system, its performance should be evaluated to ensure the public health

problems are being monitored efficiently and effectively. We evaluated the performance of the NCDCMS with the 9 surveillance system attributes based on the guidelines for evaluating public health surveillance systems developed by the US CDC: simplicity, flexibility, data quality, acceptability, sensitivity, predictive value positive, representativeness, timeliness, and stability [16]. As public health surveillance systems vary in objective, methods, purpose, and scope, attributes that are important in one system might be less important in another. Taking into account the purpose and characteristics of NCDCMS, we selected 6 attributes to evaluate the performance of NCDCMS. The definitions of these 6 attributes are presented in Table 1 [17].

Table 1. Definitions of surveillance system attributes.

Attributes	Definition
Simplicity	System's structure and ease of operation
Flexibility	Ability to adapt to changing information needs or technological operating conditions with little additional time, personnel, or allocated funds
Data quality	Completeness and validity of the data recorded in the system
Acceptability	Willingness of persons and organizations to participate in the system
Representativeness	Ability to accurately describe the occurrence of a health-related event over time and its distribution in the population by place and person
Timeliness	Speed between steps in a system

Ethical Considerations

Because the construction of NCDCMS is also a component of the Ningbo Smart City Project, it is a governmental initiative rather than a study. The ethical issues need to be addressed but could be different from general scientific studies. In the process of system construction, the protection of residents' personal privacy has been fully taken into account. Moreover, the regional health information platform of Ningbo is nationally certified and has reached the maturity level of IV, which is considered the highest level of regional information protection. Thus, it is legal and safe to collect residents' data through the system.

Ethics Approval

The study was approved by the Ethics Review Committee of Ningbo Municipal Centers for Disease Control and Prevention.

Availability of Data and Material

The data sets generated/analyzed during this study are not publicly available due to the protection of residents' personal privacy but are available from the corresponding author on reasonable request.

Results

Data Collection and Exchange

In NCDCMS, 4 types of notifiable NCDs (diabetes mellitus, ischemic heart disease and cardiac arrest, cerebrovascular disease, malignant neoplasms, and benign neoplasm of central nervous system) report cards are collected through a stepwise

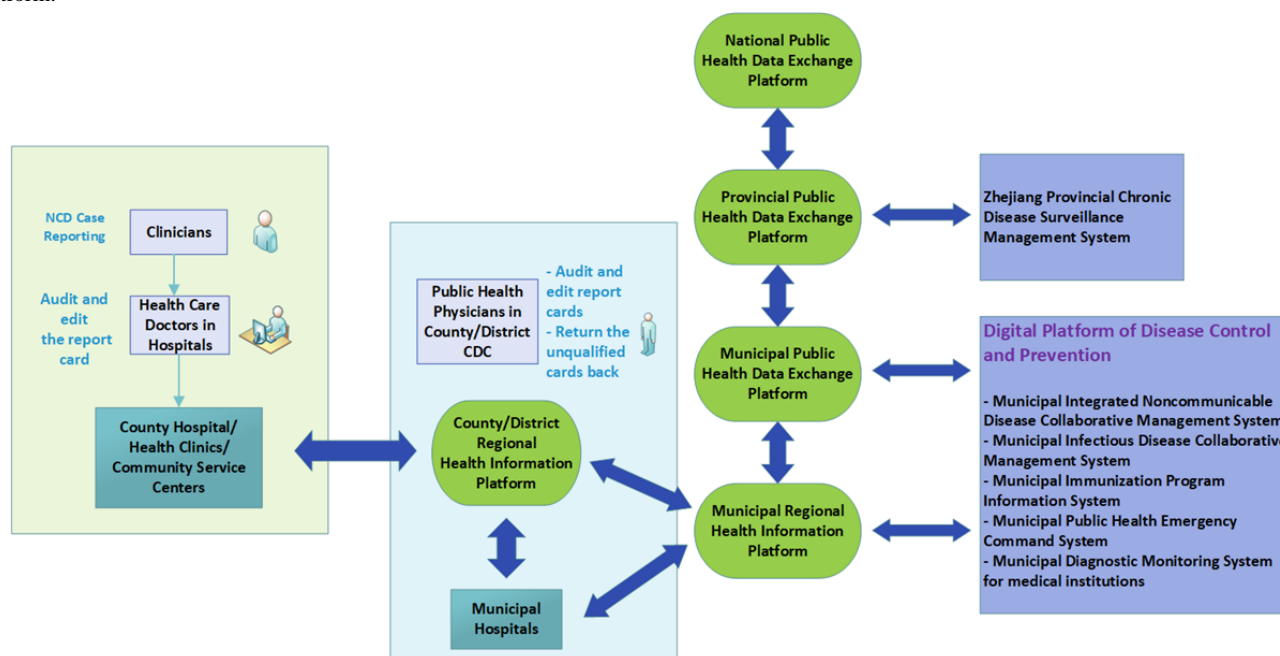

3-level public health data exchange platform. The types of NCDs and the corresponding ICD-10 codes are listed in Table 2. Besides, a vital registration system is integrated into NCDCMS, which is able to collect cause-of-death data accurately and efficiently, from which we can obtain insights into the underlying causes of death.

When a clinician diagnoses a notifiable chronic disease on his/her clinic system, a disease reporting card pops up automatically that presents data about that specific patient, which are extracted from the HIS or EHR. Clinicians only need to type in their diagnosis and treatment information to complete the whole report card, which takes only a few minutes. Health care doctors working in hospitals will then review the card to ensure the accuracy and logicity of the information. Besides, public health physicians who work in county/district CDC will double check the information afterward. If the content does not meet the standard requirements, the card will be returned to the health care doctors along with the feedback so as to be further edited. Once this has been done, the data will be transmitted to the regional health information platform immediately. Through a stepwise data exchange process, report cards will be transmitted to the Zhejiang Provincial Chronic Disease Surveillance Management System, and finally to the national system. Furthermore, these data will be exchanged with the Ningbo Digital Platform of Disease Control System and be shared across branch systems as shown in Figure 2. The process of data exchange and data sharing through a 3-level public health data exchange platform is presented in Figure 2. The data type collected on report card of notifiable NCDs is shown in Table

3. Data collected on regional health information platform include residents' personal information, demographic characteristics, outpatient information, hospitalization information, results of examinations and laboratory tests, prescription lists, and

immunization information. For municipal hospitals, the NCD cards reporting process is consistent with the reporting process of county hospital/health clinics/community service centers depicted in Figure 2.

Figure 2. The process of data exchange and data sharing through a 3-level (county, district, and municipal provincial level) public health data exchange platform.

Importantly, the purpose of building NCDCMS is not only to monitor the incidence of NCD but also to achieve better health management of patients with NCDs. Data exchange among platforms is not unidirectional, but rather a bidirectional data exchange process. When the NCD data are transmitted to the upper-level platform, cause of death and other branch surveillance system data (eg, infectious diseases, immunization records) of that particular patient will eventually be integrated into the EHR and transmitted back to the county/district regional information platform in order to achieve a two-way data

exchange based on the principle of 1 person 1 file. Even if the NCD card is reported outside the place of residence, as long as it is reported within the Zhejiang Province, it will be returned to the place of residence following a bidirectional data exchange process.

Based on the stepwise 3-level public health data exchange platform, routine monitoring of 4 types of notifiable NCDs can be achieved on NCDCMS. Tables and charts can be automatically generated from surveillance data to track changes as needed.

Evaluations of System Performance

Simplicity

Previously, during the data reporting process, clinicians first filled in NCD cards (either paper card or electronic card in HIS),

and then health care doctors in hospitals manually entered the data into the Zhejiang Provincial Chronic Disease Surveillance Management System. Clinicians using electronic cards reported each patient information variable one by one (ie, on separate fields) into the HIS. It is well-known that manual data entry

consumes a huge amount of human resources. Therefore, the NCDCMS was developed to offset the inefficiency of manual entries. Now, in the current system, when a clinician diagnoses a notifiable chronic disease on his/her clinic system, an NCD reporting card pops up automatically that presents much of the data about that specific patient, which are extracted from the HIS or EHR. Clinicians only need to type in their diagnosis and treatment information to complete the whole report card, which takes only a few minutes. Public health doctors in hospitals do not need to manually enter the reporting data in the surveillance system; instead, they only need to audit the report card and click the upload button, which transmits the data to the regional health information platform.

Meanwhile, because the NCDCMS realized the data collection process through a stepwise 3-level public health data exchange platform, which combined various independent platforms into one interconnected model, once a case has been reported, the data can be used in multiple ways and serve a variety of purposes. The data need to be reported by the clinicians only once and after the process is completed, the reported data can be transmitted directly to each platform in real time. This allows to eliminate duplicate entries.

Flexibility

To connect HIS with the data exchange platform, all medical institutions were required to adjust their public health module in HIS in accordance with the uniform data standards and the interface specifications; importantly, this adjustment is neither time consuming nor costly. In addition, the establishment of NCDCMS has a solid preliminary informatization foundation: (1) Ningbo is a city with a high level of informatization. (2) The 3-level direct reporting of notifiable infectious diseases by the 3-level public health data exchange platform was successfully achieved in 2016. (3) The key component of the system was structured by one company, which also increased the feasibility of the system to adapt to various requirements afterward. Because the adjustment of the public health module in HIS is neither time-consuming nor costly, with the solid informatization foundation of the whole city, the flexibility of the system can be guaranteed.

Data Quality

The quality of data collected by NCDCMS can be guaranteed in the following 4 aspects: (1) Each level of platform has a built-in logic check system and each type of NCD report card has several required items to be filled in. If the required items are not filled in completely or the contents of the report data do not meet the requirements of logical check, the report card information cannot be uploaded to the upper-level platform. (2) As mentioned above, a multilevel audit for all data reported will allow the data entered to be reviewed by health care doctors and public health physicians, which further ensures the accuracy of the collected data. (3) As the data platforms are directly related to each other, patient's EHR file can be accessed during the case review process. In this way, data errors made by clinicians can be detected on time and accuracy of the data can be improved. (4) We perform data cleaning regularly and issue data analysis reports on a monthly, quarterly, and yearly basis to ensure that data quality meets the requirements. In addition,

to ensure the authenticity of the reported data and have a continuous understanding of patients' health status, a first visit within 1 month of data entry and a yearly follow-up of each NCD patient are conducted.

Acceptability

In the initial stages of the system construction, we selected 2 counties and 1 municipal-level hospital for model pilot tests. These early trials provided us with a great deal of experience in system construction. One year after the completion of the pilot tests, the system was gradually promoted and expanded to the whole city. This progressive approach of system construction also increased the acceptability of NCDCMS.

The construction of NCDCMS was government managed. The Health Commission of Ningbo explicitly demands every medical institution in Ningbo to complete the public health module adjustment to achieve the 3-level direct reporting of notifiable NCD diseases. Meanwhile, the completion of adjustment was considered as an indicator in the annual performance assessment of medical institutions. Therefore, China's national conditions determine that this model can be widely accepted among medical institutions of Ningbo. At the time of this writing, among the 205 medical institutions that are required to report notifiable chronic diseases in Ningbo, 201 have completed the module adjustment, with the completion rate of 98.1% (201/205).

Representativeness

NCDCMS is totally based on the case reporting of medical institutions and has a facility coverage rate of 98.1% (201/205), meaning that as long as patients with NCDs visit medical institutions, either in hospital or in community, they will be reported by clinicians. Therefore, the NCD cases we collected via NCDCMS can reflect the actual situation of the whole population in Ningbo over time. In addition, based on the data collected by the system, the occurrence of 4 types of notifiable NCDs over time and their distribution in the population by place and person could be accurately described. Because of the continuous monitoring, the incidence trend of NCDs could be displayed and compared.

In addition to the NCDs data collected from NCDCMS, with the patient's identity card number as a unique data matching criterion, more information can be drawn from other sources such as HIS and HER, which allows to build a more comprehensive database at the back end. Technically, from this comprehensive database, each patient's data including his/her personal information, demographic characteristics, hospitalization information, results of examinations and tests, prescriptions, and survival situations could be obtained. Furthermore, branch surveillance systems are linked by the Ningbo Digital Platform of Disease Control and Prevention, and hence the data from these branch systems can also be shared and used for multiple purposes. From this perspective, using the data collected from Ningbo NCDCMS, the priorities of public health issues can be identified and the burden of disease can be measured in an accurate and convenient approach.

Timeliness

In the past, if a clinician reported an NCD card, irrespective of whether using a paper card or an electronic card, health care doctors working in hospitals had to manually enter report data variable one by one (ie, separately on each field) into the provincial chronic disease surveillance management system within 7 days. Although these cards are not immediately audited by county/district CDC staff, according to the registration and validation procedure established by provincial CDC, the staff are required to audit these cards within 7 days after data entry. Thus, this process, from initial data reporting on cards to the final completion of review, usually took several days, with a maximum duration of up to 14 days. However, because of escalating burden of NCDs in China, this procedure consumed a great deal of human resources, time, and costs.

Following the implementation of the new model, health care doctors' working hours have been greatly reduced because of the removal of duplicate entries. Thus, more of their working time could be devoted to controlling the overall quality of the report card and training and improving the clinicians' reporting skills. Thanks to the automatic popping up of the report card and information extraction approach, clinicians could fill in the report card when patients visit their clinic, or during the patient's hospitalization, allowing simpler and faster completion. In addition, with the great improvement in the overall effectiveness of the new model, staff members from district/county CDC will review report cards on a daily basis. This new process greatly reduces the total time from reporting to reviewing of NCD cards, from the previous maximum of 14 days to the current minimum of 1 day. Compared with the past, the average card entry time is reduced from 10 minutes to 1 minute. Besides, the time taken for clinicians to enter relevant data at first visit and follow-up is reduced from 15 minutes to less than 1 minute, respectively. Excluding the time taken for manual auditing and reviewing, data are exchanged in real time between different platforms.

Data Utilization

Using the data collected from NCDCMS and EHR, one study was conducted to describe the epidemiological characteristics of patients with diabetes mellitus (DM) diagnosed with oculopathy in one district in Ningbo. The diagnosed DM cases generated from NCDCMS were matched with the oculopathy cases generated from the regional health information platform by ID number and EHR number. The results showed that 1819 patients with DM were diagnosed with oculopathy in 2015. Among them, 195 patients with DM were newly diagnosed. The oculopathy comorbidity rate of the patients with DM and those newly diagnosed with DM in 2015 were 12.78% and 19.25%, respectively. The time intervals of patients with type 1 DM and type 2 DM from being diagnosed with diabetes to comorbidity of oculopathy was 4.00 and 3.00 years, respectively [18]. By linking diabetes cases and cancer cases generated from NCDCMS, one study implied that the patients with newly diagnosed type 2 DM, who were taller and had normal BMI, had a higher risk of cancer. Compared with their overweight (standardized incidence ratio 0.62) or obese (standardized incidence ratio 0.35) counterparts, the all-cause standardized incidence ratios of the normal BMI group was 1.13. Patients

with normal BMI had a high risk of liver, pancreatic, esophagus, and ovary cancers [19].

Instead of field surveys, which consumed a large amount of human resource for data collection and analysis, the ecological studies and pilot epidemiological studies can be conducted directly through this 3-level public health data exchange platform. Moreover, we have started collecting NCD surveillance data since 2009 and each NCD case is required to be followed up once per year. These data will therefore contribute to carrying out different kinds of population-based cohort studies. Different variables needed for building cohorts can be obtained from multiple sources as mentioned earlier. Meanwhile, the information on all-cause mortality is also being collected, meaning that we can obtain data on the reliable survival situation of each patient with NCD. In one district of Ningbo, a cohort based on regional health information platform has been built to predict the risk factors of cardiovascular diseases [20]. Thus, big data tools can be applied for analyzing different data collected from the 3-level exchange platforms, with the results likely to be useful for decision making on various policies and strategies related to NCDs prevention and treatments.

Discussion

To the best of our knowledge, NCDCMS is the first platform in China that achieved the 3-level direct reporting model based on regional health information platform. NCDCMS currently covers 201 medical institutions throughout the city, including municipal hospitals, county hospital, health clinics, and community service centers. The evaluations of the system performance showed that NCDCMS has high levels of simplicity, data quality, acceptability, representativeness, and timeliness. This 3-level direct reporting model helps relieve the burden of case reporting, as it allows real-time reporting, eliminates unnecessary redundancies, reduces the amount of underreporting, and provides a better database of chronic diseases.

The Ningbo Model is an innovative practice that aimed to develop a reliable population-based surveillance system via a real-time bidirectional 3-level data exchange process. It completely reshaped the traditional process of NCD surveillance data reporting and had three unique advantages: (1) It reduces the work burden of different stakeholders by data sharing and exchange. Previously, NCD reporting was completely dependent on manual data entry, which cannot guarantee the accuracy and was time-consuming. Now, clinicians could complete the case reporting during patient's visit; thus, both the patient's visit time and the work burden of clinicians are reduced due to the reduction of duplicated entries and repeated inquiries. Besides, the workload of health care doctors who were responsible for checking the report card submitted by clinicians is reduced. (2) The amount of underreporting was greatly reduced through the automatic popping up of the report card. Some hospitals also link NCD reports with the discharge summary submission procedure. If the NCD cases are not reported as required, clinicians cannot eventually transfer the medical records of discharged patients to the medical record room. (3) The system

contains better databases that allow data sharing among different platforms. A fairly complete personal health file can be obtained at the back end by linking different sources mentioned above. On this basis, the follow-up data, mortality data, and EHR data can be built into different kinds of NCD cohorts and the risk prediction models can be established. Different types of risk factors can be addressed and evidence-based interventions can also be performed. These research results can help policy makers to make decisions in an evidence-based way.

In the 2 years of NCDCMS construction, one difficulty was how to convince all medical institutions to use the uniform data standards and interface specifications. Because different medical institutions used different HISs developed by various companies, coordination among multiple stakeholders was initially expected to be difficult. In this aspect, the Health Commission of Ningbo and Ningbo CDC played important roles in facilitating the construction of the whole model. However, in order to obtain more accurate and reliable databases, a great amount of effort was still needed. Although we had the assistance of computer technology that helped avoid most logic mistakes in case reporting, a standardized training for case reporting was still important, especially for the clinicians who just started to use the system. The rapid development of health informatization also increased the need to establish better requirements for data security. Although the issue of underreporting has been greatly decreased, this situation could be reduced further with the progress of system development.

Considering the high level of health informatization in Ningbo, it seems that this model might be difficult to replicate in the provinces and cities with low level of health informatization. However, based on China's current national conditions, there is an irresistible trend for improving informatization level in health industries nationwide, thus the feasibility of promoting and implementing this model nationwide is still achievable. After the completion of NCDCMS in 2018, the average number of visitors from the Health Commission and the CDCs located at different provinces and cities throughout the country was about 100 per year (as per data from Ningbo CDC), which also proved the enthusiasm for building health information platforms nationwide. At the time of writing, NCDCMS has been promoted and implemented in 5 cities in Zhejiang Province.

Driven by the development of health informatization in China, the Ningbo Model created a win-win situation for all stakeholders. Moreover, it actually enabled the possibility of performing population-based research with few human and material resources and helped achieve better data accessibility and utilization. The model has high replicability and generalizability in terms of standard establishment, workload reduction, elimination of underreporting, and improvement of data sharing and utilization. In China, it will guide the construction and establishment of systems for NCDs surveillance and management system in the future.

Acknowledgments

This study was supported by the National Key R&D Program of China (Grant Nos 2017YFC1310902 and 2018YFC1315305), National Natural Science Foundation of China (Grant No. 81872721), and Ningbo Health Branding Subject Fund (Grant No. PPXK2018-10). The authors thank all staff working in the noncommunicable disease surveillance department at the 10 county/district CDCs, general hospitals, community health service centers, and township hospitals for their hard work and assistance in collecting and revising surveillance data. We also thank all participants who contributed to build the Ningbo Model.

Authors' Contributions

SiL and HL were responsible for drafting and writing the manuscript, designing the functions of NCDCMS, and coordinating different stakeholders during the construction of the model. LZ was responsible for building the architecture of NCDCMS and data security. ShL and RH were responsible for literature collection and manuscript revision. SiL and LZ contributed equally to this work.

Abstract

Background: Despite extensive literature describing the use of social media in health research, a gap exists around best practices in establishing, implementing, and evaluating an effective social media knowledge translation (KT) and exchange strategies.

Objective: This study aims to examine successes, challenges, and lessons learned from using social media within health research and to create practical considerations to guide other researchers.

Methods: The Knowledge Translation Platform of the Alberta Strategy for Patient-Oriented Research SUPPORT Unit formed a national working group involving platform staff, academics, and a parent representative with experience using social media for health research. We collected and analyzed 4 case studies that used a variety of social media platforms and evaluation methods. The case studies covered a spectrum of initiatives from participant recruitment and data collection to dissemination, engagement, and evaluation. Methods and findings from each case study as well as barriers and facilitators encountered were summarized. Through iterative discussions, we converged on recommendations and considerations for health researchers planning to use social media for KT.

Results: We provide recommendations for elements to consider when developing a social media KT strategy: (1) set a clear goal and identify a theory, framework, or model that aligns with the project goals and objectives; (2) understand the intended audience (use social network mapping to learn what platforms and social influences are available); (3) choose a platform or platforms that meet the needs of the intended audience and align well with the research team's capabilities (can you tap into an existing network, and what mode of communication does it support?); (4) tailor messages to meet user needs and platform requirements (eg, plain language and word restrictions); (5) consider timing, frequency, and duration of messaging as well as the nature of interactions (ie, social filtering and negotiated awareness); (6) ensure adequate resources and personnel are available (eg, content creators, project coordinators, communications experts, and audience stakeholder or patient advocate); (7) develop

an evaluation plan a priori driven by goals and types of data available (ie, quantitative and qualitative); and (8) consider ethical approvals needed (driven by evaluation and type of data collection).

Conclusions: In the absence of a comprehensive framework to guide health researchers using social media for KT, we provide several key considerations. Future research will help validate the proposed components and create a body of evidence around best practices for using and evaluating social media as part of a KT strategy

KEYWORDS

social media; knowledge translation; health research; engagement; dissemination; exchange; evaluation

Introduction

Background

The concept of social media has been constantly evolving alongside advances in technology and the development and abandonment of various platforms. Social media has now become an integral means for sharing information while engaging and interacting with others across all sectors of society [1,2]. Subsequently, engaging with anyone, anywhere, at any time has presented opportunities for people, businesses, nonprofit organizations, and health care organizations to engage with a wide audience [3,4]. Social media have changed people's relationships with how they find and use information. Health care consumers (ie, members of the public) can now use web-based platforms to search for health information, seek others' experiences and opinions, create their own interest and advocacy groups to raise awareness, fundraise, and share information among like-minded communities. Similarly, health researchers have started to capitalize on social media for a number of purposes, from patient engagement to research dissemination and exchange, with countless applications in between [5-7]. Evidence suggests that health researchers largely hold favorable views with respect to the use of social media in a professional capacity [8,9], considering it to provide an engaging and convenient source of information [10], while meeting their need to gain and exchange knowledge with relevant stakeholders [6]. Despite the enthusiasm, there remains a gap around best practices in developing and implementing social media as part of a successful knowledge translation (KT) strategy.

Knowledge Translation Theories and Social Media Models

Many KT strategies (often guided by theories, models, or frameworks) require that the goals, audience, and messaging be carefully considered to ensure success. However, there is no current KT theory, model, or framework that addresses what makes a successful *social media* KT strategy. The unique requirements that social media has around the what (materials and procedures needed), who (provider), and how (mode of delivery and platform and to whom) are quite nuanced. Likewise, current social networking theories and models do not adequately address all facets of dissemination, exchange, and application of knowledge needed to develop (and evaluate) a KT strategy [2,11-13].

Integrated KT models emphasize that translation of knowledge is expedited when knowledge producers (eg, researchers and

scientists) and knowledge users (eg, patients, caregivers, and policy makers) are known to one another and are familiar with one another's needs, preferences, and circumstances [14,15]. Pick et al [16] conceptualized the 4 Cs of social media in an attempt to describe how social media is used, proposing that *content* is developed within a given *context*, to make *connections* leading to *conversations*. However, the ability of social media users to successfully share, mobilize, and cocreate knowledge still needs to be understood.

Connecting the Dots: Social Media and Knowledge Translation

We propose that to facilitate effective use of social media as part of a KT strategy, researchers need to know how to reach and engage their target audience through social media, with the information the research teams want to share. Likewise, considerations around what stakeholders want to hear and learn need to be incorporated. There are 3 components of social media that can be classified as explanatory and predictive, which could help guide this [17]:

1. Posting frequency, which means how often a user (person, group, or enterprise) circulates content, asks for input, or responds to a comment or request, without respect to any other factor, that is, quality, depth of detail (whether a post is a simple headline or a detailed infographic), and kind of post (response to another user, announcement of an event or a resource, or key findings of a study) [17-19].
2. Whether and to what degree the user can affect or create a sense of awareness (or negotiated awareness) of who they are, their purpose, their location, the character of their expertise or experience, and the precise services or information they have on hand for their intended audience [17].
3. Whether and to what degree the user allows or affords other users to select effectively within their content and to find what they need to find and whether and to what degree the selection activity is used by the user as grounds to optimize or refine their offerings (social filtering) [20].

To date, no KT or social media framework incorporates these explanatory and predictive components. In the absence of a suitable framework, we draw on 4 case studies using social media for engagement and dissemination of health research. We summarize the successes, challenges, and lessons learned and present recommendations for others considering social media as part of a KT strategy.

Methods

General Approach

In 2016, the Alberta Strategy for Patient-Oriented Research (SPOR) SUPPORT Unit's Knowledge Translation Platform hosted a national meeting (which included a number of KT and communication experts, platform staff, and consumers) to explore the potential linkage between social media and KT research. Subsequently, a national working group was formed of representatives (n=12) from academia (ie, faculty and research staff) and community (ie, knowledge brokers and parent representative), all with experience using social media as part of a KT strategy for health research. The working group defined the approach to the topic and scope of the project. The goal was to create a document that compared researchers' experiences and provided considerations to guide other researchers wanting to utilize social media as part of a KT strategy. The working group met monthly over the course of a year (November 2017 to November 2018), collectively identified possible case studies for inclusion based on pre-established inclusion criteria (described below), and developed data collection forms for extracting key findings. Once data from each case study were collected and summarized, deliberative dialogue [21] was used to draw out important concepts and points to consider for discussion. Working group members were then responsible for creating considerations for other researchers through iterative discussions. All working group members were invited to help draft the final report and be part of the authors' team.

Social Media Case Studies

The aim was to collect case studies of social media use in health research that covered a spectrum of KT initiatives as well as a mix of social media platforms and evaluation methods. Case studies had to be focused on child health, include an evaluation component, and have been published in the past 5 years. The working group (n=12) first looked internally to gather case studies and evaluated the collective breadth of experience using social media for KT activities. An invitation was then extended to other research groups to supplement the working group's experiences. Researchers providing case studies were also invited to be part of the working group and authors' team. Four case studies were selected by the working group for inclusion.

The authors of the case studies were then asked to provide information and data about the project in a pre-established data collection form. The data collection form gathered information about the case study's topic and objectives, intended audience, project logistics (eg, social media platform(s) used, staffing requirements, and project timeline), use of any predictive or explanatory factors such as posting frequency, negotiated awareness and social filtering, dimensions of communication used ([Multimedia Appendix 1](#)), evaluation methods (including outcomes and metrics), key findings, and self-reported lessons learned (ie, successes and challenges). To ensure validity and reliability of the data collected from the case studies, collated and summarized data were presented to case study authors for review.

Group Discussions and Development of Considerations

Once data were collected, a summary document that highlighted the similarities and differences between the case studies was created. Self-reported barriers and facilitators to KT encountered when using social media were also collated. Barriers and facilitators were coded into categories based on what part of the KT strategy they impacted (eg, planning, doing, and evaluating). These categories were then broken down into specific elements that formed part of each category (eg, planning—personnel and resource requirements, platform used, and scope of messaging). This prompted focused discussions on the overall key successes and challenges. Working from the summary tables and coded elements, deliberative dialogue [21] (facilitated by SE) was used to draw out important concepts and points to consider for discussion. Through an iterative discussion process, the working group converged on considerations for researchers planning to use social media for KT, guided by the explanatory and predictive components of social media.

Results

Summary of Case Studies

The 4 case studies are summarized in [Table 1](#). More details are presented in [Multimedia Appendix 2](#).

Here, we synthesize the common case study elements (processes of implementing the social media KT strategies) with regard to lessons learned and challenges faced.

Table 1. Case study summaries.

Case study	Objective	Intended audience	Platform	Dimensions of communication ^a	Time frame and intensity (posting frequency)	Social filtering	Negotiated awareness	Staffing requirements	Evaluation
Cochrane Child Health [7]	Dissemination	Child health HCP ^b , child health researchers, and health care organizations	Twitter and blog	Asynchronous, one to many, dynamic, pull, remote, and iconic indexical	6 months, weekly blog posts, daily tweets, monthly journal club on Twitter	Influencers were tagged in tweets; hashtags were used to identify conditions under discussion	Content shared by influencers tagged and research group stakeholders	0.2 FTE ^c RC ^d , 0.2 FTE, information specialist, and 0.3 FTE graduate student or RA ^e	Twitter analytics, Bitly statistics, Altmetric scores, journal club, and participant survey feedback
#ItDoesntHaveToHurt [22]	Dissemination and engagement	Parents (primarily mothers)	Blog, Twitter, Facebook, Instagram, YouTube, and stakeholder websites	Asynchronous, one to many, dynamic, remote, recorded, focal, push, durable, phonetic syllabic, and iconic indexical	12 months, varied with approximately 3 posts per month plus amplification and sharing	Content appeared on partner website and social media with a well-established community of parents, influencer promotion and engagement (parent bloggers across the country amplified content using their own social channels), hashtag use #ItDoesntHaveToHurt	Content shared by influencers, stakeholders, research groups' social media channels, and research partners' social media channels	0.75 FTE RC, 0.2 FTE, stakeholder PC ^f , and digital content creators, as needed	Web-based analytics, pre- and postsurveys and interviews, social listening and sentiment analysis, media analysis, partnership analysis, and patient engagement evaluation
Hirschsprung's Disease Community [23]	Engagement (with caregivers to identify knowledge gaps) and knowledge exchange	Caregivers of children with Hirschsprung disease	Twitter, Facebook, and blog	Asynchronous, many to one, dynamic, and remote	1-month, daily interaction from parent-led administrative team, weekly posting and reminders during research	Community was pre-established	Posts and messages were from the administrator of an established community; the community has a clear focus, consistent posting, and committed membership	0.5 FTE RA, parent partner (ongoing community management), and communication staff (ongoing community management)	Google analytics and number of surveys completed
Parents Participating in Research Facebook Group [24]	Knowledge exchange and dialogue	Parents and caregivers of special needs children and child health researchers	Facebook	Asynchronous, many to many, and synchronous	9 months, varied with approximately 4 posts per week	Parent moderators direct messaged or tagged topics to parents and research contributors with possible perspectives to add to the discussion	Content shared by moderators, parent and caregivers, or researchers	2 parent moderators—approximately 0.4–0.7 FTE; KT ^g committee and parent moderator liaison—approximately 0.5 FTE	Analytics of engagement and activity (eg, number of posts and number of comments) and web-based survey of members

^gKT: knowledge translation.

Planning

It was unanimous that advanced planning was a key component to a successful social media KT strategy. Furthermore, a prior understanding of what theory, model, or framework best suited the goal of the KT strategy was helpful in planning the different approaches. The *Cochrane Child Health* strategy focused on disseminating information. As knowledge producers, they planned and implemented approaches to push (disseminate) knowledge toward audiences who they believed could benefit from receiving it (health care providers and researchers). The *Hirschsprung's Disease Community* and *#ItDoesntHaveToHurt* employed strategies to build upon pre-established web communities. They leveraged partnerships to foster engagement and expedite information exchange with their intended audience (parents). The *Hirschsprung's Disease Community*, *#ItDoesntHaveToHurt*, and *Parents Participating in Research Facebook Group* initiatives planned and implemented strategies to gather knowledge from sources (parents and caregivers) they identified as producing knowledge that was useful to their decision making and research agenda (priority setting and knowledge gaps). Additionally, to further build their communities, they planned to engage with their users through an interactive process (exchanging information through discussion boards, question and answer sessions, survey responses, and feedback sessions).

It was also noted that case studies focusing on a specific topic or disease led to engaging a more saturated audience. One case study reported that it was difficult to tap into any specific existing audience when posting about diverse clinical topics, whereas others that had a more focused topic (that meshed well with the focus of the pre-existing group) felt that a tighter community was developed, which enhanced information sharing.

Planning for the required staff and resources to successfully implement and maintain the KT strategy, including frequent posts and audience interactions, was challenging. The time frame from the case studies ranged from 1 month to 1 year. Case study authors reported not knowing how long a strategy needed to be for it to be effective. The main driver for the length of a strategy was the availability of financial and human resources support.

Many case studies made use of programs to help manage their social media campaigns. Tools such as Buffer (Buffer Inc, 2010) were used to preschedule tweets (the bulk of the campaigns), allowing for monitoring and interactions to be completed throughout the campaign. To keep track of this, the case studies used tools such as TweetDeck (Twitter, 2008) or Hootsuite (Hootsuite Inc, 2008), which provided a user-friendly interface to track and monitor the account, as well as log interaction notifications and collect analytics.

Doing

Platforms, Models of Communication, and Posting Frequency

A variety of different platforms were utilized among the case studies to increase reach and engagement. Three of the case studies used a multiplatform approach in which Twitter, Facebook, Instagram, and blogs were used to cross-post information and engage with multiple audiences across an expansive social network. Cochrane Child Health, whose target audience was health care providers, researchers, and organizations, focused on using Twitter and blog posts and hosting web-based journal clubs. Case studies targeting parents and caregivers, however, tended to use Facebook, YouTube, and Instagram in addition to Twitter. This was a strategic element, based on prior work to understand who their audiences were and where they gathered on the web. It was also noted that having an established platform or network (eg, Cochrane Child Health had >3500 followers at the time of the campaign) was easier than building a network from scratch for a specific campaign. Those that had a pre-established web presence or leveraged partners with such a pre-established presence reported greater interactions and reach.

A common element throughout the case studies was the dimension of communication, with all using an asynchronous approach in which messages were exchanged intermittently rather than in a steady stream. The intensity of communication varied greatly from daily to weekly between and within each case study. Across all case studies, we found that engaging the intended audience through specific posts, rather than constantly passively pushing information, amplified the sharing of information between users. However, it was noted that there was more web-based interaction overall with more frequent posts. Posting frequency was also dictated by platform use. On a platform in which information exchange occurs rapidly in real time (eg, Twitter), it was found to be important to post quite frequently; otherwise, users tended to disengage. On other platforms such as Facebook, 1 case study received feedback from their audience, suggesting that the ability for members to be able to read and contribute at any time (day or night) was what kept them engaged. Allowing users to contribute to ongoing community conversations enhanced engagement and exchange practices.

Negotiated Awareness, Social Filtering, and Content Development

Negotiated awareness and social filtering were valued by all case studies for their ability to expand the reach (numerically and geographically) of the KT strategy. Two case studies (*Cochrane Child Health* and *#ItDoesntHaveToHurt*) used specific social filtering techniques, utilizing social media influencers and hashtags to categorize messages, leading individuals to conversations and discussions pertaining to a

specific topic or theme. These techniques also helped researchers tap into existing networks that amplified sharing by engaging partners and audiences through their own social media networks and interests.

One case study highlighted that the use of an expert media partner who could create compelling digital content and who already had an established reach ensured that content creation was done more efficiently and effectively than traditional academic-led dissemination campaigns. For other case studies, developing content was often time- and resource-intensive, and there was often a trade-off between effort and return. All case study leads agreed that having a team member or partner who specialized in digital content creation is likely an important element of a successful campaign (audience engagement and resource development).

Stakeholder Engagement

The case studies in which patient or parent partners co-designed and facilitated the strategies had an extended reach and higher level of engagement from the web community than the ones in which information was just pushed out by researchers. Capitalizing on a recognized and established network, community, or partnership enabled efficient and effective content creation and sharing.

The *Hirschsprung's Disease Community* and *Parents Participating in Research Facebook Group* projects highlight that working with someone from the campaign's intended audience (eg, parent and clinician) leads to relevant content being produced, developed, and created with that specific audience in mind.

Collaborating with a parent moderator who had credibility within the parent and caregiver community and who understood the needs of the researchers and the overall purpose of the collaborative helped nurture the interconnectedness between members of those web-based communities. It was proposed that having a moderator or stakeholder known within the community added to the perceived credibility of the campaign. Additionally, peer mediation was found to be a facilitating factor in the exposure and diffusion of information on the web. The *Parents Participating in Research Facebook Group* project found a shift in emphasis from its primary goal of creating an advisory group for the researchers to being an active group of knowledge exchange for parents (ie, asking questions, deciphering the research, and providing peer support). Parents reported feeling a sense of belongingness to the community where they could safely share stories, ask questions, and provide support for other members. This provided the researchers with a deeper understanding of what issues were most important to the daily lives of families, a unique insight that might not have come to fruition if the researchers were guiding the discourse.

Resource Requirements

Project teams and personnel needs varied across the case studies. Resources, types of skills, and tasks also varied within and between campaigns. Regardless of the campaign length, all projects required at least the equivalent of one full-time position. All case studies employed a research coordinator. Digital content creators, information specialists, students, or parent partners

were also involved depending on the specific nature of the project.

Evaluating

All case studies used various analytics (ie, Twitonomy, Facebook, Bitly, and Altmetric scores) to assess reach and engagement and understand how different facets of the strategies performed. A common evaluation component was web analytics to evaluate engagement (eg, likes, shares, and retweets) and uptake or use (eg, publication downloads and surveys completed) of information. However, not all web analytic programs were created equal. For example, harnessing accurate Facebook analytics with a private Facebook community was challenging because of privacy settings. Additionally, metrics such as Altmetric scores did not allow for the isolation of the study-specific impact and were time dependent (ie, older publications had more time to accumulate higher scores). The variability in the range of reporting periods for these statistics also influenced the usefulness of their collection, with availability ranging from a period of 30 days to all time. This was found to be a limiting factor when information was posted weekly or daily, making assessment of the impact of each post difficult.

A multimodal methodological approach (multiple qualitative and quantitative data collection) used by *#ItDoesntHaveToHurt*, *Hirschsprung's Disease Community*, and the *Parents Participating in Research Facebook Group* helped evaluate less tangible aspects, such as passive involvement or interactions between community members or a shift from research teams pushing information out to audiences facilitating pull. However, it was felt that there was often a trade-off between scientific rigor (ensuring appropriate methods and analytics were used) and being able to adequately evaluate and report impact (more broadly than number of citations, downloads, etc). Case study authors noted that researchers need to understand that social media KT success is not an easily quantifiable measure and that unconventional methods of evaluating success may be needed.

A common challenge was the inability to assess and gain an understanding of passive involvement and attribute knowledge sharing to behavior change and its impact on health and health system outcomes. The main goals of most KT strategies were increasing awareness, knowledge, and uptake of evidence. Although analytics can provide details on proxy indicators (ie, reach, usefulness, use, and collaboration), the ability to assess more distal health outcomes was limited and perhaps unrealistic in these case studies.

Ethics Considerations

The constraints placed by needing ethics approval to evaluate and capture participant behavior as well as to vet media posts (in some cases) was seen as a major challenge. One case study needed to have ethics approval for each social media post, which hindered their timeliness of engaging with the group on the web and highlighted a number of points for consideration. These include the value of spontaneous and organic conversation or the trade-off between not sharing information and the concern of providing health care advice rather than information to participants.

It was also noted that the need for ethics approval and informed participant consent was dictated by the outcomes evaluated. For example, the *Parents Participating in Research Facebook Group* set up rules of engagement that participants had to agree to before joining the community. However, to harvest the ideas and concerns of the group posted to the page to help other researchers know what was important to families, informed consent would have been needed. It felt that this may have stifled conversation, posing the following question: does the discourse of the web-based conversation change when participants are aware of ongoing monitoring and evaluation?

Recommendations and Considerations

From these collective experiences, we put forward recommendations and points to consider when using social media as part of a KT strategy for health research. As with any KT initiative, key areas include clearly defining the purpose (ie, engagement, dissemination, and exchange or dialogue), goals, intended audience, type and volume of resources needed, project scope, study design, and evaluation. In addition, we encourage researchers to carefully consider the 3 explanatory and predictive components of social media (ie, posting frequency, social filtering, and negotiated awareness) when developing an approach and choosing a platform.

The checklist for researchers has been provided in [Table 2](#).

Table 2. Checklist for researchers: what to ask and consider when developing a social media knowledge translation strategy.

Phase	Probing questions	Considerations
Planning		
Purpose and goal		
	What is the purpose of using SM ^a for this KT ^b strategy?	Are you wanting to engage, disseminate, or create a dialogue?
	What are the objectives of the campaign?	Identify a theory, framework, or model that aligns with the project's purpose ^c (eg, dissemination), objectives (eg, increase knowledge vs behavior change), and topic area (eg, health, sociology, and psychology)
	N/A ^d	The scope of messages (ie, one clear message repeated over time in different formats or messages on multiple topics)
	N/A	Create evaluation framework in planning phase
	What will success look like?	What metrics for quantitative data will you collect and when (eg, at what point, how often, and for how long)?
	How are you going to measure success?	Do you need qualitative evaluations?
Intended audience		
	Who is the intended audience?	Conduct formal or informal research to help answer these questions
	What are the characteristics of the intended audience?	Conduct a social networking map of the intended audience
	What SM platforms do they use? How do they interact on the web?	Involve some from the intended audience in planning (concepts of integrated KT)
	How do they like to receive information?	This may differ for each end-user group
Duration and intensity		
	How long will the campaign run?	What resources do you have available?
	How many posts a day or week or month?	This will be dependent on what platforms you use and your intended duration of interactivity
	Can you incorporate social filtering?	What hashtags are currently used for your topic area, and is there already a presence on the web?
Doing		
Platform and messaging		
	What resonates with the intended audience?	Depending on resources and team expertise, you may use one or multiple platforms
	Are they already gathered in an SM community or are you creating a new presence or community?	Invest in a SM management tool (eg, Hootsuite, Buffer, and Twitonomy)
	What will work best for the campaign's purpose?	Tailor strategy to ensure compatibility with each platform used
	How will messages be structured and delivered (scope, format, plain language, figures, pictures, etc)?	Ensure messages are tailored to target audience needs
	Are you incorporating social filtering or negotiated awareness techniques?	Map out who the influencers are that you want to reach
	Have you reached out to stakeholders? Do you have a campaign champion (preferably a peer of the target group)?	Find someone who will act as a community or peer mediator to build trust within the target group
Personnel, logistics, and other resources		
	Who are the key personnel involved?	Content and communications experts are minimum requirements
	What skill sets are needed?	Resources, time, and funding needed will differ across platforms
	Do you have an advocate or opinion leader from the intended audience or community?	Connect with organizations with infrastructure already in place
	How and how often will they post or interact with the audience or community?	N/A
	Can you link in with a larger organization?	N/A
Ethics		

Phase	Probing questions	Considerations
	Is everyone a research participant or peripherally involved because of interactions with a participant?	Evaluate the nature of participant involvement and prospectively consider the potential risks to individuals
	Does the audience understand informed consent and expectations for privacy?	Tailor communication about risks and expectations
	Are you aware of the privacy policies governing the different SM platforms?	Work closely with governing bodies and develop standards of practice (eg, create SM policy or “rules of engagement” document)
Evaluating		
Planning		
	Relates back to the goals—what are you hoping to achieve (eg, increased reach, engagement, and uptake)?	Create a logic model mapping goals to output indicators and ensure output indicators are measurable
	How will you determine whether the SM campaign or strategy was successful?	Build an interim evaluation to ensure goals are being met and redeploy efforts and resources effectively
Collecting		
	Are you able to collect the data you need (eg, quantitative, qualitative, or both)?	Invest in web analytic tracking platforms

Discussion

Case Study Findings

Social media has become prevalent in many people's lives as a means to communicate and exchange knowledge. The diverse formats of multiple, easily accessible platforms allow the creation, sharing, and exchange of ideas and information to various audiences. Users of social media can become interactive and are given equal opportunity for participation in the diffusion of information [28,29]. This shift in the communication landscape has paved the way for different stakeholders to interact and engage with intended end users in less traditional formats.

The case studies identified in this collection highlight the potential of using social media to engage with an intended audience and support collective action. Elements integral to the appeal of social media, personalization, presentation, and participation [30,31], overlap with those of KT. Furthermore, social media platforms may provide a rapid, accessible, and cost-effective means of implementing a widespread KT strategy [9]. Although there is no singular framework to guide the use of social media in a health research context, there are a number of factors that need to be considered when creating, implementing, and evaluating a social media KT strategy.

Considerations

Understand Why You Want to Use Social Media as Part of Your Knowledge Translation Strategy

Social media has the power to engage with a wide variety of end users. Depending on the purpose of the strategy (eg, increase access to health information among the intended audience, increase reach and uptake of information, increase awareness

or knowledge, and engage intended audience in dialogue [eg, for priority setting or information sharing]) and process (ie, letting it happen vs making it happen), there are many models that can be applied. These focus on dissemination, communication exchange, engagement, or behavior change [25,27,32-36].

We recommend that researchers select one or more social media platforms that align best with their purpose(s). For example, to create dialogue with patients who experience a common condition, a private Facebook group may be more appropriate than a live tweet chat. However, if the goal is broad dissemination, then tapping into an existing web network such as Twitter and posting frequently using social filtering and negotiated awareness techniques would be advantageous to rapidly reach a broader audience.

The scope of the messaging will also need to be taken into consideration during the development of the strategy. Focusing on a single message (one clear message repeated over time in different formats) or multiple messages (on multiple topics) will have implications for which platform you use, resourcing needs, and campaign length.

How to Understand and Engage Web Audiences?

Understanding your intended audience (eg, those engaged in a topic that can inform priority setting, those less engaged who need to access information, or those resistant to messaging and change in behavior) can help create a targeted strategy.

An in-depth understanding of the social network that you are trying to reach is also necessary to evaluate the current web environment. Understanding the structure of the web-based social networks of the intended audience might lead to the development of web-based algorithms that can detect trusted or influential users [37]. These users can then be identified and

approached (in advance) to help engage a wider audience and disseminate information.

In the context of social media platforms, the users were self-selected; the question, therefore, becomes, how do we reach the users who were already there with the information that they need? Posting frequency is the grossest of metrics but can also be the most highly predictive [38-42]. Followers disengage when they perceive a channel or source to be dormant or dead. If you fail to post frequently in a noisy channel (eg, Twitter or any blog), you effectively do not exist. Additionally, people are more likely to draw close to those whose web activities are clear and apparent; this is why posting focused, tailored content frequently is beneficial. Users can then determine how the group of interest came to know of each other, what type of information (intent or agenda) they provide, and how it is being conveyed (personality). These factors can help them decide whether they want to connect with or follow the group. Social filtering, also collaborative filtering, is how a group organizes to allow people to find what could be useful or entertaining [43-45]. For example, if a tweet gets a lot of likes or retweets or a blog post is circulated across Twitter, Facebook, and numerous aggregators, this is interpreted as the judgment of the community.

By building on both direct (ie, proximate relationships and immediate relationships) and indirect (ie, distal relationships, connected by common factors, or influenced by external factors) social relationships, researchers can find users with similar interests. The impact this has on social capital (greater interactions generate a greater sense of community) should be considered and leveraged to enhance the success of a social media KT strategy. Targeted messaging and sharing content and knowledge that has been contributed or endorsed by other users can then be successfully capitalized on to reach the intended audience [46].

How Can a Social Media Platform Be Chosen?

Articulating the goal(s) of the strategy will help guide what platform should be used and for what purpose. Due to the unique functionality, interface, and content each platform offers, it is expected that people use and actively engage with the various platforms in different ways. For example, Voorveld et al [47] found that Facebook allowed people to respond, share, and be updated on information quickly (social interaction and topicality), whereas Twitter ensured people were quickly informed and up to date but had little topicality. Additionally, as there is often little overlap between different platforms regarding user demographics and conversations, multiple platforms may be necessary to reach all intended audiences [47,48].

Although empirical data to confirm whether cross-posting enhances reach and engagement are lacking, anecdotal evidence suggests that linking posts to multiple social media sites can enhance visibility and reach [47-49]. To gauge this, we suggest having representatives from the intended audience (eg, patient, consumer adviser, and other stakeholders) as part of the team or as a consultant. This will help determine which platform is most suitable and inform how best to engage with the intended audience from a messaging perspective. Additionally, whether

one is establishing a presence on single or multiple channels, a pre-established platform or following is easier to partner with rather than building a new network during the campaign.

What Personnel and Resources Will You Require?

Many different skill sets and dedicated personnel are required to effectively execute a social media KT strategy [50]. Many grant-funded research projects are under resourced, and employing staff to come onboard for a select amount of time to execute a strategy may be unsustainable. To overcome some of the constraints placed on researchers, partnering with stakeholder organizations, networks, or advocacy units that have the necessary resources is advantageous. Additionally, media partners can alleviate some of the burden placed on research teams who do not have the necessary skill sets or time to develop multiplatform-compatible social media content or nurture a social media strategy to gain widespread traction.

Although Young et al [51] have suggested a framework for building an effective web-based health community through 4 key phases (ie, inception, establishment, maturity, and mitosis), the applicability of its use within an asynchronous or push-pull communication format via a single social media channel is yet to be determined. In other words, it seems feasible to create a closed Facebook group that is self-sustaining and that will grow organically, yet it is unclear if it is possible to create a similar model on a broader, less confined (less private) platform such as Twitter.

How Will You Evaluate Success and Impact?

The evaluation piece of a social media KT strategy needs to be embedded from the beginning (eg, to be able to see the number of times a link was accessed, the link needs to be set up as a traceable link before the strategy is implemented). There is an ongoing debate about which metrics are the most useful and relevant to determining the success of a KT strategy. Although the number of times a post is viewed or interacted with on social media may give an indication of reach, it is insufficient for assessing influence. Assessing the direct impact on change in attitude or behavior is not easily quantifiable, and alternative methods of measuring success are needed [52].

A range of quantitative analytics can be used to identify the components of a campaign that are most effective for assessing reach and uptake. However, consideration of their reporting periods and comparability across platforms is needed. If assessing reach and engagement, metrics such as likes, shares, and retweets are effective; traceable links and the number of downloads (often available from journals) are useful measures of engagement. Evaluating engagement in more depth can be done by posing questions or comments and assessing the reaction of the audience. However, unless these are monitored in real time, a retrospective evaluation of the number of comments and interactions between researchers and the consumer audience can be difficult and time-consuming (posts are often moved further down the conversation as more relevant posts are made). Although qualitative data collection could assist in this area, easily obtaining and collecting this information may not be feasible on a broad scale.

One construct that has the potential to enhance our understanding of KT success is social network analysis (SNA). SNA proposes a network-level perspective that examines how connections among individuals or entities and the nature of the associated interactions influence an outcome (eg, accessing or sharing evidence and changing practice behaviors based on evidence) [53]. However, little research evidence is available on the success of social media to improve the understanding or communication of health research findings to patients and families and the public (or those not specifically seeking treatment). Research in this area would benefit the health research community.

Do You Need Ethics Approval?

Regardless of whether evaluation is to be done formally or informally, the ethical considerations around web-based data collection and transmission need to be adhered to by researchers. As these are constantly evolving and changing to reflect both the researchers' need for information and participants' desire for privacy and confidentiality, it is imperative that research institutions and researchers are in agreement and compliance with what constitutes the need for informed consent in the digital world. As privacy policies are variable between social media sites and change frequently, they need to be checked before implementing a strategy, and the constraints imposed by varying privacy policies considered during the planning stages.

Ethics around the use of qualitative data acquired also need to be considered. Often, web-based patient groups can be a rich source of information for researchers wanting to understand the experience and views of patients around a particular condition or care need. The line between public and private domains then becomes blurred, with web-based data collection presenting unique issues during data transmission. According to Eysenbach and Wyatt [54], there are 3 main types of data collection and analysis possible from these web-based social media networks: (1) passive analysis, in which information posted on discussion groups is evaluated without researchers embedding themselves into the network; (2) active analysis, in which researchers participate in communications (response to questions by the group and posting questions to the group for discussion); (3) when researchers identify themselves and explicitly set out to gather information and data (surveys and focus groups). In the first 2 types, internet community members do not expect to be research subjects, which brings the need for and approach to consent into consideration.

Researchers and institutes need to work together to develop a code of conduct that benefits the participant as well as the project's integrity and intended purpose. In 2015, the Connected and Open Research Ethics initiative was launched, providing practical and accessible guidance for researchers designing social media-enabled studies [55]. We recommend that

researchers consult these guidelines during the development of any social media KT strategy.

Limitations

Our study used a convenience sample of 4 pediatric case studies, which may not be representative of all health researchers' experiences utilizing social media for KT. However, the generalist recommendations we provided are relevant to all health researchers and propose a broad set of considerations to others wanting to utilize social media for KT.

Although we did not specifically set out to complete a formal consensus building process (eg, Delphi), we acknowledge that this may have been a useful approach to avoid any bias associated with *group think*. Instead, we utilized deliberative dialogue. This process involved listening to other points of view; exploring and searching for new ideas, perspectives, and points of agreement; and bringing unexamined assumptions into the open. The end result produced a number of considerations based on collective insight and judgment on how best to utilize social media as part of a KT strategy.

As data were collected in 2017 to 2018, the findings may not reflect health researchers' current experiences with social media. We evaluated a snapshot of social media use, which may have already changed given the direction and development of new platforms beyond Facebook and Twitter. The findings do, however, provide unique insights and ideas for future research.

Conclusions

Social media has the potential to build and link web-based communities and to engage with, disseminate, and exchange information. Interconnections between people on social network sites as well as negotiated awareness and social filtering can enhance the process of information transfer and exchange and amplify the influence of that information. However, this comes with a cost. Ensuring adequate resources and time are available is essential to ensure a successful social media KT strategy.

A greater understanding of how best to evaluate social media as a KT tool for both active and passive engagement is needed to direct researchers in planning and evaluating their intended strategy. The elements and challenges discussed herein are important for researchers to consider to plan and evaluate a strategy that harnesses the power and personal aspects of social media for KT.

Perhaps a greater challenge is understanding how knowledge sharing and engagement contribute to behavior change and health outcomes and how we can gather and evaluate such outcomes. Further research is needed to help validate the proposed components and create a body of evidence around best practices for utilizing and evaluating social media as part of a KT strategy in health research.

Acknowledgments

The authors would like to thank Ms Megan Nuspl for helping initially coordinate the project and Ms Jennifer Sprung for providing a parent perspective on important outcomes for successful end-user engagement. This work was supported by the Alberta SPOR SUPPORT Unit Knowledge Translation Platform, which is funded by the Alberta Innovates and the Canadian Institutes of Health

Research. LH is a Canada Research Chair in Knowledge Synthesis and Translation. SS is a Canada Research Chair for Knowledge Translation in Child Health. LH and SS are Stollery Science Lab Distinguished Researchers. CC is a Canada Research Chair in Children's Pain. KW is supported by Dr John M Bowman, Chair in Pediatrics and Child Health, through the RH Institute Foundation and University of Manitoba.

Authors' Contributions

SE, MD, DT, GZ, and LH designed the study. Data collection and analysis were conducted by SE with input from MD, CC, KW, and DJR. All authors contributed to iterative discussions and summary of recommendations. SE and LH drafted the manuscript with input from MD, GZ, and GW. All authors reviewed the manuscript and approved the final version. The funders had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Abstract

Background: Blended face-to-face and web-based treatment is a promising way to deliver smoking cessation treatment. Since adherence has been shown to be an indicator of treatment acceptability and a determinant for effectiveness, we explored and compared adherence and predictors of adherence to blended and face-to-face alone smoking cessation treatments with similar content and intensity.

Objective: The objectives of this study were (1) to compare adherence to a blended smoking cessation treatment with adherence to a face-to-face treatment; (2) to compare adherence within the blended treatment to its face-to-face mode and web mode; and (3) to determine baseline predictors of adherence to both treatments as well as (4) the predictors to both modes of the blended treatment.

Methods: We calculated the total duration of treatment exposure for patients (N=292) of a Dutch outpatient smoking cessation clinic who were randomly assigned either to the blended smoking cessation treatment (n=130) or to a face-to-face treatment with identical components (n=162). For both treatments (blended and face-to-face) and for the two modes of delivery within the blended treatment (face-to-face vs web mode), adherence levels (ie, treatment time) were compared and the predictors of adherence were identified within 33 demographic, smoking-related, and health-related patient characteristics.

Results: We found no significant difference in adherence between the blended and the face-to-face treatments. Participants in the blended treatment group spent an average of 246 minutes in treatment (median 106.7% of intended treatment time, IQR 150%-355%) and participants in the face-to-face group spent 238 minutes (median 103.3% of intended treatment time, IQR 150%-330%). Within the blended group, adherence to the face-to-face mode was twice as high as that to the web mode. Participants in the blended group spent an average of 198 minutes (SD 120) in face-to-face mode (152% of the intended treatment time) and 75 minutes (SD 53) in web mode (75% of the intended treatment time). Higher age was the only characteristic consistently found to uniquely predict higher adherence in both the blended and face-to-face groups. For the face-to-face group, more social support for smoking cessation was also predictive of higher adherence. The variability in adherence explained by these predictors was rather low (blended $R^2=0.049$; face-to-face $R^2=0.076$). Within the blended group, living without children predicted higher adherence to the face-to-face mode ($R^2=0.034$), independent of age. Higher adherence to the web mode of the blended treatment

was predicted by a combination of an extrinsic motivation to quit, a less negative attitude toward quitting, and less health complaints ($R^2=0.164$).

Conclusions: This study represents one of the first attempts to thoroughly compare adherence and predictors of adherence of a blended smoking cessation treatment to an equivalent face-to-face treatment. Interestingly, although the overall adherence to both treatments appeared to be high, adherence within the blended treatment was much higher for the face-to-face mode than for the web mode. This supports the idea that in blended treatment, one mode of delivery can compensate for the weaknesses of the other. Higher age was found to be a common predictor of adherence to the treatments. The low variance in adherence predicted by the characteristics examined in this study suggests that other variables such as provider-related health system factors and time-varying patient characteristics should be explored in future research.

KEYWORDS

blended treatment; smoking cessation; adherence; predictors; tobacco; prevention

Introduction

Background

As smoking remains the leading cause of preventable death, cessation treatment is pivotal for public health promotion [1]. The introduction of electronic health (eHealth) [2] represents the expectation of information and communication technologies to improve health care [3]. However, adherence is generally low in web-based treatment [4] as well as in cessation treatment in general [5]. Low adherence is problematic because adherence has been shown to be an indicator of a treatment's acceptability and a determinant of treatment effectiveness [6-9]. Therefore, adherence should be optimized because—assuming a dose-response relationship [10]—patients are more likely to quit smoking if they are more exposed to active ingredients of the treatment [6]. Adherence in general can be defined as the extent to which a person's behavior (eg, taking medication, following a diet, or executing lifestyle changes) corresponds with recommendations from a health care provider [6]. In the context of behavioral change treatments such as smoking cessation, adherence issues are mainly related to premature termination of treatment and failure to perform tasks and exercises between sessions [11].

Blended Treatment

In the past few decades, a variety of effective interventions for smoking cessation have become available [12,13], including more recently developed eHealth services such as web-based interventions [14,15] or mobile phone interventions [16,17]. At present, traditional face-to-face interventions on the one hand, and both web-based and mobile phone interventions on the other hand are increasingly being transferred to blended treatment. Blended treatment is a promising eHealth service, because it is expected that the strengths of one mode of delivery will compensate for the weaknesses of the other [4,18-23]. The main strength of face-to-face treatment is to provide personal attention of a professional, which could compensate for the lack of face-to-face contact in web-based treatment. In turn, a main feature of web-based care is the accessibility anytime and anywhere, which could compensate for the time between face-to-face sessions when the user needs support. Blended treatment is applied in diverse settings (eg, individual vs group

setting [24]), addresses several health issues (eg, depression [25], anxiety [26], or addiction [10,22]), uses various tools (eg, web platforms, email, SMS text messaging, apps [20,27]), and uses different modes of delivery (eg, mainly web-based [28,29] vs mainly face-to-face [26,30] or integrated [10,22] vs sequential [29]). Since a clear definition of blended interventions is still missing [18], in this paper we define blended treatment as a combination of face-to-face sessions and web-based sessions to an integrated treatment that can be delivered by health care professionals on an outpatient basis. The blended intervention adopted in this study is an integrated equal blend of face-to-face treatment and treatment via an online platform.

Adherence to Blended Treatment

Blended treatment has been shown to positively influence adherence [4,31-33]. However, to the best of our knowledge, no studies to date have directly compared adherence to a blended treatment with adherence to either a web-based treatment or a face-to-face treatment with identical active components. In this study, we used data from the LiveSmokefree study [22], which is a randomized controlled trial (RCT) comparing the effectiveness of a blended face-to-face and web-based smoking cessation treatment to a comparable face-to-face treatment. In a prior study, we explored measurement methods and levels and predictors of adherence to the blended treatment by including the blended treatment group participants of the RCT only [10]. In the current study, we extended this previous work by including participants from the face-to-face treatment, allowing for a direct comparison of the levels of adherence between blended and face-to-face treatments. Furthermore, to explore whether both modes of delivery within the blended treatment were used in equal frequency, we also focused on levels of adherence within the blended group in the two modes.

Predictors of Adherence

When adherence is low, adherence predictors become an area of interest because they may provide insight into the cause of low adherence and can help to generate new approaches to improving treatment or better alignment between the patient and treatment. Adherence, in general, is determined by provider behaviors, health system factors, and patient characteristics, and the latter have been most extensively examined as predictors of adherence to traditional interventions [6]. Within the context

of smoking cessation treatment—including both face-to-face and web-based treatments—several demographic, smoking-related, and health-related predictors of adherence have been examined. To date, several studies have indicated that the likelihood of being adherent may increase with a higher age [34,35], male gender [35], higher internet skills [36,37], negative attitude toward smoking and higher motivation to quit at baseline [38,39], higher self-efficacy at baseline [39], early success in quitting after the start of the treatment [7,34,40], and lower nicotine dependency at baseline with fewer withdrawal symptoms after quitting [35,38]. For blended treatment, our previous study showed that higher adherence was best predicted by marital status (ie, having a partner) and social modeling (ie, more nonsmoking friends/partner) [10]. Building on this work, we have expanded on these previous findings in the current study by examining the predictors for adherence to both treatment arms (blended and face-to-face) and additionally the two modes of delivery (face-to-face mode and web mode) in the blended arm.

Objectives

In detail, this study explored the following questions. With respect to adherence, we asked (1) how adherent are participants to blended compared to face-to-face treatment? and (2) within the blended treatment group, how adherent are the participants to the face-to-face mode compared to the web mode? With respect to predictors, we asked (1) which demographic, smoking-related, and health-related patient characteristics predict adherence to blended and to face-to-face treatments, and to both groups combined? and (2) within the blended group, which of these characteristics predict adherence to the face-to-face mode and to the web mode?

Methods

Study Subjects

In this study, we used the already available data from patients (blended $n=130$; face-to-face $n=162$) of a not yet completed nonblinded RCT on the effectiveness of a blended smoking cessation treatment compared with a face-to-face treatment (LiveSmokefree study, $n=172$ allocated per group to determine a difference in abstinence rates of 5 percentage points with a power of 80% and $\alpha=.025$) [22]. The patients were referred to the outpatient smoking cessation clinic at Medical Spectrum Twente hospital (Enschede, the Netherlands) by the treating physicians of the hospital or by their general practitioners, and attended the initial treatment session between May 2015 and September 2018. Inclusion criteria were: (1) willing to quit smoking, (2) aged 18 or older, and (3) current daily smoker (at least one cigarette a day). Exclusion criteria were: (1) no internet access (ie, email, websites) and (2) not able to read or write in the Dutch language. In line with the Dutch Medical Research Ethics Committee guidelines, the study was approved by the accredited MEC Twente (P14-37/NL50944.044.14). Before initiation, the study was registered in the Netherlands Trial Registry (NTR5113). All patients had to sign an informed consent form before they were randomized.

Randomization

Patients were randomly assigned to either the blended or face-to-face group. Randomization was performed at the individual level (allocation ratio 1:1) using QMinim Online Minimization [41]. The minimization was stratified according to: (1) level of internet skills [42], (2) level of nicotine dependence (Fagerstrom) [43,44], and (3) the quitting strategy favored by the patient (stop at once, gradual change, scheduled reduced smoking; for details see the description of the study intervention below). The data used for QMinim minimization were collected using the baseline questionnaire completed online by the patient at home prior to the start of treatment.

Study Interventions

The study interventions to be compared were a blended face-to-face and web-based smoking cessation treatment and a face-to-face treatment alone. Except for the differences in mode of delivery (ie, face-to-face mode and web mode), both treatments included the following same features: (1) high-intensity treatments comprising 10 sessions with a total treatment time of 230 minutes (20 minutes each, except for the first that was 50 minutes); (2) delivered by health care professionals in an outpatient cessation clinic; (3) derived from the Dutch Guideline for Tobacco Addiction [45] fulfilling the requirements of the Dutch care module for smoking cessation [46]; (4) executed by counselors registered in the Dutch quality register of qualified smoking cessation counselors; (5) treatment costs reimbursed by the patient's health insurance; (6) supporting three quitting strategies that were chosen at the start of the treatment (stop at once, change gradually by increasing the number of daily activities that are performed smoke-free, or decrease smoking at regular intervals such as scheduled smoking reduction 100%-75%, 75%-50%, etc). The chosen quitting strategy did not influence the course of the treatment in general. The order, pace, duration, and intensity were the same for all strategies.

Both the blended and face-to-face treatments included the following behavior change techniques, according to BCT taxonomy v1 of Michie et al [47]: 1.1 Goal setting (behavior), 1.2 Problem solving, 1.3 Goal setting (outcome), 1.4 Action planning, 1.5 Review behavior goal(s), 1.6 Discrepancy between current behavior and goal, 1.8 Behavioral contract, 1.9 Commitment, 2.3 Self-monitoring of behavior, 2.4 Self-monitoring of outcome(s) of behavior, 2.6 Biofeedback, 2.7 Feedback on outcome(s) of behavior, 3.1 Social support (unspecified), 4.2 Information about antecedents, 4.3 Reattribution, 5.1 Information about health consequences, 5.2 Salience of consequences, 5.3 Information about social and environmental consequences, 5.4 Monitoring of emotional consequences, 5.5 Anticipated regret, 5.6 Information about emotional consequences, 6.2 Social comparison, 6.3 Information about others' approval, 7.4 Remove access to the reward, 8.1 Behavioral practice/rehearsal, 8.2 Behavior substitution, 8.3 Habit formation, 8.4 Habit reversal, 8.6 Generalization of a target behavior, 8.7 Graded tasks, 9.1 Credible source, 9.2 Pros and cons, 9.3 Comparative imagining of future outcomes, 10.7 Self-incentive, 10.9 Self-reward, 11.1 Pharmacological support (eg, nicotine replacement therapy [patches, gum], bupropion,

varenicline), 11.2 Reduce negative emotions, 12.1 Restructuring the physical environment, 12.2 Restructuring the social environment, 12.3 Avoidance/reducing exposure to cues for the behavior, 12.4 Distraction, 13.1 Identification of self as role model, 13.2 Framing/reframing, 13.5 Identity associated with changed behavior, 14.4 Reward approximation, 14.5 Rewarding completion, 14.6 Situation-specific reward, 14.7 Reward incompatible behavior, 14.8 Reward alternative behavior, 15.1 Verbal persuasion about capability, 15.3 Focus on past success, and 16.3 Vicarious consequences.

The face-to-face treatment consisted of 10 face-to-face sessions delivered at the outpatient smoking cessation clinic. The blended treatment comprised 5 face-to-face sessions at the outpatient clinic and 5 web-mode sessions delivered via an online treatment platform. Both the face-to-face and blended treatments consisted of both counselor-dependent and counselor-independent components. The counselor-dependent web-based components of the blended treatment were interactive and relied on (asynchronous) communication (email, messaging) between the counselor and participant. The counselor-independent components such as psychoeducational content or a smoking diary were used by the participants on their own and in their own time. In the face-to-face group, these components were provided in a paper manual that the participants took home. In the blended treatment, these components were accessible online. As such, both treatments were equivalent with regard to content

and intensity. An additional benefit of the blended treatment was that the content of previous counselor-dependent components remained accessible as email and messaging correspondence saved online.

The most characteristic feature of the blended treatment examined in this study is an equal balance between the face-to-face and web mode sessions; that is, the focus of the treatment is neither on face-to-face mode nor web mode. In addition, there is constant alternation and interactive use of the two modes. [Table 1](#) shows the order, timing, main features, duration, and modes of delivery of the treatment sessions in the face-to-face and blended treatments. Although an equal distribution was planned for the blended treatment with regard to the number of sessions, there was an uneven distribution for the duration of treatment because the first session (50 minutes for face-to-face mode) was longer than the remaining sessions (20 minutes for the face-to-face mode or 20 minutes for web mode); therefore, the participants in the blended group spent 130 minutes in face-to-face mode and 100 minutes in web mode.

A detailed description of the treatments can also be found in the protocol article of the RCT [22] and in the description of the user experience of the blended smoking cessation treatment [48]. Screenshots of the web sessions of the blended treatment are shown in [Multimedia Appendix 1](#) to provide an impression of the look and feel of the web interventions.

Data Collection

Patient Characteristics

As part of the RCT (LiveSmokefree-study), 33 demographic, smoking-related, and health-related characteristics were assessed with the intake measurement using an online questionnaire. A detailed description of these characteristics is available in the protocol article of the RCT [22].

Measuring Adherence

Established measures for adherence to a blended treatment are still lacking. Therefore, for the 2018 study [10], we constructed a customized measure for adherence by selecting 18 patient activities (eg, using a web-based smoking diary tool, responding to counselors' messages) to trace adherence to the blended treatment. Adequacy of this adherence measure was confirmed by the observed dose-response relationship between adherence and the likelihood of quitting, which is consistent with the

smoking cessation literature [6-9]. However, this activity-based method was quite detailed and labor-intensive and was particularly interesting from a methodological point of view. Since the current study was mainly focused on comparing treatment modalities in a clinical context, we used a simpler time-based method for measuring adherence, which was proven to be as suitable for clinical research as the activity-based method and was also found to be more efficient [49,50]. Although this time-based method was not as accurate as the activity-based method, it was applicable in this case because the primary goal of this study was to determine differences between the groups in terms of levels and predictors of adherence. Therefore, the analysis of relative level differences was more relevant than an exact measurement of absolute levels. Furthermore, the time-based method allowed for analysis of a larger sample and thus more accurate statistics, as it required less time and money.

For this time-based approach, we used treatment data from the hospital's electronic patient record system. This record system contains basic information of the patients' treatment status such as when the patient started treatment; which counselor was offering the treatment; time, day, and type of appointments; time and day of telephone consults; and which kind of treatment was offered in each appointment [51]. In this record system, the counselors reported, in an encoded form, which type of sessions were completed. Each code represents a fixed, average number of minutes invested in face-to-face mode or web mode, as shown in Table 2. These fixed numbers of minutes per sessions were used to calculate the total number of minutes in treatment for each patient for the blended and face-to-face treatments, as well as for the face-to-face mode and web mode in the blended treatment.

Table 2. Codes, descriptions, modes of delivery, and duration of face-to-face (F2F) and blended treatment sessions used to measure adherence.

Code	Description of the session	Mode	Duration (minutes)
RSN	First individual F2F session at treatment start	F2F	50
RSAB	Like RSN, but visiting a patient at another department of the hospital	F2F	50
RSNS	Like RSN, but with 2 patients at the same time (eg, husband and wife)	F2F	35
RSC	Usual individual F2F session	F2F	20
RSAC	Additional consult (to add to RSN/RSAB/RSNS/RSC if more time is needed)	F2F	20
RSTC	Individual telephone consult	F2F	20
RSOC	Any other individual consult	F2F	10
RSIC	Web-mode treatment session via rokendebaas.nl	Web	20
RSEC	Email consulting	Web	10

Statistical Analysis

All analyses were performed using SPSS version 24.

Patient Characteristics

For both the blended and face-to-face groups, 33 demographic, smoking-related, and health-related characteristics were measured and are reported as means (SDs) for normally distributed continuous variables and as medians (IQRs) for nonnormally distributed continuous variables. Categorical variables are reported as numbers with corresponding percentages. To identify between-group differences within the 33 demographic, smoking-related, and health-related patient characteristics, independent *t* tests or Mann-Whitney *U* tests were performed as appropriate for continuous variables; the Pearson Chi-square or Fisher exact test was performed for categorical variables.

Adherence (Time Spent in Treatment)

Based on the hospital administrative records, both the absolute treatment time (in minutes) and the proportional treatment time (in percentage) of the patients who had started treatment were calculated for the blended and face-to-face groups, as well as for the face-to-face mode and web mode of the blended treatment. Bar charts were used to compare how many patients spend how much time in the blended and face-to-face treatment

on the one hand and in each mode of the blended treatment on the other hand. Mann Whitney *U* tests were performed to compare the absolute treatment time of the blended and face-to-face treatments and the proportional treatment time for the face-to-face and web modes in the blended treatment.

Predictors of Adherence

To identify the predictors of adherence (as a continuous variable) within the 33 demographic, smoking-related, and health-related patient characteristics, Pearson or Spearman correlation tests were performed as appropriate for continuous variables; independent *t* tests or Mann-Whitney *U* tests were performed for dichotomous variables. Variables with significance at $P < .15$ were considered as candidates for multivariate linear regression analyses. They were first tested with univariate linear regression analyses so that univariate and multivariate odds ratios could be compared, and were entered in the multivariate linear regression analyses after checking for multicollinearity. The variables were either all entered and removed step by step via the backward selection method (all patients; blended group; face-to-face group; face-to-face mode of the blended treatment) or entered step by step via the forward selection method (web mode of the blended treatment). Variables were entered or eliminated step by step based on the model fit. In the case of multicollinearity, the variable with the best model fit was selected for linear analyses.

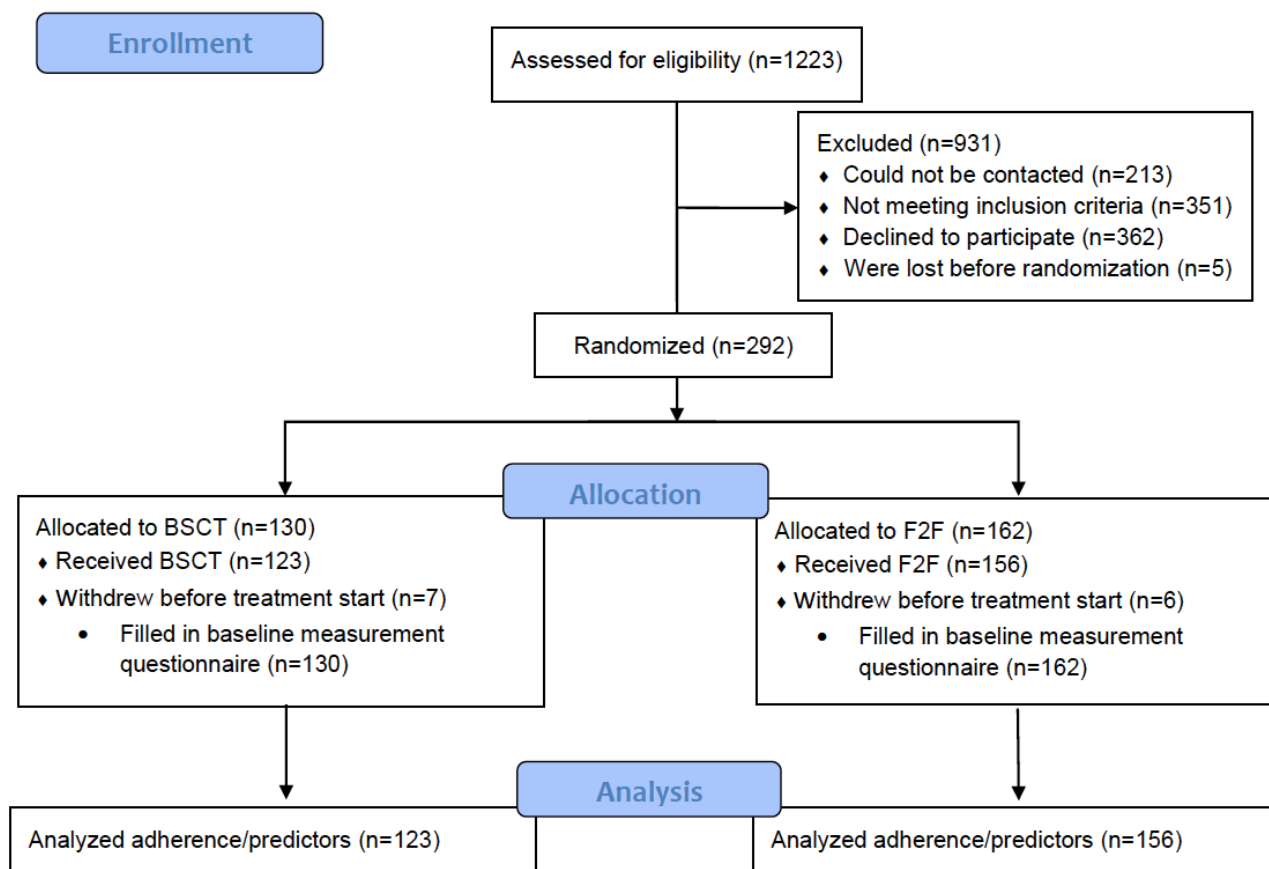

Results

Participant Flow

Figure 1 shows the flow of participants through the study. A total of 292 patients were eligible for the study, provided written consent, filled out the baseline questionnaire, and were

randomized (blended $n=130$; face-to-face $n=162$). Before the start of treatment, 7/130 (5.4%) patients of the blended group and 6/162 (3.7%) patients of the face-to-face group withdrew. Finally, data from 123/130 (94.6%) patients in the blended group and 156/160 (96.3%) patients in the face-to-face group were available for adherence analysis.

Figure 1. Flow of participants through the study. BSCT: blended smoking cessation treatment; F2F: face-to-face.

Patient Characteristics

Table 3 shows the patients' characteristics for both the blended group ($n=130$) and the face-to-face group ($n=162$). Significant differences ($P<.05$) between the blended and face-to-face group

were found for 6 of the 33 characteristics. Patients in the face-to-face group had higher internet skills, used more medication in general, reported less health complaints, and scored higher on the Depression Anxiety Stress Scale (DASS) subscales depression and anxiety, and on the total DASS score.

^mScored on a scale of 0-64; a higher score indicates more smoking-related complaints.

ⁿScored on a scale of 0-104; a higher score indicates poorer health status and more smoking-related complaints.

^oScored on a scale of 0-42; a higher score indicates a higher level of depression/anxiety/stress.

^pDASS: Depression Anxiety Stress Scale; sum of the Depression, Anxiety, and Stress subscale scores (range 0-126; a higher score indicates a more negative emotional status).

^qEQ-5D-3L: societal-based quantification of health status (range 0-1; a higher score indicates better health status).

^rEQ VAS: visual analog scale for quality of life (range 0-100; a higher score indicates better health status).

Adherence (Time Spent in Treatment)

As illustrated in Figure 2, adherence to the blended and face-to-face treatments was comparable. Patients in the blended group (n=123, 7 patients dropped out between inclusion and the first treatment session) spent a median of 246 (IQR 150-355) minutes in treatment (106.7% of the intended total treatment time); in the face-to-face group (n=156, 6 patients dropped out between inclusion and first treatment session), the patients spent a median of 238 (IQR 150-330) minutes in treatment (103.3% of the intended total treatment time). There was no significant

difference between the two groups ($P=.30$). However, within the blended group, as shown in Figure 3, patients were more adherent to the face-to-face mode than to the web mode. Patients in the blended group (n=123) spent a mean of 198 (SD 120) minutes in face-to-face mode and 75 (SD 53) minutes in web mode. In proportion to the intended treatment time for each mode of delivery (face-to-face mode=130 minutes; web mode=100 minutes), patients in the blended group spent twice the time in face-to-face mode (mean 152%, SD 92% of 130 minutes) than in web mode (mean 75%, SD 53% of 100 minutes) ($t_{122}=10.03$; $P<.001$).

Figure 2. Adherence to blended smoking cessation treatment (BSCT) vs face-to-face (F2F) treatment.**Figure 3.** Adherence within the blended smoking cessation treatment group to the two modes of the treatment: face-to-face (F2F) mode vs web mode.

Predictors of Adherence

For both treatments together, 7 predictors (Table 4) were significantly associated with higher adherence in the univariate analysis (assessed at $P < .15$), including male sex, older age, housing situation (living without children), higher readiness to quit, higher social support, lower social modeling (less smokers in the social environment), and higher use of other medication. Multivariate regression analyses (Table 5) revealed that age was the best predictor of adherence ($R^2 = 0.047$). Per life year, patients spent 2.5 more minutes in treatment (95% CI 1.2-3.8; $P = .001$).

For the face-to-face group, 6 predictors (Table 4) were significantly associated with higher adherence in the univariate analyses (assessed at $P < .15$), including older age, higher readiness to quit, more social support, lower social modeling, higher use of other medication, and higher smoking-related complaints. Multivariate regression analyses (Table 5) revealed that age and social support together were the best predictors of

adherence ($R^2 = 0.076$). Per life year, patients spent 2.2 minutes more in treatment (95% CI 0.4-3.9; $P = .02$). For social support, graded from 0 (low social smoking cessation support) to 5 (high social smoking cessation support), each unit increase was associated with 20.5 more minutes in treatment (95% CI 2.3-38.8; $P = .03$).

For the blended group, 8 predictors (Table 4) were significantly associated with higher adherence in the univariate analyses (assessed at $P < .15$), including higher age, housing situation (living without children), lower nicotine dependency (Fagerstrom), higher negative attitude toward quitting, lower social modeling, lower health complaints, lower anxiety, and lower stress. Multivariate regression analyses (Table 5) revealed that age was the best predictor of adherence ($P = .01$). Per life year, patients spent 2.6 more minutes in treatment (95% CI 0.5-4.6; $R^2 = 0.049$).

For the face-to-face mode of the blended treatment, 3 predictors (Table 6) were significantly associated with higher adherence in univariate analyses (assessed at $P < .15$), including higher age,

housing situation (living without children), and lower internet skills (Table 6). Multivariate regression analyses (Table 7) revealed that housing situation was the best predictor of face-to-face mode adherence ($R^2=0.034$). Patients living without children spent 49.7 more minutes in the face-to-face mode of the blended treatment (95% CI 92.7-6.8; $P=.02$) (Table 7).

For the web mode of the blended treatment, 16 predictors (Table 6) were significantly associated with higher adherence in univariate analyses (assessed at $P<.15$), including male sex, older age, main income (income support), main day activity (other than paid work), extrinsic reason to start treatment, lower nicotine dependency (Fagerstroem), higher negative attitude toward quitting, higher self-efficacy, lower social modeling, lower health complaints (assessed on the Maudsley Addiction Profile Health Symptoms Scale [MAPHSS]), lower smoking-related complaints, lower health and smoking-related complaints, lower anxiety, lower stress, lower DASS, and higher

quality of life (EQ-5D-3L). Health and smoking-related complaints and the DASS were not used for multivariate regression because of multicollinearity. Multivariate regression analyses (Table 7) revealed that reason to start treatment, negative attitude toward quitting, and health complaints (MAPHSS) together were the best predictors of web mode adherence ($R^2=0.164$). Patients with an intrinsic motivation spent 21.5 less minutes in the web mode of the blended treatment (95% CI -39.8 to -3.3; $P=.02$). For negative attitude toward quitting (range -12 to 0; lower numbers indicate a more negative attitude toward quitting smoking), each unit increase (ie, a less negative attitude) was associated with 3.6 more minutes in web mode of the blended treatment (95% CI 0.9-6.4, $P=.01$). For health complaints (range 0-40; higher numbers indicate poorer health status), each unit increase (ie, additional complaint reported) was associated with 2.4 less minutes in the web mode of the blended treatment (95% CI -3.8 to -1.0, $P=.001$).

Discussion

Principal Findings

Since the emergence of web-based health promotion counseling a few decades ago, blended treatments have recently been introduced. The aim of the present study was to directly compare adherence to a blended treatment with a face-to-face treatment for smoking cessation with similar content.

Based on the treatment times documented in the hospital administration, we found comparable adherence levels for the blended and face-to-face treatments. However, within the blended treatment, we found that patients spent twice as much time in face-to-face mode (152% of the intended treatment time) than in web mode (75% of the intended treatment time), suggesting a tendency to substitute web sessions by additional face-to-face sessions.

Older age was the only characteristic consistently found to predict higher adherence to both the face-to-face and blended treatments. For the face-to-face group, we found that both older age and perceived social support for smoking cessation predicted higher adherence. Age is known as a relevant demographic characteristic for predicting adherence [34,35], but more social support to quit smoking has not yet been indicated as an independent predictor of adherence.

Within the blended treatment, no consistent predictor of adherence was found for its two modes of delivery. Higher adherence to the face-to-face mode was predicted by the housing situation (ie, living without children), whereas adherence to the web mode was predicted by an extrinsic motivation to quit, a less negative attitude toward quitting, and less health complaints. Although these models contained statistically significant predictive patient characteristics, the predicted proportion of variability in adherence was small, ranging from 3.4% to 16.4%. Thus, it seems immature to interpret these findings in an attempt to understand the mechanisms in adherence to blended smoking cessation treatment, and it is difficult to find a meaningful pattern in these predictors. To explain this low model fit, two

aspects can be considered. First, this could indicate that the predictors examined in this study, namely only the patient characteristics, are not comprehensive. For example, it seems likely that provider-related variables and health care system factors such as treatment costs, failure to recall a receipt of a prescription, and access to free nicotine replacement therapy [6] also play a role. As no data on these factors were available in this study, this could not be further verified. Second, all patient-related predictors used in the current study were evaluated at the start of treatment, which means that changes in these characteristics during treatment (eg, due to negative treatment effects such as weight gain, adverse events, or withdrawal symptoms) were not considered. As an example of a positive treatment effect, in the context of smoking cessation treatment, the bidirectional relation between quitting success and adherence is known, in which early quitting success predicts higher adherence [34], while higher adherence predicts (long-term) abstinence [6-9]. Another example is the user experience that patients build during the course of treatment. Patients may experience the treatment as “useful,” “easy to follow,” or “stimulating” and adhere to the treatment accordingly [48,52].

In general, the finding for the blended group that treatment time not used in web mode was compensated by face-to-face mode treatment would support the expectation that in blended treatment, the strengths of one mode of delivery will compensate for the weaknesses of the other [4,18-23]. This expectation is also supported based on our recently published qualitative study on user experience with this blended smoking cessation treatment [48,52], in which we also found that the strengths of the face-to-face mode can compensate for the weaknesses of the web mode. It is noteworthy that this compensation is mainly unidirectional: face-to-face mode compensates or replaces web mode and not vice versa. By exceeding the planned face-to-face treatment time by 100 minutes on average, the vast majority of patients in the blended group (118/123, 95.9%) spent significantly more time in face-to-face mode than in web mode. By contrast, only 5/123 (4.1%) patients spent slightly more time (an additional 27 minutes on average) in web mode than in

face-to-face mode. Perhaps the new and challenging web mode is not used optimally, as it can (easily) be compensated by the traditional, familiar face-to-face mode.

Although the main objective of this study was to provide a treatment time–based comparison of adherence, we would like to briefly mention two aspects that surprised us when comparing the results with one of our previous studies [10] that used a different operationalization of adherence.

First, the current study revealed rather high adherence to both the blended and face-to-face treatments. Due to differences in interventions, measurements of adherence, adjunctive support, and investigated populations, adherence rates for smoking cessation treatment vary widely between different studies (5%–96%) [6]. This makes it difficult to compare adherence rates in general. Moreover, little is known about adherence rates for blended treatment. We only found one study that reported adherence rates: in a blended depression treatment, adherence to the blended treatment (90.5%) and the face-to-face treatment (95.1%) was comparable [53]. Our study seems to agree with this previous study, as we also found comparably high adherence to the blended (106.7%) and face-to-face (103.3%) treatments. Surprisingly, for the blended treatment, the findings in this study seem to contradict our findings from a previous study among participants of the blended treatment in the same sample [10], in which we reported that adherence to the blended treatment seemed rather low. These apparent contradictory results may be explained by different operationalizations of adherence and different measurement methods in the two studies. In the 2018 study, we traced treatment activities of the patients in detail (not only treatment time as used in the current study) and strived for a categorical threshold-based classification of patients as being either adherent or nonadherent. This activity-based method used in the 2018 study correlates with the time-based measurement applied in the current study, but it was more specific [49,50] and therefore resulted in lower absolute adherence rates [10].

Second, in our 2018 study [10], we found that in the blended treatment, based on patients' activities, there was no significant difference in adherence to the face-to-face mode compared with the web mode. Surprisingly, in the current study, based on treatment time, the adherence levels differed significantly. Patients spent only 75.2% of the intended treatment time in the web mode, but 152.3% of the intended treatment time in the face-to-face mode. This shows that in practice it is rather a 2/3 to 1/3 ratio between face-to-face mode and web mode in the blended group than the planned equal ratio. This could mean, for example, that patients in face-to-face mode need more time than planned for their activities, or that additional unplanned activities take place within the treatment time. This could be an indication of therapist drift—a known weakness of face-to-face treatment [30]—and thus bring the topic of treatment fidelity into focus. From a clinical point of view, the question then arises as to whether the planned times for face-to-face mode and web mode are appropriate.

Limitations and Implications for Future Work

To the best of our knowledge, this is the first study to compare adherence and predictors of adherence in patients randomly assigned to either a blended smoking cessation treatment or a

face-to-face treatment with identical active components. Moreover, this is also the first study to compare adherence and predictors of adherence to the face-to-face mode with those to the web mode of a blended smoking cessation treatment. One limitation of this study is that the measurement of adherence was based on the treatment time documented in the hospital's administrative records, as this documentation is mainly used for financial accounting and therefore does not reflect in detail the contents and the exact temporal proportions of the treatments. Even though we assume that we have a sufficiently valid measure for the comparison of adherence and for the determination of predictors, these data unfortunately do not provide deeper insight into the adherence to the treatment process in detail. For example, the specific treatment activities carried out in different time frames remain unclear. In addition, the time data for the sessions were standard values and not exactly determined as treatment time per session. Individual sessions may therefore have been shorter or longer than evaluated. The absolute time values should therefore be interpreted with caution. Furthermore, in view of the differences between the results of this study and those of the 2018 study [10], in which different operationalizations of adherence were applied (time-based vs activity-based), the methodological question also arises as to which operationalization best reflects adherence. From our previous studies [49,50], we know that activity-based measurement has better predictive validity, which makes it seem more adequate when adherence is considered a determinant of efficacy (dose-response relationship). In this study, however, we used a time-based measurement because it requires less financial and time effort, the possibility of analyzing a larger sample size allowed us to expect more accurate statistics, and because we wanted to gain more experience with its application in clinical practice. The differences found in adherence between the 2018 study and the present study bring forth an interesting issue that deserves more attention and should be targeted in future studies, such as by addressing the research questions of this study using activity-based measurement to analyze the entire sample.

Another limitation is the low variability of adherence explained by our prediction models. The question arises as to whether the chosen predictors and their measurement are sufficient. Future research should further investigate which additional predictors (eg, provider behavior, health system factors, or other patient characteristics) should be included and how these can be measured, not only at the beginning but also over the course of treatment, so that they fit optimally to the research question.

Another point of interest should be the difference in predictors and levels of adherence to the two modes of delivery in the blended treatment. The characteristics associated with adherence are quite different (adherence to the face-to-face mode of the blended treatment was mostly associated with demographic characteristics, whereas adherence to the web mode of the blended treatment was mainly associated with smoking-related and health-related characteristics). Future research should examine the causation of these differences. For example, it is possible that web-mode treatment is better suited for patients with less health complaints because they rely less on a hospital setting and the direct contact to a health care professional such

as the smoking cessation counselor. Alternatively, web-mode treatment might be better suited for externally motivated patients because they already arrive at the treatment with a default desire to do what they are told and are therefore more likely to stick to the web mode.

Furthermore, the differences in the blended treatment adherence levels are noteworthy. In web mode, the adherence level was in the expected range, whereas there was overadherence found for the face-to-face mode. This could be related to the fact that the treatment basically starts with a rather long face-to-face session and therefore results in a type of face-to-face default mode. Therefore, it is possible that the result would have been different if the treatment had started in web mode. The overadherence raises another question as to which level of adherence is optimal to reach the treatment goals; that is, is higher adherence (152% adherence to face-to-face mode) better than lower adherence (ie, 75% adherence to web mode)?

Conclusion

This study represents one of the first attempts to thoroughly compare adherence and predictors of adherence of a blended

smoking cessation treatment to a face-to-face treatment. Our results showed that the levels of adherence to both treatments were comparable. However, within the blended treatment, we found that adherence to face-to-face mode was significantly higher than that of web mode, although the intended total treatment time for the blended treatment was fairly broadly adhered to. This supports the idea that in blended treatment, one mode of delivery can compensate for the weaknesses of the other. Older age was found to be a common predictor of adherence to the treatments. However, within the blended treatment, adherence to each mode was predicted by different characteristics: adherence to the face-to-face mode was associated with demographic characteristics only, whereas adherence to the web mode of the blended treatment was also associated with several smoking-related and health-related characteristics. This may indicate that these characteristics should be taken into account when designing a blended treatment. However, the finding that only a small amount of the variance could be determined by the characteristics examined in this study suggests that provider-related health system factors and time-varying patient characteristics can also play an important role and should be explored in future research.

Acknowledgments

This research is funded by the Technology, Health & Care Research Group at Saxion University of Applied Sciences and the Centre for eHealth and Well-being Research at University of Twente. We would like to thank the directors and the personnel of Medisch Spectrum Twente Hospital and Tactus Addiction Treatment, and the patients of the outpatient smoking cessation clinic of Medisch Spectrum Twente Hospital.

Authors' Contributions

LS, MEP, MGJBK, and MGP identified the study questions, and designed the study and its measuring instruments. LS is the principal investigator and wrote the first draft of this manuscript. LS, MEP, MGJBK, MGP, RS, and SBA edited the manuscript. LS, MEP, MGJBK, MGP, and RS revised the manuscript. LS wrote the final version. All authors approved the final version of this manuscript for publication.

Abstract

Background: Despite many advantages of web-based health behavior interventions such as wide accessibility or low costs, these interventions are often accompanied by high attrition rates, particularly in usage under real-life conditions. It would therefore be helpful to implement strategies such as the use of financial incentives to motivate program participation and increase adherence.

Objective: This naturalistic study examined real-life usage data of a 12-week web-based physical activity (PA) intervention (Fitness Coach) among insurants who participated in an additional incentive program (incentive group) and those who did not (nonincentive group). Users in the incentive group had the perspective of receiving €30 (about US \$33) cash back at the end of the intervention.

Methods: Registration and real-life usage data as part of routine data management and evaluation of the Fitness Coach were analyzed between September 2016 and June 2018. Depending on the duration of use and the weekly recording of tasks, 4 adherence groups (low, occasional, strong, and complete adherence) were defined. Demographic characteristics were collected by a self-reported questionnaire at registration. We analyzed baseline predictors and moderators of complete adherence such as participation in the program, age, gender, and BMI using binary logistic regressions.

Results: A total of 18,613 eligible persons registered for the intervention. Of these, 15,482 users chose to participate in the incentive program (incentive group): mean age 42.4 (SD 14.4) years, mean BMI 24.5 (SD 4.0) kg/m², median (IQR) BMI 23.8 (21.7-26.4) kg/m²; 65.12% (10,082/15,482) female; and 3131 users decided not to use the incentive program (nonincentive group): mean age 40.7 (SD 13.4) years, mean BMI 26.2 (SD 5.0) kg/m², median BMI 25.3 (IQR 22.6-28.7) kg/m²; 72.18% (2260/3131) female. At the end of the intervention, participants in the incentive program group showed 4.8 times higher complete adherence rates than those in the nonincentive program group (39.2% vs 8.1%), also yielding significantly higher odds to complete the intervention (odds ratio [OR] 12.638) for the incentive program group. Gender significantly moderated the effect with men in the incentive group showing higher odds to be completely adherent than women overall and men in the nonincentive group (OR 1.761). Furthermore, older age and male gender were significant predictors of complete adherence for all participants, whereas BMI did not predict intervention completion.

Conclusions: This is the first naturalistic study in the field of web-based PA interventions that shows the potential of even small financial incentives to increase program adherence. Male users, in particular, seem to be strongly motivated by incentives to complete the intervention. Based on these findings, health care providers can use differentiated incentive systems to increase regular participation in web-based PA interventions.

Introduction

Promoting a healthy lifestyle, especially reducing sedentary behavior and increasing physical activity (PA), is crucial in the prevention of chronic diseases such as cardiovascular disease, type 2 diabetes, breast and colon cancer as well as hypertension [1]. Persons who follow the PA recommendations of the World Health Organization [2] show a 27% decreased risk of mortality [3]. Besides numerous face-to-face PA interventions [4,5], electronic health (eHealth) and mobile health (mHealth) interventions have become increasingly popular to promote health behavior change such as increasing PA levels [6]. These interventions have the potential to reach large numbers of people in a cost- and time-efficient way [6]. Testing the effectiveness of internet interventions for behavior change, in particular for promoting PA, has yielded positive results despite small effect sizes with standardized mean differences ranging from 0.14 to 0.20 for self-reported PA [7-10].

Based on this evidence, many stakeholders in health care including health insurers have developed web-based interventions promoting PA as a public health approach [11,12]. However, *program adherence* to web-based interventions, that is, using the program as intended by the developers over the course of the intervention, has always been a major challenge (law of attrition [13]). Despite the positive effects on PA described above, internet interventions suffer from high dropout rates of up to 80% at the end of the intervention [14-16]. This lack of program adherence is likely to negatively influence *behavior adherence* [17,18], that is, the maintenance of newly acquired PA behavior in the real life after the program is finished.

To increase program and behavior adherence of web-based interventions, many providers such as health insurers revert to financial incentives such as cash, bonus points, or charity rewards [12,19]. The rationale behind using such external rewards to change health behavior is based on the assumption that this strategy may trigger an increasingly intrinsic motivation for PA that stabilizes the behavior even after the incentive removal [19]. In *face-to-face* settings, financial incentives have been shown to increase real-life exercise adherence (behavior adherence) in the short term and partially even in the long term among children, adolescents, and adults [20,21]. Similar results have also been found for *web-based* interventions with increased PA levels reported by incentivized groups after the intervention [12,19,22-24]. It appears that those incentives do not need to be of high value. Small financial incentives of about US \$1.50 per day or collecting loyalty points for coupons have been shown to substantially impact on uptake rates of eHealth or mHealth interventions [12,25,26].

Only a few studies using incentives for *web-based* PA interventions report *program adherence* rates for incentivized groups [12,23]. Results are equivocal: A web-based step count intervention for patients with ischemic heart disease lasting 24 weeks found a substantial difference between the incentivized

group and the control group regarding program adherence (62.1% vs 51.2%) [23]. The incentive group was given US \$14 per week and they could lose US \$2 per day if they did not achieve their step goals. The results of this loss-framed incentive study point toward a beneficial effect of financial incentives to increase program adherence in web-based PA interventions. In another randomized controlled trial with insurants in Switzerland, differences between the incentivized and control groups were not significant after 3 months. However, program adherence rates were rather high in both groups with 92.1% in the incentive group (US \$10 per month) and 90.5% in the control group [12]. Both groups were given discount to an activity tracker and they had to wear the tracker every day which probably also motivated the control group to participate regularly.

Data on program adherence rates of *app-based* PA interventions (daily step counts) are provided by the Carrot Rewards App Study (N=32,229) in which all users of the app collected loyalty points that could be redeemed for travel, groceries, or movies [22]. Results revealed that 61.9% of those who had initially registered as users completed the intervention after 12 weeks [22]. Unfortunately, there was no control group without incentives in the study, and therefore, their specific effect remains unclear here. From other app-based PA interventions, however, it is known that program adherence is markedly lower when no incentives are provided. For instance, in a naturalistic study by Guertler and colleagues [15], only 25% continued to use the PA promotion app after 6 weeks.

In sum, using incentives in web- or app-based PA interventions has the potential to increase program adherence in clinical trials. However, little is known about the effects of incentives on program adherence in real-life settings. All of the above reported results on program adherence were taken from studies in which users knew that they were part of a study and their data were tracked for study purposes. There is evidence that usage behavior differs substantially between people who use the programs on their own (ie, open-access users) and those who know that they are participants of clinical trials [6,27,28]. For example, Wanner and colleagues [27] showed that only 25.8% of the open-access users visited the PA internet intervention repeatedly compared with 67.3% of the trial participants [27]. This result reflects the high discrepancy of trial and real-life usage and points toward the need for naturalistic studies investigating the effects of incentives among open-access participants [6].

Besides real-life adherence rates, there is also no research on the factors that moderate program adherence in web- or app-based PA interventions using financial incentives. From studies without incentives, we know that age and gender may be significant predictors of PA program adherence. Thus, older age groups have been shown to participate more frequently than younger adults in web-based PA interventions with odds ratios (ORs) ranging between 1.02 and 2.61 [15,27,29,30]. Regarding gender, results are more inconsistent. Whereas some reviews

and studies revealed that women have a higher chance to complete an internet-based behavior change intervention (OR 2.24) [14,29], other investigations demonstrated that men use such interventions more continuously (OR 1.2; reduced hazard ratio to drop out 0.85) [15,27]. Studies that also included BMI in their analyses found that this parameter did not predict program adherence [27,29,31,32]. Given these age and gender differences in web-based program adherence, it is interesting to see how these differences are affected by the application of incentives.

This study's purpose was to expand upon previous research about incentives in web-based PA interventions by examining naturalistic data (ie, real-life usage data) of the largest health insurance company in Germany. Members interested in the web-based intervention *Fitness Coach* could choose to participate in an additional incentive program at the beginning of the intervention. Based on earlier studies [22], we hypothesized that real-life adherence would be higher in the incentive than in the nonincentive group. Furthermore, we considered the effects of moderators and predictors such as age, gender, and BMI on program adherence. This is the first study to examine the role of incentives for program adherence to a web-based PA intervention in a naturalistic, large-scale study of over 18,000 participants.

Methods

Study Design, Setting, and Participants

This investigation is a naturalistic study examining the real-life usage data of open-access users who participated in a web-based intervention called *Fitness Coach*. Naturalistic (observational) studies do not "involve any intervention [...] on the part of the investigator" [33] and the data are not affected by the actions of researchers [34]. Using such a naturalistic study design might help us better understand real-life program adherence to web-based PA interventions. We followed the Strengthening of Reporting of Observational Studies in Epidemiology (STROBE) guidelines [35].

This study includes usage data from September 2016 to June 2018 of the *Fitness Coach* intervention provided by a large German health insurance company. The *Fitness Coach* intervention was freely accessible to everyone in Germany, but only insured persons could participate in the incentive program and noninsured persons could just use the intervention for at least four weeks. Most of the users in this study were members of the insurance company providing the intervention. In the first session of the *Fitness Coach*, they were screened for their suitability to exercise with the Physical Activity Readiness Questionnaire (PAR-Q +) [36]. Exclusion criteria were being younger than 18 years or being pregnant. If users met one or both exclusion criteria, they were advised to ask a physician about participating in the program.

All data entered by the open-access users including information about website use were collected and stored under a pseudonym by Vilva Healthcare GmbH (Berlin, Germany). Prior to the intervention, all users had to sign a data protection declaration in which they were informed that all data obtained could be

further analyzed for research purposes. The Guidelines of the Declaration of Helsinki were followed. Given the retrospective examination of the real-life usage data, no ethical approval was obtained prior to data collection.

Intervention

The *Fitness Coach* is a 12-week long, tailored, and technically guided internet intervention promoting PA. It is based on the MoVo concept consisting of motivational and volitional strategies [37] as well as training progression concepts [38]. The intervention was developed in 2005 by an insurance company in Germany and was relaunched in September 2016 in an updated version [11]. All users of the intervention receive an individualized training program tailored to their personal goals and daily life. This consists of training videos that match the person's goals, that is, becoming stronger, improving one's endurance, or becoming more flexible ([Multimedia Appendices 1 and 2](#)). Users also receive psychological input to help them initiate and maintain their behavior change. The intervention contains multiple behavior change techniques such as goal setting, action planning, self-monitoring, and feedback as well as coping planning [39].

Incentive Program

As a form of primary prevention, health insurance companies in Germany are legally obliged to use incentives for promoting healthy behavior (eg, increasing PA and reducing weight). There is also evidence that investing approximately €30 (about US \$33) per person and per year in incentives for health behavior change reduces the overall costs for the insurance company by approximately €100 (about US \$112) per person and per year [40,41]. Based on these findings, all users of the web-based intervention who were insured by the insurance company could register for the incentive program at the beginning of the intervention. In order to receive the incentive, the users had to log the completion of at least three tasks (eg, strength, endurance, or mobility exercises; evaluating one's well-being; reading background information) per week in 10 of 12 weeks. In case of adherence to the intervention, they received 500 credit points on their health insurance account. Upon the collection of 500 further credit points within 1 year (earned via membership in sports clubs or gyms, regular medical check-ups, or participation at a sporting event), they could choose between €30 (about US \$33) cash back and €60 (about US \$68) health credit. This health credit could be used for additional medical and health services such as professional tooth cleaning, acupuncture, osteopathy, and fees for gyms or sports clubs.

Variables and Statistical Analyses

Demographic characteristics of all users including age, gender, and BMI were obtained from the self-report questionnaire included in the first session of the intervention. Each login to the intervention per day was captured, reported as mean (SD), resulting in a minimum number of 1 and a maximum number of 84 logins over the 12-week intervention span (16.9 [SD 16.8]). In order to categorize adherence, login data were summarized per week. If a user had at least one login per week with at least three logged tasks in the week, the user was adherent and participation in that week was defined as successful

[42]. Based on the health insurance company's definition of successful participation (ie, ≥ 10 weeks), we classified the number of weeks with successful participation into 4 categories or adherence groups:

The *low adherence* group included all users participating for 1-3 weeks during the 12-week intervention span. *Occasional adherence* was defined as participation between 4 and 6 weeks. If users had 7-9 weeks of successful participation, we categorized them as *strongly adherent*. All persons completing 10 or more weeks successfully were defined as the *complete adherence* group (Figure 1). The last group was incentivized by the health insurance company.

Given the naturalistic sample, group sizes differ substantially in all 4 adherence groups as well as in the incentive and nonincentive groups (Table 1). We compared demographic variables between incentive and nonincentive groups using two-tailed Welch *t* tests and chi-square tests.

To investigate which characteristics would increase the chance of complete adherence and thus allowing the users to receive

the incentive, binary logistic regressions were conducted using SPSS Statistics version 25 (IBM Corporation). We combined the first 3 adherence groups (low, occasional, and strong; =0) and compared them with the complete adherence group (=1) to best display the incentive effect on adherence. Incentive participation (0=no incentive, 1=incentive), gender (0=female, 1=male), and age and BMI (both continuous variables) were considered as baseline predictors. Furthermore, the interactions of incentive \times age, incentive \times gender, and incentive \times BMI were considered as moderators for the association between incentives and program adherence. There were no missing data for adherence, incentive participation, age, and gender. Because it was not mandatory to enter height and weight, BMI data were missing in 530 cases, resulting in a total number of 18,083 users included in the logistic regression. After checking for multicollinearity between incentive participation, age, gender, and BMI (variable inflation factors between 1.024 and 1.066), all demographic variables and interactions were included in the regression model. Model fit was judged using Nagelkerke R^2 . The level of significance was set at $P < .05$.

Figure 1. Percentage of Fitness Coach usage over 12 weeks divided into 4 adherence groups (N = 18,613).

Table 1. Demographic characteristics of the sample, grouped by adherence and incentive status.

Results

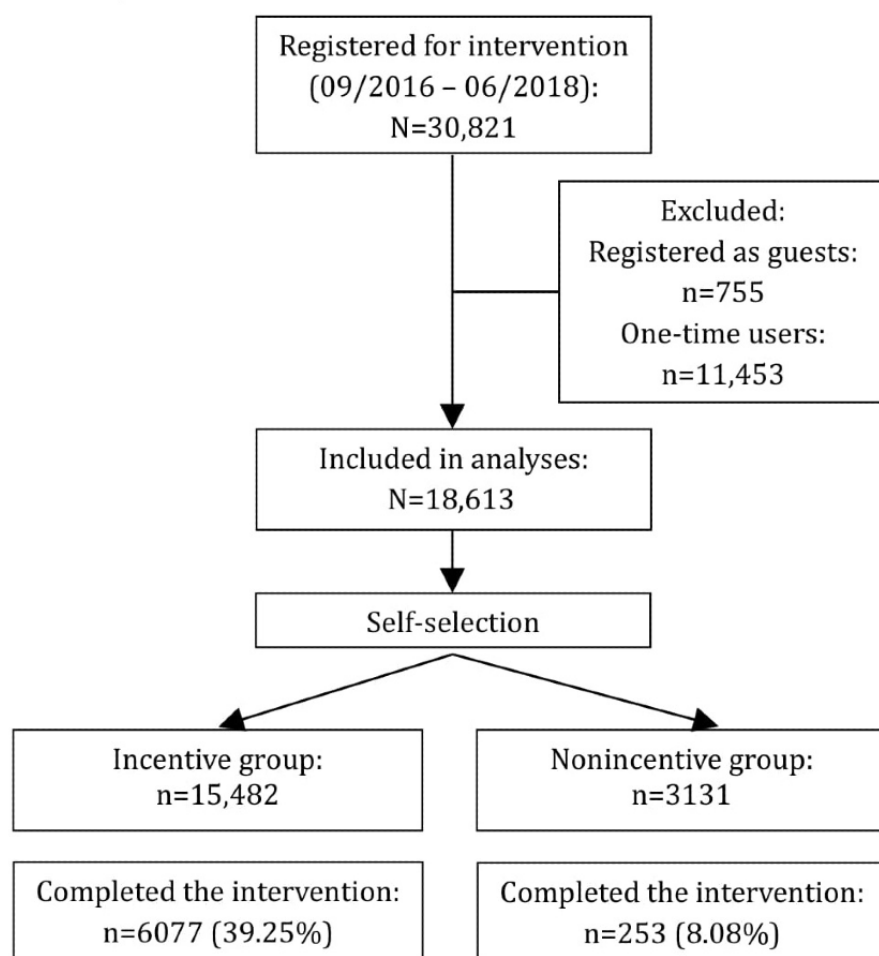

Participants

From September 2016 to June 2018, a total of 30,821 persons registered for the Fitness Coach intervention. Of these, 755 (2.45%) registered as guests who were not insured by the health insurance company and were therefore unable to participate in the incentive program. In addition, there were 11,453 (37.16%) insured persons who visited the internet intervention only once

and had no further login. All guests and one-time users were excluded from further analyses, so the demographic analyses included the total number of 18,613 insured users (Figure 2).

Demographic characteristics differed significantly between the incentive and nonincentive groups. Age ($P<.001$), BMI ($P<.001$), and gender ($P<.001$) differences indicated that older and more male users with a lower BMI register for the incentive (Table 1). Table 1 also displays the total sample size for each group at the start and at the end of the intervention (complete adherence).

Figure 2. STROBE flow chart of Fitness Coach participants.

Participation and Attrition Rates

In total, 34.01% of users (6330/18,613) were completely adherent (Figure 2). Among those complete adherers, the participation rate in the incentive group was 4.8 times higher than that in the nonincentive group: 39.25% (6077/15,482) of all members in the incentive group versus 8.08% (253/3131) of all members in the nonincentive group. By contrast, 73.14% (2290/3131) of members in the nonincentive group were classified as being lowly adherent, which means participating in less than 4 out of 12 weeks of the intervention, in comparison to 33.15% (5133/15,482) of members in the incentive group.

The overall nonusage attrition rate (low, occasional, and strong adherence combined) in the nonincentive group reached 91.92% (2878/3131) compared with 60.75% (9405/15,482) in the incentive group (Table 1). The cutoff point of nonusage attrition was set at 9 or less successful intervention weeks.

Predictors of Intervention Completion

Binary logistic regressions revealed that participating in the incentive program was a statistically significant predictor ($P<.001$) at baseline for completing the intervention (OR 12.638, 95% CI 5.614–28.449; Table 2). There were also moderating effects on the association between incentive participation and

program adherence. Male users in the incentive group showed significantly higher odds to complete the intervention than female users overall and male users in the nonincentive group (OR 1.761, 95% CI 1.272-2.438). By contrast, the interactions between the incentive group and age or BMI did not yield significant odds for intervention completion.

Without taking the financial incentive participation into account (main effect), both age ($P<.001$) and gender ($P=.017$) proved to be significant baseline predictors of complete adherence to the Fitness Coach intervention for all users (Table 2), with older users having higher odds of Fitness Coach completion than younger ones (OR 1.023, 95% CI 1.013-1.033) and women having lower odds to be completely adherent than men (OR 0.679, 95% CI 0.494-0.933).

Discussion

Principal Findings

This large-scale, naturalistic study with a nationwide sample of 18,613 users examined the effect of an incentive program and its moderators on program adherence to a web-based PA intervention. Participants were members of the largest German health insurance who either decided to take part in an additional incentive program at the beginning of the intervention or rejected the use of the incentive program. Results showed that complete program adherence was 4.8 times higher in the incentive group than in the nonincentive group. In line with this finding, binary logistic regressions revealed incentive program participation to be a strong and significant predictor for complete adherence (OR 12.638, 95% CI 5.614-28.449, $P<.001$). This incentive effect on program adherence was moderated by gender, but not by BMI and age. Males in the incentive group showed the highest odds for program completion. Furthermore, gender and age also exhibited significant main effects on program adherence: being male and being of older age were associated with higher program adherence. However, BMI was not a significant predictor of program adherence.

Our findings demonstrate that even a small incentive (chance of €30 [about US \$33] cash back at the end of the intervention) was able to enhance program adherence by almost five times, emphasizing the important motivating role of external rewards, at least in the initial phase of a new health behavior [19,39,43]. This result gains in importance because it is based on real-life usage data, which allows for a higher ecological validity. To the best of our knowledge, this is the first study investigating the effects of incentives on program adherence in a web-based PA intervention on the basis of naturalistic data. Therefore, no

direct parallels can be drawn with data from the literature. However, comparisons can be made with similar real-life studies in which no incentives were used [27,28]. Those studies reported program adherence rates of 10%-25.8%. Compared with these findings, the program adherence rate of our nonincentive group (8.08%, 253/3131) is at the lower end of this range. By contrast, the program adherence rate of our incentive group (39.25%, 6077/15,482) substantially exceeded the program adherence rates of those two studies, suggesting once again that incentives might make a clear difference in the compliance with web-based PA interventions.

This study also found a *moderating effect* of gender on the association between incentive participation and program adherence. Men in the incentive group had significantly higher odds to complete the intervention than female users overall and male users in the nonincentive group, indicating that financial incentives may appeal particularly to men. This is supported by Czap and colleagues [44] who reported men to be more attracted to financial incentives than to other nonfinancial nudges. Given this clear gender difference in the motivational power of financial incentives, future research could investigate more closely which equivalent incentives might be more appealing to women.

By looking at the *main effects* of age on program adherence, we found older users to be significantly more inclined to complete the intervention than their younger counterparts, yet with a small OR of 1.023 (95% CI 1.013-1.033; $P<.001$). This result is well known from the literature, which indicates that older users have higher chances to be adherent than younger users [15,27,29,30]. It appears that on average users in their mid-40s are the most adherent ones to the web-based PA intervention. Regarding the main effect of gender on program adherence, there were more women than men participating in

the Fitness Coach, suggesting that improving one's fitness via internet appeals at first sight to women. This is in line with previous research reporting higher uptake rates of web-based PA interventions among women [6,8]. However, if we do not look at uptake rates but at adherence rates, the picture is quite different: women in our sample showed significantly lower odds to be completely adherent than men. There are several studies which support the finding that men are more adherent to these kinds of interventions [15,27]. For example, a large-scale, open-access evaluation from Switzerland yielded a significantly higher chance (OR 1.23) for men to participate repeatedly in a web-based intervention than for women [27].

The scope of this study was on *program adherence*; therefore, no definite conclusions can be drawn on the actual adherence to regular PA after the end of the 12-week intervention (behavior adherence). However, it is in the logic of time-limited behavior change programs that after finishing the program the newly acquired health behavior has to be continued in everyday life on one's initiative. We cannot be certain how successful the health behavior change has been in the present sample, yet there is evidence that a higher level of program adherence also leads to sustained health behavior change in everyday life [17].

Strengths and Limitations

This study is the first large-scale examination that investigated whether financial incentives increase program adherence to a web-based PA intervention under real-life usage conditions. Because of the naturalistic study design, the results of this investigation have high ecological validity.

However, some limitations need to be addressed. Internal validity might be threatened as the assessment of program adherence depends on self-reported participation behavior. There is also a risk that self-reported data on age and BMI may be distorted by socially desirable response tendencies or even worse, false data, to reveal as little information about oneself as possible. The study uses a naturalistic design with self-selection of participants into the incentive or nonincentive conditions. Given this design, it was not possible to randomize users into these two groups. Overall, both groups differed substantially regarding age, gender, and BMI with older users, more men, and users with lower BMI choosing to participate in the incentive program. It might be hypothesized that participants in the incentive group were more motivated from the beginning to use the program than users who did not register for the incentive.

Given the unequal sample sizes for incentive and nonincentive groups (15,482 vs 3131) as well as for the low, occasional, and strong adherence groups combined and the complete adherence group (12,283 vs 6330), the results of binary logistic regressions might be overestimated. This is reflected, for example, in very large CIs and statistical significance despite small OR (eg, $OR_{Age} 1.023$, 95% CI 1.013-1.033; $P < .001$). However, the decision for the large comparison group was made from a content perspective focusing on representativeness and external validity. The unbalanced analyses took account of the naturalistic data and better displayed how complete adherers differ from the other users who did not successfully finish the intervention. The logistic regression was also based on large sample size. While the unbalanced distribution might have affected the width of the confidence intervals, it has not affected the ORs in the logistic regression because there is enough power in this analysis.

Because only age, gender, and BMI were assessed at registration, we cannot exclude that other factors which were not investigated, such as education or socioeconomic status, may have influenced the results. The user's socioeconomic status, in particular, might be of great interest for incentive participation and adherence as users with lower income are more likely to be appealed by the incentives [19] and are more adherent to interventions changing health behavior [12,45].

Conclusions

This examination points out that financial incentives in the form of cashback or health credits have the potential to increase program adherence in a web-based PA intervention. Incentives are likely to act as an external motivator that enhances program adherence, which in turn can be the basis for a more intrinsically motivated, longer-lasting PA behavior in real life after the program has ended (behavior adherence). Therefore, health care providers may encourage program participation by providing differentiated incentives depending on gender, age, or BMI in web-based interventions promoting PA. Further investigations are needed to support these findings; in particular, it is necessary to further clarify the moderating role not only of gender, age, or BMI, but also of other potentially relevant factors such as socioeconomic status or education. The study results are based on naturalistic data with a high ecological validity; in the next step, it is necessary to confirm these findings in more controlled studies (eg, randomized controlled trials) with higher levels of internal validity.

Acknowledgments

The project was funded by Techniker Krankenkasse (German Health Insurance Company) and the article processing charge was funded by the University of Freiburg in the funding program Open Access Publishing. The project funder had no role in study design, management, analysis and interpretation of data, writing of the report, and the decision to submit the report for publication. We thank the Techniker Krankenkasse, in particular Dr Nicole Knaack, Dagmar Koeppel, and Dr Kerstin Hofreuter-Gaetgens for supporting this project. Besides, we thank Dr Boris Gauss, Susanne Dworschak, and Valeska Zarwell of Vilva Healthcare GmbH for providing the data and for their technical support. Finally, a big thank you goes to Lisa Sophia Schmiedeshoff for her excellent work on data preparation and data management.

Authors' Contributions

RW, AM, CR, and RF designed the study; RW, AM, CR, JB, and RF analyzed and interpreted the data; RW drafted the manuscript; AM, CR, JB, and RF revised the manuscript.

Conflicts of Interest

RW, AM, and JB report grants for the development and evaluation of the Fitness Coach by Techniker Krankenkasse. CR and RF do not report conflicts of interest.

Abstract

Background: Virtual reality (VR) technology is a powerful tool for augmenting patient experience in pediatric settings. Incorporating the needs and values of stakeholders in the design of VR apps in health care can contribute to better outcomes and meaningful experiences for patients.

Objective: We used a multiperspective approach to investigate how VR apps can be designed to improve the periprocedural experiences of children and adolescents, particularly those with severe anxiety.

Methods: This study included a focus group (n=4) and a survey (n=56) of clinicians. Semistructured interviews were conducted with children and adolescents in an immunization clinic (n=3) and perioperative setting (n=65) and with parents and carers in an immunization clinic (n=3) and perioperative setting (n=35).

Results: Qualitative data were examined to determine the experience and psychological needs and intervention and design strategies that may contribute to better experiences for children in three age groups (4-7, 8-11, and 12-17 years). Quantitative data were used to identify areas of priority for future VR interventions.

Conclusions: We propose a set of ten design considerations for the creation of future VR experiences for pediatric patients. Enhancing patient experience may be achieved by combining multiple VR solutions through a holistic approach considering the roles of clinicians and carers and the temporality of the patient's experience. These situations require personalized solutions to fulfill the needs of pediatric patients before and during the medical procedure. In particular, communication should be placed at the center of preprocedure solutions, while emotional goals can be embedded into a procedure-focused VR app to help patients shift their focus in a meaningful way to build skills to manage their anxiety.

Introduction

A fundamental role of clinicians looking after children having medical procedures in hospitals is to try to minimize any distress associated with that procedure. A negative experience of a medical procedure has implications more extensive than the immediate distress of that event. The imprint will be left on the child for all subsequent medical procedures. A range of approaches may be attempted as a periprocedural intervention (ie, intervention prior, during, or after the medical procedure) to mitigate such negative experiences, especially in the context of significant anxiety associated with needles in children requiring vaccinations [1]. In-hospital sedation services facilitate vaccination in patients who are otherwise unable to complete their immunization schedule due to severe avoidance behavior. Improved immunization experiences for patients, their caretakers, and staff may reduce the need for pharmacological intervention in the form of sedation, which may be difficult to administer or sometimes harmful [2]. Other approaches, such as exposure therapy, require long-term time commitments and significant resources [3]. In this paper, we present an exploratory study into ways through which virtual reality (VR) might best be employed to enhance the pediatric patient experience.

Technology-mediated solutions for focus-shifting or distraction positively alter the periprocedural experiences of children, to reduce anxiety and decrease pain response [4]. Current evidence suggests efficacy for technologies such as hand-held video games [5], tablet computers [6], immersive 360 videos [7], and interactive VR games [8]. VR technology has been explicitly explored as an anxiety management intervention in the context of vaccination [9] and acute procedures such as laceration repair and wound care [10]. With recent advances in commercial VR Head-Mounted Display (HMD) devices (eg, Oculus Quest by Oculus VR), the availability of this technology has dramatically increased. Recent market research [11,12] found that of 1917 children (aged <15 years) surveyed in the United States of America, only 19% were unaware of VR technology in the Spring of 2017. This mainstream awareness of VR technology presents an opportunity that we can leverage to develop effective interventions to support pediatric treatment.

The efficacy of VR apps is often attributed to the distraction created by the immersive environment, which creates an illusion of presence in the virtual world [13] and therefore reduces the user's cognitive resources to attend to distressing stimuli. Distraction in VR may be achieved in two ways: passive and active [14]. Passive engagement can be in the form of viewing an immersive 360-degree video without guiding the user's attention. Active distraction engages the user in gameplay or cognitive tasks in order to shift their focus to virtual objects and away from the negative stimuli [15]. Distraction can be more effective if patients are engaged in emotionally relevant VR experiences [16] as it enables them to dissociate their virtual and physical bodies [17].

Current examples of VR for managing pediatric anxiety do not exploit the multitude of strategies possible in VR, particularly active distraction. Additionally, there is a lack of knowledge about the needs of pediatric patients as well as the role of other

stakeholders involved in patient care, including clinicians and parents, that can be incorporated into future pediatric VR solutions [18]. This study aimed to investigate opportunities for designing VR apps for children and adolescents in order to improve their experience and help them manage anxiety in the context of perioperative care and immunization.

To achieve this aim, we followed a unique multiperspective and qualitative approach. We collected in-depth data from multiple stakeholders to explore factors that can inform the design of future VR solutions. We conducted a focus group and surveyed clinicians to collect their views on typical strategies for managing pediatric anxiety in periprocedural settings. To understand patient responses to current anxiety management strategies, we conducted semistructured interviews with children and their carers.

Methods

This study included a focus group and survey of clinicians, in addition to interviews with children and parents using protocols approved by the Sydney Children's Hospitals Network Human Research Ethics Committee (HREC Reference Number-LNR/18/SCHN/160 HREC/17/SCHN/429). All study participants were recruited from The Children's Hospital at Westmead, NSW in Australia and provided written informed consent before participation. Focus groups and semistructured interview sessions were audio-recorded.

Clinicians

Focus Group

Four health professionals were recruited to participate in a 90-minute focus group convened by two researchers; one anesthetist and one human-computer interaction (HCI) researcher. The aim was to gain a better understanding of the strategies used by clinicians to manage periprocedural anxiety in their pediatric patients. The session started with a brief explanation of VR technology, followed by questions that guided the discussion, like "Do you use any particular strategies to shift the focus of children during the procedures?" and "How do you choose which approach will work for which patient?"

Survey

A total of 56 clinicians were recruited by email and direct approach to complete a survey, repeated three times, and focusing on children in three age groups: 4-7, 8-11, and 12-17 years old. The questionnaire was developed by researchers with a background in clinical anesthesia based on their experience. Participants rated the likelihood of 13 items to induce anxiety in children and adolescents in the preoperative, operative, and postoperative phases (5-point scales, ranging from "not at all" to "very much"). Participants were then asked to describe strategies based on their experience that made the patient feel good, calm, or reassured before going in for an operation.

Children and Adolescents

Semistructured Interview in the Immunization Clinic

Three participants were recruited from the immunization clinic for 90-minute interview sessions convened by two HCI

researchers and a child-life therapist. Participants attended the meetings with their parent(s) but were interviewed without them being present in the room. The interview started with, “Can you tell us about what it was like last time you came in for immunizations?” We then explained the VR technology and asked, “what would you like to see or do in VR?” Drawing and clay play were used to help participants communicate their ideas.

Semistructured Interviews in the Perioperative Setting

Patients presenting for day surgery were approached in the hospital preoperative waiting room for 15-minute interview sessions. Members of the research team with a background in clinical anesthesia developed questions for semistructured interviews that included a series of rating scales to capture how much the participant knew about the hospital visit on the day of the procedure (4-point scale, ranging from “nothing at all” to “everything”). Additional open-ended questions inquired about things that make children feel good about going to sleep for an operation and things about which they were concerned. A final question asked about the quality of previous experiences of anesthesia where relevant (4-point scale, ranging from “very bad” to “very good”).

Parents and Carers

Semistructured Interview in the Immunization Clinic

Three parents were recruited (children were interviewed separately) for 90-minute interviews aimed to gain insight into immunization experiences and strategies that helped their child, like “can you tell us what it was like for your child last time you come in for immunizations?” and “what sort of things have you or someone tried to make the experience easier?” Participants were then briefed on VR technology and asked if they thought it could help their child.

Semistructured Interviews in the Perioperative Setting

Parents and carers were recruited while in the postoperative waiting area, shortly before discharge from the hospital. Each interview lasted about 10 minutes. We used rating scales and

open-ended questions, which were developed by researchers with a background in clinical anesthesia based on issues raised by parents and carers in their clinical practice. Participants rated how much they knew about various aspects of the appointment (4-point scale, ranging from “nothing at all” to “everything”). Open-ended questions included “what were good or difficult aspects of their hospital visit and postoperative time?” and “what can be improved?” and whether they were worried about the operation (yes/no). When children had an experience of prior anesthetics, participants rated the quality of that experience (5-point scale, from “very bad” to “very good”).

Results

All interviews and focus group recordings were transcribed. Two researchers performed thematic analysis separately and discussed the outcomes until they agreed on a coding scheme based on similarity in meanings associated with participants’ statements, following what Braun and Clarke [19] identify as a bottom-up or inductive approach. The coding scheme included four themes based on the interview data obtained from children and adolescents in the immunization group, which exhibited similarity to the parents’ group in the same setting. The themes were then used as a coding scheme to analyze interview data in all three groups in that setting. Survey data was tabulated in Excel (Microsoft Corporation), and average ratings defined. Participants’ comments in the perioperative setting were analyzed to identify areas of interest and strategies that helped with calming children based on their experiences.

Clinicians

Focus Group

Participants (2 males, 2 females) were anesthetists (n=2), a registered nurse (n=1), and a child life therapist (n=1). Participants worked with children in a variety of settings, including perioperative care, procedural sedation settings, and immunization services. All participants were familiar with VR technology, but none had used it in their practice. Four themes were identified in the participants’ statements (Textbox 1).

Textbox 1. A summary of clinicians' perspectives on design and intervention strategies that fulfill the experience and psychological needs of pediatric patients to manage their periprocedural anxiety.

Experience needs

- Patient's prior experience
- Parent's attitude
- Patient's attitude

Psychological needs

- Sense of agency
- Privacy

Intervention strategies

- Set achievable goals for the patient
- Provide distraction
- Improve communication
- Personalize intervention
- Educate

Design strategies

- Provide positive emotional experiences
- Embed narrative storytelling
- Accomplishment and satisfaction through game tasks
- Match contextual requirements

Experience Needs

The patient's prior experience and their parent's attitude towards their child's anxiety can hinder a child's ability to manage their periprocedural anxiety or even promote anxiety. In response to prior negative experiences, some children become anxious as soon as the nurse or doctor enters the room. This response is often exacerbated if children detect parental anxiety. Our participants identified three typical personas based on the patient's attitude: *trusting child* (who is easy to connect with and instruct), *timid child* (engaging with whom requires additional effort by clinicians), and *anxious child* (engaging with whom requires the most effort, and sometimes multiple visits to the hospital).

Psychological Needs

Providing a sense of agency (eg, offering realistic choices to the patient) and ensuring privacy throughout the appointment are essential considerations for fulfilling the psychological needs of pediatric patients to manage their anxiety.

Intervention Strategies

Typical strategies for pediatric anxiety management include setting achievable goals, so the patient gains a sense of accomplishment, distraction through activities, such as singing songs, blowing bubbles, playing games, communication of information, and allowing time for familiarization. One participant noted, "I gave a mask to a patient to take home, and they practiced diligently every day before the next appointment and were then able to complete the procedure more

comfortably." Participants suggested they tailored their strategies to the specific needs of the patient, such as by adjusting the level or form of distraction. A fundamental difference was evident among the strategies sought by the anesthetists, the child life therapist, and the nurse. Anesthetists' interactions with children typically last a few minutes. They are focused on negotiating alternative scenarios with the child (eg, a choice between taking the mask or needle injection), whereas the therapist and the nurse in the group wanted to communicate, educate, and prepare children for future appointments.

Design Strategies

Participants suggested future VR solutions should provide enjoyable emotional experiences (eg, the thrill of riding a roller coaster), embed narrative storytelling (eg, adventure and exploration), and create a sense of accomplishment in children. Additionally, participants suggested creating virtual experiences that correspond to the events of the physical environments (eg, seeing the wind blow in VR precisely at the time as receiving gas during induction of anesthesia). Physical interaction with the device was noted as important, eg, operating a device with both hands is impractical if one hand must be still for the clinician to establish intravenous access.

Survey

Participants were anesthetists (n=23), anesthesia recovery nurses (n=19), and preoperative nurses (n=8). The clinical experience of participants varied from 1 to 30 years (mean 11, SD 8.28). Average clinician ratings indicate their views on what pediatric patients worry about before, during, and after an operation. As

shown in [Table 1](#), the top three worries for the 4-7 year age group were: going to sleep with a needle (mean 4.62, SD 0.60), being surrounded by strangers (mean 3.76, SD 0.92), and not knowing what is about to happen (mean 3.68, SD 1.02). In the 8-11 age group, the top three worries were: going to sleep with a needle (mean 4.08, SD 0.72), not knowing what is about to happen (mean 3.76, SD 0.80), and possible pain after the procedure (mean 3.48, SD 0.89). For patients aged 12-17, the top worries were: pain after the procedure (mean 3.94, SD 0.68), waking up during anesthesia (mean 3.92, SD 0.85), and not knowing what is about to happen (mean 3.64, SD 0.98).

When asked what things could make the child feel good, calm, or reassured before an operation, clinicians specified some strategies that were common to all age groups:

- Being friendly and creating a positive experience to set a favorable precedent,

- Creating a calm perioperative environment,
- Using distraction techniques (eg, blowing bubbles) to provide experiences of joy or surprise, was stated as particularly important for younger children (4-7 and 8-11),
- Keeping familiar items such as toys that are comforting to pediatric patients,
- Effective communication and providing adequate, truthful and age-appropriate preoperation information was described as more relevant to older children (12-17),
- Positive and friendly engagement, eg, sitting with the patient rather than standing, particularly with younger age groups (4-7 and 8-11),
- Allowing parents to be present, keeping parents calm, and
- Acknowledging the child's agency by offering them choices (eg, gas or needle).

Table 1. The average rating (likelihood of each item occurring on a 5-point scale ranging from “not at all” to “very much”) of clinician's responses to the repeated survey on the experience of pediatric patients in three age groups (n=56).

Survey question	Patients		
	4-7 years, mean (SD)	8-11 years, mean (SD)	12-17 years, mean (SD)
When it comes to the preoperative phase, do you think children are most worried about...			
Not knowing what is about to happen?	3.70 (1.02)	3.8 (0.80)	3.6 (0.98)
Waiting in the pre-op area?	2.6 (0.84)	2.8 (0.97)	2.6 (0.95)
Going into theatres?	3.6 (0.73)	3.4 (0.25)	3.1 (0.87)
Being surrounded by strangers?	3.8 (0.92)	2.9 (0.79)	2.2 (0.71)
Going to sleep with a mask?	3.5 (0.76)	2.9 (0.74)	2.4 (0.86)
Going to sleep with a needle?	4.6 (0.60)	4.1 (0.72)	3.4 (0.70)
Reflecting on how kids think about the actual operation, do you think they are worried about...			
Complications that might happen during the operation?	2 (0.82)	2.7 (0.92)	3.5 (1.01)
Waking up during anesthesia?	2.4 (1.14)	3.3 (1.04)	3.9 (0.85)
Reflecting on what kids think about what will happen after the surgery itself, do you think they are worried about...			
Pain after the procedure?	3.2 (0.98)	3.5 (0.89)	3.9 (0.68)
Feeling sick after the procedure?	2.1 (0.95)	2.6 (0.99)	3.1 (0.97)
Being okay to go home?	2.5 (1.18)	2.8 (0.91)	3.2 (0.87)
Complications after the procedure?	1.7 (0.82)	2.3 (0.89)	3.2 (0.90)
Having a scar after the operation?	1.8 (0.71)	2.6 (1.13)	3.4 (0.92)
Making a full recovery?	2.1 (1.02)	2.6 (1.16)	3.2 (1.00)

Children and Adolescents

Semistructured Interviews in the Immunization Setting

Three participants (2 males, 1 female) aged 12-15 years (mean 13) were recruited. All participants said they had prior

experience of severe anxiety associated with needles. All participants were familiar with VR technology. Four themes were identified ([Textbox 2](#)).

Textbox 2. Children and adolescents' perspectives of their experience and psychological needs and intervention and design strategies that can help them manage their periprocedural anxiety.

Experience needs

- Disconnect from the surroundings through an immersive experience
- Engage in simple activities that are easy to learn
- Engage in recreational activities such as creating art

Psychological needs

- Sense of agency
- Experience a range of emotions
- Set emotional goals

Intervention strategies

- Provide distraction
- Time the distraction well to start distraction before the procedure begins
- Involve other stakeholders (such as parents) in the intervention
- Build resilience through empathic relationships (eg, with pets)
- Personalize intervention

Design strategies

- Embed narrative storytelling
- Familiar yet novel design elements
- Mask unpleasantness, particularly noises

Experience Needs

Participants suggested that prior negative experience impedes their ability to manage their anxiety during hospital visits. VR was suggested to be helpful as it is “immersive,” unlike tablet or mobile technology, and it can disconnect them from their physical environment. One participant said, “I just want to get out of there” and wanted to wear the VR headset at the beginning of the appointment to avoid seeing the needle. Simple VR games that are easy to learn and play in a short time were suggested, eg, creating art, playing a favorite sport, singing, and playing music.

Psychological Needs

Participants recognized that a useful VR experience must help them calm down autonomously through gameplay. They gave examples of including emotional goals, starting with “excitement” to match their state before receiving an injection (eg, going on exciting VR adventures) and ending with a “relaxing” experience. One participant said, “I know I can never be relaxed immediately, so I want something exciting to begin with.”

Intervention Strategies

Distraction strategies were discussed, such as involving other stakeholders in the game experience (eg, an accompanying parent or carer). Participants noted the importance of personalization if these were to occur in VR. One participant wanted to take their pet to the appointment for comfort, which

may suggest the relevance of empathic interactions for coping strategies.

Design Strategies

Several themed narratives were suggested for a VR app, such as nature, superpowers, learning something new, and playing familiar games. Participants also discussed interactive sensory experiences such as “fast-paced” music to mask procedure noises.

Semistructured Interviews in the Perioperative Setting

A total of 65 (44 males, 21 females) participants aged 4-16 (mean 10, SD 3.89) were recruited. Overall, 49 (75%) participants had previous experiences of anesthetics (1 to 17 times, mean 4 times) and rated the quality of those experiences at a mean score of 2, SD 0.81 (4-point scale, “very bad” to “very good”) (Table 2).

Overall, 37 (56%) participants claimed they had worries “about the operation or any other things that might happen before, during, or after the operation.” Worries about what happens while they are asleep were: having bad dreams, inadequate analgesia, duration or depth of sleep, a repeat of a bad experience, and the surgery itself. Worries about the anesthetics were: change of location, loss of sensation, uncontrolled movement while asleep, sharp objects such as needles, and missing friends and school. Finally, worries related to the postoperative experience were: being alone, emotional lability, the presence of an intravenous cannula, overnight admission, removal of tapes, and surgical outcomes.

Concerning children's knowledge about their hospital visit, the highest rating was given to knowing what happens during the anesthesia (mean 2.28, SD 0.97) and the lowest rating to

knowledge about going into the rooms where the operation happens (mean 2.11, SD 0.99).

Table 2. Children's average ratings of how much they knew about the hospital visit on the day of the procedure (4-point scale, ranging from 1="nothing at all" to 4="a lot or everything").

Survey question	Mean (SD)
How much did you know about what it would be like when you got to the hospital?	2.28 (1.02)
How much did you know about where you would spend time before the surgery?	2.19 (1.03)
How much did you know about who you would meet before the operation?	2.19 (0.90)
How much did you know about what it would be like going into the operation room?	2.11 (0.99)
How much do you know about what happens during an anesthetics?	2.28 (0.97)
How much do you know about what happens during surgery?	2.16 (1.01)
How much do you know about what happens to you after the surgery?	2.19 (0.94)

Additional comments revealed opportunities to improve preoperative experiences across all age groups, such as effective communication of preoperative information (knowing they will not be able to feel the pain or needles during the surgery), having a parent present, and anticipation of positive surgical outcomes. Distraction was mentioned by children in age groups 4-7 and 8-11, but not by those age 12+, who additionally mentioned "staff attitude" and "a child-friendly environment." When asked what could be fun with the anesthetics and operation, responses varied from having access to toys, games, and music, getting well, sleeping, and the hospital facility itself.

Parents

Semistructured Interview in the Immunization Clinic

All three participants identified their child as having severe anxiety related to needles. Only one parent was familiar with VR technology. Details of the four themes are discussed below:

1. *Experience needs.* Participants discussed their emotional experiences, such as helplessness due to their perceived inability to help with their children's anxiety. One parent felt that they did not have the means or time to prepare their child for appointments at the hospital.
2. *Psychological needs.* Parents mentioned that having information about the procedure affords their child a level of control, whereas feeling that someone is trying to control their child's response to anxiety only diminishes their ability to manage it. They suggested that being allowed to take personal items to the appointment (eg, their favorite music) is often helpful.
3. *Intervention strategies.* Two strategies were suggested for regulating anxiety during immunization appointments. One was distraction (eg, playing games) so that the child does not "see" the needle, and the other was goal setting to shift their focus from the unpleasant elements.
4. *Design strategies.* Parents described their children as being sensitive (eg, building things up in their head that adds to

their anxiety) who sometimes feel guilty for their anxiety. They suggested that a VR experience could help them build a sense of accomplishment and pride.

Semistructured Interview in the Perioperative Setting

A total of 35 parents and carers were recruited. Their children were aged 4-16 (mean 9.86, SD 3.85). Overall, 23 (65%) parents identified their children as having prior experiences of anesthesia (prior instances mean 4.3, SD 4.66), with an average quality of prior experiences rated 3.91, SD 1.04 (5-point scale, "very bad" to "very good"). In total, 12 parents were concerned about what might happen before, during, or after the operation.

When asked how they might describe their child at the beginning of anesthesia (4-point scale, "anxious" to "calm"), the average rating was 3.31 (SD 0.76). The average knowledge about various aspects of the procedure is shown in Table 3. Most items were rated above 3, with the lowest ratings given for knowledge about waiting before the operation (mean 3.09, SD 1.03) and what happens during surgery (mean 3.09, SD 0.97).

When asked about what might improve their child's preparation for anesthesia, parents suggested making children feel safe to set a better precedent for future appointments. They also suggested creating a positive environment (eg, smaller waiting rooms), distracting and keeping the child occupied (eg, gameplay), clear communication of what to expect, positive engagement with trusting and caring staff and allowing a parent to be present at the time of induction.

When asked about what they found difficult at the hospital, participants cited preoperative anxiety and fasting, worrying about the child will wake up during the surgery, the postoperative state of their child (eg, being disoriented), long waiting times, the environment not being child-friendly, and lack of information about the procedure and logistics (eg, car park).

Table 3. Parents' (n=35) average ratings of how much they knew about the procedure before arriving at the hospital (4-point scale, ranging from 1="nothing at all" to 4="everything").

Survey question	Mean (SD)
Before arriving today, how much did you know about what to do when you got to the hospital?	3.32 (0.64)
Before arriving today, how much did you know about what the room where you wait before the operation would be like?	3.09 (1.03)
Before arriving today, how much did you know about who you would meet before the operation?	3.30 (0.92)
Before today, how much did you know about what it would be like going into the actual operating room?	3.18 (0.87)
Before today, how much did you know about what happens during an anesthetic?	3.15 (0.82)
Before today, how much did you know about what happens during surgery?	3.09 (0.97)
Before today, how much did you know about what happens after surgery?	3.21 (0.88)

Discussion

There is currently a substantial gap in meaningful and truly human-centered applications of VR for managing pediatric anxiety, which can be addressed by putting design and the needs of the patients at the heart of VR development [20]. In order to characterize effective VR design strategies that are suitable for this population, we conducted a multiperspective investigation. Data obtained through a focus group, survey, and interviews allowed us to synthesize the perspectives of three stakeholder

groups: patients, parents, and clinicians. Based on the findings, we propose 10 factors that highlight opportunities for future VR design beyond simple distraction, to enhance the experiences of children and adolescents in the periprocedural setting. These are discussed next.

Factors Determining a Positive Experience for Pediatric Patients

Table 4 summarizes 10 factors to guide the design of future pediatric VR solutions.

Table 4. A list of 10 design factors that can be used as input when devising a solution to assist children with managing their periprocedural anxiety. Groups of participants (clinicians, children, and parents) who have mentioned each factor are identified with an "x."

Design factors	Example	Clinicians	Children	Parents
Empathic experience	Diversifying a range of positive experiences such as reassurance, empathy, calm	x	x	x
Welcoming Environment	Creating a child-friendly and warm environment with minimal complexity in procedures	x	x	x
Stimulation & distraction	Offering fun and enjoyable experiences (eg, positive surprise) that distract from negative stimuli	x	x	x
Personalized strategies	Setting achievable goals that are tailored to the child's ability and providing a sense of accomplishment	x	x	x
Effective communication	Providing useful information and answering questions helps children deal with their anxiety and increases their confidence	x	x	x
Engagement with staff	Positive engagements with staff improve emotional support and reduce anxiety	x	x	x
Involving parents	Feeling that parents are close and part of the procedure provides a feeling of safety and diminishes anxiety in children	x	x	x
Acknowledging agency	Feeling in control and having some choices provides a sense of agency and confidence in managing anxiety	x	x	x
Fulfilling emotional needs	Acknowledging the child's emotional expectations helps them cope with their anxiety (eg, not expecting them to calm down immediately and helping them to work through their emotions)		x	x
Familiar design	Familiar forms of technology and design can improve the child's belief that they have the tools to manage their anxiety	x	x	x

Experience

VR can offer a positive experience of reassurance, empathy, and calm to negate children's anxiety. Empathy, in particular, is demonstrated valuable in *Farmoo*, a VR app that allows pediatric cancer patients to care for a virtual farm and companion character [21].

Welcoming Environment

Immersive VR environments can establish a sense of presence in a child-friendly, intimate, and age-appropriate virtual space with proportionality cultivating confidence and preventing the child from feeling small.

Stimulation and Distraction

Our findings suggest distraction paired with stimulating emotional experiences such as positive surprise, is desirable

and may help children disconnect from distressing elements of the environment. Positive emotions are shown to alleviate psychological stress [22] and improve the efficacy of distraction through VR [18].

Personalized Strategies

Distraction in VR can be tailored to a patient's age and abilities and preferences to set achievable goals and elicit a sense of accomplishment, as noted by parents and clinicians in our study. All three stakeholder groups agreed that VR solutions should affirm the child's belief that they have the tools to manage their anxiety. From our findings, we can infer that the clinicians' perception of "what would make a child feel good, calm and reassured" is primarily based on their existing knowledge of an average child's cognitive abilities appropriate to that age group. Therefore, for the oldest age group (12-17), clinicians cited "effective communication such as providing adequate, truthful and age-appropriate preoperative information" while considering "using distraction techniques" and "positive staff engagement" as vital to the 8-11 and 4-7 age groups. However, children from all three age groups cited that it was effective communication that made them feel good about going to sleep for the operation. Although distraction was mentioned by the younger children (4-7 and 8-11), it was not mentioned by those in the adolescent group. This result was different from the clinicians' response that distraction was a priority for the 12-17 age group.

Effective Communication

Our findings demonstrated the importance of providing adequate information for reducing pediatric anxiety. In our study, 56% (n=36) of children and nearly 30% (n=12) of parents in the preoperative setting expressed worry about all stages of an operation when their knowledge about the operating room was lowest. This result confirms the need for better communication of information with patients and their carers. There have been some examples in this area, with mixed results. Ryu et al [7] showed a VR tour of the operating room to children aged 4-10 and found it significantly reduced their anxiety. However, Liszio and Masuch's [23] playful VR simulation of an MRI procedure for children aged 8-15 did not produce a significant reduction in patients' anxiety. Instead, it reduced the parents' anxiety and enhanced clinician satisfaction. Eijlers et al [24] similarly used VR to show the operating room to children (n=191, aged 2-12) before surgeries. They also found no significant changes in self-reported anxiety; however, patients needed rescue analgesia significantly ($P=.002$) less often (55%) than the control group (95.7%). The challenges of measuring the efficacy of VR intervention are not trivial. Although self-reported anxiety was not reduced in these cases, meaningful clinical measures (ie, rescue analgesic requirement) did confirm a significant difference. Future studies may need to examine the impact of integrating multiple design factors (in Table 4) into a holistic VR plan for children to manage their anxiety.

Engagement With Staff

In addition to supporting the implementation of VR solutions, staff can partake in a virtual experience to further connect with the patient and even personalize the VR app based on the patient's age and abilities. *Voxel Bay*, for example, is a VR app where some game features are controlled by the clinician to provide a positive surprise to the child [8].

Involving Parents

Similar to engagement with staff, VR provides an excellent platform to create a parental presence during the procedure. All three groups of stakeholders in our study stated this is crucial for managing pediatric patient's anxiety.

Acknowledging Agency

All groups involved in our study confirmed that fostering agency is vital to pediatric patient's ability to manage their anxiety. Agency is exemplified in *Voxel Bay* VR app [8] in the form of several choices afforded to the patient from customizing their cardboard VR headset to picking a companion game character.

Fulfilling Emotional Needs

Our research identified emotional goal-setting as a unique strategy to support anxiety management. Children interviewed in our study independently identified that at the commencement of procedures, significant anxiety results in a state of heightened arousal, which a VR experience should match before any attempt to induce relaxation or distraction. To our knowledge, this remarkable finding has not been implemented in any study or existing app. Surprisingly, this strategy was not suggested by clinician participants in our research, further illustrating the relevance of a multiperspective approach for mapping future design opportunities.

Familiar Design

Both clinicians and children in our study stated that having familiar items at the hospital is comforting. This need for a comfort item can be achieved in VR by embedding a familiar design or music in the app, potentially reducing barriers to app learnability, as noted by our young participants.

Future Design Directions for Pediatric VR Solutions

The diversity of the 10 design factors generated based on our findings reveals the complexities and potential challenges in meeting the experiential, psychological, and intervention needs of pediatric patients and their carers through one VR solution. Ahmadpour et al [18] called for skill-building in VR to allow patients to become active agents in their care in a variety of ways. Building meaningful skills in VR necessitates a holistic approach due to the temporality of periprocedural experience with different needs becoming prominent at different stages of the procedure. Therefore, any individual VR solution cannot encompass all 10 factors. Instead, the factors can be mapped to address specific needs at different points of the patient's journey (before the medical procedure and during the procedure), as shown in Figure 1.

Figure 1. The patient journey mapped across the medical procedure phases (before and during) with design factors that can make an impact in either or both of those phases.

This effort may start with a *communication-focused* VR app to familiarize the patient and carers with the details of their procedure in advance. This can then be coupled with an *procedure-focused* VR solution to strategically shift the patient's focus and set emotional goals to help them manage their anxiety autonomously. Design elements that are stimulating, welcoming, and engaging of staff or parents through gameplay, may enhance the effectiveness of these apps.

The research presented in this paper is part of the larger Kids Immersive VR (KiDiVR) project, a collaboration between The University of Sydney and The Children's Hospital at Westmead, which aims to establish a suite of VR apps to augment the pediatric patient journey. This study helped us scope and define the opportunities within the KiDiVR suite. The next phase will involve ideation and prototyping. Specifically, we seek to create a novel VR app to test the efficacy of using emotional goals to guide patient arousal from high to low in order to reduce their anxiety. Our approach is iterative, and therefore we will seek feedback from multiple stakeholders throughout our process to ensure their values are captured, and their needs are met.

Limitations

This study has several limitations. We collected qualitative and quantitative data using tailored questions. This decision was made due to the exploratory nature of our study as a preliminary effort to capture the values and needs of multiple stakeholder groups. The findings should, therefore, be verified using validated tools in the future. The validity of the 10 proposed design factors should be examined using VR prototypes and through controlled clinical trials. We identified a limitation in methods used to assess the efficacy of pediatric VR apps in the literature when testing mainly relied on self-reported anxiety. Future research could address this limitation by investigating the efficacy of VR apps using a combination of meaningful

clinical measures (eg, need for rescue analgesia), physiological measures of anxiety, and qualitative assessment (eg, satisfaction), as suggested by Ahmadpour et al [18].

Our participants were recruited from one hospital in Australia. The sample size in our immunization group was small, which limited our interactions with this potential but important target user group. Although we were able to recruit a wide range of respondents in our perioperative group, more diversity in the sample and recruitment from other institutions may result in different perspectives. There is also the potential for selection bias to be introduced, as volunteers for this form of research may represent a more engaged and active group than the general population. All clinicians in the focus group were familiar with VR technology, as were the children and adolescents in the immunization group. All but one parent from the latter group were also familiar with VR. The clinicians and participants in the immunization group were recruited based on direct contact, which may be classified as a convenience sampling approach. Our participants in the immunization group self-identified as having severe anxiety, which was not formally assessed. These may be considered as limitations of our study and challenge the reliability of our findings. We will address these limitations in future studies by recruiting a larger sample using random methods to ensure participants represent a variety of subgroups (eg, those not familiar with VR technology) and performing data triangulation.

Conclusions

This research highlights the value of obtaining multiple perspectives for identifying the needs and values of patients. We identified 10 factors that may inform future VR solutions to enrich the periprocedural experiences of children and adolescents. A striking similarity was evident in the key factors identified by children, parents, and clinicians, including

personalization of strategies to help children build skills to deal with their perioperative anxiety. Many existing VR apps are used to mediate distraction techniques equally to all users irrespective of their abilities, needs, and preferences. There is an opportunity to maximize the utility of VR as a procedural

support tool at different points of patients journey, particularly by using a communication-focused solution before the appointment and an procedure-focused solution during the appointment to set meaningful goals for the patient.

Acknowledgments

This research was made possible through funding by the Westmead Program, Faculty of Engineering and IT, and the Sydney School of Architecture, Design, and Planning. The authors thank all participants and staff at The Children's Hospital at Westmead for their help and support. The authors also thank the Kids Research Institute for providing access to infrastructure for the studies.

Abstract

Background: In Taiwan, which has one of the most rapidly aging populations in the world, it is becoming increasingly critical to promote successful aging strategies that are effective, easily usable, and acceptable to institutionalized older adults. Although many practitioners and professionals have explored aromatherapy and identified its psychological benefits, the effectiveness of combining 3-dimensional (3D) virtual reality and hands-on aromatherapy remains unknown.

Objective: A quasi-experimental trial was designed to evaluate the effectiveness of this combination in lowering perceived stress and promoting happiness, sleep quality, meditation experience, and life satisfaction among institutionalized older adults in Taiwan.

Methods: A total of 60 institutionalized elderly participants either received the combined intervention or were in a control group. Weekly 2-hour sessions were implemented over 9 weeks. The outcome variables were happiness, perceived stress, sleep quality, meditation experience, and life satisfaction, which were assessed at baseline and after the intervention.

Results: Generalized estimating equation (GEE) analyses indicated that the experimental group showed significant post-intervention improvements in terms of scores for happiness, perceived stress, sleep quality, meditation experience, and life satisfaction ($n=48$; all $P<.001$). Another GEE analysis showed that the significant improvements in the 5 outcome variables persisted in participants aged 80 years and older ($n=35$; all $P<.001$).

Conclusions: This is the first trial to explore the effectiveness of a combination of 3D virtual reality and hands-on aromatherapy in improving older adults' psychological health. The results are promising for the promotion of psychological health in institutionalized older adults.

Trial Registration: ClinicalTrials.gov NCT04324216; <https://clinicaltrials.gov/ct2/show/NCT04324216>.

Introduction

Scientific and technological advancements and the resulting improvements in human living environments and medical treatments have resulted in a gradual aging of the human population. In 2016, the global average life expectancy at birth was 72.0 years. It is estimated that by 2050, the proportion of adults over 60 will double [1,2]. Taiwan's elderly population is one of the fastest growing in the world, and with a 14.1% elderly population rate in 2018, the country has become an aged society. This figure is expected to exceed 20% by 2026, with Taiwan then becoming a super-aged society. In order to actively plan and prepare for successful aging under these circumstances, evidence-based health promotion programs for elderly persons have gained top priority so that elderly persons can have healthy and productive lives.

However, previous studies showed poor psychological health among older residents of Taiwanese nursing homes. For example, the prevalence rates of unhappiness, poor sleep, depression, and anxiety among surveyed residents of Taiwanese nursing homes were 50% [3], 46.4% [4], 37% [5], and 26.3% [6], respectively. In addition, diminished life satisfaction and higher depression [7] were identified in nursing home residents compared with their community-dwelling counterparts, which indicates the need for psychological health interventions for the institutionalized population.

Aromatherapy, also known as essential oil therapy, is a complementary treatment that uses ingredients from different parts of plants, such as leaves, flowers, and seeds, to yield aromatic essential oils using different extraction techniques. Aromatherapy is widely used clinically in the treatment of chronic pain, anxiety, depression, cognitive disorders, insomnia, and stress-related diseases [8-10]. Studies have shown that essential oils can alleviate participants' depression [11,12] and perceived stress [11,12] and improve sleep quality [13], meditation experience [14], and quality of life [15].

A descriptive exploratory study investigating the prevalence and type of complementary and alternative medicine (CAM) use among older Taiwanese patients with depression found that 69.6% of participants reported using at least one form of CAM, and 20.9% used aromatherapy in the past 12 months; in addition, 6.8% and 7.3% reported using aromatherapy for treating their depression weekly and daily, respectively [16]. The researchers concluded that the popularity of CAM appears to be a consequence of individuals' preferences for a more holistic approach to health care.

Another study in Taiwan indicated that among 3 alternative remedies, aroma massage was a more effective intervention than cognitive stimulation therapy and reminiscence therapy in alleviating the agitated behavior and depressive symptoms of residents with dementia in 10 nursing homes [17]. Aroma massage has the advantage of being an easy-to-learn intervention for staff working with persons with dementia. The findings of this study contributed to clinical practice in nursing homes [17].

Three-dimensional (3D) virtual reality (VR) involves participants using devices, such as helmets and joysticks, to

observe a virtual scene. This approach allows situational teaching; it provides an interactive learning environment that is not limited by time and space, thereby increasing convenience in learning and allowing real-time practice. The 3D virtual world provides rich interactions to maintain users' attention in environments similar to the real world. Furthermore, 3D VR is interactive, integrated, and imaginative, and can be used to aid learning [18]. A strong relationship was found between depth of interaction and engagement duration, with user engagement time increasing due to the high interaction with the environment [19]. The advantages of 3D VR educational activities include avoiding the laborious traffic of learners, increasing social participation and interpersonal communication, and not being limited by time. Since these activities can be experienced and practiced any time, they are convenient for older adults with mental disabilities. Furthermore, the effectiveness of 3D VR programs for the psychological health improvement of older adults is well supported by prior literature [20].

The combination of 3D VR and hands-on aromatherapy allows for a powerful learning experience and facilitates the construction of a 3D space for aromatherapy products. There is some evidence that VR can help increase learners' interest and motivation and effectively support knowledge transfer, since the learning process can be settled within an experiential framework [21]. In this regard, 3D VR could provide experiences with new technologies through actual use—learning in VR environments requires interaction, thus encouraging active participation rather than passivity.

Until now, it has been difficult to provide elderly persons with an opportunity to practice before performing hands-on aromatherapy activities. However, the emergence of 3D VR can solve this problem. If 3D VR can be successfully used, the difficulties elderly participants experience when engaging in hands-on aromatherapy activities might be overcome. Another advantage of a 3D VR educational activity is that it can prevent the waste of materials in hands-on activities for institutionalized older adults.

Because older adults' hearing and hand-eye coordination are relatively poor compared with young and middle-aged adults, they are more likely to struggle with the hands-on aromatherapy activities, based on our practical experience. Thus, older adults need more workers and material support for successful engagement in hands-on activities. If the elements of 3D VR technology can be integrated into the aromatherapy intervention and reduce the burden of human and material resources, it will significantly contribute to the CAM literature. It is reasonable to conduct research that explores 2 effective strategies combined to improve the psychological health of institutionalized older adults. Therefore, the purpose of the present study was to explore the effectiveness of a combined program of 3D VR and hands-on aromatherapy in improving institutionalized older adults' psychological health.

Methods

Participants

We used a quasi-experimental design, which was found to be a common study design in aromatherapy studies in a meta-analysis [22]. The research team visited 2 nursing homes and gave an introduction to the purpose and methods of the study. The nursing home which provided the consent earlier than the other was assigned as the experimental group. The other nursing home became the control group and received a compact intervention program after completion of the study. The experimental nursing home included 432 beds, and residents had a mean age of 85.2 years (male: 134/432, 31.0%). The control nursing home included 248 beds, and residents had a mean age of 84.6 years (male: 82/248, 33.1%).

A total of 30 participants were recruited from each nursing home through posters and advertisements, and the total number of participants was 60. According to Kirk [23], for an estimated effect size (estimated population mean group difference divided by the estimated population standard deviation) of .80, the approximate sample size required is 26 for each group when α is set at .05 and the power is set at .80. A previous aromatherapy study yielded significant pre-post intervention improvements in psychological health with an identical sample size [24]. Therefore, the sample size in this study ($N=60$) was large enough to detect intervention effects. At the end of the intervention, 6 older adults withdrew from the intervention because of serious sickness, hospitalization, etc.

The elderly participants in this study were all older than 65 years. The selection criteria included having the ability to understand verbal instructions, provide simple responses, and operate a joystick freely with at least one hand. The exclusion criteria were (1) a history of severe psychiatric conditions, (2) dementia, (3) significant visual or hearing impairment, (4)

marked upper motor difficulties that could affect the participant's ability to participate in the study, and (5) currently suffering from severe illnesses (eg, stroke, Parkinson disease).

Ethics Statement

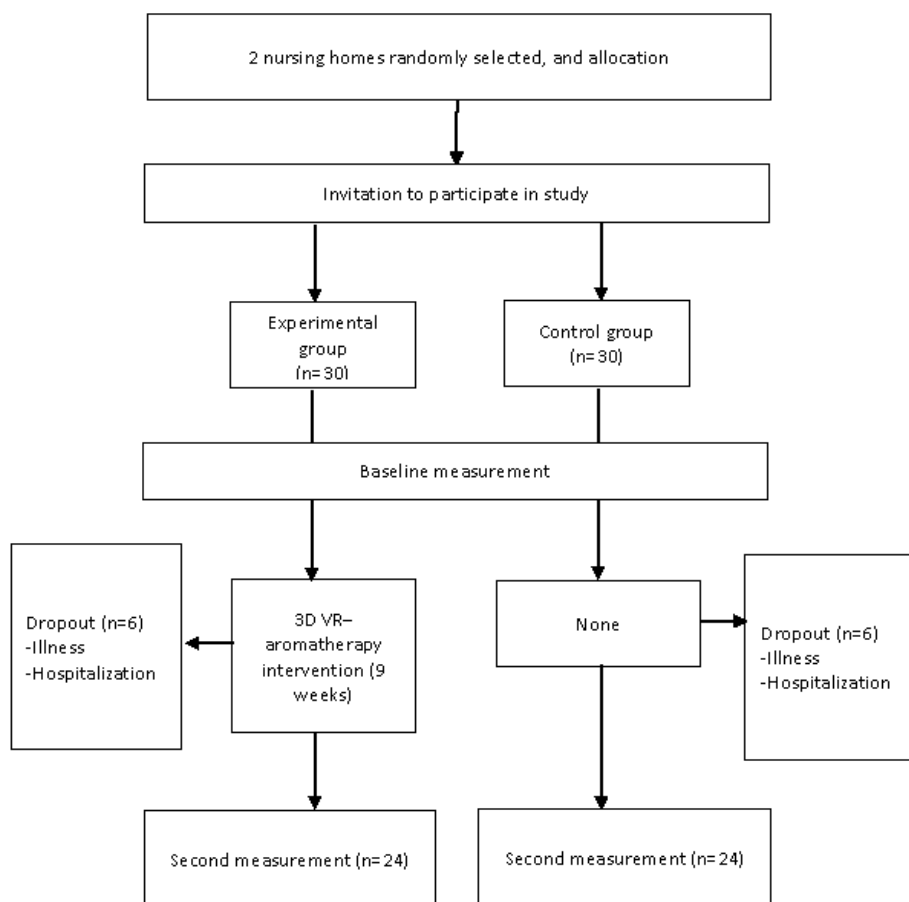

The study received approval from the Research Ethics Review Committee of National Taiwan Normal University (201903HM012). We confirm that we have obtained verbal permission to use images of the individuals included in this article.

Recruitment and Baseline Procedure

A flowchart outlining participant enrollment and assessments is provided in Figure 1. After selecting the elderly care institutions, the research team approached the executive director and staff to explain the research purpose, method, and protocol. After obtaining permission to conduct the study, we posted recruitment messages to invite potential participants who met the inclusion criteria to participate in this study, and we scheduled one-on-one visits. Before obtaining written consent, we provided face-to-face explanations to potential participants, and participants then signed the consent form.

After potential participants were identified, we provided an orientation session with 3D VR and hands-on aromatherapy to test the feasibility and acceptance of the combination program. Participants indicated their appreciation of this arrangement and reported that the 3D VR program could help them perform better in the subsequent hands-on aromatherapy activities. The research team members collected their baseline data in a quiet room provided by the nursing home.

During the implementation period of the intervention, a medical professional, staff of the nursing home, and an aromatherapy professional were available to ensure the safety of the participants. The counterparts in the control group did not receive the aromatherapy intervention at the same time.

Figure 1. Flowchart of participant enrollment and assessment. 3D: 3-dimensional. VR: virtual reality.

Combination of 3D VR and Hands-On Aromatherapy

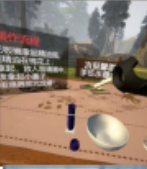

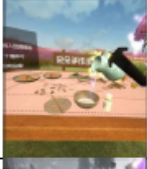

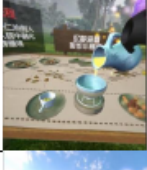

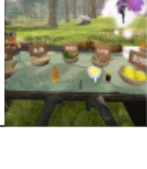

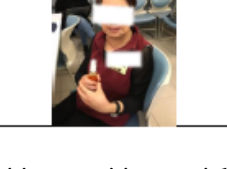

The intervention consisted of 2-hour weekly sessions over 9 weeks. The first week involved ice-breaking activities, during which the participants were taught to wear 3D VR helmets and operate VR handles with familiar VR scenes so that the participants could practice multiple times to avoid dizziness. The contents of the program are shown in [Figure 2](#).

The research team developed the combination program, involving aromatherapy, long-term care, elderly health promotion, and health education professionals. The characteristics of the 3D VR and hands-on aromatherapy program were appropriate for the psychological status of the elderly participants. The final versions of each session (see [Multimedia Appendix 1](#)) were prepared after multiple careful revisions of the program. Each session was delivered over 2 hours once a week, and in each session, the participants received hands-on guidance for preparing an aromatherapy product that they could use for the next 7 days. Conducted by 2 trained aromatherapy professionals with certifications from both the UK International Federation of Aromatherapists and the US National Association of Holistic Aromatherapy, with graduate

students working as facilitators, the intervention was designed to promote happiness, stress relief, sleep quality, meditation experience, and life satisfaction. The prior findings in the “Introduction” section provided the evidence that helped us determine the program components and select the responsive psychological outcomes in the study.

The participants in the experimental group were divided into multiple groups with a facilitator to enhance individual engagement and solve the problems associated with operating the 3D VR device. A staff member of the nursing home asked participants to record a 7-day log of daily usage of the hands-on aromatherapy product, seen in [Figure 2](#). This log was aimed at increasing the intervention intensity of the program to secure the expected effects. The staff checked participants’ logs weekly during the intervention period. All the participants successfully finished the 8-week logs with the support of the assisting staff. The participants were paired with the same group members and facilitator throughout the intervention in order to build rapport. Facilitators received a 2-day training workshop (16 hours total) to acquire knowledge of 3D VR and aromatherapy skills to assist in the activities performed by the participants.

Measures

Sociodemographic variables assessed at baseline included age, gender, and educational level. The psychological outcome variables are presented below.

Happiness

The Oxford Happiness Inventory was used to measure happiness. It consists of 29 items and assesses the following 7

concepts: positive cognition, social commitment, positive affect, sense of control, physical fitness, satisfaction with self, and mental alertness [25]. Each item is scored on a Likert-type scale ranging from 1 to 4, with higher scores indicating a higher level of happiness. The Cronbach α coefficient was .92 during its development [26] and .90 in this study.

Perceived Stress

The Perceived Stress Scale is a self-reported scale that measures the degree of stress experienced by an individual over the last month. In comparison with life events, it has shown good predictive validity for various health outcomes [27]. The scale consists of 14 items [27], 7 positive and 7 negative, and was translated into Chinese. Each item is scored on a Likert-type scale that ranges from 0 (never) to 4 (very often). The scale has been shown to have good internal reliability, with a Cronbach α coefficient of .84 during its development [27] and .85 in this study.

Sleep Quality

The Pittsburgh Sleep Quality Index [28] was used to measure sleep quality. It is an effective instrument used to measure the quality and patterns of sleep in older adults. It differentiates poor from good sleep by measuring 7 domains over the last month: subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleep medication, and daytime dysfunction. The scoring plan was followed according to the description provided in a previous study [28].

Meditation Experience

A shortened version of the 10-item Experiences During Meditation (EOM-DM) scale [25] was used to measure the experience of meditation. The original EOM-DM contains the following 5 subscales: cognitive effects, emotional effects, mystical experiences, relaxation, and physical discomfort. The first 2 subscales were appropriate for our study and were thus selected to measure the meditation experience. Each item was scored on a Likert-type scale from 1 to 5, with higher scores indicating a higher level of experience during meditation. The Cronbach α coefficients for the 2 subscales were .83 and .87 during its development [25] and .90 and .89 in this study.

Life Satisfaction

The life satisfaction scale for older adults developed by the Health Promotion Administration of the Ministry of Health and Welfare [29] was used to measure participants' life satisfaction. This scale is a short-form version containing 10 items from the 20-item Life Satisfaction Index A [30]. Items are scored as 0 (disagree) and 1 (agree). The total raw score ranges from 0 to 10, with higher scores indicating a higher level of life satisfaction. The reliability of the Kuder-Richardson Formula 20 was 0.72.

Data Analyses

Descriptive analyses were conducted for demographic and outcome variables. A 2-tailed t test and a chi-square test were used to compare differences in age, education level, and gender between the experimental and control groups. Because the use of a fragmented univariate test may lead to an inflated overall type 1 error, Hotelling T^2 test (multivariate 2-group test) was performed for group comparisons of the 5 outcome measures at baseline [31]. A generalized estimating equation (GEE) was used to investigate the effect of time point, group, and their

interaction on the outcome variables; GEEs enable an understanding of the patterns of change and their effects at both the individual and group levels by estimating the average response of the population (the population average effect), rather than regression parameters that would enable prediction of the effect of changing one or more covariates on a given individual [32]. Statistical analyses were conducted using SPSS (version 20.0; IBM Corp).

After the first-round analysis, we found that all outcome variables showed significant improvements ($P<.001$). This indicated that we could conduct a further analysis for the smaller sample of participants aged 80 and older (very old adults) in order to explore the intervention effects for this group. This further analysis is meaningful because a growing number of residents in nursing homes are in this age group, and these results are important to secure information on the implementation of the combined program for this population.

Results

Sociodemographic Data

The participants' average age was 83.03 (SD 7.6) years and 81.92 (SD 9.0) years in the experimental and control group, respectively. There were no statistically significant differences in participants' education levels and gender distribution between the experimental and control groups. Hotelling T^2 results revealed that the 5 outcome measures at baseline were not significantly different between the groups ($T^2=10.95$; $F_{5,40}=2.00$; $P=.10$). Since the overall result was not statistically significant, we did not analyze each outcome variable separately.

Improvements in Outcome Variables

Group differences in the patterns of change over time are shown in Figure 3. The results of GEE analyses indicated that the experimental group showed significant postintervention improvements in comparison with the control group in terms of the scores for happiness, perceived stress, sleep quality, meditation experience, and life satisfaction, as seen in Table 1. There was a significant group time interaction for the 5 outcome measures. The experimental group showed an improvement in the scores for happiness (GEE coefficient=12.58; $P<.001$), perceived stress (GEE coefficient=12.00; $P<.001$), sleep quality (GEE coefficient=-4.72; $P<.001$), meditation experience (GEE coefficient=11.92; $P<.001$), and life satisfaction (GEE coefficient=1.79; $P<.001$).

The majority of participants were adults aged 80 years and older ($n=20$ and $n=15$ in the experimental and control group, respectively), and the GEE analysis yielded a significant group time interaction for the 5 outcome variables. The experimental group showed an improvement in the scores for happiness (GEE coefficient=12.43; $P<.001$), perceived stress (GEE coefficient=13.00; $P<.001$), sleep quality (GEE coefficient=-4.46; $P<.001$), meditation experience (GEE coefficient=12.15; $P<.001$), and life satisfaction (GEE coefficient=1.55; $P<.001$).

Discussion

Principal Findings

To our best knowledge, this is the first interventional study to use 3D VR and hands-on aromatherapy in a combined program and verify its effects on the psychological health of institutionalized older adults through an appropriate research method. A unique feature of this study is that the participating older adults engaged in hands-on preparation of aromatherapy products that they were then encouraged to use daily over the subsequent week. In addition, a research team member tracked the participants' 7-day use of each aromatherapy product over 8 weeks. We believe that these strategies successfully increased the intervention intensity compared with previous studies, which

often lacked a supporting strategy and tracking design for the daily use of hands-on aromatherapy products [33]. These results hold promise for the promotion of this combined aromatherapy program in nursing homes. In addition, the subgroup analyses targeting very old adults also demonstrated similar effects, which suggests that combined aromatherapy programs could be successfully adopted by decision-makers in nursing homes, given the recent sharp increase in the percentage of very old adults in these facilities. The number of very old adults is projected to increase more than threefold from 137 million to 425 million between 2017 and 2050 [2].

We used the outcome variable of happiness instead of depression, which was used in another study [34]. Therefore, we selected the Oxford Happiness Inventory, which is derived

from the Beck Depression Inventory but contains more concepts. Congruent with previous studies, the current findings support the positive effect of short-term interventions on happiness among older adults. Tang and Tse [12] also found short-term improvements with hands-on aromatherapy for patients with depression. However, our posttest scores indicated that the intervention effect was observed after a 9-week intervention, which is different from a previous study [35] that only reported the short-term effect of aromatherapy for older adults with depression.

Moreover, we found an alleviating effect of aromatherapy on perceived stress, which is in line with a previous study [12] in which participants verbally reported stress relief after the first week of the 2-week aromatherapy intervention for stress management. The intervention effect observed in the posttest scores in our study indicated that the use of aromatherapy to decrease perceived stress in older adults is a promising approach. Aromatherapy could successfully reduce the levels of stress hormones and stimulate the production of β -endorphins [36]. For example, a previous study indicated that inhaling lavender and rosemary essential oils can increase free radical-scavenging ability and reduce cortisol secretion, relaxing muscles, relieving stress, and producing calmness [37].

Regarding sleep, a meta-analysis of 12 studies showed that the use of aromatherapy was effective in improving sleep quality [22], suggesting that readily available aromatherapy treatments appear to be effective in promoting sleep. Another systematic review and meta-analysis [13] including 31 trials with a randomized controlled design also indicated a significant effect of aromatherapy on sleep quality. In line with this, our participants reported a significant improvement in sleep quality ($P<.001$) in terms of posttest scores.

Smith and Kyle [38] indicated that the effects of aromatherapy are mediated by the stimulation of the limbic system by the chemical components or molecules of essential oils that are detected by the olfactory system after inhalation, which activates the hypothalamus and pituitary gland. Olfactory nerves then send signals to the limbic system to trigger memories and emotional responses and thus relieve mental stress.

However, in a systematic review and meta-analysis [13], 11 of 31 trials did not demonstrate any significant effects on sleep quality associated with the use of aromatherapy delivery modes such as inhalation, massage, and oral ingestion; the use of a blend of essential oils or a single essential oil; or the delivery with a mixed method (eg, acupressure massage). Thus, sleep quality interventions using aromatherapy should be administered on the basis of specific guidelines to ensure an efficient use of aromatherapy. We also propose that guidelines should be developed via a systematic approach by conducting appropriate research.

Regarding meditation, a previous study examining 20 adults' meditation processes demonstrated electroencephalogram changes with lavender inhalation, which presented as an increase in fast theta and slow alpha activities in the frontal area during meditation [39]. Redstone [14] reported that meditation and aromatherapy caused a patient to say, "This is the first time I can sit for more than 5 minutes." In line with the findings of

previous research, our findings supported the significant effect of the combination of 3D VR and hands-on aromatherapy on the meditation experience. The effects of the combined program on the experience during meditation is an interesting topic that researchers can further explore in the future.

Aromatherapy has been found to be effective in improving psychological symptoms as well as overall quality of life, especially among patients with cancer [40]. We focused on a different study population, namely residents of nursing homes, which will have a wide application in the future. However, some previous studies have also indicated that aromatherapy did not improve life satisfaction [41] or quality of life [42] in the experimental group compared with the control group. These discrepancies might result from differences in the essential oils and targeted psychological variables in the studies. For example, Soden et al [42] used lavender essential oil and an inert carrier oil in their aromatherapy group, and their results were unable to demonstrate any significant long-term benefits of aromatherapy or massage in terms of improving quality of life.

A Cochrane systematic review [43] indicated that aromatherapy is commonly delivered with massage, which serves as complementary therapy that can reduce symptoms and improve the quality of life of patients with cancer. However, although the review found that there was some indication of benefit in the aromatherapy - massage group, this benefit might not be clinically significant due to the small sample size of the studies. The contribution of our study is that it delivered a combination of 3D VR and hands-on aromatherapy to residents of nursing homes, which successfully enhanced their psychological health. Our findings are promising and could encourage researchers and practitioners to provide interventions combining technology and aromatherapy. Our findings suggest that aromatherapy confers benefits for psychological health. However, the methodologies employed in previous studies were heterogeneous, lacked replicable assessments and long-term follow-up, and employed small sample sizes. Replication, longer follow-up periods, and larger trials are critical in future research to accrue the necessary evidence for the research and development of aromatherapy.

Limitations

First, because the program integrated 3D VR and hands-on aromatherapy, the contribution of either approach cannot be easily isolated using the current study design, as they are linked to each other. To validate the effectiveness of the 2 approaches separately, additional studies should be conducted using controlled trials with enough power. Second, we cannot comment on the longer-term effectiveness (ie, 12 months postintervention) of our program. Additional follow-up is needed to determine how the described intervention program affects older adults' psychological health beyond 12 months after completion of the intervention. Third, the intervention might not apply to frail older adults, but it indicated that if more support is provided, such as the involvement of family members and caregivers, frail older adults could also participate in the program.

Conclusion

The results are important for supporting similar future programs for institutionalized older adults. Our program adopted an innovative approach to improve psychological health among institutionalized older adults. A combination of 3D VR and hands-on aromatherapy activities provides more learning opportunities compared with other aromatherapy interventions. In addition, tracking the participants' use of each aromatherapy product for 7-day periods over 8 weeks was a successful approach, as it extended the connection with participants outside the classroom and contributed to the significant improvements in psychological health among participants. In the future, the effectiveness of this approach may be scientifically verified by comparing 2 groups: those who receive only the aromatherapy program and those who receive the aromatherapy program and a monitoring approach such as usage logs.

To ensure early interventions for institutionalized older adults who experience psychological distress and to prevent the

development of multiple psychological disorders, researchers and staff in nursing homes should target the older adults who are still in a state of psychological subhealth. Providing one-on-one interventions in nursing homes may not always be feasible or affordable. To reduce the burden of instruction, learning contents could be delivered through a 3D VR program, which can provide a safe and supportive learning environment and empower researchers and practitioners to play a vital role in solving problems, leading discussions, facilitating older adults' learning, and providing feedback. During the intervention period, 2 staff members at the experimental nursing home were interested in participating in the delivery of the intervention and wished to act as facilitators to encourage participants to engage in the interventional activities. This indicates that our program can easily be implemented in nursing homes. Since the implementation is not complicated, nursing home staff receiving short-term training can deliver the program successfully to promote residents' psychological health.

Abstract

Background: Obstacles to current tobacco cessation programs include limited access and adherence to effective interventions. Digital interventions offer a great opportunity to overcome these difficulties, yet virtual reality has not been used as a remote and self-administered tool to help increase adherence and effectiveness of digital interventions for tobacco cessation.

Objective: This study aimed to evaluate participant adherence and smoking cessation outcomes in a pilot randomized controlled trial of the digital intervention Mindcotine (MindCotine Inc) using a self-administered treatment of virtual reality combined with mindfulness.

Methods: A sample of 120 participants was recruited in the city of Buenos Aires, Argentina (mean age 43.20 years, SD 9.50; 57/120, 47.5% female). Participants were randomly assigned to a treatment group (TG), which received a self-assisted 21-day program based on virtual reality mindful exposure therapy (VR-MET) sessions, daily surveys, and online peer-to-peer support moderated by psychologists, or a control group (CG), which received the online version of the smoking cessation manual from the Argentine Ministry of Health. Follow-up assessments were conducted by online surveys at postintervention and 90-day follow-up. The primary outcome was self-reported abstinence at postintervention, with missing data assumed as still smoking. Secondary outcomes included sustained abstinence at 90-day follow-up, adherence to the program, and readiness to quit.

Results: Follow-up rates at day 1 were 93% (56/60) for the TG and 100% (60/60) for the CG. At postintervention, the TG reported 23% (14/60) abstinence on that day compared with 5% (3/60) in the CG. This difference was statistically significant ($\chi^2_1=8.3$; $P=.004$). The TG reported sustained abstinence of 33% (20/60) at 90 days. Since only 20% (12/60) of participants in the CG completed the 90-day follow-up, we did not conduct a statistical comparison between groups at this follow-up time point. Among participants still smoking at postintervention, the TG was significantly more ready to quit compared to the CG (TG: mean 7.71, SD 0.13; CG: mean 7.16, SD 0.13; $P=.005$). A total of 41% (23/56) of participants completed the treatment in the time frame recommended by the program.

Conclusions: Results provide initial support for participant adherence to and efficacy of Mindcotine and warrant testing the intervention in a fully powered randomized trial. However, feasibility of trial follow-up assessment procedures for control group participants needs to be improved. Further research is needed on the impact of VR-MET on long-term outcomes.

Introduction

Background

Tobacco use remains one of the biggest threats to public health and the leading preventable cause of mortality and morbidity worldwide [1]. Interventions on web-based platforms and mobile apps, among them smoking cessation apps, can deliver effective interventions for various diseases and behavioral disorders [2-16]. Smartphone-based smoking cessation apps can provide an important channel for offering interventions to the entire population [17]. However, participant adherence remains a challenge, and many of these apps struggle to maintain high levels of adherence, thus limiting their potential effectiveness [18].

In addition to smartphone-based interventions for smoking cessation, there have been promising developments in the use of virtual reality (VR). VR is defined as “real-time interactive graphics with [3-dimensional] models, combined with a display technology that gives the user the immersion in the model world and direct manipulation” [19]. The use of VR in digital medicine has been applied in consultancy and hospitals and accompanied by a health professional [20]. It has been demonstrated that the introduction of VR into treatment can improve patient engagement in a range of chronic disease interventions [21]. However, such technology has never been tested for tobacco use disorder as a self-assisted and remote solution to take advantage of the knowledge on how virtual environments can be used to elicit and reduce cravings and support smoking cessation.

Cravings are defined as intense urges or impulses for substance use [22] and are an essential component of substance use disorders, as they provoke drug-seeking behavior [23]. External cues can provoke cue-induced cravings [24] and thus provoke relapse [25,26]. Taken together, these findings suggest that craving is a critical target in the development of novel therapeutics for tobacco use disorder treatment [27,28].

Cue exposure therapy for substance use disorders involves controlled and repeated exposure to drug-related cues in order to extinguish cue-induced cravings [29], and VR technology is a potential mode of cue presentation [30,31]. Virtual reality exposure therapy (VRET) has already been used for smoking cessation [32,33], and studies have applied rigorous systematizations in VRET and cognitive behavioral therapy (CBT) [34-37], providing further evidence that this technique can reduce craving and smoking behavior, with similar effectiveness as stand-alone CBT.

Mindfulness is usually thought of as the awareness to attend to any thought, feeling, or sensation that occurs by simply acknowledging it, without attempting to regulate emotions [38]. Mindfulness training is already used in mobile health (mHealth) smoking cessation interventions [39] by teaching individuals to pay attention to the present moment, understand affective states and cravings to smoke as they appear, and consciously choose to let them pass without impulsively reacting to them. Preliminary evidence suggests that mindfulness-based interventions are associated with increased efficacy compared with other smoking cessation treatments [40,41]. Despite these promising results, in-person mindfulness training continues to present certain challenges. It requires experienced psychotherapists, increases time demands, limits access, and elevates costs [39].

An Innovative Intervention: Mindcotine

The aim of the current study was to develop an accessible and cost-effective digital intervention for smoking cessation that uses the latest technology adapted for large-scale use and to evaluate participant adherence and smoking cessation outcomes. Our novel intervention combines exposure to smoking-related cues in ecological situations using virtual reality and mindfulness as a tool to cope with in situ cravings, bodily sensations, affective states, and automatic reactions. The merge of these psychological frameworks are expected to work synergistically by reducing cravings. On the one hand, cue exposure treatment involves repeated exposure to smoking-related stimuli in order to elicit and, over time, extinguish cue-induced cravings. In addition, mindfulness techniques work on top of the immersive experience by helping the user to focus on cravings in the present moment. Mindfulness practice includes elements of acceptance and compassion through a perspective of curiosity towards the emerging sensations. Taken together, this intervention can help the user stay grounded in the present moment while acknowledging internal and external triggers. Moreover, these virtual reality and mindfulness sessions are part of a classic cognitive behavioral smoking cessation program that provides information on relevant topics daily through CBT notifications and community support among users moderated by psychologists and mindfulness facilitators. We hypothesized that this novel intervention approach would increase both adherence and abstinence rates among participating smokers compared to a treatment-as-usual control group.

Methods

Research Design

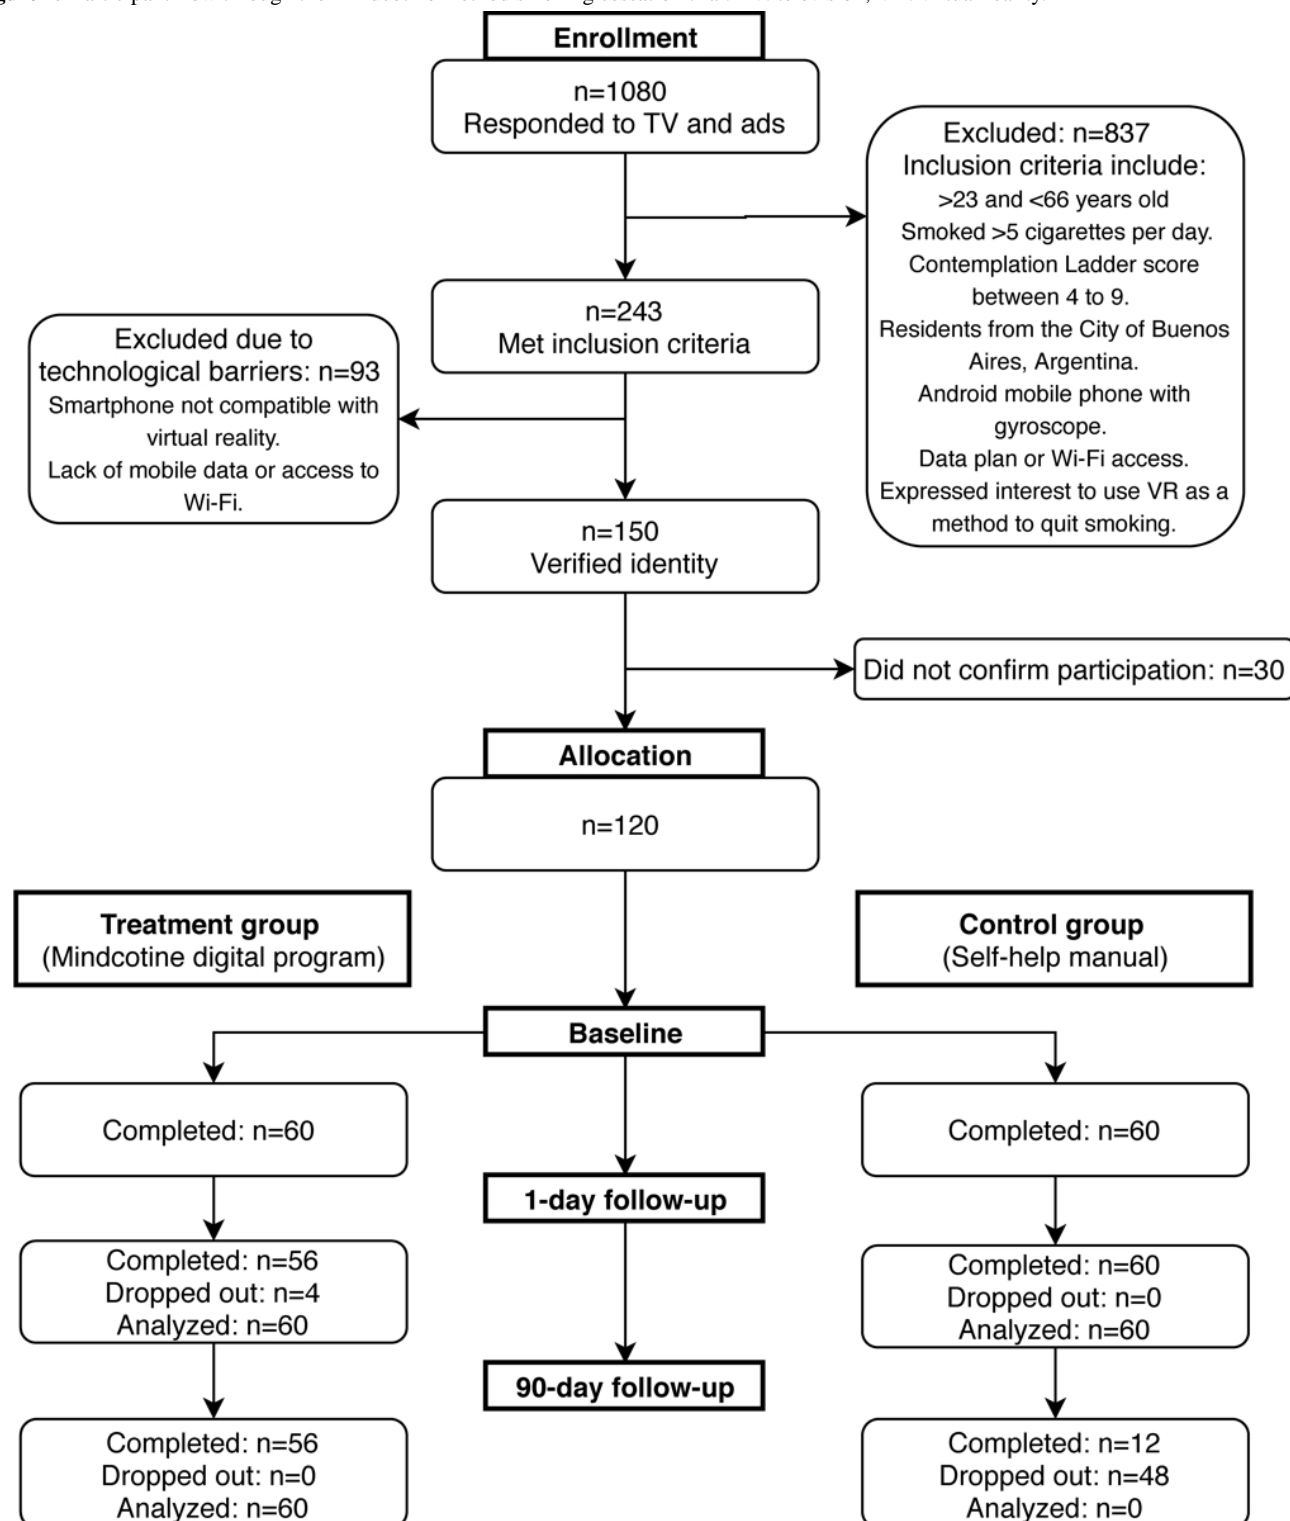

The design of the study follows the recommendations for clinical trials in health using virtual reality, in particular, tier VR2 [42], focusing on acceptability, feasibility, tolerability, and initial clinical efficacy. We conducted a clinical trial with a control group, including baseline and follow-up assessments at days 1 and 90 posttreatment.

Procedure

The study was conducted from February to April of 2018 with a group of smokers from Buenos Aires, Argentina. The administration to the treatment group was carried out through an onboarding process that established the framework of the experience and the basic principles of the use of VR. The treatment was remotely self-administered through the use of a mobile app. The control group received a smoking cessation manual of the Argentine Ministry of Health.

The intervention group completed the onboarding process, which included digital informed consent, and received an intervention kit, which included guidelines that explained the use of the program, a unique ID to access the app, one cardboard headset, three stickers to announce smoke-free areas, and two wrist bracelets as a behavior replacement method that smokers could

use to snap on their wrists when faced with a craving to smoke. Participants were also instructed to download the mobile app from the Google Play Store (Google Corp). The participants were trained in assembling the cardboard headset (see [Multimedia Appendix 1](#)) and app usability, and they completed the baseline assessment and received an explanation of the activities to be carried out during the 21-day intervention phase. The control group signed a digital informed consent sent to their emails and received the online version of the smoking cessation manual developed by the Office of the President of the Argentine Nation [43]. Intervention group participants received the first follow-up 1 day after they completed all 21 days of intervention content, which for some participants took longer than 21 days (postintervention follow-up) and another follow-up assessment at day 90 of posttreatment. Control group participants were assessed at days 30 and 90 after they had received the smoking cessation manual. All assessment invitations were sent via email and assessments were completed online using the Typeform (Typeform SL) platform. [Figure 1](#) shows the participant flow diagram of the study. Participants did not receive any incentives. All study procedures were approved by the Institutional Review Board of the University of Flores, Buenos Aires, Argentina. The trial was registered in the International Standard Randomized Controlled Trial Number Registry (50586181).

Figure 1. Participant flow through the Mindcotine method smoking cessation trial. TV: television; VR: virtual reality.

Participants

In order to be included in the study, the selected participants had to meet the following criteria: (1) be aged between 24 and 65 years, representing smokers with a high prevalence of daily smoking [44]; (2) consume a minimum of 5 cigarettes per day, with a score of 4 to 9 on the Contemplation Ladder [45]; (3) be residents in the city of Buenos Aires; (4) own an Android mobile phone with gyroscope; (5) have a data plan or Wi-Fi access; and (6) have an interest in using VR as a method to quit

smoking. Each of these criteria was based on previous work with mobile apps for smoking cessation [46]. The one difference in our inclusion criteria compared with this existing research was that we also included smokers that scored below 7 on the Contemplation Ladder in order to investigate intervention effects for smokers not motivated to quit. Participants were excluded if they were diagnosed with a current psychiatric disorder.

For the recruitment of treatment and control group participants, unpaid advertisements were posted for 75 days on the

chat was moderated by a psychologist and a mindfulness facilitator to promote engagement and respond to participant questions.

Fifth, Mindcotine support could be prompted. If participants were inactive for a certain amount of time, they received a text message (after 2 days) and a phone call (after 4 days) to

encourage engagement within the program. Participants could contact Mindcotine for technical support by email anytime as well.

These components can be seen in [Figure 3](#) (mindfulness exercises), [Figure 4](#) (nightly reflection), [Figure 5](#) (dashboard), and [Figure 6](#) (VR-MET).

Figure 3. App screenshot of the home screen showing mindfulness activities.

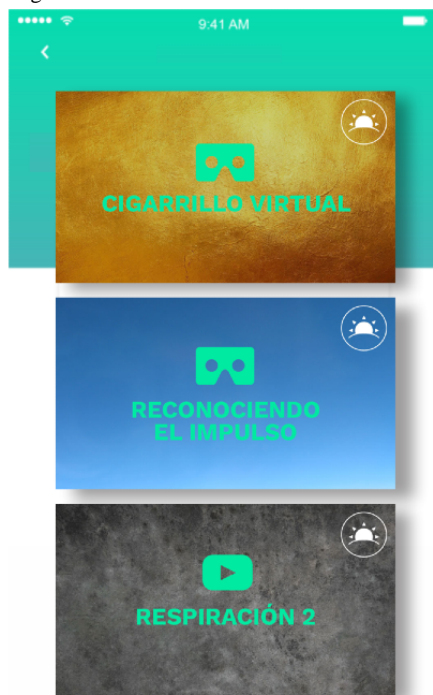

Figure 4. App screenshot of the nightly reflection.

A screenshot of a mobile app's 'REFLEXIÓN DIARIA' (Daily Reflection) screen. The background is a teal-to-white gradient. At the top, there's a status bar with signal strength, Wi-Fi, and the time 9:41 AM. Below the status bar is a back arrow icon. The main content is titled 'Día 16'. Below the title is a question: '¿Cuántos cigarrillos consumiste hoy?'. Below this question is a slider control with a teal circle and the text '2 veces al día'. Below the slider is another question: '¿Qué motivos crees que te llevaron a consumir?'. Below this question is a list of five reasons, each with a radio button: 'Por aburrimiento', 'Para pasar el rato', 'Para deshinibirme socialmente', 'Para tomarme un descanso en el trabajo', and 'Porque he tomado unas copas con amig@s'.

Figure 5. App screenshot on the dashboard showing statistics about money and the number of smoked cigarettes.**Figure 6.** Virtual reality mindful exposure therapy screenshot: Act of Smoking.

Measures

Baseline Assessment

The baseline assessment was conducted on the app and included demographic data (age, gender, education), smoking behavior (number of cigarettes per day, years of smoking, previous cessation attempts, readiness to quit), characteristics of the environment and family context (marital status, children, living

with smokers), and other health-related characteristics (body mass index, physical activity, previous meditation experience).

Primary Outcome

The primary outcome was self-reported abstinence at postintervention, assessed 1 day after the end of the program. The question used for assessment was “Did you smoke tobacco in the last 24 hours?”

Secondary Outcomes

Sustained Abstinence

Sustained abstinence was self-reported abstinence at 90 days after the end of the program in the TG. The question used for assessment was “Did you smoke tobacco in the last 90 days?”

Adherence

Adherence was assessed using log file data collected by employing the platform Amplitude (Amplitude Inc) [54], which measured total use of the app for each participant. Adherence to treatment was categorized as the percentage of participants who completed all daily activities and all daily diary questionnaires throughout the intervention with intervals of discontinuity no greater than 4 consecutive days. We operationalized full adherence as to whether or not the participant completed the treatment in the suggested time (ie, 21 days without any breaks), regular adherence as whether participants completed all daily activities in up to 60 days, and depth of adherence as the total number of mindfulness training minutes [55]. Chat room activity beyond the initial onboarding post was measured by the number of participant comments in the chat room and dichotomized to any activity versus no activity.

Cigarette Consumption

Participants were instructed to report the number of cigarettes they smoked each day during treatment as part of their daily self-reports, at postintervention, and at 90-day follow-up. Over the treatment period, the daily number of cigarettes was stored and averaged per week.

Craving

Craving was assessed using the Questionnaire for Smoking Urges (QSU) [56], which consists of a 7-point Likert scale. These data were collected through an online survey at baseline, at the end of days 7 and 14, and at postintervention. The internal consistency for the overall scale was adequate ($\alpha=.87$).

Mindfulness

Mindfulness was assessed using the Five Facet Mindfulness Questionnaire (FFMQ) [57]. The 5 dimensions are observing, describing, acting with awareness, not judging internal experience, and not reacting to internal experience. These data were collected through an online survey at baseline, at postintervention, and at 90-day follow-up.

Readiness to Quit

Readiness to quit was assessed using the Contemplation Ladder [45], which consists of 11 rungs and 5 anchor statements

reflecting the stages of change and was designed to measure readiness to quit smoking. It was assessed through an online survey at baseline and at postintervention.

Nicotine Dependence

Nicotine dependence was assessed using the Fagerström Test of nicotine dependence [58], which consists of a 6-item self-report scale and observes responses suggestive of physiological dependence on nicotine. These data were collected through an online survey at the beginning of the program, at the end of day 7, day 14, postintervention, and 90-day follow-up. The internal consistency for the overall scale was adequate ($\alpha=.81$).

Data Analysis

Statistical analysis was performed with SPSS for Windows (version 22; IBM Corp). Abstinence rates between groups were compared using a chi-square test. Participants with missing data at follow-up were assumed to be smoking. Repeated measure analyses of variance (ANOVAs) were used to determine between-group differences and intervention effects for continuous variables. The group factor had 2 levels, corresponding to intervention and control group, and the time factor had 3 levels, corresponding to the 3 assessment points (baseline, postintervention, and 90-day follow-up). Post hoc analyses were conducted to determine significant pairwise comparisons. ANOVAs and post hoc tests were conducted to determine changes within the treatment group over time. All *t* tests in the study were 2-tailed.

Results

Recruitment and Participation in the Intervention

Participant baseline characteristics are displayed in Table 1. On average, participants in the sample were 43.25 years old (SD 10.06) and 47.5% (57/120) were female. The largest group in terms of completed educational level was high school (45/120, 37.5%), followed by university (43/120, 35.8%). On average, the sample started smoking 19.15 years ago (SD 12.35) and consumed an average of 10.77 (SD 5.47) cigarettes per day. Of all participants, 14.2% (17/120) lived with other smokers in their homes. The entire sample reported a moderated nicotine dependence index, based on the mean scores obtained in the Fagerström Nicotine Dependence Test [58], of 4.48 (SD 1.55). Only 40.8% (49/120) had practiced meditation at least once in their life. No statistically significant differences were observed between treatment and control group on any variables at baseline.

Table 1. Participant baseline characteristics (N=120).

Characteristics	Full sample (N=120)	Treatment group (n=60)	Control group (n=60)
Age (years), mean (SD)	43.25 (10.06)	44.06 (9.89)	42.44 (10.23)

^aFTND: Fagerström Test of Nicotine Dependence.

^bQSU: Questionnaire for Smoking Urges.

Primary Outcomes

At postintervention, the TG reported 23% (14/60) abstinence on that day compared with 5% (3/60) of the CG. This difference was statistically significant ($\chi^2_1=8.3$; $P=.004$).

Secondary Outcomes

Sustained Abstinence

The TG reported 33% (20/60) sustained abstinence on the 90-day follow-up, compared with 5% (3/60) of participants in the CG. Since only 20% (12/60) of participants in the CG completed the 90-day follow-up, we did not conduct a statistical comparison between groups at this follow-up time point.

Adherence Rates

Intervention adherence was analyzed only in the TG, and 93% (56/60) of participants finished the 21-day program. Of those who finished, 41% (23/56) were fully adherent to the program (ie, completed all daily sessions and nightly reflections 21 days in a row) and 59% (33/56) were regularly adherent (ie, completed the program in >21 days), completing the program in 28.56 days on average. At the postintervention, 30% (7/23) of fully adherent participants reported smoking abstinence,

while only 21% (7/33) of regularly adherent participants were abstinent. At the 90-day follow-up, smoking abstinence rates were 39% (9/23) among fully adherent participants and 33% (11/33) among regularly adherent participants. A statistically significant difference in readiness to quit was found between the fully and the regularly adherent group at baseline ($t_{55}=3.092$; $P=.003$), with fully adherent participants reporting greater readiness to quit. No differences were found regarding nicotine dependence ($t_{55}=1.206$; $P=.23$) at baseline, nor regarding abstinence rates between the 2 adherence groups at postintervention ($\chi^2_1=6.1$; $P=.43$) and at 90-day follow-up ($\chi^2_1=1.9$; $P=.66$).

If participants had not engaged with the program for 2 subsequent days, they were contacted in order to improve engagement. A total of 92% (54/60) of participants were contacted through SMS text messaging once; 65% (39/60), twice; 53% (32/60), thrice; and 34% (20/60) were contacted through both SMS text messaging and phone call reminders. Depth of adherence for all participants, measured by the number of minutes of mindfulness training during the program (including virtual reality, video format, and audio format), was

259.05 minutes on average, with a maximum of 386 minutes and a minimum of 216 minutes.

For those who reported abstinence at postintervention, the average mindfulness minutes trained was 250.43 minutes, while the average was 261.93 minutes among those who continued smoking. Statistically significant differences were not found between groups ($t_{55}=-1.291$; $P=.20$).

Participant activity in the chat room beyond an initial introduction message suggested in the onboarding process was low and only 13 participants commented in the chat room beyond the onboarding. Chat room activity was not associated with smoking cessation outcomes, having only 1 participant that successfully quit smoking while being active in the chat.

Cigarette Consumption

Statistically significant differences in cigarettes per day over time were found between the TG and the CG ($F_{5,114}=95.73$; $P<.001$) in the third week of the intervention and at postintervention. At intervention week 3, the TG consumed significantly fewer cigarettes than the CG (TG: mean 6.92, SD 5.26; CG: mean 9.03, SD 5.42; $P=.03$). Significant differences in cigarettes per day between groups were also found at postintervention (TG: mean 5.07, SD 5.65; CG: mean 9.53, SD 0.56; $P<.001$).

Readiness to Quit

The means comparison in the Contemplation Ladder for the TG and the CG showed statistically significant differences between groups ($F_{2,113}=4.55$; $P=.01$). Post hoc comparisons revealed that there were no differences at baseline (TG: mean 6.53, SD 0.14; CG: mean 6.83, SD 0.18; $P=.32$), but there were at postintervention (TG: mean 7.71, SD 0.13; CG: mean 7.16, SD 0.13; $P=.005$).

Mean Differences Within the Treatment Group Over Time

Cigarette Consumption

Post hoc tests after ANOVA were conducted for cigarette consumption, and statistically significant differences over time were found within the TG ($F_{4,52}=13.79$; $P<.001$). Participants significantly reduced their cigarettes per day from baseline (mean 11.09, SD 5.27) to postintervention (mean 6.05, SD 5.67; $P<.001$), as well as from baseline to 90-day follow-up (mean 5.07, SD 5.65; $P<.001$).

Mindfulness

Moreover, according to paired t test comparisons for FFMQ scores, no statistically significant difference was found between baseline (mean 123.95, SD 9.55) and postintervention (mean 122.61, SD 6.31; $t_{55}=0.772$; $P=.44$). However, FFMQ at 90-day follow-up (mean 115.89, SD 12.30) was significantly lower than scores at baseline ($t_{55}=5.594$; $P<.001$) and postintervention ($t_{55}=3.234$; $P=.002$).

Craving

A significant reduction in self-reported craving over time was observed in the treatment group (baseline: mean 30.28, SD

11.72; intervention week 1: mean 30.01, SD 11.75; intervention week 2: mean 28.00, SD 13.00; postintervention: mean 26.00, SD 11.37). These differences over time were statistically significant ($F_{1,24}=3.725$; $P=.005$).

Discussion

Principal Findings

This is the first study to report results of a pilot trial testing a VR smartphone-based smoking cessation program using remote and self-assisted delivery. At postintervention, the intervention group had a significantly higher abstinence rate (14/60, 23% abstinence) compared with the control group, which received a smoking cessation manual (3/60, 5% abstinence). Moreover, the intervention resulted in a 33% (20/60) abstinence rate at 90-day follow-up and high levels of adherence and engagement. Findings suggest the potential efficacy of a smartphone-based VR intervention that combines exposure therapy and mindfulness for smoking cessation.

When compared with other smoking cessation app studies, abstinence rates observed in the current study were in a similar range. For instance, an 8-week single-arm trial of a smartphone app that delivered essential features of US clinical practice guidelines with personalization resulted in a 26% abstinence rate at 30-day follow-up [59]. Another single-arm trial based on acceptance and commitment therapy had abstinence rates of 33% at 7-day follow-up and 28% at 30-day follow-up [60]. These rates are similar to the 23% (14/60) and 33% (20/60) observed in our study and provide confidence for further development and testing.

With 93% (56/60) of participants finishing the 21-day program, the current study had a high completion and low dropout rate. In line with other studies, we used several strategies to enhance adherence, including SMS text messaging and phone call reminders [55]. Consistent with our findings, adherence rates were also above 80% in the above-mentioned 8-week single-arm clinical trial [59] and in a randomized controlled trial of a text messaging program [61]. Of all 56 TG participants who finished the program, 23 completed without any gaps in treatment adherence and were classified as fully adherent, while the other 33 participants took an average of 28.56 days to complete the program and were classified as regularly adherent. The fully adherent group reported greater readiness to quit at baseline. Abstinence at postintervention and 90-day follow-up was higher among fully adherent participants compared with regularly adherent participants. These findings suggest that repeated exposure to smoking-related cues in virtual environments alongside mindfulness practice on a consecutive daily basis may increase abstinence outcomes compared with sessions that are more spaced out over time. Thus, a more consistent and disciplined training using virtual reality mindfulness-based exposure therapy to both internal and external triggers over a shorter period of time may result in better outcomes. Based on other studies [62], the chat room activity was low probably due to the lack of promotion to increase engagement through tailored material by the moderators. Overall, the methods used to strengthen engagement have been shown to have value and can be further developed.

Our results also indicate that mindfulness scores measured by the FFMQ significantly decreased within the TG from baseline to 90-day follow-up. It is unclear what may have caused this decrease despite the promising smoking cessation outcomes of our intervention. Given that the current study is the first to combine virtual reality exposure therapy and mindfulness-based relapse prevention for smoking cessation, replication of these findings is needed. Moreover, future studies should further explore the mechanisms of action of this novel intervention approach.

Other studies using VR and exposure therapy in smoking cessation showed similar results in decreasing cue-induced craving, such as a randomized clinical trial that combined CBT and virtual reality cue exposure therapy (VR-CET), which found a significant reduction of cue-induced cravings after group-based sessions over the course of 6 months with 5 individual sessions of VR-CET [37]. In the current study, the virtual reality environments exposed participants to smoking-related cues and at the same time presented a mindfulness narrative based on relapse prevention. Therefore, the intervention simultaneously elicits cravings by means of VRET and provides the user with tools for reducing these cravings by means of mindfulness. Our results of QSU craving scores over time show that scores did not decrease during the first week of treatment, in which there was no exposure therapy. However, self-reported cravings decreased during the following 14 days of the program, in which VR-MET was delivered.

Feasibility of conducting the trial was demonstrated by the fact that we were able to recruit 120 participants in the current pilot trial. However, feasibility of collecting follow-up data from a control group needs to be improved. The delivery of the intervention was feasible and acceptable to participants; 41% (23/56) of intervention participants completed the entire intervention content in 21 days, as recommended, and the average adherence to mindfulness training was 259.05 minutes per participant. Feasibility of the VR component as a central element of the program was high, with all participants practicing at least 15 informal mindfulness practice sessions lasting 10 minutes each. Even though this intervention introduced VR and mindfulness training to a population that had almost never tried any of these approaches before, the intervention had high engagement rates, suggesting remote and self-administered VR can be used as a strategy for improving adherence to mHealth interventions. These findings are in line with those of existing studies, which have shown that VR can enhance treatment fidelity by having behavioral interventions delivered by a programmed avatar [21] and that VR environments offer existing opportunities to enhance a patient's involvement in treatments [63].

Given that VR in mental health to date has predominantly been used in inpatient hospital environments [20], the recruitment method used in the current study to test the potential of VR as a self-administered and remote smoking cessation intervention on an outpatient population is worth mentioning. After appearing on national television, more than 1000 volunteers from all over Argentina registered within a few hours. The average age of

these volunteers was 41 years, which was considerably older than we had anticipated. The fact that we were able to recruit this population for a smartphone-based smoking cessation study using a VR cardboard headset demonstrates that this intervention can be accessible to populations that do not need to be exceptionally tech savvy. In light of existing challenges to recruit participants for mHealth interventions [64], this particular recruitment strategy may prove valuable for future research.

The creation of Mindcotine involved a group of psychologists, psychiatrists, and other physicians, as well as developers, actors, and mindfulness facilitators, and took over 6 months. While initial development costs were high, the fact that this program can be delivered remotely and self-administered makes it a low-cost and accessible intervention to promote smoking cessation.

Limitations

The current study has several limitations. The follow-up time was relatively short, given that only between 3% and 5% of smokers remain abstinent within the first year of quitting [65]. Follow-up assessment time points were not identical across intervention and control groups. Before the current pilot trial, we did not know how long participants would take to complete the entire program, thus we selected a 30-day follow-up time point for the control group. Future research will adhere to a consistent follow-up assessment time point across intervention and control groups. Completion of the 90-day follow-up in the control group was low. It is possible that control group participants may not have been motivated to complete follow-up surveys due to not seeing changes in their behavior, not receiving a digital intervention, or not receiving any monetary incentive. Control group follow-up rates need to be improved in future trials of this intervention. Other limitations include that at baseline, participants were not regular users of VR, the virtual intervention content was not interactive, only an Android version of the intervention app was available, and the version of the intervention tested in the current study did not include features for the users to track cravings on the app and in virtual reality environments. These features are currently in development for future versions of the intervention. Moreover, abstinence at follow-up was self-reported and subsequent investigations should include biochemical verification of outcomes.

Finally, the face-to-face meeting and the onboarding process at the beginning of the program could have impacted the high adherence rates observed in this trial and online onboarding may work differently. Future studies should administer the entire program remotely.

Conclusion

Overall, our VR smartphone-based Mindcotine intervention to support smoking cessation showed great potential with regard to participant adherence and initial efficacy. These findings warrant testing the intervention in a fully powered randomized trial including longer follow-up intervals to investigate relapse prevention and biochemical verification of abstinence.

Acknowledgments

This research was supported financially by the University of Flores (internal protocol number 17EX04), by a grant received from the Argentine Ministry of Production (Seed Fund project number 3291022226), and through sponsorship by MindCotine Inc.

Authors' Contributions

EG and MRC participated in the study design. NR and CW participated in the data collection process. JU participated in the data analysis. MRC, EG, and JT participated in the interpretation of data. EG and JT wrote the first draft of the manuscript. All authors participated in revising the manuscript.

Conflicts of Interest

JT's contribution to this publication was as a member of the Advisory Board of MindCotine Inc. This arrangement has been reviewed and approved by the Johns Hopkins University in accordance with its conflicts of interest policies. EG, NR, and CW have shares in MindCotine Inc, the company that developed the VR environments and the app for this study. JU and MRC have no conflicts of interest.

Abstract

Background: The internet is a relevant source of health-related information. The huge amount of information available on the internet forces users to engage in an active process of information selection. Previous research conducted in the field of experimental psychology showed that information selection itself may promote the development of erroneous beliefs, even if the information collected does not.

Objective: The aim of this study was to assess the relationship between information searching strategy (ie, which cues are used to guide information retrieval) and causal inferences about health while controlling for the effect of additional information features.

Methods: We adapted a standard laboratory task that has previously been used in research on contingency learning to mimic an information searching situation. Participants (N=193) were asked to gather information to determine whether a fictitious drug caused an allergic reaction. They collected individual pieces of evidence in order to support or reject the causal relationship between the two events by inspecting individual cases in which the drug was or was not used or in which the allergic reaction appeared or not. Thus, one group (cause group, n=105) was allowed to sample information based on the potential cause, whereas a second group (effect group, n=88) was allowed to sample information based on the effect. Although participants could select which medical records they wanted to check—cases in which the medicine was used or not (in the cause group) or cases in which the effect appeared or not (in the effect group)—they all received similar evidence that indicated the absence of a causal link between the drug and the reaction. After observing 40 cases, they estimated the drug–allergic reaction causal relationship.

Results: Participants used different strategies for collecting information. In some cases, participants displayed a biased sampling strategy compatible with positive testing, that is, they required a high proportion of evidence in which the drug was administered (in the cause group) or in which the allergic reaction appeared (in the effect group). Biased strategies produced an overrepresentation of certain pieces of evidence at the detriment of the representation of others, which was associated with the accuracy of causal inferences. Thus, how the information was collected (sampling strategy) demonstrated a significant effect on causal inferences ($F_{1,185}=32.53$, $P<.001$, $\eta^2=0.15$) suggesting that inferences of the causal relationship between events are related to how the information is gathered.

Conclusions: Mistaken beliefs about health may arise from accurate pieces of information partially because of the way in which information is collected. Patient or person autonomy in gathering health information through the internet, for instance, may contribute to the development of false beliefs from accurate pieces of information because search strategies can be biased.

Introduction

Background

In recent years, we have witnessed an increase in diseases, such as measles, that had almost been eradicated in the Western world [1]. One of the factors underlying this outbreak is the antivaccination movement, led by individuals who do not adhere to recommendations for vaccinations (for themselves or their children). Reluctance with respect to vaccination led to the World Health Organization listing vaccine hesitancy as 1 of 10 threats to global health in 2019 [2]. Although vaccine hesitancy is a complex phenomenon [3], common reasons for refusing vaccination are the underestimation of its benefits or the overestimation of its negative side effects; a high proportion of these concerns are based on information disseminated by the media or received from acquaintances [4]. Moreover, previous research [5] has shown that people use the internet as an information source about vaccines, and that side effects and possible negative outcomes of vaccination are one of the most searched topics.

In fact, the internet is an important source of health-related information [6–11]. Newly diagnosed cancer patients perceive the internet as a tool for acquiring information and for making informed decisions [12–14]; patients with diabetes use the internet to seek general information about the disease or about treatment options [15]. The relevant role of the internet, in this context, is not restricted to pathological states. Women who are pregnant use the internet to get informed about topics such as fetal development or to make pregnancy-related decisions [6,16], and after pregnancy, parents use the internet to retrieve health information regarding their infants [8,17].

The internet has accessibility, anonymity, and interactivity as advantages, but these advantages do not come without risks [18]. Some of these risks, such as information overload or lack of credibility, can be considered intrinsic limitations of the internet as a source for health information; however, there are other risks that are based on human skills and cognitive abilities. For example, the huge amount of information available on the internet forces users to engage in an active process of information selection to filter content. As we will discuss later, this information sampling process may play a crucial part in establishing and maintaining mistaken beliefs.

Evaluating the Risks and Benefits of Medical Treatments

When people judge the risks and benefits of a treatment option, they infer the causal relationship between two events—the

treatment and its effect. Unfortunately, causal inferences of this kind are highly difficult because, among other reasons, causality is not directly observable; rather, it must be inferred from cues such as contingency [19,20]. The principle of contingency posits that, unless hidden factors are at play, all causes correlate statistically with their effects.

Consider the simplest case in which a person may try to judge the effect of only one factor (cause) on one given outcome (effect). For the sake of simplicity, it can be assumed that both cause, C , and effect, E , are binary variables—they either occur or do not occur. In this situation, the person can collect information that fits into one of the following four possibilities (Figure 1, panel A)—*type a*, in which both the cause and the effect occur; *type b*, in which only the cause occurs; *type c*, in which only the effect but not the cause occurs; and *type d*, in which neither the cause nor the effect occurs—which define the cause and effect contingencies. Although different indices have been proposed to represent contingency [21,22], the most popular is, perhaps, the Δp index [23] which is computed as the difference between the probability of the effect conditional on occurrence of the cause, $E|C$, and the probability of the effect conditional on absence of the cause, $E|\sim C$, as shown in the equation,

$$\Delta p = p(E|C) - p(E|\sim C) = a/(a + b) - c/(c + d)$$

where Δp can take on values between -1 and 1 . Positive values indicate a generative relationship, and negative values indicate a preventive relationship. When the potential cause and the effect are not related to each other, the index equals zero and contingency is null.

Previous research [23–28] has shown that people are sensitive to contingency between events, and that contingency is used as a cue to make causal inferences; however, under some circumstances, people systematically deviate from the normative standard. Researchers have described two systematic deviations: the influence of the probability of effect occurrence [29–34], when the effect occurs frequently, the causal relationship tends to be overestimated (Figure 1, panel B); and the influence of the probability of occurrence of the cause [24,35,36], when the probability of the cause is high, the contingency perceived between cause and effect is also high (Figure 1, panel C). These biases can be detected even if the contingency between the cause and the effect is null, leading to causal illusions [37].

Figure 1. Contingency matrices where (A) shows the four information types as a function of whether the cause and the effect are present, (B) shows an example with a high probability of the effect with null contingency, and (C) shows an example with a high probability of the cause with null contingency.

Health-Related Information Seeking and Causal Illusions

Imagine someone who is worried about the potential relationship between a vaccine and autism. Usually, it is not possible to evaluate the effects of the vaccine by administering and not administering the vaccine and observing the outcomes since people rarely have the opportunity to conduct a randomized controlled trial. Instead, people will search for information about the relationship between the vaccine and the side effect by consulting an expert, by consulting a friend, or by searching the internet.

Perhaps the most obvious concern about internet-sourced information is the lack of quality control. Internet users may come across and trust information that is not supported by evidence; however, the act of information seeking may entail additional and specific concerns. For example, people who worry about the safety of vaccination and its relationship with autism may look for information about the vaccine (exploring its side effects and the probability of experiencing those side effects, etc). If they are concerned about autism, they may focus their search on autism (exploring which factors have been related with the development of autism or what the proportion of vaccinated children is among those who were diagnosed with autism). In the former, cause (ie, the vaccine) is the cue that guides the search, while in the latter, effect (ie, autism) is the cue that guides the search.

The sampling strategy (how people search for information) will affect their final inference about the relationship between vaccination and autism. If people search for information about the vaccine (ie, the potential cause of autism), they may introduce the name of the vaccine on the search engine, and they will mostly retrieve instances of type a and type b information. This information will allow them to make a general estimation of the probability of the effect (ie, autism) when the potential cause (ie, the vaccine) has been presented; however, in this case, their sampling strategy is biased toward the cause, and therefore, no information about the effect in the absence of the cause, that of either type c or type d, is collected. This will eventually bias their judgements. Indeed, even when sampling is not completely biased toward the cause and some type c or type d instances are collected, it has been repeatedly shown that the higher the tendency to sample information about the cause, the higher the probability of overestimating the cause–effect relationship [37–39].

In our example about the effects of vaccination, this strategy may, nevertheless, be considered as not particularly dangerous.

The prevalence of autism spectrum disorders is actually low (1 out of 160 children) [40]; therefore, this sampling strategy will retrieve more type b information than that of type a. In this example, the low base rate of the effect may protect people from developing a causal illusion [41], but in other cases, this protection does not exist (imagine, for example, potential effects such as nausea, high temperature, headache, or any other common effect).

As previously noted, people may also gather information using the effect as their cue for sampling; they may search using terms related to the effect rather than those related to the cause. If people use this sampling strategy for collecting information, they may learn which factors have been associated with autism and will discover that many children among those who developed autism spectrum disorders had been vaccinated. Thus, information sampling will be biased, overrepresenting information in which the effect (ie, autism) is present. In the long run, this strategy will increase the proportion of type a and type c information (relative to that of type b and type d) and will favor a sampling-induced overestimation of the relationship (Figure 1, panel B). This sampling-induced illusion may explain how concerned and educated parents end up overestimating the potential risks of vaccination [42]. Since many countries usually have systematic immunization programs, when information sampling is biased toward effect, the probability of collecting type a information (ie, cases in which autism and vaccination coincide) is even higher than the probability of collecting type c information (ie, cases in which autism occurs in the absence of vaccination). This increases the probability of overestimating the link between vaccination and autism—ie, the probability of experiencing a causal illusion.

The vaccination and autism example illustrates quite well how information sampling may become a crucial element for establishing and maintaining mistaken beliefs; however, the biases in sampling strategies can be extended to a wide range of health issues; people interested in assessing the causal relationship between any common behavior and an infrequent disease will find a high proportion of information where the behavior and the disease coincide if they use the effect as a cue in their internet search. Correspondingly, people using the cause to guide their internet search may end up neglecting the base rate of the effect and end up overestimating the causal relationship when the effect is frequent [43]. For example, a recent study [44] which tracked internet-browsing behavior in a controlled setting showed that when women were required to consult the internet for health information after the hypothetical onset of an unfamiliar breast change (eg, nipple rash), most

participants used rash-related search terms (a cue-guided sampling strategy), and the majority accessed websites containing breast cancer information with National Health Service Paget disease of the nipple being the most visited site. In this situation, even when information is accurate, the potential relationship between both events could be overestimated at a substantial emotional cost. Note that, if considering no other information, a nipple rash may be produced by other skin conditions with high incidence rates (such as eczema) rather than by Paget disease, which is a rare type of breast cancer [45].

Information sampling biases may also affect inferences about treatment effectiveness; it is also possible for a biased sampling strategy to induce a perception that underestimates a treatment that is actually effective, or a perception that overestimates the effectiveness of alternative practices proven by clinical trial to perform no better than placebos [39,46].

Study Goals

As previously described, research on contingency learning has demonstrated how people may use different pieces of information to infer causal relationships [19,20,47]. We have also mentioned that individual behavior may bias information sampling, and consequently, causal inferences; however, these behavior-induced causal illusions have only been explored in situations in which the potential cause was used to guide information sampling. As far as we know, the influence of an equivalent effect-driven sampling has not yet been explored. In addition, these causal illusions have been explored using procedures that usually include motivational components or additional goals which may affect information gathering and causal inferences. For example, participants may be required to evaluate the effects of a fictitious medicine while at the same time trying to heal as many patients as possible [48,49]. It is not clear whether a causal illusion can be detected in an information sampling setting when motivational components or secondary goals are removed, or when sampling strategies are guided by the effect rather than by the cause. The research reported herein explores these two possibilities.

Methods

Participants

A sample of adults ($N=193$) with a mean age of 34.07 (SD 11.41) years consisting of women (83/193, 43.0%), men (109/193, 56.5%), and one (1/193, 0.5%) nonbinary participant were recruited via Prolific Academic internet platform [50]. They were compensated £0.75 (US \$0.93) for their participation, which worked out to approximately £5.01 (\$6.19) per hour. Enrollment was only offered to individuals in Prolific Academic's pool whose first language was English (to ensure that instructions were correctly understood) and to individuals who had not taken part in previous studies carried out by our research team. We did not use any exclusion criteria (all participants were included in reporting). Participants were randomly assigned to experimental groups—a cause group ($n=105$) and an effect group ($n=88$).

Instruments

Because of ethical considerations, we avoided using a real-world example in this experiment and instead used a simplified fictitious scenario that is often used in causal learning research; we adapted the allergy task [20,51] for presentation as a web app based on World Wide Web Consortium standards [52]. A demonstration of the program can be downloaded from the Open Science Framework [53].

Experimental Design and Procedure

We adapted the allergy task [20,51] to make it akin to an information gathering situation with no goal other than that of assessing the causal link between two events. This procedure has been widely used in causal learning research and allows for the assessment of causal illusions while controlling other relevant parameters, which ultimately ensures a high degree of internal validity.

The procedure was set to allow for cause-driven and effect-driven sampling by including a reduced number of changes. Participants were required to gather information to discover whether a fictitious drug (ie, “Batatrim”) caused a fictitious allergic reaction (ie, “Lindsay syndrome”). Participants in the cause group were allowed to sample information based on the potential cause, therefore, could choose to retrieve patient medical records based on patient treatment (whether the patient was treated with Batatrim or not treated with Batatrim), whereas participants in the effect group were allowed to sample information based on the effect, therefore, could choose to retrieve the records based on the development of the syndrome (whether the patient developed Lindsay syndrome while hospitalized or did not). Detailed instructions for the task can be found in [Multimedia Appendix 1](#).

The probability of the cause was under participant control in the cause group whereas the probability of the effect was under participant control in the effect group. Information presented objectively reflected the absence of a causal link between the two events. The probability of the effect in cause group and the probability of the cause in effect group were fixed to 0.75. This design allowed for the evaluation of sampling-dependent causal illusion in a null contingency situation with a high probability of the outcome (cause group) and with a high probability of the cause (effect group).

We expected causal estimations to vary depending on sampling strategy. For participants in the cause group, we expected estimations to increase as the participants increased the probability of the cause—the more biased the participant behavior toward cause-present events, the higher the probability of experiencing causal illusion. Analogously, for participants in the effect group, we expected estimations to increase as participants increased the probability of the effect, also resulting in an increased likelihood of experiencing causal illusion. The procedure used in this study was approved by the ethical review board of the University of Deusto.

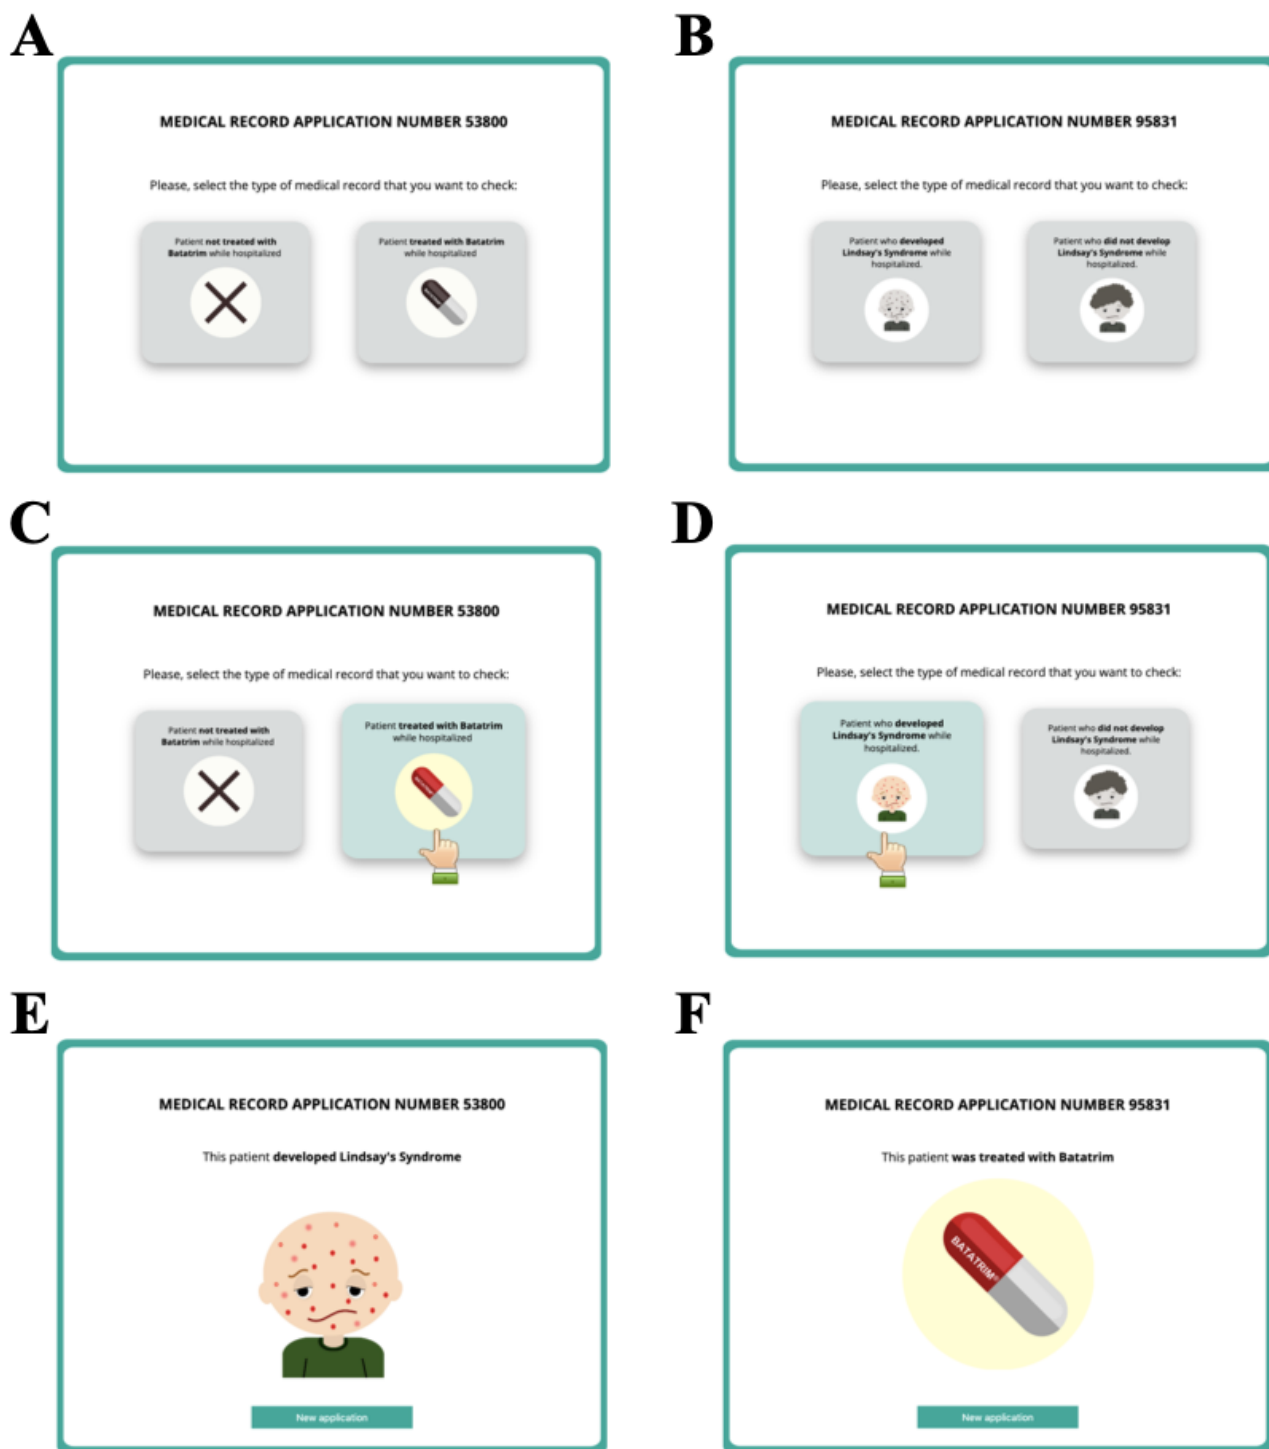

Learning Task

A series of 40 patient records was presented, each in a separate trial. Each trial started with a screen on which participants were

required to indicate which type of medical record they wanted to check by pressing one of two buttons (Figure 2, panels A and B). The location of each button (left or right) was randomized for each participant. When participants moved the cursor over the buttons, the button colored and zoomed, and a hand pointer appeared to indicate that a response could be made (Figure 2, panels C and D). Once a button was clicked, all the information presented on the screen was removed (with the exception of the sentence stating the medical record application number which

remained for esthetic purposes, and for which a random number was used). The information that had been removed was replaced with information about the syndrome when viewed by those in the cause group, or about the treatment when viewed by those in the effect group (Figure 2, panels E and F). One second later, a green button with the words “New application” was presented. After clicking this button, all elements were removed, and after one second, a new trial (a new patient record) appeared. There was no time limit for progressing through the task.

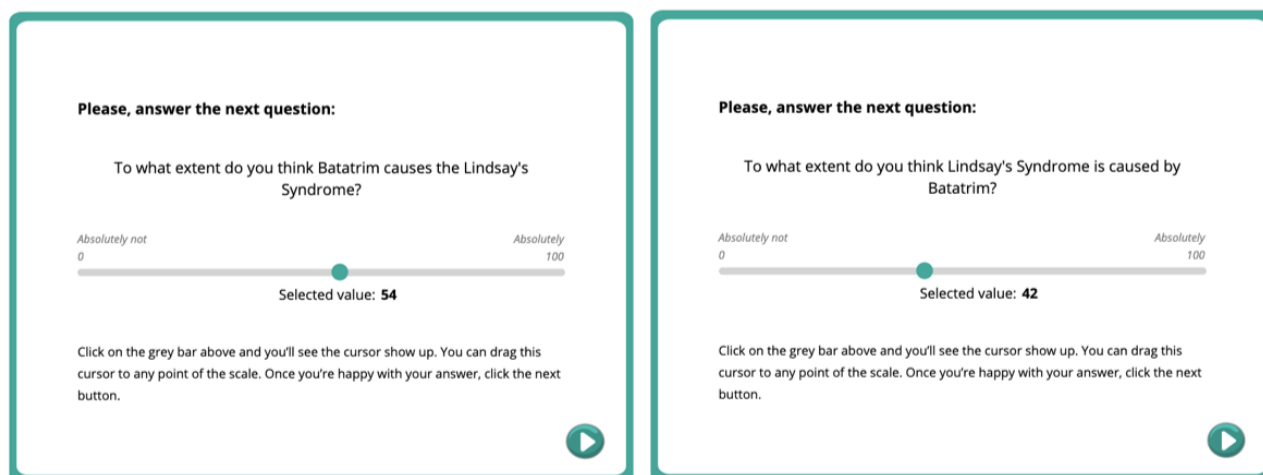

Figure 2. The sequence of events within a trial presented to the cause group (panels on the left) and to the effect group (panels on the right).

When participants completed the training stage, they were required to use a 100-point scale to make a global estimation about the causal relationship between Batatrim and Lindsay Syndrome. The question was formulated in the direction of either cause-to-effect “To what extent do you think Batatrim

causes the Lindsay syndrome?” or effect-to-cause “To what extent do you think Lindsay syndrome is caused by Batatrim?” The format of the question was randomized among participants (Figure 3). In both cases, the response scale was from 0 (absolutely not) to 100 (absolutely).

Figure 3. The final screen where the causal relation between Batatrim and Lindsay syndrome is assessed. The question is shown worded as cause-to-effect (left) or effect-to-cause (right).

Measures

Causal estimations at the end of the learning task were used as a measure of causal inference [39]. For each participant, we also calculated a sampling strategy index and a measure of experienced contingency.

As previously described, participants in the cause group could choose records based on patient treatment (patients treated or not treated with Batatrim), while participants in the effect group could choose records based on the development of the syndrome (patients who developed or who did not develop the syndrome). Participants could display an unbiased information gathering strategy, asking for a similar proportion of records in both categories; however, it was also possible for participants to display a biased sampling strategy, ie, to preferentially ask for one type of medical record more often than for the other. To measure bias in the information sampling strategy, we calculated a sampling strategy index from training responses as the probability of choosing records of patients treated with Batatrim (in the cause group) or records of patients who developed Lindsay syndrome (in effect group); therefore, the sampling strategy index could range between 0 and 1. Values near 1 indicated a strong preference for checking the medical records of patients treated with Batatrim or patients who developed the syndrome (depending on the group). Values near 0 indicated the opposite strategy, that is, a preference for checking medical records of patients who were not treated with Batatrim or who did not develop the syndrome. A value of 0.5 indicated an unbiased strategy with no preference for either of the two strategies. The higher the index, the higher the probability of retrieving a medical record in which the potential cause and the consequence coincide (type a information), and consequently, the higher the probability of developing a causal illusion.

Additionally, and given that participants could decide which type of medical record they wanted to check, experienced

contingency could depart from the programmed value ($\Delta p=0$) and also affect their causal estimations [35,54]; therefore, a measure of experienced contingency was calculated (Δp using the actual number of type a, b, c, and d trials to which each participant was exposed).

Statistical Analysis

Unless noted otherwise, $P<.05$ was deemed as statistically significant. Two-tailed independent t tests were used to determine if sampling strategy indices were significantly different from 0.50 (neutral strategy) in either group.

A 2×2 analysis of variance (ANOVA) was performed to assess the effect of group (cause versus effect) and button position (left versus right) on information sampling strategy (sampling strategy index).

An analysis of covariance (ANCOVA) was performed using group (cause or effect) and directionality in which the causal estimation was required (cause-to-effect or effect-to-cause) as fixed factors and information sampling strategy (sampling strategy index) as a covariate to determine the effect on causal estimation. We expected causal estimation to vary as a function of sampling strategy index in both groups—the higher the index, the stronger the causal overestimation of the relationship between the cause and the effect. Additionally, and since the probability of the outcome in the cause group and the probability of the cause in the effect group were fixed at the same high rate, $p(C)=p(E)=0.75$, we explored whether the effect of sampling strategy on causal estimations was equivalent in both groups. We also explored if causal estimations were affected by directionality.

A t test was used to compare experienced contingencies with the programmed value ($\Delta p=0$). In participants who exhibited an extremely biased strategy by checking only records of patients treated with Batatrim (ie, a sampling strategy index

equal to 1), no trials without the cause were sampled, and the probability of the effect in the absence of the cause $p(E|\sim C)=0$, and consequently experienced contingency, could not be computed since $c/(c+d)=0/0$.

To explore sampling strategies, learning phase data were split into 8 blocks of 5 trials, and a sampling strategy index was calculated for each block. A repeated measures ANOVA was used to explore the effect of block (from 1 to 8) and group (cause and effect) on sampling strategy index. Posthoc analyses (28 comparisons) were performed using Bonferroni correction.

Results

Sampling strategy indices were significantly different from 0.50 (neutral strategy) in both groups. Participants preferentially checked the medical records of patients who, in the case of the cause group, were treated with Batatrim (mean 0.54, SD 0.17; $t_{104}=2.18$, $P=.03$, Cohen $d=0.21$), or who, in the case of the

effect group, developed the syndrome (mean 0.57, SD 0.16; $t_{87}=4.07$, $P<.001$, Cohen $d=0.43$).

The 2×2 ANOVA demonstrated that the sampling strategy index did not differ between groups ($F_{1,189}=2.30$, $P=.13$, $\eta^2_p=0.01$), and it was not affected by the position in which buttons were presented ($F_{1,189}=1.31$, $P=.26$, $\eta^2_p=0.01$). The group \times button position interaction also was not significant ($F_{1,189}=0.14$, $P=.71$, $\eta^2_p=0$); therefore, both groups showed a similar sampling strategy, selecting the medical records of patients who were exposed to the potential cause or who suffered the effect more often than the medical records of patients who were not exposed to the potential cause or who did not suffer the effect.

Only a significant effect of sampling strategy index ($F_{1,185}=32.53$, $P<.001$, $\eta^2_p=.15$) was demonstrated by the ANCOVA, suggesting that the relationship between information searching strategy and causal estimation was independent of group and directionality (Table 1 and Figure 4).

Table 1. Summary of ANCOVA analysis for variables predicting causal estimations.

Effect	<i>F</i> test (<i>df</i> ₁ , <i>df</i> ₂)	<i>P</i> value	Partial eta square
Sampling strategy index	32.53 (1,185)	<.001	0.15
Directionality	0.61 (1,185)	.44	0
Group	0.20 (1,185)	.66	0
Sampling strategy index \times directionality	0.22 (1,185)	.64	0
Sampling strategy index \times group	0.01 (1,185)	.93	0
Directionality \times group	1.63 (1,185)	.20	0.01
Sampling strategy index \times directionality \times group	1.60 (1,185)	.21	0.01

Figure 4. Causal estimations as a function of sampling strategy index and group.

Note that any analysis that included experienced contingency did not take into account 5 participants who exhibited an extremely biased strategy (sampling strategy index=1).

No differences were found between experienced contingency and the programmed value ($p=0$) either in the cause group ($t_{99}=1.49$, $P=.14$, Cohen $d=0.15$) or in the effect group ($t_{87}=0.54$, $P=.59$, Cohen $d=0.06$) meaning that most participants experienced a near zero contingency. Once the 5 participants for whom it was not possible to calculate Δp were discarded, no relationship between sampling strategy and experienced contingency was detected ($r=0.06$, $P=.41$); therefore, the effect

of sampling strategy on causal estimation could not be attributed to experienced contingency.

The repeated measures ANOVA showed a significant effect of block ($F_{7,1337}=5.24$, $P<.001$, $\eta^2_p=.027$). The sampling strategy index was significantly higher in block 1 than in the other seven blocks, while no other significant differences were found (Table 2 and Figure 5). In block 1, 93% (98/105) of participants in the cause group selected the medical record of a patient treated with Batatrim as their first choice, and similarly, 86% (76/88) of participants in the effect group selected the medical record of a patient who developed the syndrome.

Table 2. Posthoc comparisons.

Comparison	Mean difference	<i>t</i> test (<i>df</i>)	<i>P</i> value (Bonferroni ^a)	<i>P</i> value (uncorrected ^b)

Discussion

Principal Results

The main goal of this experiment was to assess the potential relationship between information gathering biases and causal inferences using an experimental procedure. Thus, we adapted a standard laboratory task which has previously been used in research on causal illusions in order to imitate an information searching situation. Results showed a significant relationship between causal illusion and information sampling strategy. When the potential cause was used to collect information, the causal link can be overestimated when cause-absent information is undersampled. Similarly, when the effect is the cue that drives information gathering, causal estimations can be overestimated when effect-absent information is insufficiently sampled.

Although we did not explicitly include any manipulation aimed at biasing sampling strategy, we found a general preference for checking the medical records of patients treated with Batatrim or patients who developed the syndrome (depending on the group). We may explain this preference as the result of a positive testing strategy driven by a confirmation bias [55]. Instructions presented the treatment with Batatrim as a potential cause for the allergic reaction: “You suspect that Lindsay syndrome may be caused by a medical treatment called Batatrim...” Consequently, we provided participants with the initial hypothesis that Batatrim caused Lindsay syndrome. People using a positive testing strategy will search for information that confirms their hypothesis. Under the initial hypothesis that Batatrim causes Lindsay syndrome, a positive testing strategy involved searching information to obtain coinciding events. When a search is based on the cause, the strategy that allows for retrieving cause-effect coincidences is to select cases in

which the cause is present (ie, medical records of patients treated with Batatrim) whereas the way to obtain these coincidences when searching is driven by the effect is by selecting cases in which the effect occurred (ie, medical records of patients who developed the syndrome). These two biases resemble the sampling strategy bias detected in our experiment. Our results about the relationship between information searching strategy and causal estimation (a significant effect of sampling strategy index on causal estimation) also showed the danger associated with this testing strategy—information collected using a positive testing strategy will lead to an overrepresentation of cue-present trials and will increase the likelihood of a causal illusion.

Since a positive testing strategy has been claimed to be a general default heuristic that is often used in the absence of specific information identifying some tests as more relevant than others [55], it is not necessary to assume that a confirmation bias support our results; however, previous beliefs should be taken into account when the information sampling strategies are tested in real contexts given that personal interest and motivation may exert a heavy influence boosting the effect of a default-biased strategy. The role of confirmation bias has already been explored in health information sampling research suggesting that it may significantly affect how information is collected. In recent research, Meppelink et al [56] investigated the role of confirmation bias in information seeking with respect to early-childhood vaccination and found that a priori vaccination beliefs biased selection of online health information—people predominantly selected information that was consistent with their existing beliefs (ie, selective exposure) [57]. The significant effect of sampling strategy index on causal estimations showed that, in addition, a partial selection of information in which belief-supporting evidence is overrepresented may be related

to damaged causal estimation (note that the correlational nature of our design does not allow us to discriminate whether the biased searching caused the estimates to be biased, or whether a stronger initial belief about the causal relationship might have biased the sampling strategy, strengthening the initial belief).

Limitations and Strengths

In order to ensure strong experimental control of the variables involved and a high internal validity, we decided to use a standard and very simple procedure that is often used to study how people make causal inferences in laboratory settings. Our use of this procedure in the current situation, however, resulted in limitations related to its ecological validity. Our procedure does not exactly mirror how internet users search for information. Most internet users do not sequentially select information about individual people in the same way as was done in the experimental task; however, the process of collecting information and the subsequent processes of integration, combination, and interpretation of the information are, fundamentally, the same.

Participants searched for and collected pieces of evidence that ultimately were used to shape their estimation about the relationship between the events. Similarly, internet users may use web search engines which provide them with discrete bits of information that are used as evidence to support or reject the causal relationship between the events under assessment. In our experiment, these pieces of information were less enriched than those collected in real-world settings, but they did contain the core information needed for causal inference. Reducing the ecological validity of our procedure ensured a high level of internal validity—an advantage that made our procedure a better option than other naturalistic paradigms. The most relevant advantage was that it allowed us to explore information sampling biases while controlling for the effect of additional information features.

Real situations contain a high degree of ambiguity and subtle information nuances that may limit research inferences by weakening internal validity. For example, website design or the perceived authority of the author have been shown to influence the trust and credibility of web-based health information [58], which may affect how specific pieces of information are weighted and integrated to make causal inferences. Instead, the experimental approach allowed for the isolation of searching strategy from other factors. Another advantage of the experimental approach was that we were able to control which information was presented, and consequently, whether the information objectively supported any relationship between the cause and the alleged effect in order to detect causal illusions.

Finally, by using a fictitious scenario instead of a real-world example, we avoided the potential consequences of experimentally induced causal beliefs on real-life decisions and controlled for any contribution of a priori beliefs.

Future Work

Now that the contribution of sampling strategies on causal inferences has been documented in a laboratory setting, future research may extend our results to real-world situations to assess the generalizability of our findings when information collection is more complex. This research may be considered a first step in building interventions aimed at protecting people when using the internet to search health information.

Conclusions

The internet has become a relevant source of health-related information [6-8]. Despite its advantages, using the internet to gather information requires several considerations such as the lack of quality control of the information and the subsequent possibility of misinformation dissemination. A relevant example is misinformation concerning scientific strategies that are aimed at protecting and promoting public health such as vaccination. Although, the determinants of vaccine uptake are complex, online misinformation has been claimed to contribute to the phenomenon of individuals foregoing vaccinations [59,60] and major search engines and social media organizations have been recently called to actively support fact-based communication programs that positively contribute to restoring confidence in vaccinations [61]. Using the internet to gather health information may cause additional concerns beyond those of information quality. How people search for information may determine which information is retrieved [62,63], shaping their beliefs about health, and eventually, their health-related behavior, such as vaccination refusal [64,65]. Results from our study have shown that sampling biases are related to causal perceptions. Thus, partial selection of information may induce an uneven representation of information that may produce and perpetuate causal illusions.

Laboratory-based research on contingency learning has been shown to be a successful approach to real-life problems because of its ability to detect relevant factors that may contribute to causal inferences, but also because it has been the foundation for designing and testing evidence-based interventions that have proven to be effective in improving critical thinking skills, and therefore, at reducing potentially harmful causal misconceptions in real contexts [48,49]. Future research may extend our results to real-world contexts in order to design interventions aimed at protecting users when using the internet.

Acknowledgments

Support for this research was provided by grants RTI2018-096700-J-I00 and PSI2016-78818-R from *Agencia Estatal de Investigación* of the Spanish government awarded to MMMF and to HM, respectively, and Grant IT955-16 from the Basque Government awarded to HM.

Abstract

Background: The internet has become an increasingly important resource for health information. However, with a growing amount of web pages, it is nearly impossible for humans to manually keep track of evolving and continuously changing content in the health domain. To better understand the nature of all web-based health information as given in a specific language, it is important to identify (1) information hubs for the health domain, (2) content providers of high prestige, and (3) important topics and trends in the health-related web. In this context, an automatic web crawling approach can provide the necessary data for a computational and statistical analysis to answer (1) to (3).

Objective: This study demonstrates the suitability of a focused crawler for the acquisition of the German Health Web (GHW) which includes all health-related web content of the three mostly German speaking countries Germany, Austria and Switzerland. Based on the gathered data, we provide a preliminary analysis of the GHW's graph structure covering its size, most important content providers and a ratio of public to private stakeholders. In addition, we provide our experiences in building and operating such a highly scalable crawler.

Methods: A support vector machine classifier was trained on a large data set acquired from various German content providers to distinguish between health-related and non-health-related web pages. The classifier was evaluated using accuracy, recall and precision on an 80/20 training/test split (TD1) and against a crowd-validated data set (TD2). To implement the crawler, we extended the open-source framework StormCrawler. The actual crawl was conducted for 227 days. The crawler was evaluated by using harvest rate and its recall was estimated using a seed-target approach.

Results: In total, n=22,405 seed URLs with country-code top level domains .de: 85.36% (19,126/22,405), .at: 6.83% (1530/22,405), .ch: 7.81% (1749/22,405), were collected from Curlie and a previous crawl. The text classifier achieved an accuracy on TD1 of 0.937 (TD2=0.966), a precision on TD1 of 0.934 (TD2=0.954) and a recall on TD1 of 0.944 (TD2=0.989). The crawl yields 13.5 million presumably relevant and 119.5 million nonrelevant web pages. The average harvest rate was 19.76%; recall was 0.821 (4105/5000 targets found). The resulting host-aggregated graph contains 215,372 nodes and 403,175 edges (network diameter=25; average path length=6.466; average degree=1.872; average in-degree=1.892; average out-degree=1.845; modularity=0.723). Among the 25 top-ranked pages for each country (according to PageRank), 40% (30/75) were web sites published by public institutions. 25% (19/75) were published by nonprofit organizations and 35% (26/75) by private organizations or individuals.

Conclusions: The results indicate, that the presented crawler is a suitable method for acquiring a large fraction of the GHW. As desired, the computed statistical data allows for determining major information hubs and important content providers on the GHW. In the future, the acquired data may be used to assess important topics and trends but also to build health-specific search engines.

KEYWORDS

health information; internet; web crawling; distributed system

Introduction

Overview

The internet has become an increasingly important resource for health information, especially for laypeople [1-10]. Web users perform online searches to obtain health information regarding diseases, diagnoses, and different treatments [1]. However, with a growing amount of web pages, it is nearly impossible for humans to manually keep track of evolving and continuously changing content in the health domain. According to the (German) Good Practice Guidelines for Health Information, “evidence-based health information is...a trustworthy state of the medical knowledge” [11]. Even if health information is found via well-known search engines, it does not necessarily meet with this definition and may be influenced by commercial interests [12].

Therefore, it is important to identify health content providers and assess their relevance [13]. In this context, an automatic web crawling approach can help to understand the structure of the health-related web (ie all web pages offering health-related information). By focusing only on such content, it is possible to (1) identify information hubs for the health domain, (2) find content providers of high prestige, and (3) identify important topics and trends within the health-related web. In future work, the identified content providers of high prestige could be analyzed for their respective trustworthiness and their compliance with the criteria of evidence-based health information [11].

According to Van der Bosch et al [14], in 2015 the (indexed) web was estimated to consist of roughly 47 billion web pages. However, only a fraction of those web pages contain health-related information. So, in order to determine the structure of the health-related web, it is crucial to determine for each web page's content whether it is health-related or not.

A related filter method can be used within a web crawler to filter out irrelevant web pages, therefore reducing the total number of web pages that need to be crawled. This saves time and financial resources for the crawling task. Nevertheless, analyzing such an amount of data requires high performance hardware and parallelization approaches.

Yet, to the best of the authors' knowledge, no study has been previously conducted and published about the health-related web. This study provides a first analysis of the health-related web limited to web pages in German, the so-called German health web (GHW). In this regard, we restrict our study to the three mostly German-speaking countries Germany, Austria and Switzerland (D-A-CH).

A distributed focused crawler for the GHW is outlined and evaluated as part of this study. Using the acquired data it is possible to extract the graph structure of the GHW for the goals

listed above and provide access to health-related text material for linguistic analysis and further research purposes.

Related Work

Importance of Health Information on the Web

The World Wide Web and its graph structure have been a subject of study for many years [15-17]. However, domain-specific and/or country-dependent analysis of graph properties have not been the primary scope of research in the recent years [18,19]. Moreover, a review by Kumar et al [20] shows that research related to focused crawling was popular in the late 1990s and mid 2000s but seems to have lost attention in the last decade. As the internet is an important resource for health information [21], finding relevant content remains an important task [8].

Web Crawling of Health Information

In 2005, Tang et al [22] investigated the use of focused crawling techniques to assess the topic relevance and quality of medical information. For this purpose, n=160 seeds from the category depression of the Open Directory Project (now Curlie) were selected. They found that such an approach fetches twice as many pages as a crawler without topic focus. In another study, Pirkola et al [23] described the use of focused crawlers to acquire text from the genomics domain. They found, that “the source of seed URLs and the issues related to the multilinguality of the web” are major challenges in this area.

Abbasi et al [24] used a focused crawler to collect credible medical sentiments and opinions in the context of drug surveillance. In this context, their crawler was evaluated on “a set of 100 seed URLs pertaining to health and drug-related websites” and achieved a harvest rate of 10.06% (1,243,074/12,362,406). In 2016, Abbasi et al [25] demonstrated the use of a focused crawler to acquire credible online medical content in the context of postmarket drug surveillance. Their method was able to “collect over 80% of all relevant credible content in the first 20% of the crawl.”

In Xu et al [26], a user-oriented adaptive focused crawler was implemented and applied in the cancer domain (ie, on breast and lung cancer). The authors found “that the new crawler can substantially accelerate the online user-generated content acquisition efforts for cancer researchers.”

Amalia et al [27] presented a focused crawler for the acquisition of health-related articles written in Indonesian. In this study, different crawling strategies and their relative impacts on crawler performance were investigated. They found that crawling larger sites first improves the number of crawled articles.

In 2016, Rheinländer et al [28] studied the scalability of an information extraction framework using a focused crawling approach to collect and analyze “a 1 TB collection of web text from the biomedical domain” written in English. For this purpose, they generated a set of n=485,462 seeds using

commercial search engines with which their focused crawler achieved a harvest rate of 38%.

Aims of the Study

The authors decided to concentrate on health-related web pages available free of charge on the internet in the D-A-CH region that can be found under the respective country-code top-level domains (ccTLDs) .de, .at, and .ch. In this context, the aim of this study was fourfold:

- Demonstrate the suitability of a focused crawler approach for the acquisition of health-related content in the D-A-CH region
- Provide a curated list of seed points for the health domain in the D-A-CH region
- Provide a crowd-validated evaluation data set consisting of health-related and non-health-related URLs that can be used to evaluate other classifiers used in focused crawlers for the health domain in the D-A-CH region
- Give preliminary insights into the graph structure of the GHW

To the best of the authors' knowledge, no similar study has been previously conducted on a large scale. In particular, this has not been done for the GHW.

Besides a statistical analysis of the GHW, this paper shares our experience in building and operating a highly scalable focused crawler. Thus, researchers who want to perform a similar

analysis for web pages of the health domain in their country can benefit from the experiences gained.

Methods

Focused Web Crawling

Basic Web Crawling Process

As depicted in [Figure 1](#), a web crawler traverses the directed graph of the web [29,30]. Starting from a given set of seed URLs, the web crawler fetches web pages. After the download is successful, the HTML of a web page is parsed and hyperlinks to other web pages are extracted. These links are then analyzed and added in a priority queue called frontier [30,31]. The web graph is then visited via those URLs kept in the frontier. The crawler repeats this process until the frontier is empty or it is stopped manually.

Due to the enormous size of the web [14], one must focus on a certain domain of interest to speed up the crawl. In this context, a focused crawler only visits those outgoing links of a web site that appear to be relevant for the given topic. To determine whether a link is relevant or not, the assumption is made that web pages of a certain topic are most likely linked to other web pages of the same topic [32]. To assess the relevance of a certain web page, a focused crawler often uses techniques from the field of machine learning [16,31]. Classifiers are then leveraged to filter irrelevant content during the crawl process and assign priority on extracted URLs based on the classification result.

Figure 1. Schematic representation of the web graph traversal by a crawler. Pages colored in blue represent processed pages; in green, pages referenced in the frontier; in gray, undiscovered web content. Pages in dashed blue represent so-called initial seed pages.

System Architecture and Processing Workflow

Given the results of the Van der Bosch study [14], it is obvious that sequential processing of such an amount of data would take a tremendous amount of time and/or financial resources. For this reason, a parallel and distributed system architecture as described by Shkapenyuk [33] is necessary to crawl within a reasonable amount of time: to make results available before the web has notably changed. Therefore, such an architecture must be designed to handle thousands of worker threads to fetch web pages in parallel. Besides efficiency in terms of throughput, a crawler should also respect crawler ethics [29,34] (ie, it should honor the robot exclusion protocol [robots.txt]) [29,35,36]; this protocol allows web site administrators to inform the web crawler which parts of a web site should not be processed. In addition, a crawler should not overwhelm the target web server by sending too many request in a short period of time. For this reason, applying a politeness delay (time between requests to the same server) is mandatory. Furthermore, it must be robust protection against so-called spider traps, or web sites containing programmatic errors or dynamically generated links that cause the crawler to be trapped in an infinite loop [29]. Moreover, the HTML parser must tolerate broken and/or invalid markup [29,37,38]. In addition, text extraction components must handle boilerplate detection in an appropriate way [39,40].

There are several frameworks that realize such distributed crawlers; we built our system on top of the open-source framework StormCrawler [41], a software development kit for building low-latency, scalable crawlers based on the Apache Storm framework [42]. It lacks out-of-the-box components for focused crawling but offers the possibility of adding custom extensions and configuration options. For this reason, we extended it with classifiers and the necessary logic to implement a focused crawler. Figure 2 depicts the architecture of StormCrawler (black) with our focused crawler extension (orange).

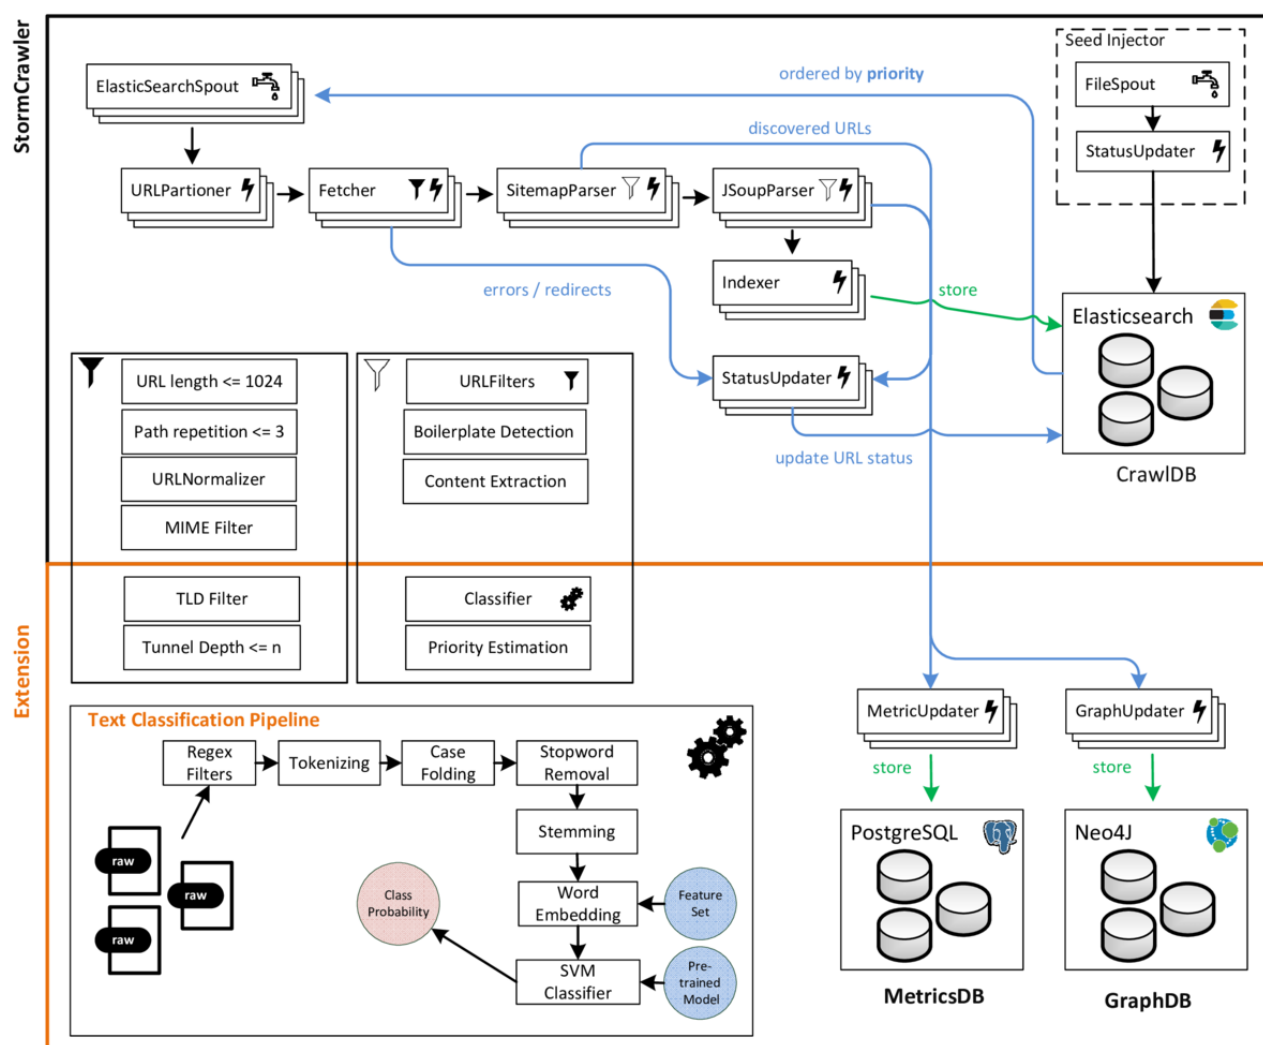

The StormCrawler software development kit provides a conventional recursive crawler architecture (upper part of Figure 2); a seed injector is used to read URLs from a text file and adds them to the CrawlDB, which acts as the crawl frontier and content storage. Next, a set of spouts emit yet unseen URLs from the crawl database. To maintain politeness, these URLs are then assigned to cluster nodes (based on their resolved hostname) and directed to the fetchers. The latter will download the respective web pages and forward them to the parsers for link and content extraction; unseen URLs are added to the frontier. Next, the content is sent to the indexers, which store it inside the CrawlDB (in this case an Elasticsearch cluster [43]).

To add focus to StormCrawler, the framework was extended by adding additional bolts and filter components (lower part of

Figure 2). After a web page is parsed, the raw text is extracted by using boilerplate detection and XML path language expressions. It is then processed by a text classification pipeline to compute the relevance to the health domain as described by Joachims [44] and Zowalla et al [45]. If a web page is classified as relevant, it is marked for further processing.

Next, a priority value (in this case a value between 0 and 127) is assigned to every URL contained on the given web page [46]. This is done by using (1) the class probability of the current web page [29,32], (2) a check whether the extracted URLs target the same hostname (a web site covering a certain topic will most likely contain more web pages of that topic) [29,32], (3) the anchor text of that link [47], and (4) the link itself using an n-gram approach [48]. Higher priority values will guarantee earlier processing.

Figure 2. Architecture of a focused crawler based on the StormCrawler software development kit. Spouts (tap symbol) emit data (here: URLs), bolts (lightning symbol) process data (ie fetch, parse, and store the extracted content). Bolts can be enhanced with URL filters (white filter symbol) or parse filters (black filter symbol). URL filters are used to remove URLs based on predefined criteria. Parse filters include URL filters but are primarily used to clean the parsed content and compute topic relevance and priority.

System Environment and Hardware Setup

In total, 22 virtual machines participate in the computing cluster providing the infrastructure for the crawler. The corresponding services are used to run, manage, and analyze the crawled web pages on the fly. For this setup, two physical servers of a Cisco

In addition, we implemented a soft focused crawling strategy using tunneling to avoid stopping at the first irrelevant page. For example, many front pages of portals may be classified as irrelevant but link to relevant health-related content [28,31]. To do so, a specific filter component tracks the depth and stops after given n steps (eg, n=2, n=3). Irrelevant web pages are not indexed.

To build the web graph of the health domain, during the crawl process a specific bolt keeps track of the visited and discovered links and adds them to a clustered Neo4J graph database. For statistics and metrics related to the crawl, another bolt continuously updates the crawling progress inside a PostgreSQL database. The crawling and classification process is repeated until the frontier is empty or it is stopped manually by the user.

unified computing system provide the computational resources and run as a virtualization platform to allow shared resource allocation.

Each server offers two physical central processing units (Intel Xeon E5-2689) with 8 cores each and 256 GB of memory. On

the network side, the Cisco unified computing system is attached to two optical 10 gigabit ethernet fibers that provide high bandwidth and ensure scalable throughput. A network attached storage system provides a total disc capacity of 60 TB to persist crawled data and store participating virtual machines via the network file system protocol. This network attached storage is also connected via optical fibers to our university's core router.

Evaluation Measures for Focused Web Crawling

Several studies state that the primary metric in evaluating focused crawler performance is the harvest rate [20,29,31,49,50]. Harvest rate is defined as “the fraction of webpages crawled that satisfy the relevance criteria among all crawled webpages”

[20]. Previous studies reported that the harvest rate ranges between 10% and 45% for such systems [24,28,31,51].

In addition, the recall (also known as sensitivity) measure can be estimated by using the seed-target approach [29,52,53]. In this context, the initial set of seed pages is split into two sets of which one can be used as seeds and the other as targets (T). Figure 3 depicts the relationship between relevant (R), crawled (S) and target web pages.

According to Liu [29], the recall may be estimated if T is a representative, unbiased sample of R independent of the crawling process by the equation in Figure 4 at any time t.

Figure 3. Relationship between target, relevant, and crawled web pages. Recall is estimated based on known relevant target pages and underlying independence assumption.

Figure 4. Recall estimate equation.

$$R_T(t) = \frac{|T \cap S_t|}{|T|}$$

Text Classification

Support vector machines (SVMs) originate from the field of machine learning and are known to perform well for text classification tasks [44,45]. For this reason, we relied on an SVM to determine a web page's relevance within the health domain. Figure 5 depicts the system's workflow for the training and classification phase.

To build our SVM-based text classifier, we followed related methods as described by Joachims [44]: as a first step toward

a health text classifier, automatically gathered health-related articles (contained in a document collection [D]) were cleaned from syntactic markup (eg, boilerplate code, HTML tags). Each article was then tokenized (ie, split into single word fragments) and each character was converted to lower case (also known as case folding). Stop words (eg, the, and, it) were removed as these kinds of tokens do not carry any relevant information. Next, stemming techniques were applied in order to map tokens to their stem forms and reduce morphological variations of words (eg, goes becomes go). Each article was transformed into a document vector containing all distinct terms. To do so, it is

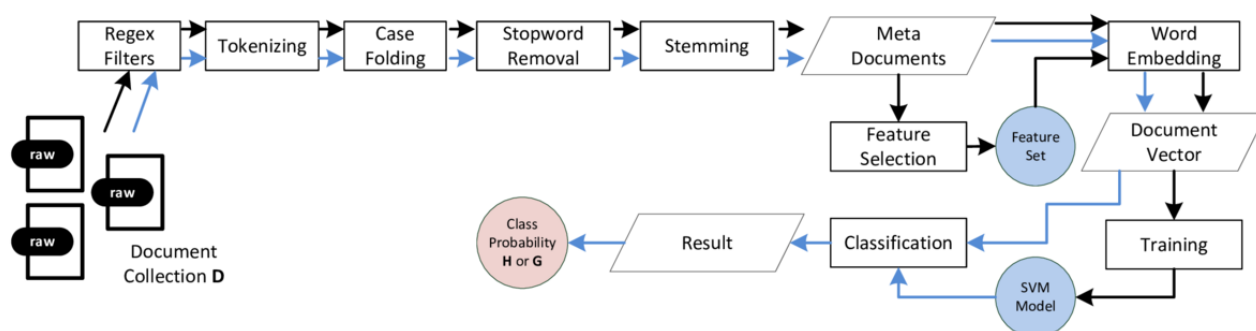

necessary to compute the terms that are representative for every article. A so-called feature selection produces a smaller subset of features (F) which yields the most relevant features for each article, limited by a predetermined threshold [54]. Given D and F , an SVM was trained to distinguish between vectors of health-related (H) and non-health-related (G) articles. The resulting classifier may be applied to previously unclassified web pages in order to predict their health-relatedness. To evaluate the classifier's quality, we used well-established metrics from the field of information retrieval such as accuracy, recall, and precision [29].

LIBSVM [55] and its object-oriented binding zlibsvm [56] were used as an SVM implementation of the text classifier. For

building and training the SVM, the process described by Joachims [44] was applied. To reduce dimensionality, the feature selection method *information gain* was used [54]. Word embedding was conducted using *tfidf* [57] as a term-weighting approach.

To find an optimal hyperparameter combination for the chosen radial basis function kernel, a grid search using 10-fold cross-validation, as recommended by the LIBSVM authors [55], was conducted. According to the Pareto Principle, training and test data were constructed using an 80:20 split [58]. In addition, the classes inside these data sets were equally balanced according to Wei and Dunbrack [59] as the real-world class distribution of H and G is unknown.

Figure 5. Workflow of an support vector machine–based text classification system: black lines indicate the training process; blue lines indicate the classification process; slanted boxes represent data; rectangular boxes represent computational steps.

Graph Metrics

The graph structure of the web has been extensively analyzed in several studies [15,17,60,61]. In this context, a graph node represents a web page and an edge represents a link between two web pages. We generated a so-called host-aggregated graph from the original web graph in order to reduce its computational complexity and explore its properties [61]. In this process, single web pages are combined and represented by their parent web site (including outgoing and ingoing links). On the resulting host-aggregated graph, we applied the following metrics:

- Average degree is the average number of edges connected to a node [62]. For a (directed) web graph, this is defined as the total number of edges divided by the total number of nodes. The average in-degree denotes the average number of ingoing edges to a node (ie, links to a web site). The average out-degree is defined as the average number of outgoing edges of a node (ie, links targeting other web sites).
- Modularity measures the strength of division of a graph into clusters or groups [62,63]. Graphs with a high modularity have dense connections between the web sites within certain clusters but sparse connection to other web sites, which are contained in different clusters.
- PageRank is a centrality-based metric that allows identification of web sites (nodes) of importance inside a graph [64]. The underlying assumption is that an important or prestigious web site will receive more links from other important web sites (ie, higher in-degree).

Other metrics such as network diameter and the average path length (ie, the average number of clicks which will lead from one web site to another) are frequently used for graph analysis [62,65].

Data Acquisition

Seed Generation

The selection of seed sources is crucial for the performance of a focused crawler [24,28,66-68]. For certain top-level domains (TLDs; eg, .com), the domain name system zone files are available to the public free of charge containing all registered domains for the given TLD. These zone files can then be used to extract seeds. However, due to data protection regulations, accessing and using the domain name system zone files for the ccTLDs .de, .at, and .ch was not possible.

Other studies leverage search engines with specific queries [28,66,69] to obtain high-quality seeds. However, most search engines restrict the amount of queries and limit the returned amount of results. Also, the results might be influenced by commercial interests and crafting high-quality search queries demands time and/or financial resources.

Another widely used seed source is the web taxonomy Curlie [22,29,31,66,70,71], which provides human-maintained precategorized web sites. Seeds can be harvested as dumps and are available free of charge. In addition, it is possible to reuse the results of a previous crawl to generate seeds. For this study, we relied on Curlie and the data of a previous health-related crawl conducted in 2016 [72].

Machine Learning Data Sets

Training and Test Corpus

To obtain a large enough data set for training and testing the SVM text classifier used within the focused crawler, web pages from various German content providers were obtained. First, the web pages were downloaded by specialized web crawlers implemented in Java using the crawler4j framework [73]. Next, boilerplate detection and data cleaning were conducted using regular expression filters. After this step, the cleaned textual content was stored in a relational database for further processing. Regarding each content provider, a random sample was manually inspected by the authors in order to assess data quality.

Each content provider and all related articles were put into one of the two classes: health-related language (H) or general language (G). The coding was based on (1) the organizations providing the content, (2) health-related content certification (eg, Health On the Net Foundation Code of Conduct), and (3) a manual inspection by the authors, in which the topic relevance of a random sample for each content provider was assessed.

Crowd-Validated Test Corpus

As the training and test corpus were generated by using a priori knowledge of each content provider, the authors decided to construct an additional independent human-validated data set to evaluate the classifier's performance.

Recent studies have shown that crowdsourcing can produce comparable results to human experts at a faster pace [74-78]. Thus, crowdsourcing was used to assess the evaluation data set. Figure 6 depicts the process of building this validated data set.

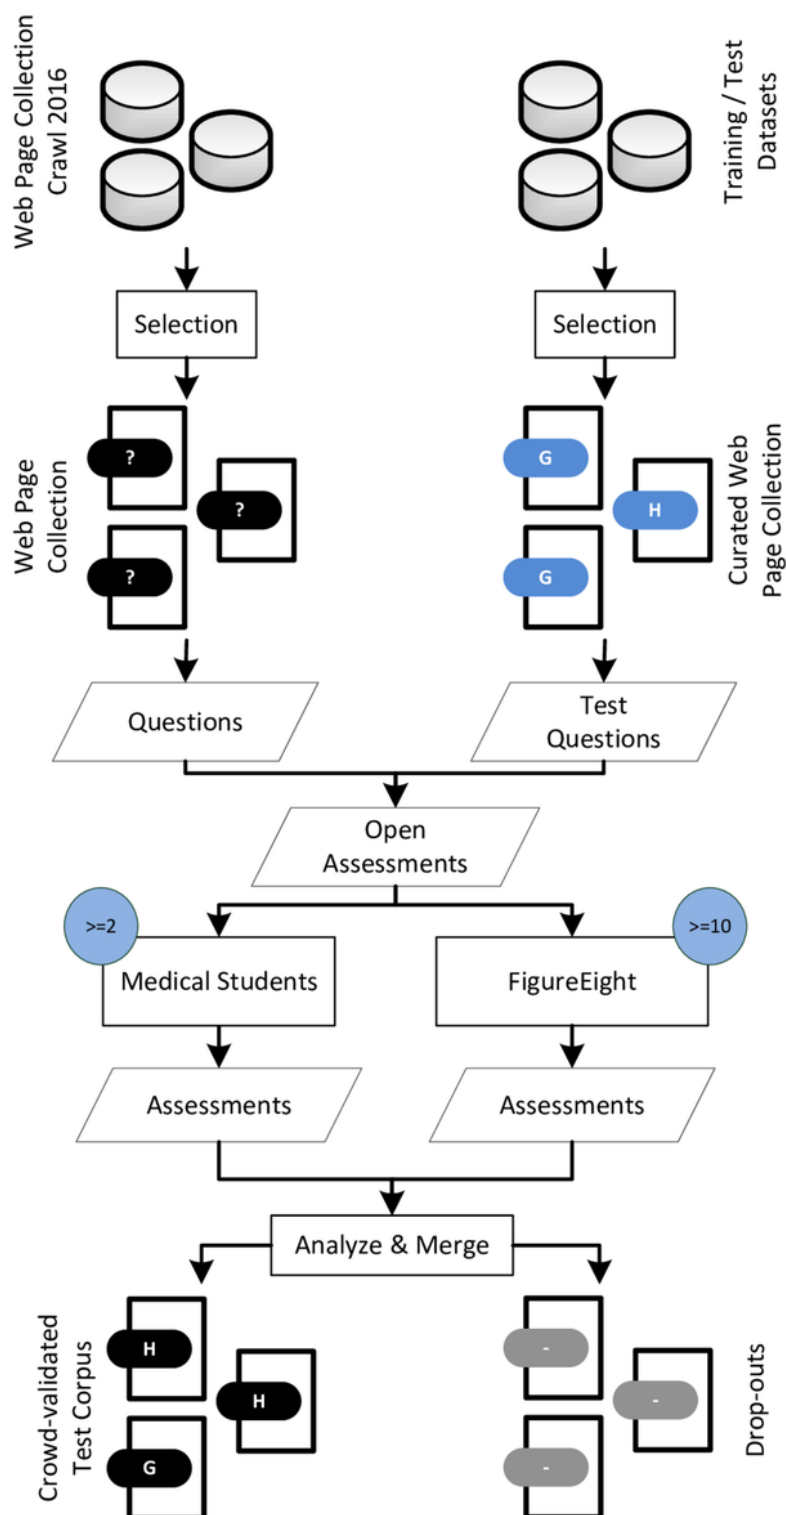

First, web pages were manually selected from a crawl conducted in 2016 [72]. It was ensured that the selected pages were neither included in the training set nor in the test corpus generated in the previous step. Next, each web page was assessed by a group of workers and categorized as H or G. Raters were given clear instructions on how to categorize given web pages (see Multimedia Appendix 1). In addition, each rater successfully completed a quiz-based training before they could participate in the study [79-83]. Precategorized web pages (test questions) were mixed into the rating process as test questions to keep the attention of the raters at a high level.

If a rater failed to answer a specific amount of such test questions, the assessments of this rater were considered as dropouts. Following the recommendation by Carvalho et al [84], each web page was assessed by at least 10 crowd-workers on the commercial crowd-working platform FigureEight [85]. In addition, the same web pages were coded by final year medical students (at least two students per web page) at the University of Heidelberg in the context of the lecture Medical Informatics. Study participation was voluntary.

If there was no clear majority vote for a certain class between the crowd-workers, the assessments of the medical students were taken into consideration. If there was still no agreement, the web page was listed as a dropout.

The statistical software R version 3.4.4 (R Foundation for Statistical Computing) on an Ubuntu 18.04 LTS 64-bit computer was used to compute percent agreement [86] and Fleiss κ [87].

Figure 6. Workflow of the crowd-sourcing approach to build a test corpus for the purpose of classifier evaluation. Black lines indicate the assessment process; slanted boxes represent data; rectangular boxes represent processing steps.

Results

Seeds

Seeds were obtained from the health category (German: Gesundheit) of Curly and a health-related crawl conducted in 2016 targeting health-related web sites in German [72]. In total, $n=22,405$ seeds with ccTLDs .de (19,126/22,405, 85.36%), .at (1530/22,405, 6.83%), .ch (1749/22,405, 7.81%) were collected

and used in this study. The full list of seeds can be found in [Multimedia Appendix 2](#).

Machine Learning Data Sets

Data Set Characteristics

Web pages from various German content providers were collected between April 24, 2018, and August 16, 2018. A detailed list and description of each content provider is shown

in Table 1. In total, 98,442 articles were collected. The average word count for each document was 741; the average sentence count was 44.

For category H, we collected 9638 articles from the categories “medicine” and “medical report” from Deutsches Ärzteblatt (a magazine tailored to physicians) and 1907 from Apotheken Umschau (a magazine freely available in German pharmacies, tailored to lay citizens). In addition, we acquired 235 and 636 articles from the medical content providers Institute for Quality

and Efficiency in Healthcare and Onmeda, respectively. Moreover, 2829 documents were obtained from the national health portal of the Republic of Austria. In addition, 28,436 health-related articles from Wikipedia Health were gathered by using the Wikipedia category graph. For category G, 18,364 random articles from Wikipedia General were collected, which were not related to the category Health (German: Gesundheit). In addition, 36,297 German web pages were selected randomly from the Common Crawl Foundation.

Table 1. Total number of acquired articles and respective class labels of various German content providers.

Content provider	Class	Cert ^a	Organization	Articles	Words (mean)	Words (median)	Sentences (mean)
Wikipedia Health	H ^b	no	Wikimedia Foundation	28,436	429	254	31
Wikipedia General	G ^c	no	Wikimedia Foundation	18,364	736	266	26

Training and Test Corpus

For training and evaluation of the SVM classifier, 87,562 articles were used. Table 2 lists the final data sets. In total, 80.00%

(70,048/87,562) of articles were used for training the classifier and 20.00% (17,514 of 87,562) were used for testing.

Table 2. Total amount of articles used in the training and test corpus per content provider with corresponding class labels: health-related language (H) and general language (G).

Content provider	Class	Documents		
		Training	Test	Total

Crowd-Validated Test Corpus

A total of 432 web pages (216 per class) were manually selected from a health-related crawl conducted in 2016 [72]. The selected web pages were neither contained in the training nor in the test corpus (see Table 2).

Each web page was assessed by 10 crowd-workers between February 2, 2019, and February 16, 2019, on the commercial crowd-working platform, FigureEight [85]. In total, 4367 assessments by 28 crowd-workers were collected at a cost of US \$36.06. The overall satisfaction (as measured by FigureEight) was 4.45 out of 5 possible points (instructions clear: 4.5/5; test questions fair: 4.55/5; ease of job: 4.5/5; payment: 3.65/5); 14 out of 28 (50%) workers participated in this voluntary exit survey. Percent agreement was 0.855; Fleiss κ was 0.279.

In addition, the same web pages were coded by medical students ($n=40$). Study participation was voluntary. Each web page was assessed by at least two students. Percent agreement was 0.719;

Fleiss κ was 0.337. According to Landis and Koch [88], these κ values correspond to a fair agreement.

The resulting data set contained $n=384$ web pages (192 per class). This corresponds to a dropout rate of 11.1% (48/432). The full list of coded web pages is given in Multimedia Appendix 3.

Classifier Performance

The classifier was evaluated against the test and crowd-validated data set, and the results are presented in Table 3. The classifier achieved a precision of 0.934, a recall of 0.940, and an accuracy of 0.937 on its test data set; 5.96% (522/8757) of health-related web pages were falsely classified as nonrelevant by the SVM. On the other hand, 6.57% (575/8757) of the nonrelevant pages were classified as health-related.

On the crowd-validated real-world data set, the classifier achieved an accuracy of 0.966, a precision of 0.954, and a recall of 0.989. Only 1.0% (2/192) of the health-related web pages were falsely classified as nonrelevant, and 5.7% (11/192) of nonrelevant web pages were classified as health-related.

Table 3. Listing of the confusion matrix and related evaluation metrics for the test and crowd-validated data set.

Crawler Performance

Our system achieved a download rate of 7 to 10 documents per second. This sums up to 227 days of pure crawling and classification of approximately 133 million web pages.

The crawl yielded approximately 13.5 million presumably relevant web pages and approximately 119.5 million nonrelevant web pages. [Figure 7](#) depicts the harvest rate during the crawl.

The overall mean harvest rate was 19.76% ($HR_{t=222}=HR_{max}=36.45\%$; $HR_{t=53}=HR_{min}=0.00\%$). HR_{max} was

achieved at day 222 as the crawl was resumed after infrastructure maintenance due to urgent security updates; HR_{min} was recorded on day 53. It was caused by a data center outage in which the infrastructure had to be shut down.

As an additional measure, we estimated the recall of our focused crawling by using the seed-target approach [29]. For this purpose, the initial seed set ($n=22,405$) was divided into a set of seeds ($n=17,405$) and targets ($n=5000$); ccTLD distribution was maintained in each sub set, and 4105 out of 5000 targets (82.10%) were contained in the crawl. This corresponds to an estimated recall of 0.821.

Figure 7. Harvest rate over time measured at the end of each day (dashed line represents the mean harvest rate). Note that the drop at day 53 is related to an outage at our data center. Peak at day 106: storm cluster was extended by three additional virtual machines. Peaks at days 157, 158, 191, 194 and 222: crawl was resumed after infrastructure maintenance due to urgent security updates that required a restart of the host system and/or of the virtual machines.

Graph Structure

The graph database Neo4J in v3.5.4 and its graph algorithm plugins [89] were used to compute the metrics as described in Graph Metrics on an Ubuntu 18.04 LTS 64-bit server. In order to reduce graph complexity, all web pages belonging to the same web site were aggregated and substituted by their parent web site (including outgoing and ingoing links; see Graph Metrics). The resulting graph contains 215,372 nodes (web sites) and 403,175 edges (links between web sites). A total of 82.56% (177,816/215,372) of the web sites belong to the ccTLD .de; 7.95% (17,126/215,372) to .at, and 9.49% (20,430/215,372) to .ch.

The graph has a network diameter of 25. The average path length is 6.466. The average degree is 1.872, the average in-degree is 1.892, and the average out-degree is 1.845. Modularity was computed to be 0.723.

During the analysis, several types of website publishers emerged: public institutions, nonprofit organizations, and private organizations or single individuals. As the ccTLD .de has the highest share within the graph, a global ranking according to PageRank would be dominated by .de web sites. For this reason, the following paragraph will present the top 25 web sites according to PageRank for each ccTLD separately.

Table 4 lists the 25 top-ranked web sites according to PageRank with their respective publisher for .de; 12 out of 25 (48%) are published by public institutions, 32% (8/25) are published by nonprofit organizations, and 20% (5/25) by private organizations. The top-ranked 25 web sites for .at are shown in Table 5; 12 out of 25 (48%) are published by public institutions, 4% (1/25) are published by nonprofit organizations, and 48% (12/25) by private organizations (see Table 5). For the ccTLD .ch, 24% (6/25) are published by public institutions, 40% (10/25) originate from nonprofit organizations, and 9/25 (36%) are published by private organizations (see Table 6).

Overall, 40% (30/75) are web sites published by public institutions, 25% (19/75) are published by nonprofit organizations, and 35% (26/75) by private organizations.

The graph visualization tool Gephi v0.9.2 [90] was used on a bare-metal Windows 10 64-bit computer to explore the host-aggregated graph structure. Unfortunately, we experienced serious performance issues while running Gephi's visualization algorithms. This is a main reason why we illustrate just a small example extract of the host-aggregated graph: Figure 8 consists of 94 nodes and 243 edges and presents basic aspects of the graph's structure. The focus is on www.rki.de as the top-ranked web site for the ccTLD .de (according to our analysis from below). The surrounding nodes represent health-related web sites in close proximity of www.rki.de.

Figure 8. A small extract of the host-aggregated web graph with focus on the website www.rki.de. The surrounding nodes represent websites with a maximum link-distance of two starting from www.rki.de. An edge between two nodes implies that there exists at least one hyperlink between some web pages of the hosting websites in either way. Only those websites are included whose content is highly health-related (ie, which were automatically classified as belonging to H with a probability equal to or greater than 0.93). Moreover, they have at least one ingoing and one outgoing link. The bigger a node and its caption, the higher is its page rank. For illustration reasons, directional arrows were not included.

Discussion

Principal Findings

One aim of the study was to demonstrate the suitability of a focused crawler approach for the acquisition of health-related content. Our system achieved an average harvest rate of 19.76% during the entire crawl. In addition, the results show that the majority of the target seeds (4105/5000) could be obtained, which corresponds to a recall of 0.821. Therefore, we are confident that the proposed method is suitable to acquire most health-related content on the web and generate a suitable domain-specific graph representation.

A first manual investigation of several hundred randomly selected pages suggests that our approach produces accurate results. The results indicate that the web sites and web pages of major German, Austrian, and Swiss health-related public institutions have indeed been discovered, even though they were not contained in the initial seeds.

With respect to the study aims 2 and 3, we were able to provide a curated list of 22,405 seed points for the health domain in the D-A-CH region extracted from Curlie (see [Multimedia Appendix 2](#)). In addition, a data set with 396 items was created and evaluated by crowd-workers that can be used by other researchers to evaluate similar text classifiers (see [Multimedia Appendix 3](#)).

A first analysis of the graph structure (see study aim 4) shows that public institutions and nonprofit organizations have a higher importance according to their PageRank than web sites of private players inside the GHW.

Limitations

Several limitations apply for this study. First, we are not sure whether the seed pages cover a broad spectrum of topics within the health domain as we only acquired seeds from Curlie and a previous health-related crawl [72]. Using specifically crafted queries against established search engines would have increased the amount of available seeds and could have influenced the crawl in a positive way [28,66,69]. However, due to limited amounts of resources and time, we did not follow this approach as the web taxonomy Curlie and a previous crawl gave faster access to seed URLs. As Curlie is a community-driven web taxonomy, the publication process of new URLs is not strictly regulated. This might be a reason for the high share of private players within the top ranks of the web graph as everybody is eligible to publish a web site's URL on Curlie. In addition, the community behind Curlie is rather small compared with its predecessors (ie, URLs pointing to rather new content providers might not be contained in it). Therefore, corresponding web pages and their out-links might have been missed during the crawling process. This implies that reported graph properties might have been influenced by the chosen seed sources.

Second, with a mean accuracy of 0.951, our classifier might have produced false positive results during the crawl process. Third, we only considered the ccTLDs .de, .at, and .ch to avoid the need for a language classification system, as most web sites on these ccTLDs are written in German. Therefore, the data crawled covers only a certain fraction of the GHW, for example, as web sites in German published under .org are not contained.

Comparison With Prior Work

Previous studies investigated the use of focused crawler techniques to harvest biomedical or health-related text material [27,28]. In both analyses, the authors report that the use of focused crawlers requires a lot of computational effort to collect the data and analyze it in an appropriate way, which we can confirm by our observations.

Compared with the study by Rheinländer et al [28] in which they report an harvest rate of 38%, our system achieved an harvest rate of only 19.76%. This might be caused by (1) our system using a soft-focused crawling strategy meant it did not stop at the first encountered irrelevant web page, leading to an increase in irrelevant web pages and crawling time and (2) our crawl was limited to the ccTLDs .de, .at, and .ch as we did not implement a language classifier. This might have influenced the harvest rate of our system as well, yet it achieved a harvest rate in the typical range for such systems [24,28,31,51] (see Related Work).

In contrast to the studies by Rheinländer et al [28] and Amalia et al [27], we focused on the German language and the GHW. This study contributes to the field by demonstrating the

suitability of a focused crawler approach for the acquisition of German health-related content in the D-A-CH region. A secondary study outcome is a curated list of seed points for the health domain in the D-A-CH region (see [Multimedia Appendix 2](#)). In addition, the crowd-validated evaluation data set (see [Multimedia Appendix 3](#)) can be used to evaluate other text classifiers for the given purpose. Moreover, this study gives first insights regarding the graph structure of the health-related web in the D-A-CH region.

Conclusions and Further Research

In this study, a system was presented which uses a focused crawling approach to gather the structure of the GHW. The system used an SVM-based classifier that was trained to assess the relevance of a web page for the health domain. The results indicate that the presented focused crawler is a suitable method for acquiring large health-related textual datasets and can be used to generate domain-specific graph representations. In future work, the authors intend to expand their web crawl by leveraging seed lists generated via search engine providers.

We also plan to analyze the linguistic characteristics of the crawled data as well as identify important topics and trends within this data. This will also include the identification of credible content providers and a comparison of the health-related web between Germany, Austria, and Switzerland. Moreover, future work will include a deeper exploration and analysis as well as a visualization of the resulting graph structure. Using these insights and with the acquired data available, an implementation and evaluation of a health-specific search engine for information seeking citizens will be possible.

Acknowledgments

The authors would like to thank Dr Monika Pobiruchin and Martin Wiesner of Heilbronn University for their feedback and valuable input to the work.

Abstract

Background: Web-based technology has recently become an important source for sharing health information with patients after an acute cardiac event. Therefore, consideration of patients' perceived electronic health (eHealth) literacy skills is crucial for improving the delivery of patient-centered health information.

Objective: The aim of this study was to translate and adapt the eHealth Literacy Scale (eHEALS) to conditions in Norway, and to determine its psychometric properties. More specifically, we set out to determine the reliability (internal consistency, test-retest) and construct validity (structural validity, hypotheses testing, and cross-cultural validity) of the eHEALS in self-report format administered to patients after percutaneous coronary intervention.

Methods: The original English version of the eHEALS was translated into Norwegian following a widely used cross-cultural adaptation process. Internal consistency was calculated using Cronbach α . The intraclass correlation coefficient (ICC) was used to assess the test-retest reliability. Confirmatory factor analysis (CFA) was performed for a priori-specified 1-, 2-, and 3-factor models. Demographic, health-related internet use, health literacy, and health status information was collected to examine correlations with eHEALS scores.

Results: A total of 1695 patients after percutaneous coronary intervention were included in the validation analysis. The mean age was 66 years, and the majority of patients were men (1313, 77.46%). Cronbach α for the eHEALS was $>.99$. The corresponding Cronbach α for the 2-week retest was .94. The test-retest ICC for eHEALS was 0.605 (95% CI 0.419-0.743, $P<.001$). The CFA showed a modest model fit for the 1- and 2-factor models (root mean square error of approximation >0.06). After modifications

in the 3-factor model, all of the goodness-of-fit indices indicated a good fit. There was a weak correlation with age ($r=-0.206$). Between-groups analysis of variance showed a difference according to educational groups and the eHEALS score, with a mean difference ranging from 2.24 ($P=.002$) to 4.61 ($P<.001$), and a higher eHEALS score was found for patients who were employed compared to those who were retired (mean difference 2.31, $P<.001$). The eHEALS score was also higher among patients who reported using the internet to find health information (95% CI -21.40 to -17.21 , $P<.001$), and there was a moderate correlation with the patients' perceived usefulness ($r=0.587$) and importance ($r=0.574$) of using the internet for health information. There were also moderate correlations identified between the eHEALS score and the health literacy domains appraisal of health information ($r=0.380$) and ability to find good health information ($r=0.561$). Weak correlations with the mental health composite score ($r=0.116$) and physical health composite score ($r=0.116$) were identified.

Conclusions: This study provides new information on the psychometric properties of the eHEALS for patients after percutaneous coronary intervention, suggesting a multidimensional rather than unidimensional construct. However, the study also indicated a redundancy of items, indicating the need for further validation studies.

Introduction

Electronic health (eHealth) delivery provides an opportunity to redesign and improve health care services and health information using web-based technologies that can be accessed over the internet following diagnosis and discharge from hospital [1]. eHealth interventions have shown promising results using a behavioral approach and are recommended for supporting clinical and secondary prevention care for coronary artery disease such as after coronary revascularization (eg, percutaneous coronary intervention) [2]. eHealth has also been shown to be a cost-effective solution essential to increase geographical accessibility to secondary prevention programs, particularly as an addition to existing programs or when other offers are not available. eHealth interventions can be targeted within the natural settings where patients receive access to resources at their discretion [2]. However, patient-related barriers, specifically low health literacy and socioeconomic status, remain obstacles to the large-scale deployment of eHealth in cardiology [1]. Furthermore, patients with low eHealth literacy have lower odds of using eHealth sources to communicate with health care professionals and gain access to health information [3]. Understanding the varying eHealth literacy of patients—defined as the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to address or solve a health problem [4]—is thereby pivotal when developing and implementing eHealth resources. Assessing eHealth literacy to identify skill gaps makes it possible to better assist those with low comfort levels in taking advantage of the potential benefit that eHealth can offer, and can empower patients to fully participate in health-related decision making [4]. To assess these benefits, the identification and validation of patient reported outcome measures (PROMs) assessing patients' perceived eHealth literacy skills are therefore crucial to developing efficient patient-centered eHealth information strategies in the future [5].

To date, there has been limited evidence on PROMs that are most appropriate for assessing eHealth literacy. Systematic

reviews have reported that the eHealth literacy scale (eHEALS) was the only PROM used to measure eHealth literacy in more than one study [6,7]. The eHEALS assesses patients' perceived eHealth literacy skills based on the eHealth literacy Lily model, which combines six literacy types [4,8]. The categories traditional, media, and information literacy are analytic components that involve skills applicable to a broad range of information sources, whereas the scientific, computer, and health literacy categories are context-specific that rely on more situation-specific skills. Combined, these six literacy types form the foundational skills required to fully optimize patients' experiences with eHealth. The underlying theories of the eHEALS are based in part on self-efficacy theory and social cognitive theory. These two theoretical frameworks promote competencies and confidence as precursors to behavior change and skill development [4,8]. More specifically, the eHEALS is based on the premise that the core literacies in the Lily model are not static but rather process-oriented skills that evolve over time as new technologies are introduced and the personal, social, and environmental contexts change [8]. In this way, the Lily model is clearly related to social cognitive theory, as it is based on a model of causation where behavior, environmental influences, and personal factors all interact and influence each other [9]. This means that eHealth literacy is influenced by a patient's presenting health issues, educational background, health status at the time of the eHealth encounter, motivation for seeking the information, and the technologies used [4,8].

The eHEALS has been adapted to different languages in Asia [5,10-13] and Europe [14-18]. Furthermore, the psychometrics properties have been evaluated in different populations such as in students [4,12,15,19,20], adults [9,11,16-18,21], and patients with chronic diseases [5,14,22,23], as well as in different cultures in Australia [9,24] and North America [9,17,20-22]. The internal consistency reliability coefficient was shown to be acceptable (ranging from .80 to .90) in the majority of the linguistic versions of the eHEALS [4,11-13,15-19,23], indicating a reliable scale. According to construct validity, the majority of the studies supported a 1-factor model [5,10,12-14,16,22,23,25] recommended by the original scale

[4], whereas a few other studies have recommended a 2-factor [11,15,18] or 3-factor [9,21,24] model. However, all of these studies varied contextually when evaluating the dimensions of the eHEALS construct. To our knowledge, no validated version of the eHEALS from the Nordic-Baltic countries has been published to date, and there is limited evidence on its use in patients in the acute coronary care setting such as after percutaneous coronary intervention.

Therefore, in this current study, hypotheses were tested and evaluated against existing knowledge. For instance, a lower eHEALS score has been demonstrated among people with chronic illnesses [3], and differences in eHEALS scores according to age and education have been reported [5,14].

Significant relationships between the eHEALS score and physical and mental health composites among patients with heart failure have been described [23]. An association was also reported between eHealth literacy and health literacy on patients' perceptions of the usefulness of eHealth in a population with moderate-to-high cardiovascular risk [26], whereas there was a weak-to-moderate correlation between the eHEALS score and health-related internet use among patients with rheumatic disease [14]. This evidence formed the basis for our hypothesis testing according to the COnsensus-based Standards for the selection of health status Measurement INstruments (COSMIN) criteria for validation [27] on the relationship between eHEALS scores and demographic information, health-related internet use, health literacy, and health status in this study (Table 1).

Table 1. Hypotheses regarding the relationship between eHEALS^a scores and demographic information, health-related internet use, health literacy, and health status based on previous evidence.

Variables	Evidence (relationship with eHEALS) ^a	CONCARD-PCI hypothesis	Analysis
Demographic information			
Age	Weak [14,16,18] or significant [5]	Weak to moderate relationship	Pearson correlation
Gender	Weak [5,16,18]	Weak relationship	<i>t</i> test
Education	Weak [14,16,18] or significant [5]	Weak relationship	ANOVA ^b
Employment	Weak [5]	Weak relationship	ANOVA
Health-related internet use			
Used the internet to find information about health	Weak [14], moderate [18], and significant [5]	Moderate relationship	<i>t</i> test
Patient's interest in using the internet for health information in general (frequency of information-seeking)	Significant [5,16]	Moderate relationship	Spearman correlation
Health literacy			
Ability to find good health information	Moderate [11]	Moderate relationship	Pearson correlation
Appraisal of health information	Positive [26]	Moderate relationship	Pearson correlation
Health status based on RAND-12 ^c (mental and physical component)	Weak [5] or significant [16,23]	Moderate relationship	Pearson correlation

^aeHEALS: Electronic health literacy scale.

^bANOVA: analysis of variance.

^cRAND-12: 12-item short-form health survey.

Thus, the aim of this study was to translate and adapt the eHEALS to conditions in Norway, and to determine its psychometric properties. More specifically, we set out to determine the reliability (internal consistency, test-retest) and construct validity (structural validity, hypotheses testing, and cross-cultural validity) of the eHEALS in a self-report format administered to patients after percutaneous coronary intervention.

Methods

Design

This validation study used a cross-sectional design and was part of a larger prospective multicenter cohort study, CONCARD^{PCI}, which seeks to identify bottlenecks and hurdles in the patient journey, and to suggest the optimal timing of services and

alignment with preferences for patients with coronary artery disease undergoing percutaneous coronary intervention [28]. The study adheres to the COSMIN taxonomy of relationships of measurement properties for reliability and construct validity throughout the validation process. The COSMIN taxonomy was developed with the aim to improve the selection of health measurement instruments. It comprises three domains (reliability, validity, and responsiveness), which contain the measurement properties [27]. The COSMIN taxonomy has been widely used for the selection of health measurement instruments for observational studies. To ensure appropriate reporting, the validation study was also performed in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statements, which constitute an established checklist of items that should be addressed in articles reporting within the three main study designs of analytical

epidemiology: cohort, case-control, and cross-sectional studies [29].

Procedure and Participants

The study included 1695 patients at index admission for percutaneous coronary intervention at three large Norwegian university hospitals from June 12, 2017 through December 2018 (Figure 1). These three Norwegian university hospitals were selected based on the presence of a committed research team,

including CONCARD^{PCI} study nurses and a local principal investigator, and prior research experience, including research infrastructure, geographic location, and size. The percutaneous coronary intervention centers perform between 900 and 2000 (mean 1531) procedures annually, have 482 to 1400 beds (mean 860), and are referral centers for coronary angiography and percutaneous coronary intervention for a total of 17 local hospitals.

Figure 1. Flow chart of the inclusion process. PCI: percutaneous coronary intervention; TAVI: transcatheter aortic valve implantation.

Inclusion criteria were patients undergoing percutaneous coronary intervention, ≥ 18 years of age, living at home at the time of inclusion, and having access to electronic equipment with internet access at the time of inclusion. Exclusion criteria were the inability to speak Norwegian or inability to fill out the self-reported questionnaire due to reduced capacity. To prevent a substantial difference in follow-up time or participants responding based on different assumptions, the patients who were likely to die within less than 1 year were excluded from the study. Institutionalized patients, who may be less likely to have follow up by a primary health care provider or to use the internet to find health information, were also excluded. Similarly, patients undergoing percutaneous coronary intervention without stent implantation and patients undergoing percutaneous coronary intervention related to transcatheter aortic valve implantation or MitralClip often have other indications for the examination or treatment including other follow-up routines and were therefore also excluded from this study.

Self-reports relating to eHealth literacy, health-related internet use, health literacy, health status, as well as demographic information and clinical data identified through the Norwegian Registry for Invasive Cardiology and patient medical records were obtained before discharge from hospital after percutaneous coronary intervention. The self-report was administered using

a pencil and paper survey delivered with other PROMs used as part of the CONCARD^{PCI} study. A random subgroup of 100 patients was approached for an eHEALS retest after 2 weeks, 74 (74.0%) of whom completed the retest.

Translation and Cross-Cultural Adaptation of the eHEALS

A cross-cultural adaptation process was conducted to reach equivalence between the original source and the Norwegian target version of the eHEALS [30]. The translation process was conducted systematically in six steps [30]. Pilot testing was performed with a prefinal version of the eHEALS including 150 patients before being employed in the main cohort study. A summary of the overall translation procedure is described in Textbox 1. The research team encountered some difficulties in translating all of the words and phrases in the original English version of the eHEALS into Norwegian. The original eHEALS questions related to “health resources” were translated as “sources of health information” after approval from the developer of the eHEALS. The patient representatives who participated in the cognitive interviews reported that they clearly understood the items and response options and did not provide any suggestion for additional changes to the prefinal version of the instrument.

Textbox 1. Steps for translation and cross-cultural adaptation of the eHealth literacy scale (eHEALS) into Norwegian.

- Step 1: Forward translation
 - i. Two forward translations of the English eHEALS were made by two bilingual translators for whom the target language (Norwegian) was their mother tongue.
 - ii. The translators worked independently, and wrote a report (TL1 and TL2) that identified challenging phrases and described their rationale for final translation choices. An example of a difficult phrase to translate into Norwegian was “health resources.”
 - iii. The two translations were compared and discrepancies were identified.
- Step 2: Synthesis
 - i. The research team synthesized the reports (TL1 and TL2) into one consensus version (TL3) and described how they resolved discrepancies.
- Step 3: Back translation
 - i. Two individuals who had a good understanding of English and also spoke Norwegian fluently independently translated TL3 back into English (TL4 and TL5). Neither of the translators who spoke English as their native language was aware of the original version of the eHEALS.
- Step 4: Synthesis and back translation
 - i. The research team agreed on the modified Norwegian version of the eHEALS (TL6).
 - ii. The research team discussed the timing of administration and meaning of certain words and sentences, and the Likert-type scale.
- Step 5: Instrument pilot testing
 - i. The prefinal version (TL6) was discussed with patient representatives and piloted before being employed in the large-scale cohort study.
 - ii. A cognitive interview was conducted to test the feasibility and understanding of the items. The patients were asked to read the questionnaire items as well as the instructions.
- Step 6: Revised instrument
 - i. The researchers evaluated the adapted eHEALS questionnaire (TL6) and all necessary changes were made.
 - ii. Patients who answered that they did not have access to electronic equipment with internet access in the pilot found it challenging to answer the eHEALS items. Therefore, the research team decided that the eHEALS items had low relevance and released these patients from answering the questionnaire.

Study Instruments and Measures***Characteristics of the Study Population***

Demographic information collected included age, gender, civil status, smoking status, education level (secondary school, trade school, high school, college/university less than 4 years, college/university 4 years or more), and employment status (working, retired, or other, including sick leave, disability pension, seeking employment). Clinical data included medical history (peripheral vascular disease, stroke, myocardial infarction, diabetes, previous percutaneous coronary intervention, previous coronary artery bypass grafting, previous other heart surgery) and indication for percutaneous coronary intervention (stable angina pectoris, unstable angina pectoris, nonST-segment elevation myocardial infarction [NSTEMI] or ST-segment elevation myocardial infarction [STEMI]).

eHealth Literacy Scale

The original English eHEALS comprises eight items and assesses patients' own perception of their knowledge, comfort, and perceived skills at finding, evaluating, and applying eHealth information [4]. The questionnaire contains two supplementary

items to use alongside the eHEALS to better understand patients' interest in using the internet for health information in general. These items are not a formal part of the eHEALS and are not included in the total score. The original English questionnaire showed high levels of internal consistency (Cronbach $\alpha=.88$) and modest test-retest reliability [4]. The eHEALS items were used to calculate a mean score using the half rule and were linearly transformed to a 0-100 scale, with higher scores indicating better eHealth literacy. To be able to compare the mean eHEALS score with those reported in other studies, the scale was linearly converted to an 8-40 scale, computed as $8 + (\text{scale from 0 to 100}) \times (40 - 8)/100$.

Health-Related Internet Use

To assess patients' health-related internet use, the following two supplementary items in the eHEALS were used: 1. How useful do you feel the internet is in helping you in making decisions about your health? 2. How important is it for you to be able to access health resources on the internet? [4]. Another question was also developed specifically for this study with “yes” or “no” as the response options: Have you used the internet to find information about health?

Health Literacy Questionnaire

The health literacy questions were selected from the Health Literacy Questionnaire (HLQ), which assesses nine separate domains of health literacy. In this study, two domains reflecting skills to use resources and critical evaluation were used: HLQ domain 5 (appraisal of health information, 5 items) and HLQ domain 8 (ability to find good information, 5 items). The first domain had a 4-point response option scale (strongly disagree to strongly agree) and the second domain had a 5-point response option scale (ranging from cannot achieve or always difficult to always easy). The items in the appraisal of the health information domain were used to calculate a total mean score ranging between 1 and 4, and the items in the ability to find good information domain were used to calculate a total mean score between 1 and 5. A low HLQ score indicates that the respondent has difficulties within the domain, and a high score indicates greater health literacy ability. In the event of more than two missing items, the domain score was regarded as missing [31]. The HLQ shows sufficient psychometric properties [31,32], and the Norwegian version of the HLQ has been translated and validated [33].

Health Status Questionnaire

The 12-item short-form survey RAND-12 [34] was used to assess overall generic health status through 12 items covering eight domains: physical functioning (2 items), bodily pain (1 item), physical role functioning (2 items), general health (1 item), vitality (1 item), social functioning (1 item), emotional role functioning (2 items), and mental health (2 items), summarized into physical and mental health composite scores. The RAND-12 questionnaire has been validated in European populations and shows sufficient properties [35].

Expected Relationships and Subgroup Means

The hypotheses testing (convergent validity, known-groups validity, and divergent validity) regarding the relationship between eHEALS scores and demographic information, health-related internet use, health literacy, and health status was formulated a priori. The hypotheses are based on evidence from previous studies on eHEALS as summarized in Table 1.

Statistical Analyses

We investigated the psychometric properties of the Norwegian version of the eHEALS by assessing the construct validity of three aspects: structural validity, hypotheses testing, and cross-cultural validity [27]. Descriptive statistics were used to summarize patients' sociodemographic characteristics, clinical data, health-related internet use, health status, and eHEALS scores. Floor and ceiling effects were estimated. Nonparametric tests were used for ordinal variables and parametric tests were used for comparisons of continuous variables. Continuous variables were characterized by the mean (SD). The missing rates for each item were calculated.

The reliability of the eHEALS was assessed by determining its internal consistency and test-retest reliability. Test-retest reliability was calculated by the intraclass correlation coefficient (ICC). Internal consistency reliability (ie, how well the items on a tool fit together) was calculated using Cronbach α , in which $\alpha > .70$ was considered to be acceptable [27].

Confirmatory factor analyses (CFAs) were used to validate the extent to which the a priori hypotheses concerning dimensions of the eHEALS construct, based on theory and previous analyses, fit the actual data. CFA was used to explore the model fit of eHEALS as a 1-factor model as recommended by the original scale developer [4], in addition to a 2-factor model (information seeking: items 1-5 and 8; information appraisal: items 6 and 7) proposed by Soellner et al [15] and a 3-factor model (awareness: items 1 and 2; skills: items 3-5; and evaluate: items 6-8) proposed by Sudbury-Riley et al [9]. For the CFAs, the robust weighted least square mean and variance adjusted procedure (WLSMV) was used since the items are ordinal. The model fit was evaluated by various goodness-of-fit measures, including the model Chi square statistic with its degrees of freedom and *P* value, in addition to the root mean square error of approximation (RMSEA) (good fit < 0.06) and its associated 95% CI, standardized root mean square residual (SRMR; good fit < 0.08), comparative fit index (CFI; good fit > 0.95), and Tucker-Lewis index (TLI; good fit > 0.95) [27].

The convergent validity and divergent validity between the eHEALS and other constructs were assessed by computing Pearson correlation coefficients (*r*) between continuous variables and Spearman correlation coefficients (ρ) between ordinal variables. Correlation coefficients were interpreted such that 0.3 is considered a weak correlation, 0.3 to 0.6 is considered a moderate correlation, and above 0.6 is considered a strong correlation [27,36]. For known-groups validity (eg, gender, education level, employment status, and use of internet), a *t* test or one-way analysis of variance was used. If there was an indication of significant differences ($P < .05$) between groups, a posthoc analysis test for multiple comparisons that does not assume equal variances (Tamhane *T2* statistic) was used to investigate where the differences occurred.

SPSS (IBM Corp. Released 2016, IBM SPSS Statistics for Windows, Version 24.0; Armonk, NY, USA) was used for summary statistics and correlations, and for conducting statistical comparisons. Mplus (Computer software, 1998-2018, version 7) developed by BO Muthén and LK Muthén, was used to perform CFAs.

Ethical Considerations

The study was approved by the Norwegian Regional Committee for Ethics in Medical Research (REK 2015/57). All patients provided written informed consent, and confidentiality and the right to withdraw from the study were assured. The study conformed with the ethical principles outlined in the Declaration of Helsinki.

Results

Characteristics of the Study Population

A total of 1695 patients consented to participate in the study (Figure 1). The mean age of the patients was 66 years, ranging from 30 to 96 years. The majority of patients were men, married/living with partner, and hospitalized for an acute coronary event (unstable angina pectoris, NSTEMI, or STEMI). Of the patients included at index admission for percutaneous coronary intervention, a strong majority reported that they have

access to electronic equipment with internet access. Most patients reported that they used the internet to find information about health ([Table 2](#)). Overall, 37.27% (499/1339) of the patients stated that the internet was useful for making decisions

concerning their health and 41.51% (555/1337) stated that it was important to them that they could access health resources on the internet ([Multimedia Appendix 1](#)).

Psychometric Analyses

General Properties

The mean eHEALS score was 25.66 (SD 6.23). The highest mean of the eHEALS items was 3.40 and the lowest mean was 2.92. Among all respondents, 80% were most likely to select one (41%) or two (39%) response options across all items, with 34%-51% responding “undecided” and 22%-47% responding “agree” (Multimedia Appendix 1). In total, 45 (3%) maximum

possible scores and 27 (2%) minimum possible scores were identified, indicating limited ceiling and floor effects. The total mean eHEALS score for the retest was 53.52 (SD 19.79), with a floor of 5.6% (n=4) and ceiling of 1.4% (n=1).

Reliability

Cronbach α for the eHEALS was $>.99$ (Table 3). The corresponding Cronbach α for the 2-week retest was .94. The ICC for the eHEALS was 0.605 (95% CI 0.419-0.743, $P<.001$), indicating moderate stability over time.

Table 3. Mean (SD) scores and Cronbach α values of the eHEALS^a, HLQ^b, and RAND-12^c of patients after percutaneous coronary intervention (N=1659).

Item	Mean (SD)	Cronbach α
eHEALS ^a	25.66 (6.23)	$>.999$
HLQ ^b

^gN/A: not applicable; since PCS12 and MCS12 of RAND-12 are not computed as means or sum scores, there is no Cronbach α .

^hMCS: mental health composite score.

Structural Validity

The strong standardized factor loadings for the 1-factor model, ranging from 0.79 to 0.93, indicated promising item properties. The Chi square test of model fit ($P<.001$), SRMR, CFI, and TLI indices suggested a good fit. However, the high RMSEA value suggested a poor structural fit of the eHEALS in the 1-factor model.

For the 2-factor model, standard factor loadings ranged from 0.80 to 0.93. Similar to the 1-factor model, this model suggested a good fit based on the SRMR, CFI, and TLI, and a poor fit for the RMSEA (Table 4). Furthermore, examination of the modification indices through pairing items 5 and 8 to the second (appraisal) factor did not suggest an appreciable improvement

in fit for the RMSEA, although it was slightly reduced (0.176, 90% CI 0.165-0.187).

Standard factor loadings in the 3-factor model ranged from 0.84 to 0.97. Similar to the 1- and 2-factor models, the CFA supported a good fit for the three indices SRMR, CFI, and TLI, whereas the RMSEAs remained high (Table 4). Examination of the modification shown in the output file conducted by pairing item 3 in the first (awareness) and second (skills) factor, and item 5 in the second (skills) and third factor (evaluate) suggested an improvement in the model fit (SRMR=0.008, CFI=0.999, TLI=0.997, RMSEA=0.057; 90% CI 0.045-0.070). The standard factor loadings and correlations for the modifications are presented in Figure 2.

Table 4. Goodness-of-fit indices of the eHEALS^a 1-, 2-, and 3-factor structure model.

Convergent and Discriminant Validity

Demographic Information

Pearson correlation analysis showed a weak negative correlation between the eHEALS score and age. An independent-sample *t* test did not indicate substantial differences in the eHEALS score between men (mean 25.64, SD 6.15) and women (mean 25.47, SD 6.60) ($t_{1313} = -0.526$, $P = .60$) (Table 5 and Figure 3).

As shown in Table 5, the between-group analysis of variance showed a difference according to educational groups in the eHEALS score. A posthoc test indicated that patients with 4 or more years of college/university education scored higher on the eHEALS compared to those with secondary school (mean difference=4.61, $P < .001$), trade school (mean difference=3.23,

$P < .001$), and high school (mean difference=2.24, $P = .002$) education. Patients with less than 4 years of college/university education scored higher on the eHEALS than those with secondary (mean difference=3.39, $P < .001$) and trade school (mean difference=2.00, $P < .001$) education. Patients with high school education had higher eHEALS scores than those with secondary school education (mean difference=2.37, $P < .001$).

The between-groups analysis of variance also indicated a difference according to employment groups and eHEALS scores (Table 5). The posthoc test indicated a higher eHEALS score for patients who were employed compared to those who were retired (mean difference=2.31, $P < .001$). Similarly, the “other” patients group showed a higher eHEALS score compared to that of the retired patients (mean difference=1.28, $P = .05$).

Figure 3. Association between electronic health literacy scale (eHEALS) scores, gender, and age. The scale was linearly transformed to a 0-100 scale. The scale was linearly converted to an 8-40 scale (scale from 8 to 40 computed as $8 + [\text{scale from 0 to 100}] \times [40 - 8]/100$). The eHEALS scale in the figure is: 0=8, 20=14.4, 40=20.8, 60=27.2, 80=33.6, 100=40.

Health-Related Internet Use

An independent sample *t* test showed a higher eHEALS score for patients who reported that they used the internet to find information about health (mean 27.45, SD 5.10) than that of patients who did not (mean 21.27, SD 6.31) (95% CI -21.40 to -17.21, $P < .001$). Spearman correlation analysis revealed a moderate positive correlation between the eHEALS score and patients' perceived usefulness and importance of using the internet to find health information (Table 5).

Health Literacy

Pearson correlation analysis revealed a moderate positive correlation between the eHEALS score and the HLQ scale for appraisal of health information and the HLQ scale for ability to find good information (Table 5).

Health Status

Pearson correlation analysis revealed a weak positive correlation between the eHEALS score and self-reported health assessed with RAND-12 (Table 5).

Table 5. Group statistics and correlations between eHEALS^a score, patients' demographic, and other instruments.

Discussion

Principal Findings

To our knowledge, this is the first study to determine the psychometric properties of the eHEALS in patients after percutaneous coronary intervention. The Norwegian translation of the eHEALS appears to have acceptable construct validity. However, the high internal item consistency and the high RMSEA suggest that the fit of the data to the hypothesized models based on existing knowledge is not entirely adequate to fully capture the construct validity in this setting.

The structural validity was confirmed by three (SRMR, CFI, and TLI) out of four goodness-of-fit indices, indicating an adequate fit of the three hypothesized models. The RMSEA was lower in the 3-factor model [9] than in the 1-factor [4] and 2-factor [15] models. After two modifications of the 3-factor model, all four goodness-of-fit indices indicated a good fit. These results suggest that the eHEALS is a multidimensional construct that, as proposed by other studies, is a better fit for the 2-factor model [11,15,18] and 3-factor model [9,21,22,24]. However, in line with the current study, several previous studies conducting CFA showed an RMSEA value above the cut-off criteria for the 1-factor model [9,11,22], 2-factor model [15,18,22], and 3-factor model [9,24]. The high RMSEA

indicated a poor fit, suggesting that complexity exists in all three models, but the 3-factor model was found to have acceptable fit after a low number of reasonable modifications. The differences in model fit among the three CFA models suggest that it is possible to distinguish between different conceptualizations even with high redundancy.

A high proportion of patients were most likely to select the response “undecided” or “agree” across all items, suggesting that most of the patients either considered themselves as neutral (neither disagree or agree) or relatively confident about their knowledge, comfort, and perceived skills at finding, evaluating, and applying eHealth information. Although there is inconclusive evidence about the number of categories in a response scale and whether the neutral category has an impact on measurement quality [37], it has been recommended that future research should explore which response options are most appropriate to include in the eHEALS to obtain a more precise measure of eHealth literacy [22]. One explanation for the high proportion of respondents most likely to select these two response options could be that the patients experienced difficulties filling out the questionnaire in the context of an acute coronary event. Furthermore, patients with acute coronary syndrome may be more prone to survey response bias in such a manner that they select a neutral option irrespective of their

actual attitude or behavior. This suggests that the scale may work differently for patients with chronic diseases than for patients in acute settings. This finding also underpins that eHealth literacy is a process-oriented skill that evolves over time as new technologies are introduced and the personal, social, and environmental contexts change [8]. Similarly, it is also possible that the very high estimate of internal consistency is attributed to the patients' difficulties in differentiating between the meanings of the items in an acute coronary setting. A Cronbach α value above .90 has also been reported in other studies [5,10,14]. However, the very high Cronbach α in this study may indicate that there is a potential redundancy of items, wherein patients immediately after percutaneous coronary intervention may perceive that the same items are essentially rephrased in several different ways. The need for further research investigating item interpretation across populations has been suggested [14,24].

The current study indicates adequate discriminant validity of the eHEALS, and most of the demographic information and other instruments confirmed the hypotheses defined a priori. As confirmed in previous psychometric studies within general adult European populations [14,16,18], the measurement properties of the eHEALS were affected by age and gender to a lesser extent. However, the Chinese version showed a difference in eHEALS scores according to age among chronic disease patients [5]. In addition, the latter study showed that the eHEALS score was affected by education levels [5], whereas other studies reported a weak correlation with education in general adult European populations [14,18]. The results of previous studies and those of the current study diverge in this respect, indicating insufficient evidence to link perceived eHealth literacy with education. However, these findings may also be related to the fact that different methods were used to categorize and analyze education levels, and therefore should be interpreted with caution.

As the promotion of eHealth literacy takes place within a larger context, the original scale developer recommended involving other groups engaged in the literacy sectors in the work on validating the eHEALS [4]. Additionally, to address the patients' eHealth literacy level, patient integration in the evaluation is of great importance, specifically in accordance with PROMs such as health-related internet use, health literacy, and health status. A moderate correlation between the eHEALS score and patients' interest in using the internet for health information in general has been suggested, which strengthens the discriminant validity [16,18]. This provides a direction for skills, motivation, and interest that is applicable to a broad range of information sources, irrespective of the topic or context, in line with the analytic components of the Lily model [8]. Furthermore, according to the context-specific nature of eHealth literacy skills

[8], a moderate correlation was found between the eHEALS score and health literacy. Consistent with previous studies that showed a relationship between eHealth literacy and health literacy [11,26], the current study indicates that patients with higher eHEALS scores tend to be "information explorers," able to identify good information and reliable sources of information, and to resolve conflicting information by themselves or with the help of others [31]. This relationship suggests that the construct validation in the scale is adequate. However, this study also showed a weak correlation between the eHEALS score and health status. This differs from other studies [16,23], suggesting modest divergent validity of the eHEALS in terms of its relationship with health status.

Strengths and Limitations

The current study has several methodological strengths and limitations that should be addressed. The stringent linguistic, cultural, and measurement adaptation procedures are likely to have contributed to strengthening the conduct of the study. However, the Norwegian eHEALS showed mixed psychometric performance, which is likely due to the context of an acute coronary event. This indicates that hospitalization can affect the response to this type of PROM. Another key strength of the study is the large sample size, which allowed us to investigate the correlations between eHEALS scores, other PROMs, and subgroups. However, the analysis of the translated eHEALS was determined to be specific to patients who underwent percutaneous coronary intervention and cannot be generalized to other scenarios. There is therefore a need to determine the psychometric properties of the eHEALS in a more diverse population and in other settings to provide empirical evidence of the generalizability of the Norwegian eHEALS. Finally, the study only determined the administration of the eHEALS in self-reported written format (paper and pencil) in a hospital acute care setting. Further work should explore other modes of administration, including online administration developed for eHealth sources such as tablets, smartphones, and email.

Conclusion

This study provides new information on the psychometric properties of the eHEALS for patients after percutaneous coronary intervention, suggesting that the eHEALS is a multidimensional construct. Nevertheless, the RMSEA is not entirely adequate to fully capture the construct validity based on existing knowledge, and further factorial validation studies are needed. The internal item consistency was very high, indicating a redundancy of items. There is nonetheless a need for more research on the psychometric properties of the eHEALS. Moreover, use of the eHEALS in this study identified areas of eHealth literacy that are important for the further development of eHealth as a source of health information.

Abstract

Background: Over the last century, disruptive incidents in the fields of clinical and biomedical research have yielded a tremendous change in health data management systems. This is due to a number of breakthroughs in the medical field and the need for big data analytics and the Internet of Things (IoT) to be incorporated in a real-time smart health information management system. In addition, the requirements of patient care have evolved over time, allowing for more accurate prognoses and diagnoses. In this paper, we discuss the temporal evolution of health data management systems and capture the requirements that led to the development of a given system over a certain period of time. Consequently, we provide insights into those systems and give suggestions and research directions on how they can be improved for a better health care system.

Objective: This study aimed to show that there is a need for a secure and efficient health data management system that will allow physicians and patients to update decentralized medical records and to analyze the medical data for supporting more precise diagnoses, prognoses, and public insights. Limitations of existing health data management systems were analyzed.

Methods: To study the evolution and requirements of health data management systems over the years, a search was conducted to obtain research articles and information on medical lawsuits, health regulations, and acts. These materials were obtained from the Institute of Electrical and Electronics Engineers, the Association for Computing Machinery, Elsevier, MEDLINE, PubMed, Scopus, and Web of Science databases.

Results: Health data management systems have undergone a disruptive transformation over the years from paper to computer, web, cloud, IoT, big data analytics, and finally to blockchain. The requirements of a health data management system revealed from the evolving definitions of medical records and their management are (1) medical record data, (2) real-time data access, (3) patient participation, (4) data sharing, (5) data security, (6) patient identity privacy, and (7) public insights. This paper reviewed health data management systems based on these 7 requirements across studies conducted over the years. To our knowledge, this is the first analysis of the temporal evolution of health data management systems giving insights into the system requirements for better health care.

Conclusions: There is a need for a comprehensive real-time health data management system that allows physicians, patients, and external users to input their medical and lifestyle data into the system. The incorporation of big data analytics will aid in better prognosis or diagnosis of the diseases and the prediction of diseases. The prediction results will help in the development of an effective prevention plan.

Introduction

The notion of health data management systems has evolved during the last century. With the evolution of medical records from paper charts to electronic health records (EHRs) [1], health data management has undergone disruptive transitions to provide more accurate and better patient care and make qualitative use of these records. This shift is underpinned by the advancement in information technologies that led to the development of several notions of health data management systems. Those health data management systems were often misaligned with the goals of biomedical care and research. This misalignment is caused particularly by the discrepancies between advanced technologies and their adoption for biomedical care and research. Consequently, it becomes vital to address this gap by developing a new framework for the health data management system. In this paper, we provide a broader history and evolution of health data management systems underpinned by the changing definition of medical records, discuss the issues prevailing within, introduce the modern aspects of health data management systems supporting the growing size of medical data, and discuss insights and provide solutions aiming for a better health care ecosystem.

The introduction of EHRs has transformed the health care industry by providing more services, improving the quality of patient care, and enhancing the data access ability in real time, thereby creating a diverse set of health data management systems [2]. Our understanding of EHRs is that it provides a longitudinal view of a patient's medical history over his or her lifetime generated by one or more health care providers or medical organizations delivering treatments to that patient. These cohesive and summarized records include the patient's demographic and personal information, past and current diagnoses and treatments, progress notes, laboratory and radiology results, allergies, and immunizations [1]. However, an earlier form of EHRs referred to as paper charts involves written records of a patient's diagnosis and treatments for the purpose of medical teaching. Next, the term has been revised to computer-based patient records, electronic medical records, and currently EHRs. With the advancement in technological developments and the goal to provide better and efficient health care, health data management systems have evolved from a computer-based approach to client-server-based, cloud, the Internet of Things (IoT), and finally to blockchain-based system.

With the rise of big health care data and the realization of using medical data for governance and research, it becomes necessary to integrate big data analytics within health data management systems [3]. However, this brings new challenges of data aggregation and preprocessing from multiple sources to develop insights, data security, and privacy to cope with an increasing number of data breaches and hacking incidents [4]. Further challenges have been imposed on biomedical care and research by the nature and types of medical data being generated at a

rapid pace. These challenges have developed the need for a new health data management framework.

This paper analyzes the requirements for better patient care and predictive analysis that must be considered when implementing a health data management system. Considering these requirements will make the health care data management system more accurate, efficient, and cost-effective. To our knowledge, this is the first analysis of the temporal evolution of health data management systems to give insights into the system requirements for better health care.

The contributions of this paper are three-fold. First, the paper provides a taxonomy of health data management systems based on their technological advancement, and the inherent challenges and issues are discussed therein. Second, we present the reforming definitions of medical records and extract the requirements of a health data management system. Third, the paper provides insights into the health data management system research and guidelines for the future research area.

Related Works

Health data management systems are evolving for better health care. Literature reviews on these systems are classified into 2 categories: (1) electronic health (eHealth) [5-8] and (2) mobile health (mHealth) [9].

Regarding eHealth, the study by Jamal et al [5] reviews the impact of a computerized system on the quality of health care. The results showed that a health information system, if properly designed, can prevent medical errors and can support doctors and medical providers in diagnosis. The study by Van De Belt et al [6] reviews the definitions of health and medicine over 2 years (from 2007 to 2009), coming up with a common definition involving the web, patients, professionals, social networking, health information content, and collaboration. In this study, we reveal additional requirements needed for better health care: privacy, security, public insights, and patient participation in accessing and monitoring medical data. The studies by Hans et al [7] and Cunningham et al [8] focus on the definitions of eHealth from 1999 to 2004. The authors found that the themes health and technologies are most recurrent in all definitions.

Concerning mHealth, Silva et al [9] provide a review of mHealth apps and services. It highlights that the coordination, integration, and interoperability between different mHealth apps is important for better health care as well as improved performance of mobile devices in terms of device battery, storage, computation, and network.

In this study, we reviewed health data management systems based on the following 7 requirements across studies conducted over the years: (1) medical record data, (2) real-time data access, (3) patient participation, (4) data sharing, (5) data security, (6) patient identity privacy, and (7) public insights.

Methods

For the analysis and study of the evolution of health data management systems, we reviewed published research articles, reports, medical lawsuits, and health care regulations; acts about the methods of organizing medical record data; and the needs of a health data management system. The literature was searched in the Institute of Electrical and Electronics Engineers, Association for Computing Machinery, Elsevier, MEDLINE, PubMed, Scopus, and Web of Science databases from 1793 to 2020. We selected the papers that included incidents that involved the definitions of a health data management system, triggered the introduction of a new system, and/or implemented technologies for better health care. The analysis of these papers shows that advances in technologies are being adopted for accurate and efficient patient care.

Results

Taxonomy of Health Data Management Systems

Before satisfying the requirements of biomedical care and research, the evolution of the underlying health data management systems and their limitations must be understood. The capabilities of the health data management should ensure that the requirements of patient care are met. Health data management systems have undergone multiple transitions over the years alongside the advancement in information technologies as shown in Figure 1. During this evolution, several programs were established and regulation acts were passed to improve the quality of patient care. Table 1 presents the events that triggered the evolution of health data management systems. Table 2 presents the limitations of health data management systems.

Figure 1. Evolution of the health data management system.

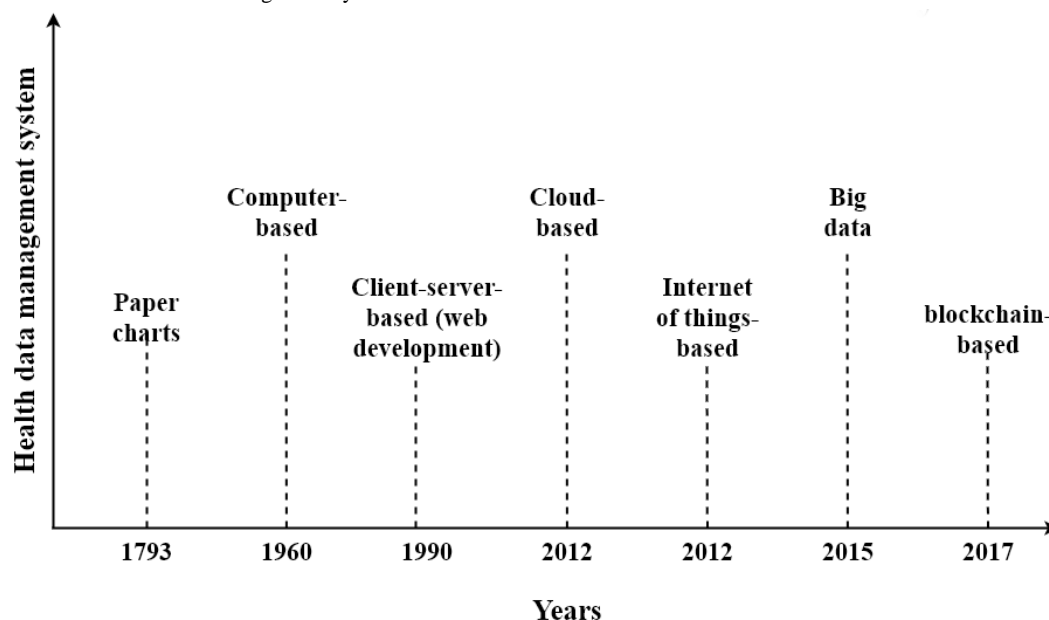

Table 1. Events that have triggered the evolution of health data management systems.

Year	Responsible authority	Evolutionary change
1793	Board of Governors of the Society of the New York Hospital	Rule to record patients' data for hospital expenditure justification was passed [10].
1805	Board of Governors of the Society of the New York Hospital	Rule to record major medical cases for education was passed provoked by a fatal dispute between an American statesman and an American politician. According to the rule, the recorded cases should be bounded in a book for inspection by the governors, medical professionals and students, and the friends of the patients [11].
1830	Board of Governors of the Society of the New York Hospital	Rule to maintain a record of all the medical cases [11].
1918	American College of Surgeons	A hospital standardization program was established to standardize the format of medical records for improved patient care [12].
1928	American College of Surgeons	American Association of Record Librarians of North America was established to enhance the standards of medical records [13].
The 1960s	Lawrence Weed	The idea to use computers for medical records was proposed to allow doctors to track a patient's medical history and provide evidence for the treatment [14]. A problem-oriented medical records model was developed to standardize the method of EMRs ^a that provided a structure to help doctors record their notes [14].
The 1960s	N/A ^b	Paper charts were termed as EMRs.
1965	Centers for Medicare and Medicaid Services	Rule to record patients' data by medical nurses for medical insurance reimbursement with the introduction of Medicare and Medicaid laws [15].
1965	Lockheed Corporation	First commercial computerized health data management system known as Clinical Information System was developed for El Camino Hospital. The system included features for laboratory tests, appointment scheduling, and pharmacy management [16].
1967	University of Utah, 3M and Latter-Day Saints Hospital	First clinical decision support system known as Health Evaluation of Logical Processing was developed to support clinical operations. The system helped doctors to identify cardiac contraction based on a patient's test results' analysis and to select an appropriate medication for infectious disease cases [17].
1968	Massachusetts General Hospital and Harvard University	The first modular computer-based health data management system known as Computer Stored Ambulatory Record was implemented. The system accommodated clinical vocabularies through clinical mapping to recognize different terms used for the same disease [18].
The 1980s	Indian Health Service	MPI ^c was introduced to keep track of patients' medical data to reduce unnecessary testing and adverse drug effects [19].
1987	Health Level Seven	Electronic standards were developed to address the standardization issues of health data management system development and adaption. The standards allowed the use of components from different vendors in a health data management system [20].
1991	Institute of Medicine	The term computer-based patient records was introduced in a report studying the benefits of electronic management of health records [21].
1996	US Congress	The Health Insurance Portability and Accountability Act was passed to safeguard patients' medical records by involving role-based access control, automatic data backup, audit trails, and data encryption [22].
1999	John Mitchell	The term eHealth ^d was coined that refers to the integration of electronic communication and information technologies for electronic transmission, storage, and retrieval of medical records both locally and remotely [23].
2000	S Laxminarayan and Robert SH Istepanian	The term mHealth ^e was coined that refers to wireless telemedicine using mobile telecommunications and multimedia technologies for the new mobile health care system [24].
2001	Gunther Eysenbach	The definition of eHealth was expanded by incorporating business and public health to health services and defining the outcomes and stakeholders of eHealth [25].
2004	Stephen S Intille	The term uHealth ^f was coined that refers to the use of biometric sensors and medical devices to monitor and improve a patient's medical health [26].
The 2000s	Health care organizations	Proposed a formal definition of the term personal health records that allows patients to access their medical history and to manage it by making part of it available to selected participants by defining access control rights [27].
2003	Institute of Medicine	The term electronic health records [28] was coined.

Year	Responsible authority	Evolutionary change
2006	Commonwealth of Massachusetts	Massachusetts health care reform law was passed that mandated for residents to have minimum medical insurance coverage and for employers with more than 10 full-time employees to provide medical insurance coverage [29].
2006	Elliott Fisher	The term Accountable Care Organizations was coined that refers to a group of doctors, hospitals, and other health care providers who volunteer to give high-quality care to their patients to avoid unnecessary duplication of services and reduce medical errors [30].
2009	US Department of Justice, Office of Inspector General, and Human and Health Services	The Health care Fraud Prevention and Enforcement Action was established to strengthen the existing programs to prevent and reduce Medicare and Medicaid frauds [31].
2010	US President Barack Obama	The Patient Protection and Affordable Care Act was signed into law with an objective to provide an expansion of medical insurance coverage [32].

^aEMR: electronic medical record.

^bN/A: not applicable.

^cMPI: master patient index.

^deHealth: electronic health.

^emHealth: mobile health.

^fuHealth: ubiquitous health

Table 2. Limitations of health data management systems.

Health data management system	Limitation
Paper charts	Illegible handwriting resulting in incorrect treatments [33] and deaths [34,35]. Requires physical storage and are susceptible to unplanned destruction such as flood, fire, rodents, and degradation. Physically cumbersome to read, understand, and search for specific information. The cost and time required for paper charts to be requested for duplication and then delivered are unacceptably high.
Computer-based	Medical records are managed by the physicians and cannot be accessed by the patients. Physicians visiting a patient have to note down or memorize the patient's medical data to return to the hospital and record it digitally, which may lead to error.
Client-server-based	A patient has no traceability on how his or her data are used. The issues of security, privacy, and single point of failure. In addition, a cohesive view of a patient's medical data from multiple hospitals is difficult. Requires repeating medical tests at times, which results in more time, cost, and effect on health conditions.
Cloud-based	Single point of failure, loss of data control and stewardship, a requirement of steady internet connection, and data reliability [36,37].
IoT ^a -based	Data security and patient privacy are a major concern.
Big-data-based	The process of data aggregation from different storage sites is time consuming, complex, and expensive. The data are stored using different formats and requires preprocessing. In addition, preserving the security of the data and privacy of the patient identity while maintaining the usefulness of data for analysis and studies is quite challenging.
Blockchain-based	The process of ledger update on multiple nodes is energy consuming [38] and suffers from the issue of low throughput [39].

^aIoT: Internet of Things.

Requirements of a Health Data Management System

Over the last century, the definition of health data management has undergone numerous reformations to address the need for better and advanced patient care alongside technological advances. We evaluated these differing examinations and rationalized the definition used in the remainder of the paper. It is important to note that, as the term health data management is rather recent, the listed definitions were taken from different

legislations and health data recording systems, even if the exact phrase *health data management* was not used. Table 3 shows the evolving definitions of health data management systems from being purely medical practice and learning-based definitions to being more patient-centric and research-based definitions. We classified health data management systems based on 7 requirements that underpin the evolution in the field as shown in Figure 2. Each number in the figure represents a definition stated in Table 3.

Table 3. The definitions of health data management systems.

Number	Year	Source	Definition
1	1793	Siegler [10]	"[...] Names and Diseases of the Persons, received, deceased or discharged in the same, with the date of each event, and the Place from whence the Patients last came [...]"
2	1805	Siegler [10]	"The house physician, with the aid of his assistant, under the direction of the attending physician, shall keep a register of all medical cases which occur in the hospital, and which the latter shall think worthy of preservation, which book shall be neatly bound, and kept in the library for the inspection of the friends of the patients, the governors, physicians and surgeons, and the students attending the hospital."
3	1941	Sayles and Gordon [12]	"Accurate and complete medical records [...] which includes identification data; complaint; personal and family history; history of the present illness; physical examination; special examinations such as consultations, clinical laboratory, x-ray and other examinations; provisional or working diagnosis; medical or surgical treatment; gross or microscopical pathological findings; progress notes; final diagnosis; condition on discharge; follow-up; and, in case of death, autopsy findings."
4	1968	Weed [14]	"The computer is making a major contribution [...] the patient will gain from his physician an immediate sympathetic understanding [...] inadequate analysis by the medical profession can be avoided."
5	1968	Weed [14]	"[...] orient data around each problem [...] complete list of all the patient's problems [...] diagnosis and all other unexpected findings or symptoms [...] The list is separated into active and inactive problems, and in this way, those of immediate importance are easily discernible [...] orders, plans, progress notes and numerical data can be recorded under the numbered and titled problem [...]"

Figure 2. Requirements of a health data management system.

Medical Record Data

Medical record data that describes the identity and health of a patient based on the personal and demographic identity, history of the medical condition, ongoing treatment, laboratory tests, and radiology results are the common requirement of a health data management system. The medical records have been a primary component throughout the evolution of health data management systems, whether in the form of printed documents or digital records.

Real-Time Data

To improve the quality of patient care, the requirement of real-time data access was highlighted in the definitions of health data management systems. This requirement reduces the medical incidents owing to the delay in data updates by the physicians. However, this requirement cannot be fulfilled by the paper-based and computer-based health data management systems. This requirement was introduced with the client-server-based management system [46-52] that enables the physicians to access and update the patient medical records in real time.

Patient Participation

With the medical records maintained by the hospitals or third-party cloud service providers, the patients cannot track how their medical data are used. Consequently, patient participation in accessing and monitoring medical data is a key requirement to develop trust in health data management systems. In addition to data access, the participation of patients in providing health conditions and lifestyle data to the physicians will aid in better prognosis and diagnosis. The introduction of IoT-based health data management system involving sensors and medical devices that monitor a patient's health and lifestyle conditions enables the patient to input their medical conditions to the system [53-59]. An analysis of personal health records management platforms based on users' perception shows that a simple easy-to-use system is required for patient engagement and satisfaction [60].

Sharing

Sharing of medical records is a vital requirement with the patient's treatment being spread across various health care providers. This is to aid other physicians to study the patient's medical history for better treatment and to avoid repetition of laboratory and radiology tests. On the basis of the list of definitions in Table 3, we classified sharing based on the users allowed to access the data into 3 different categories: (1) degree 1, where the information is shared within the same medical organization where the patient is currently receiving treatment, (2) degree 2, where the information is shared with the patient, patient's friends, and family, and (3) degree 3, where the information is shared with other medical organizations and government. The requirement of sharing is complemented by the introduction of the cloud-based health data management system [61-63]. However, to share medical record data between different health care organizations and to efficiently use the shared information, the systems should support interoperability. Interoperability can be achieved by using a standard format to store, manage, and share the medical data. There are several standard formats to store medical data and images [64]. Some of the major file formats used for medical images are Analyze [65], Neuroimaging Informatics Technology Initiative [66], Minc [67], and Digital Imaging and Communications in Medicine [68]. Health Level 7 International, standardized by the American National Standards Institute, is a health care protocol for sharing medical data [20]. It includes the rules for the integration, exchange, and management of EHRs. Wen et al [69] assessed the interoperability of eHealth systems in Taiwan for exchanging data. This is to reduce repeated medical examinations and medications for better health care. They concluded that the government should define policies to enforce interoperability.

Security

With increasing incidents of data breaching and phishing attacks, and the adoption of a third-party service provider, the security of the patients' sensitive and important data is essential. Compared with 477 health data breaches reported in 2017,

affecting 5,579,438 patient records in 2017, 503 breaches affecting 15,085,302 records were reported in 2018 [70]. The requirement of security is even high when patients' medical records are handled by a cloud service provider or when medical sensors and devices are used to gather patients' medical and lifestyle data. According to a report by Intel Security, the use of cloud services by the health care provider has reduced owing to the lack of cyber security methods implemented by the cloud service provider [71]. A report states that, on average, hospitals lose track of around 30% of their networked medical devices, making it much harder to protect against vulnerabilities [72]. More than 61% of all IoT devices and sensors on a hospital network are at high risk of cyber-attack. In recent years, blockchain technology [73,74] has gained wide popularity and has penetrated into the domain of health care to address the need for a more patient-centric supportive system for the professionals, to connect disparate systems for improved patient care, and to increase the accuracy of EHRs [75-81].

Privacy

The privacy requirement of a patient's identity in a health data management system is crucial with the increasing number of medical frauds and fake medications. The privacy of the patient cannot be compromised, especially with the rise of data analytics, where the medical record data of the patients are used for analysis. The blockchain-based health data management system aims to address this issue.

Public Insights

Prediction of health conditions is important to avoid life-threatening situations. The increasing amount of health care data [82], if properly analyzed, can facilitate the prediction of health conditions. The process of gathering, organizing, storing, and analyzing big data to discover correlations, hidden patterns, and other valuable insights is known as big data analytics. Figure 3 shows the life cycle of big data analytics.

Figure 3. Lifecycle of big data analytics.

The prediction from health care data for public insights allows to actively improve public health and to react faster to a situation [83-91]. Using personal health care data requires, of course, a well-defined balance between the assurance of the privacy of personal health care data with respect to transparency, for example, toward insurance companies. Insights into genetical personal risk factors for chronic diseases should not lead to a situation where a person has disadvantages concerning the insurance status. Moreover, the monitoring of the public health

situation has to be based on the health care data of individuals. Consequently, research projects have recently addressed the balance of personal health care data as a public good [92]. Figure 4 [92] shows the relationship between the 3 key stakeholders for defining the balance between personal health care data and the potential of these data as a public good. Companies could be health insurance providers, hospitals, pharmaceutical companies, and government organizations.

Figure 4. Personal health care data ecosystem.

The diabetes mellitus crisis or the growth of cardiovascular problems caused by nutrition patterns and lifestyle behavior in many countries and regions of the world, changing patterns of Alzheimer and dementia, or microbiome research, and the abuse of antibiotics would benefit tremendously from personal health care data as a public good [93,94]. Bringing together the insights of large initiatives such as the Health Data Exploration Project and Computational Health Sciences [92,94] promises the key for future advancement in the area of private and personal health

care data for the public good. Health care data analytics can help researchers and government officials for better prediction of chronic diseases, the development of effective therapeutic drugs, more accurate patient care, and the development of a nation-wide effective prevention plan.

Table 4 shows health data management systems presented in the taxonomy and evaluates them in terms of their adherence to the defined requirements.

Table 4. Health data management systems in the literature vs the requirements.

System	Medical record data	Real-time data	Patient participation		Sharing			Security	Privacy	Public insights
			Data access	Data input	Degree 1	Degree 2	Degree 3			
Paper-based	Allows recording of medical data for eventual use	Encounters high delays	Does not allow patients to track the use of their medical data	Does not allow patients to provide their health conditions	Supports data sharing only within the same hospital	Allows data sharing with the patient, patient's friends, and family	Does not allow data sharing with the patient, patient's friends, and family	Does not provide methods against cybersecurity attacks	Does not provide methods for preserving a patient's privacy	Does not support prediction
Computer-based	Allows recording of medical data for eventual use	Encounters high delays	Does not allow patients to track the use of their medical data	Does not allow patients to provide their health conditions	Supports data sharing only within the same hospital	Allows data sharing with the patient, patient's friends, and family	Allows data sharing with other medical organizations and government	Does not provide methods against cybersecurity attacks	Does not provide methods for preserving a patient's privacy	Does not support prediction
Client-server-based	Allows recording of medical data for eventual use	Allows data retrieval in real time	Allows patients to access and monitor their medical data	Does not allow patients to provide their health conditions	Supports data sharing only within the same hospital	Allows data sharing with the patient, patient's friends, and family	Allows data sharing with other medical organizations and government	Does not provide methods against cybersecurity attacks	Does not provide methods for preserving a patient's privacy	Does not support prediction
Cloud-based	Allows recording of medical data for eventual use	Allows data retrieval in real time	Allows patients to access and monitor their medical data	Does not allow patients to provide their health conditions	Supports data sharing only within the same hospital	Allows data sharing with the patient, patient's friends, and family	Allows data sharing with other medical organizations and government	Does not provide methods against cybersecurity attacks	Does not reveal a patient's identity	Does not support prediction
IoT ^a -based	Allows recording of medical data for eventual use	Allows data retrieval in real time	Allows patients to access and monitor their medical data	Allows patients to provide health conditions	Supports data sharing only within the same hospital	Allows data sharing with the patient, patient's friends, and family	Allows data sharing with other medical organizations and government	Does not provide methods against cybersecurity attacks	Does not provide methods for preserving a patient's privacy	Provides methods for the prediction of health conditions
Big data analytics	Allows recording of medical data for eventual use	Allows data retrieval in real time	Allows patients to access and monitor their medical data	Allows patients to provide health conditions	Supports data sharing only within the same hospital	Allows data sharing with the patient, patient's friends, and family	Allows data sharing with other medical organizations and government	Does not provide methods against cybersecurity attacks	Does not reveal a patient's identity	Provides methods for the prediction of health conditions

System	Medical record data	Real-time data	Patient participation		Sharing			Security	Privacy	Public insights
			Data access	Data input	Degree 1	Degree 2	Degree 3

Discussion

Principal Findings

This study revealed that there is a need for a secure and efficient health data management system that will allow physicians and patients to update decentralized medical records and to analyze the medical data for supporting more precise diagnoses, prognoses, biomedical research, and public insights. The early form of health data management using the manual recording of a patient's diagnosis and treatment on sheets of paper was introduced almost a century ago. Later, with the advancement in technology, health data management systems evolved to web, cloud, IoT, big data analytics, and blockchain-based systems. The definition of medical records has reformed alongside this temporal evolution of the system. The requirements for a health data management system extracted from these definitions are medical record data, real-time data, patient participation, sharing, security, privacy, and public insights. The paper-based health data management system fulfills the requirements of medical record data and sharing. However, paper charts are prone to misplacement, occupy large physical space, and involve a time-consuming and expensive data sharing process. Over time, the paper charts were replaced by electronic records in the computer-based system with the same requirements.

To achieve the requirement of real-time data access in addition to medical record data and sharing, a client-server-based health data management system was introduced. This system allows patients and health care providers to access medical data over the internet using a mobile device or a desktop computer. However, it suffers from the issues of single point of failure, data fragmentation, system vulnerability, low scalability, and high data security and patient privacy risks. To minimize the infrastructural cost and to address the issue of data fragmentation, the medical organizations and health care providers transitioned to a cloud-based system. The cloud service provider ensures the requirement of privacy of patient identity, but the security of the data is not ensured in addition to the issue of a single point of failure.

The requirement of patient participation to feed their medical data and lifestyle conditions for better prognosis and diagnosis was achieved with the introduction of the IoT-based management system. However, with the increasing number of data breaches and hacking of the medical sensors and devices,

there prevails a constant threat to the security of data and privacy of a patient's identity. With the advancement in big data analytics, increasing amount of health care data are being studied to gain insights for better prognosis and diagnosis of diseases. However, the privacy of a patient's identity still remains a concern.

The blockchain technology, which recently attracted the attention of industries, shows potential in the field of health care. A blockchain-based health data management system satisfies all the requirements needed for better patient care. However, it consumes a high amount of energy [95,96] and has low throughput [39]. There are increasing research efforts to solve these issues. For instance, to address the problem of energy consumption, Milutinovic et al [97] proposed the proof of luck consensus mechanism that ensures energy-efficient and low-latency transaction validation. Ismail et al [98] and Dorri et al [99] proposed scalable blockchain architectures for health care that use a clustering approach to increase transactions throughput.

The main requirements of a health care data management system are security and privacy, especially with the increasing number of data breaching and hacking attacks. Furthermore, the adoption of patient participation to feed health data to a health system is increasing with the introduction of disruptive technologies, such as the IoT and big data analytics. Big data analytics requires the sharing of medical information among hospitals to get insights and predictive analysis from the data. This paves the way toward a health data management system as a support to physicians and medical professionals for better diagnosis and prognosis of chronic diseases. In addition, such a system allows to derive public insights from data to develop a nation-wide prevention plan for certain diseases. The traceability feature of the blockchain ensures that the data used for developing the predictive models is accurate, leading to a precise prognosis, diagnosis, and decision support system. Consequently, we suggest an integrated blockchain-, IoT- and big data-based health data management system to ensure the requirements of smart health care: real-time access to data by physicians and patients, health data input from patients through medical sensors and lifestyle, security, privacy, and public insights. This integrated health management system should be scalable and energy-efficient, presenting new research challenges in the research era of a smart health data management system.

Conclusions

The objective of this paper was to highlight the requirements of a health data management system for biomedical care and research. In summary, it discussed the temporal evolution of health data management systems from paper charts to blockchain-based systems, along with the reformation of the

definition of what we call EHRs today. The system should satisfy the requirements of medical record data, real-time access, patient participation, data sharing, data security, patient identity privacy, and public insights. The incorporation of big data analytics aids in better prognosis and diagnosis of the diseases and the prediction of risk for the development of chronic diseases.

Abstract

Background: Physician burnout has a direct impact on the delivery of high-quality health care, with health information technology tools such as electronic health records (EHRs) adding to the burden of practice inefficiencies.

Objective: The aim of this study was to determine the extent of burnout among physicians and learners (residents and fellows); identify significant EHR-related contributors of physician burnout; and explore the differences between physicians and learners with regard to EHR-related factors such as time spent in EHR, documentation styles, proficiency, training, and perceived usefulness. In addition, the study aimed to address gaps in the EHR-related burnout research methodologies by determining physicians' patterns of EHR use through usage logs.

Methods: This study used a cross-sectional survey methodology and a review of administrative data for back-end log measures of survey respondents' EHR use, which was conducted at a large Canadian academic mental health hospital. Chi-square and Fisher exact tests were used to examine the association of EHR-related factors with general physician burnout. The survey was sent out to 474 individuals between May and June 2019, including physicians (n=407), residents (n=53), and fellows (n=14), and we measured physician burnout and perceptions of EHR stressors (along with demographic and practice characteristics).

Results: Our survey included 208 respondents, including physicians (n=176) and learners (n=32). The response rate was 43.2% for physicians (full-time: 156/208, 75.0%; part-time: 20/199, 10.1%), and 48% (32/67) for learners. A total of 25.6% (45/176) of practicing physicians and 19% (6/32) of learners reported having one or more symptoms of burnout, and 74.5% (155/208) of all respondents who reported burnout symptoms identified the EHR as a contributor. Lower satisfaction and higher frustration with the EHRs were significantly associated with perceptions of EHR contributing toward burnout. Physicians' and learners' experiences with the EHR, gathered through open-ended survey responses, identified challenges around the intuitiveness and usability of the technology as well as workflow issues. Metrics gathered from back-end usage logs demonstrated a 13.6-min overestimation in time spent on EHRs per patient and a 5.63-hour overestimation of after-hours EHR time, when compared with self-reported survey data.

Conclusions: This study suggests that the use of EHRs is a perceived contributor to physician burnout. There should be a focus on combating physician burnout by reducing the unnecessary administrative burdens of EHRs through efficient implementation of systems and effective postimplementation strategies.

Introduction

Overview of Physician Burnout

Physician wellness is vital to the delivery of high-quality health care and greatly affects the performance of health care systems [1]. Organizations have started including wellness programs among their top priorities in an attempt to reduce physician burnout [2]—a work-related syndrome involving emotional exhaustion, depersonalization, and a sense of reduced personal accomplishment [3]. Physician burnout has been associated with career dissatisfaction [4], absenteeism and job turnover [5], reduced quality of care [6], and medical errors [7]. It is increasingly being measured, with high prevalence rates (78%) among American physicians [8], and almost 30% of Canadian physicians [9] have reported symptoms of burnout. The major contributors to physician burnout include *individual factors* (eg, age and education debt) [10] and *work factors* (eg, inefficient work processes, negative leadership, and limited interprofessional collaboration or advancement) [11]. Within psychiatry, workplace variables have been found to be a major stressor and may be more likely to perpetuate burnout [12]. Demands including navigating the working relationship with clients experiencing trauma—while often becoming the target of anger, hatred, and even violence—can be emotionally draining [13]. Moreover, burnout has also been known to span all phases of a physician's career, including during medical school and residency, and a recent systematic review calculated a 33.7% burnout rate for psychiatry residents [14].

Among workplace inefficiencies, the use of health information technology such as electronic health records (EHRs) has been suggested to contribute to physician burnout in psychiatry [15,16]. With proper implementation, EHRs can improve the quality of health care by increasing time efficiency and guideline adherence and reducing medication errors [17]. However, the promise of improved quality of patient care through fast access to patient information and improved clinical decision-making support has not been attained in many health care organizations as the unintended consequences of EHRs proliferate [18].

These unintended consequences can be *technical* factors, such as poor software design, or *sociotechnical* factors, such as poor usability or workflow integration [19–22]. EHRs have often added to physicians' cognitive load through excessive data entry requirements [23,24] and reduction of time spent with patients [25,26]. The provision of mental health care, in particular, poses an added level of complexity, including navigating multidisciplinary treatment plans, varying levels of care (ie, residential and partial hospitals) that do not fit neatly into the clinical or scheduling workflows [27], and the inability to capture and find important documentation [28,29]. Despite the challenges, the adoption of EHRs remains an important policy priority in most countries, showing a steady increase over the past 10 years and reaching an adoption rate of 75% in American [30] hospitals and 81% in Canadian [31] hospitals. Moving forward, the National Academy of Medicine calls for a

human-centered approach to combat physician burnout by reducing unnecessary administrative burdens through improved design and implementation of technology and supportive regulatory policies [32].

Although there are numerous editorial and opinion pieces identifying EHRs as possible contributors to physician burnout [33,34], research in determining physicians' perceptions of the impact of EHRs on burnout is scant [35]. In addition, there is a need to apply a variety of research methods to fully understand the complexity of the phenomenon to optimize technology and clinical workflows [35], given that previous studies used subjective, perception-based data for measuring both EHR-related stressors and burnout variables.

Study Aims

This study aimed to (1) identify the extent of burnout and the perceived contribution of the EHR toward burnout among our population of physicians and learners (residents and fellows); (2) identify significant contributors of burnout and EHR-related burnout; (3) explore differences between physicians and learners among factors previously identified as contributing to EHR-related burnout (time spent, use, and documentation styles within the EHR; EHR proficiency and training; and perceived usefulness of EHR); and (4) compare self-reported perceptions on EHR usage metrics using log data.

Methods

Design, Setting, and Participants

This study used a cross-sectional survey design to gather the perceptions of physicians and learners and back-end EHR usage logs to gather use patterns. It was conducted at Canada's largest academic mental health hospital located in Toronto, Ontario. At the time of the survey distribution, the Centre for Addiction and Mental Health had 407 physicians, 208 of which were considered full-time (ie, ones who had a *primary* appointment with the hospital). Among these physicians were hospitalists and psychiatrists spread across 7 different clinical divisions. In addition, the study included 53 residents and 14 clinical fellows. Of the 37,065 unique patients admitted in the hospital, 63.10% (23,388/37,065) were treated for an admission diagnosis falling within two groups: schizophrenia or psychotic disorders and substance use disorders [36]. Physicians used a comprehensive EHR, which was implemented 5 years before this study.

Depending on the email address used for the electronic survey links, usage log data for 201 participants in May and 198 participants in June were identified, which were then used to compare metrics that were also asked within the survey.

Ethical approval was obtained from the organization's quality improvement projects ethics review board.

Data Collection

Survey

The survey was administered to the study's target population of physicians and learners (residents and clinical fellows) between May 2019 and June 2019 by sending a link to the anonymous electronic survey via email. To maximize survey participation, weekly reminders were sent out for the duration of survey recruitment (6 weeks), and engagement methods, including advertising in physician newsletters, discussions at hospital-wide meetings, and resident lunches, were used.

Research Electronic Data Capture (REDCap)—a secure web app—was used to manage the survey [37]. The app collected information about demographics, practice setting and EHR-related usage, and burnout (Table 1) and open-ended responses to capture the respondents' experience with the EHR and explore unique ways in which they use the EHR (Multimedia Appendix 1). The survey was developed using previous literature, including the study by Gardner et al [15] and KLAS Arch Collaborative Impact Report on Clinician Burnout [38], and was tested with physicians, researchers, and divisional chiefs, and their feedback was incorporated.

Table 1. Independent and dependent variables.

Variable type and category	Variables
Independent	
Demographics	<ul style="list-style-type: none"> • Age • Gender (male, female, or nonbinary) • Role (physician versus learners)
Practice	<ul style="list-style-type: none"> • Clinical academic division • Length of practice • Patient load (number of patients per week)
EHR ^a -related factors	<ul style="list-style-type: none"> • Time spent in EHR (time per patient and time after hours per week) • Frustration and satisfaction with EHR • Documentation styles (typing, back-end transcription, and voice recognition software) • EHR proficiency • EHR training needs • Perceived usefulness of EHR (on improving communication, enabling high-quality care, and patient safety)
Dependent	
Burnout	<ul style="list-style-type: none"> • General burnout: Measured using a single question from the Mini-Z survey [39] (The Mini-Z is a 10-item instrument developed from the Physician Worklife Study [40]). This single question has been previously validated for physicians [41] against the detailed Maslach Burnout Inventory [3], and it achieved a sensitivity of 83.2% and specificity of 87.4% [41]. Respondents were asked to identify their symptoms of burnout based on a 5-point scale: (1) "I enjoy my work. I have no symptoms of burnout," (2) "I am under stress, and don't always have as much energy as I did, but I don't feel burned out," (3) "I am definitely burning out and have one or more symptoms of burnout, eg. emotional exhaustion," (4) "The symptoms of burnout I am experiencing won't go away. I think about work frustrations a lot," and (5) "I feel completely burned out. I am at the point where I may need to seek help." Participants considered as "burned out" include those having one or more symptoms of burnout (ie, a score of ≥ 3 on the above scale) • Contribution of EHRs toward burnout: Measured by a single question where physicians and learners were asked "Do you think [EHR name] contributes to your symptoms of burnout?", and responses were captured on a 4-point scale: "Always," "Almost always," "Some of the time," and "Almost never."

^aEHR: electronic health record.

Usage Logs

As unique electronic survey links were used, a list of those who responded to the survey was assembled. Usage logs were extracted for all these individuals for the 2-month period (May-June 2019) of the survey administration. Although we were able to determine whether a participant had responded to the survey or not (a feature of REDCap), we were not able to identify their individual survey responses because of the anonymity of the survey. Therefore, variables extracted from usage log data were compared with responses from the survey in aggregate and not at an individual level. The data extracted were *EHR-related factors* including (1) number of patients seen per month, (2) time spent in EHR per patient, and (3) time spent in EHR after hours per month (details of the source of the

back-end EHR analytics can be found in the study by Overhage et al [42]).

The inactive time when the physician was logged into the EHR but not actively engaged in using it (eg, typing) was excluded from the analyses, and *after-hours* were defined as 6 PM to 6 AM and weekends—similar to how it was defined in the survey.

Data Analysis

Survey

Descriptive statistics were calculated for all numeric and categorical variables. The association of independent variables (including demographics, practice styles, and EHR factors) with variables measuring burnout was analyzed using Fisher exact tests and chi-square tests (when the content table was too large

for the exact Fisher test to be calculated). Fisher exact tests were used to identify differences between physicians and learners for the following variables (counts of 5 or lower in chi-square tables): age, patient load, time spent in EHRs per patient, frustration with EHR, satisfaction with EHR, perceived usefulness (on improving communication within the circle of care, enabling delivery of high-quality care, and keeping patients safe), and documentation type. All descriptive and chi-square analyses were conducted using the Statistical Package for the Social Sciences software [43], and Fisher exact tests were conducted in R [44]. When significance at .05 level was not achieved, no *P* values were reported within the study's results.

For open-ended survey responses, inductive content analysis was used [45]. After dividing the responses into two groups (low and high satisfaction with EHR based on a quantitative rating scale), the data were read and coded to capture key thoughts or concepts. Investigator triangulation was used to refine the coding scheme, and one investigator proceeded to code all data. Emergent codes were clustered into broader subcategories or themes.

Comparison: Self-Reports and Usage Log Data

As back-end EHR usage log data were extracted on a monthly basis, the 2 survey variables (patients seen per week and time spent in EHR after hours per week) were changed from *weekly* to *monthly* to ensure practical comparison. Descriptive statistics gathered from the survey responses and usage logs of all respondents were compared.

Results

Participant Profile

Demographic and practice characteristics of the study population are shown in Table 2. The survey was answered by 176 physicians and 32 learners. Response rates were 43.2% for physicians (full-time: 75% and part-time: 10%) and 47.7% for learners (fellows: 86% and residents: 40%). A total of 44.3% (78/176) of physicians and 50% (16/32) of learners were female; 46.0% (81/176) of physicians were in the 0 to 10 years practice timeframe and 26.1% (46/176) practiced for 21 years or more. Physicians saw a mean of 27 patients (median 25) per week and learners saw a mean of 14 patients (median 15).

Burnout and the Perceived Contribution of the Electronic Health Record Toward Burnout

A total of 25.6% (45/176) of all physicians and 19% (6/32) of learners identified as having one or more symptoms of burnout, as measured using the single-item measure from the Mini-Z. When asked about EHR contributing to burnout, 69.3%

(122/176) of physicians and 67% (22/32) of learners reported feeling that the EHR always or almost always contributes to their symptoms of burnout. Within the subset of those individuals who experienced one or more symptoms of burnout (n=51), this perception of the EHR contributing to burnout was slightly more prevalent (155/208, 74.5%; [Table 3](#)).

Table 3. Burnout prevalence, by experience level.

^bEHR: electronic health record.

Significant Contributions to Burnout

Physicians and learners with higher levels of frustration and lower satisfaction with the EHR were significantly more burned out (Figure 1). Other variables that were significantly associated with burnout included participants' perceptions of the EHR on keeping their patients safe ($P=.002$) and whether physicians perceived communication regarding EHR upgrades as efficient ($P=.047$).

Variables that had a significant association with perceptions of EHR contributing to burnout were low satisfaction with the EHR ($P<.001$) and frustration with the EHR ($P<.001$; Figure 1). Similarly, as with burnout, those who were content with communication surrounding EHR updates were also significantly less likely to perceive the EHR as a contributory factor to burnout ($P=.003$). Finally, those who were more proficient with the EHR were also significantly less likely to perceive it as contributing to their burnout ($P=.01$).

The experiences of physicians and learners who had *low satisfaction* with the EHR focused on usability issues and unintended consequences of the EHR on patient care. A total

of 39 individuals reported usability issues such as it being nonintuitive, having too many clicks, or not being user-friendly, with one participant referring to it as "death by a thousand clicks" (Participant #94). Moreover, 48 respondents discussed difficulties with finding or retrieving information, including inaccessible documentation. Respondents also discussed time sinks because of the system being "slow" and "clunky" and noted the impact that technology has on direct patient care, such as "...has a negative impact on...the amount of quality face-to-face time I can spend with patients" (Participant #118).

Respondents with *high EHR satisfaction* used workarounds to complete tasks in the EHR, such as "type long consult notes in [Microsoft] word then copy" (Participant #33) or "enter my appointments in my Outlook calendar..." (Participant #66). Others discussed their knowledge of customization, such as "know how to insert personal short cuts" (Participant #103), or the use of back-end dictation or "use [voice recognition software] exclusively instead of typing progress notes" (Participant #125). Satisfied participants thought that the EHR allows for "communication with other care providers" and has "the ability to forward things easily to care providers in the circle of care" (Participant #168).

Figure 1. Significant contributors to physician burnout. A: [EHR name] adds to my daily frustration ($P<.001$); B: How would you rate your satisfaction with [EHR name]? ($P<.001$); C: [EHR name] helps keep my patients safe ($P<.002$); D: Do you feel communication regarding [EHR name] changes are efficient? ($P<.047$).

Physician and Learner Differences for Electronic Health Record–Related Factors

Time Spent, Use, and Documentation Styles Within the Electronic Health Record

Time spent, use, and documentation styles were not significantly different between those participants who were burned out and those who were not burned out. There were significant differences between physicians and learners with respect to the time spent on the EHR per patient, where 47% (15/32) of learners spent over 50 min per patient compared with only 16.5% (29/176) of physicians spending the same amount of time ($P=.03$). In total, 84.1% (148/176) of physicians and 78% (25/32) of learners reported spending time on the EHR after hours, with 22.2% (2/208) of respondents spending 4 or more hours per week.

Compared with physicians (96/176, 54.5%), a greater proportion of learners (24/32, 75%) document in the EHR through direct typing only. In contrast, 2.8% (5/176) of physicians rely solely on dictation through back-end transcription or voice recognition. None of the learners used dictation only to document in the EHR. Learners that did not use direct typing as their documentation style (8/32, 25%) used a combination of direct typing and dictation, whereas 41.5% (73/176) of physicians used a combination of documentation styles.

Electronic Health Record Proficiency and Training

A total of 31.3% (55/176) of physicians and 41% (13/32) of learners felt that their initial EHR training prepared them well, and a large portion of physicians and learners (89/176, 50.6% and 13/32, 41%, respectively) felt they had ongoing training available to meet their needs. In addition, more than half of the physicians (94/176, 53.4%) and learners (22/32, 69%) felt proficient in their use of the EHR. The majority of physicians (14/176, 79.5%) and learners (24/32, 75%) reported that communication regarding changes to the EHR was effective.

Perceived Usefulness of Electronic Health Records

A total of 62.5% (110/176) of physicians and 72% (23/32) of learners indicated that the EHR adds to their daily frustration (Table 4). Although 51.1% (90/176) of physicians felt that the EHR improved communication in their circle of care, only 34% (11/32) of learners agreed with this statement. With regard to the impact of the EHR on improving patient safety, 38.1% (67/176) and 40.3% (71/176) of physicians agreed with the statement or were neutral, respectively. In contrast, 63% (20/32) of learners felt neutral about this statement and 13% (4/32) agreed. Physicians had a significantly more positive perspective on the EHR in terms of quality of care ($P=.007$), with 38.6% (68/176) agreeing that it enabled them to deliver high-quality care, compared with only 9% (3/32) of learners.

Table 4. Electronic health record factors, by experience level.

Self-Reported Perceptions and Electronic Health Record Usage Log Data Comparison

As gathered from usage logs, the median *number of patients seen per month* for all the survey respondents over the months of May and June 2019 was 60 patients (May, N=201, June, N=198), compared with the self-reported median of 80 patients (N=207). The median *time spent on EHRs per patient* for all survey respondents for the months of May and June 2019 was 16.4 min (May, N=201, June, N=198), compared with the self-reported median of 30 min (N=206). The median *time spent on the EHR after hours* (defined as 6 PM to 6 AM and weekends) for all survey respondents for the months of May and June 2019 was 2.37 hours (May, N=201, June, N=198), compared with the self-reported median of 8 hours (N=201).

Discussion

Principal Findings

Although overall satisfaction with EHRs remains low, reverting to paper documentation is not a viable alternative. This study adds to a growing body of evidence calling for a focus on EHR improvement [46]. The study data demonstrate that 67% of learners and 43% of physicians were satisfied with the system, which is comparable with other studies [47]. Among those who

perceived the EHR in a negative light, a majority (>65%) of the respondents expressed dissatisfaction with the EHR (n=97).

Burnout and the Perceived Contribution of the Electronic Health Record Toward Burnout

This study helps in understanding physician burnout attributed to technology within the Canadian mental health context. Although the general burnout rate of physicians and learners (24.6%) was comparable with the Canadian national average (30%) [9], our survey found that the majority (69.6%) of physicians and learners attributed EHR to their symptoms of burnout, even when they did not identify as being burned out. Although other institutions have completed surveys to examine the role of technology in physician burnout [15,16,48], this study adds to the existing literature, providing data from a different geography and a robust baseline at our facility. Measuring burnout rates, as well as the significant EHR-related contributors to burnout within the hospital, have direct implications on practice. Our organization has created a multipronged approach toward improving physicians' experience with the EHR, which includes direct feedback channels, improved education and communication around EHR updates, implementing speech recognition technology, and developing physician efficiency dashboards. Having a strong baseline measure of burnout allows us to measure the short- and

long-term impact of initiatives at our hospital which aim to reduce physician burnout.

Significant Contributors to Burnout

Gardner et al [15] found that those who spent excessive time on the EHR at home had a 1.9 times higher rate of burnout, and Privitera et al [48] found that EHR use at home increased burnout by 46% within their population. However, this study found no significant differences in the time spent after hours between those respondents who were and were not burned out.

Another previously affiliated factor with EHR satisfaction was gender, with men reporting significantly higher EHR workload stress than women [49]. This study did not find any significant differences between men, women, or nonbinary individuals when it came to satisfaction and frustration with EHR, as well as other EHR-related factors.

The results from this study did identify low proficiency with the EHR as a significant factor that leads physicians and learners to perceive the EHR as contributing toward their burnout, which supports the hypothesis that improved education and training can help in reducing this negative perception. Research by Dastagir et al [50] demonstrated the impact of proficiency training on significant improvements in self-reported efficiency and satisfaction, which could eventually have an effect on burnout.

Physician and Learner Differences for Electronic Health Record–Related Factors

In addition, this study found significant differences between physicians and learners with respect to the time spent in the EHR per patient, with a higher number of learners spending >50 min. Such a difference could be attributed to learners getting used to a new EHR system (as they often work with several EHRs across the various training sites) and mastering clinical practice and documentation standards. They could also be tasked with doing more designated EHR work, including documentation and orders, allocated by their supervising physician. Similar results demonstrating the extent of indirect patient care that residents take on were found in a time-motion study conducted by Penn Medicine and John Hopkins University. The study found that the residents spend almost 66% of their time interacting with patients' medical records or documentation [51].

Self-Reported Perceptions and Electronic Health Record Usage Log Data Comparison

This study found that perceptions of time spent in the EHR after hours were much higher than the actual time spent, as gathered by back-end usage logs, with an >5-hour difference between these 2 averages. It is possible that the time spent after hours for logging in and out of the system, on email, and for other digital administrative activities could be included within participants' perceived estimates. This difference resembles previous research that has found overestimations of 1.83 hours in learners and up to 4.04 hours in attending physicians [52]. This study's respondents also overestimated the time spent in the EHR per patient compared with how long they spend according to back-end usage logs (14-min difference), which

could be because of interruptions in the workflow. It is important to note that, in general, employees have been shown to overestimate the hours that they work [53].

This discrepancy between self-reported and back-end usage log data has implications for future research, where a combination of methods should be used for studying the link between EHR-related stressors and physician burnout. Although burnout is primarily measured through perceptions, the stressors related to the EHR, such as time spent in the EHR after hours, primary documentation method, and amount and frequency of training, can all be measured through more objective means.

Limitations

Due to the nature of this study, we were only able to report on associations between variables rather than causal relationships.

To improve the understanding of the complexity of EHR use, we used back-end EHR usage logs. However, because of the anonymity of the survey, we were unable to compare self-reported data with usage logs on an individual basis, and we could only provide an aggregate comparison of 3 measures. Furthermore, usage logs can lack the vital context around clinical workflows, and there has been varied validity and sensitivity of using such logs for mapping out clinical activity [54]. Validation of back-end EHR usage logs through direct observation was not carried out within this study environment; however, this analytics system has been used in previously published literature describing physicians' EHR usage [42].

Despite numerous discussions and publications, there are striking differences in the understanding of what constitutes burnout and substantial variability in prevalence estimates of burnout among physicians [55]. This study used a single question from the Mini-Z, which was previously validated by physicians, and yielded results similar to those of the more commonly used Maslach Burnout Inventory [3].

Finally, because of the heterogeneity of EHRs, implementation practices, training, and organizational contexts, there exists a potential limitation in generalizing such results to other contexts.

Conclusions

This work is the first step in better understanding EHR-related physician burnout in a Canadian academic mental health environment, where we measured general burnout rates and its perceived link to EHR use through a survey that gathered self-perceptions. In addition, we compared self-perceptions with a back-end usage log for 3 important metrics and found that participants tended to overestimate their time spent on the EHR. This finding provides a valuable contribution toward the methodology for studying physician burnout and demonstrates the need to combine self-reported perceptions with objective data sources.

The contribution of this study to the literature on physician burnout demonstrates the importance of increasing end-user satisfaction and minimizing end-user frustration with the EHR, both significant factors that were associated with burnout within the study population. The results of this study emphasize the value of developing *human-centered* effective strategies to improve physicians' experiences with EHRs, including efficient

communication about EHR upgrades. Measuring burnout and understanding the impact of EHR-related stressors within the study population serves as a strong baseline, allowing us to

measure the short- and long-term impact of multiple initiatives underway at our hospital aimed at reducing physician burnout.

Acknowledgments

The authors would like to acknowledge Thanara Rajakulendran for her work with content analysis for the open-ended survey data. The authors would also like to acknowledge the Centre for Addiction and Mental Health in Toronto, Canada, for their in-kind contributions to this work.

Authors' Contributions

DJ, TT, GS, and VS conceptualized the study. TT led the design of the survey and recruitment efforts for survey completion and analysis. JK developed data collection tools and managed the data. TT, GS, LS, and TZ drafted the manuscript and performed data analysis, along with the help of KR and MS. All authors edited and provided feedback on the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The benefits from the combination of 4 clinical information systems (CISs)—electronic health records (EHRs), health information exchange (HIE), personal health records (PHRs), and telehealth—in primary care depend on the configuration of their functional capabilities available to clinicians. However, our empirical knowledge of these configurations and their associated performance implications is very limited because they have mostly been studied in isolation.

Objective: This study aims to pursue 3 objectives: (1) characterize general practitioners (GPs) by uncovering the typical profiles of combinations of 4 major CIS capabilities, (2) identify physician and practice characteristics that predict cluster membership, and (3) assess the variation in the levels of performance associated with each configuration.

Methods: We used data from a survey of GPs conducted throughout the European Union (N=5793). First, 4 factors, that is, EHRs, HIE, PHRs, and Telehealth, were created. Second, a cluster analysis helps uncover clusters of GPs based on the 4 factors. Third, we compared the clusters according to five performance outcomes using an analysis of variance (ANOVA) and a Tamhane T2 post hoc test. Fourth, univariate and multivariate multinomial logistic regressions were used to identify predictors of the clusters. Finally, with a multivariate multinomial logistic regression, among the clusters, we compared performance in terms of the number of patients treated (3 levels) over the last 2 years.

Results: We unveiled 3 clusters of GPs with different levels of CIS capability profiles: *strong* (1956/5793, 37.36%), *medium* (2764/5793, 47.71%), and *weak* (524/5793, 9.04%). The logistic regression analysis indicates that physicians (younger, female, and less experienced) and practice (solo) characteristics are significantly associated with a weak profile. The ANOVAs revealed a strong cluster associated with significantly high practice performance outcomes in terms of the quality of care, efficiency, productivity, and improvement of working processes, and two noncomprehensive medium and weak profiles associated with medium (equifinal) practice performance outcomes. The logistic regression analysis also revealed that physicians in the weak profile are associated with a decrease in the number of patients treated over the last 2 years.

Conclusions: Different CIS capability profiles may lead to similar equifinal performance outcomes. This underlines the importance of looking beyond the adoption of 1 CIS capability versus a cluster of capabilities when studying CISs. GPs in the strong cluster exhibit a comprehensive CIS capability profile and outperform the other two clusters with noncomprehensive profiles, leading to significantly high performance in terms of the quality of care provided to patients, efficiency of the practice, productivity of the practice, and improvement of working processes. Our findings indicate that medical practices should develop high capabilities in all 4 CISs if they have to maximize their performance outcomes because efforts to develop high capabilities selectively may only be in vain.

electronic health record; personal health record; health information exchange; telehealth; general practitioners; quality of care; efficiency; organizational productivity

Introduction**Background**

Over the past several years, a consensus has emerged on the recognition of the potential of clinical information systems (CISs) to improve the health care delivered to patients and save lives [1,2].

Electronic health records (EHRs) are at the heart of the reform of health systems in many developed countries [3] as well as middle-income countries such as Brazil [4] or India [5]. An EHR can be defined as “an electronic record of health-related information on an individual that conforms to nationally recognized interoperability standards, and that can be created, managed, and consulted by authorized clinicians and staff across more than one healthcare organization” [6]. EHRs can “help address the dual problems of high costs and poor quality in health” [7]. For instance, EHRs can assist clinicians to improve the care provided to patients by promoting adherence to guidelines [8], improving medical practice management, saving time, and facilitating condition-specific queries, to name a few [9]. In the specific context of primary health care organizations or general practices, EHRs offer “a unique opportunity to collect a wide range of ecologically valid patient data to support understanding of disease burden and health trajectories over the life-course” [10].

Due to their potential benefits, previous decades have witnessed rapid growth in the adoption of EHRs in health care settings. However, despite considerable investments by governments, the adoption of EHRs in some primary care organizations has been slow, especially in small practices [11], and disparities have been observed in terms of benefits associated with CISs in primary care practices [12]. In addition, other researchers have underscored that the potential benefits of EHRs are limited when health information stored in the system is shared only within the host institution, which means that greater benefits will be realized if only health information is shared beyond the host institution [13,14] and the technology used to support such sharing is health information exchange (HIE). For this reason, the *Meaningful Use* program in the United States includes incentives for health care providers to participate in HIE [15]. Empirical evidence suggests that the exchange and sharing of patient data can decrease mortality, systemic costs, and utilization costs in the emergency department [13,16,17].

In addition to the abovementioned CISs (EHR and HIE), the personal health record (PHR) has recently been gaining attention because of its potential to support the transformation of health systems to a more patient-centered model of care [18] as well as its key role in patient engagement [19,20]. Indeed, patient engagement is recognized as a critical factor for improving the quality of care [19] and patient safety [19,21,22]. It is not surprising, then, that patient engagement measures and the sharing of health information between providers and patients are also key parts of the *Meaningful Use* program in the United

States [18,23]. Although the role of patients in the health care process is being increasingly recognized, Krist and Woolf [24] have pointed out that much of the energy of the health information movement has been devoted to the use of health information by clinicians, even though patients’ use of these technologies carries equal promise. One of the most effective ways to share electronic health data with patients is via PHRs.

Similarly, telehealth has been gaining attention because of its potential to reduce barriers to access health care and to save time and reduce costs for remote patients [25,26]. In addition, telehealth can “be clinically supportive and educative by facilitating contact with peers” and, in turn, education can enhance the quality of care provided to patients [27,28].

In conclusion, EHR, HIE, PHR, and telehealth can be considered the most important components of a modern and desirable CIS for both hospital and primary care practices. However, in previous research, these 4 CISs have been studied in isolation with little or no attention to their combination and associated implications for performance outcomes. A search in Medical Literature Analysis and Retrieval System Online (MEDLINE; March 2020) using the 4 terms, “*electronic health records*,” “*health information exchange*,” “*personal health record*,” and “*tele-health*,” in all fields yielded no hits. The same search performed in *Article title*, *Abstract*, *Keywords* in Scopus (March 2020) yielded no hits. We conclude that there is some evidence from which one can infer that the body of knowledge in the way capabilities associated with the 4 CISs empirically coexist to form *configurations* or *profiles*, and the associated implication for performance outcomes is very limited. Of note is the fact that most studies have investigated the 4 CISs in isolation, including their implications for performance outcomes. For instance, several current reviews have found ambivalent or no significant relationship between EHRs and performance outcomes in primary care settings [29,30]. For their part, Black et al [29] concluded that “there is a large gap between the postulated and empirically demonstrated benefits of eHealth technologies [such as EHR, HIE, PHR, and telehealth].”

This paper takes a configurational perspective. In a broad sense, configuration is defined as “any multidimensional constellation of conceptually distinct characteristics that commonly occur together” [31].

Following Miller [32]; Fiss, Marx, and Cambre [33]; and Delery and Doty [34], we argued that studying the configurations of CIS adoption by primary care practices will not only allow us to take a holistic view of the adoption of CIS by these organizations as it is these patterns or profiles of 4 CISs rather than single isolated CISs that are related to performance, but it will also help to reveal insights that would have been otherwise difficult to obtain. In addition, configuration approaches help to investigate *equifinality*—defined as a concept in which different primary care practice profiles with different configurations of CIS adoption arrive at the same level of the

outcome measure in terms of practice performance outcomes [35].

Objectives

This study has 4 primary goals. The first is to identify predictors of the adoption of clinical systems by general practitioners (GPs) in Europe. The second is to identify and characterize GPs by uncovering typical profiles or patterns of the combination of 4 major CIS capabilities: EHRs, HIEs, PHRs, and telehealth. Consequently, this second objective is inductive in nature, empirically based, and taxonomic, dedicated to classification and subdivision [36,37]. The third objective is to identify physician and practice characteristics that predict cluster or profile membership. Finally, given that the ultimate objective of investing in CISs is to improve the quality of care provided to patients while decreasing cost, the fourth objective is to assess the variation in levels of performance outcomes associated with practice in each configuration or profile.

Methods

Data Source and Sample

We used a data set provided by the European Commission (EC) from the 2018 survey of European GPs. The objective of this study was to understand and measure the actual adoption and use of information and communication technology (ICT) and electronic health (eHealth) applications by general practitioners (GPs) in the 27 countries of the European Union (EU27) as well as changes in uptake over time. The 2018 survey of European GPs was a follow-up study of the 2013 survey, which included the EU27 plus 4 other countries (Croatia, Iceland, Norway, and Turkey).

Given that this 2018 survey of European GPs was a follow-up of the 2013 survey, eHealth is broadly defined, as in the previous study, as “the use of Information and Communication Technologies (ICT) across the whole range of health care functions” [38]. The 2018 survey used the same methodological approach and questionnaire as the previous study. Data collection was based on a survey in the EU27 using mixed methodology (web-based; web CATI, where CATI stands for computer-assisted telephone interviews; and face-to-face) and was conducted between January and June 2018 [38,39]. The data collection process was endorsed by the European Union of General Practitioners. A detailed description of the methodological approach is provided only in the 2013 survey report. The EC team took several measures to ensure the representativeness of the sample. The details are provided in the Technical Compendium of 121 pages published by the EC and available to the public [38]. The identification of the universe of the survey was based on the definition from the World Organization of Family Doctors Europe that characterizes GPs in European countries as “specialist physicians trained in the specialty of primary care who ‘exercise their professional role by promoting health, preventing disease and providing cure, care, palliation and promoting patient empowerment and self-management’.” The universe was composed of 425,622 GPs [39].

The questionnaire was composed of 3 parts: (1) GPs’ sociodemographics, organizational settings, practice location, description of tasks, and workload; (2) ICT availability and use within a GP practice that is divided into 4 categories: EHRs, HIE, telehealth, and PHRs; and (3) attitudinal questions as well as questions related to motivations, perceived barriers, and impacts of ICT.

Following the previous 2013 survey approach, a final sample of 5793 GPs was randomly selected over the analyzed EU27, with an overall sampling error of plus or minus 1.30% [39].

Given that the 4 objectives of this study are related to CIS adoption and associated with the implications for performance outcomes, out of the initial sample of 5793 GPs, only the 5244 who had an EHR system and stored patient data electronically were considered for a subsequent analysis. Due to the presence of missing values in 3 variables (HIE, PHR, and telehealth), we applied a multiple imputation strategy. Among the 5244 subjects, 5022 (95.77%) subjects had complete data, 100 (1.91%) subjects had missing values on telehealth only, 72 (1.37%) subjects had missing values on PHR only, and the remaining 50 (<1%) subjects had other missing patterns.

We imputed the missing values using a multiple imputation procedure. On the one hand, multiple imputation methods perform better than single imputation ones. We selected the multiple imputation method of fully conditional specification with the Proc MI procedure in SAS software version 9.4 (SAS Institute) because of its flexibility in allowing us to define the multivariate model by a series of conditional models, one for each incomplete variable [40]. The 4 variables related to each CIS were chosen for the imputation model: EHR, HIE, telehealth, and PHR. For each of the 4 variables, we then chose regression because the regression model allows the specification of a minimum and a maximum value for imputed values on a variable-by-variable basis [41].

On the other hand, it is impossible to use multiple imputed data sets for cluster analysis as it produces different results of clusters, and it seems that there are no methods to combine these results. Therefore, we used the multiple imputation method as discussed but only chose *one* as the number of imputations. The final 4 variables used in the cluster analyses were the ones after imputations and then standardization: `xc_EHR_imp_std`, `xc_HIE_imp_std`, `xc_TeH_imp_std`, `xc_PHR_imp_std`.

Although the final 4 variables used for the cluster analysis were the ones with an imputation, we performed the same cluster analysis with the same variables without the imputation of missing values.

As stated earlier, the 549 GPs who did not store patients’ data electronically and those who did not have an EHR were excluded from the analysis. The final sample in our analysis was $5793 - 549 = 5244$ subjects. Table 1 compares the characteristics of the 549 and 5244 subsamples. Concerning the total sample ($N=5244$) composition in terms of countries, 8 countries represent a little less than 50% (49.77%) of the sample, each country accounting for about 5.54% and 7.15% of the sample, respectively. These countries include France, Italy,

Poland, Portugal, Romania, Spain, the United Kingdom, and the Netherlands.

Table 1. Characteristics of the respondents and their practices.

Variables, characteristics (ie, levels for categorical variables)	Nonsampled (n=549)	Sampled (n=5244)	Chi-square (<i>df</i>)	<i>t</i> test (<i>df</i>)	<i>P</i> value
Gender, n (%)					
Male	247 (45.0)	2652 (50.57)	62 (1)	N/A ^a	.01
Female	302 (55.0)	2592 (49.43)	62 (1)	N/A	.01
Age (years), mean (SD)	53.23 (10.35)	51.86 (10.82)	N/A	2.8 (5791)	.005

^aN/A: not applicable.

^bGPs: general practitioners.

Selection of Clustering Variables and Measurements

As recommended by Aldenderfer and Blashfield [42] and Hair et al [37], the selection of clustering variables is theory driven. The selection of variables was based on the fact that they have a common theoretical foundation—they relate to the functional characteristics or capabilities of 1 of the 4 CISs (EHR, HIE, PHR, and telehealth). Indeed, according to the diffusion of innovation theory (DOI) [43], the characteristics of innovation, such as the functional capabilities of CISs are important factors in explaining its adoption.

All clustering variables were dichotomous (1: available and 0: not available). In total, 44 dichotomous variables were selected based on their theoretical relationship; that is, they relate to the functional characteristics of 1 of the 4 CISs (EHR, HIE, PHR, or telehealth). We also used 5 measures of performance. Four measures (quality of care provided to patients, efficiency of the practice, productivity of the practice, and improvement of

working processes) were based on a 4-point Likert-type scale ranging from 0 (“strongly disagree”) to 3 (“strongly agree”), and 1 measure (number of patients over the last 2 years) of a categorical type with 3 categories (1: decrease, 2: remain the same, 3: increase)

A standardized average frequency or scaled frequency was computed for each group of variables, including CIS capabilities and performance, resulting in 8 scales. As presented in Table 2, in 7 out of 8 scales, the measurement of reliability is greater than 0.7 [44]. Although the reliability of telehealth was less than 0.7, we decided to keep this factor because Cronbach’s alpha is sensitive to the number of items in the scale and generally tends to underestimate the internal consistency reliability” [45] and “researchers can rely on less stringent reliability measurements for scales consisting of a few items” [46]. We then used standardized average frequencies as the clustering variables.

Table 2. Reliability of the scales.

Factors	Number of items	Cronbach alpha
Clinical system capabilities		
Electronic health record	19	.87
Health information exchange	15	.87
Telehealth	4	.59
Personal health record	6	.80
Performance measurement		
Quality of care provided to patients	6	.92
Efficiency of the practice	5	.89
Productivity of the practice	5	.83
Improvement of personal working practice	4	.80

The statistical analysis was performed in 3 parts: (1) cluster analysis, (2) ANOVAs With Tamhane T2 Post Hoc Tests, and (3) regression analysis.

Statistical Analysis 1: Cluster Analysis

As indicated earlier, we adopted a configurational approach that is taxonomic, based on cluster analysis [31,47]. General practices were classified to reveal patterns based on the available CIS capabilities related to EHR, HIE, PHR, and telehealth. Thereafter, we explored the influence of general practitioner and practice characteristics on the availability of the 4 components of CISs included in this study (EHR, HIE, PHR, and telehealth).

Broadly speaking, cluster analysis is a multivariate statistical technique that classifies items or objects (individuals, firms, or behaviors) from a given population into subgroups or clusters so that items that are classified in the same cluster are more similar to one another than they are to items in another cluster [37,48]. In doing so, the homogeneity of objects within each group is maximized, whereas the heterogeneity between the groups is maximized. Cluster analysis is a completely empirical method of classification that is inductive by nature [49]. Following previous research recommendations [48-50], our procedure was based on 2 steps that allowed the determination of the natural number of clusters in the data set, as it has been found to be more effective than other approaches in the ability to recover clusters. First, a hierarchical algorithm was employed to identify and define natural clusters and associated centroids. These centroids were then used as initial seeds in a nonhierarchical algorithm. Later, a discriminant function analysis was carried out [49] to validate the cluster solution. Several studies have used this technique to validate the results of cluster analysis [51,52].

It is important to remember that contrary to other statistical techniques such as regression analysis, which necessitate the satisfaction of the linearity assumption and have established rules for sample size calculation [53], no such assumptions are necessary for cluster analysis [54]. Given that this is a data mining technique, cluster analysis does not have *hard* sample size rules and does not need to satisfy parametric or even nonparametric statistical test assumptions [55]. Nonetheless,

Hair et al [56] underscored that “the sample size must be large enough to provide sufficient representation of small groups within the population and represent the underlying structure.” For their part, Formann [57,58] as well as Dolnicar [59] contend that there is a consensus that the minimal sample size for cluster analysis is 2^k observations (k =number of variables) to achieve sufficient power and confidence in the statistical analysis. In the same vein, Lowry et al [55], including Dolnicar [59], indicate that from a conservative perspective, the minimal sample must be no less than 5×2^k . In this study, $k=4$, which requires a minimum sample size of 80 to meet this criterion, which is obviously less than the sample size of this study ($N=5244$).

Determination of the Number of Clusters

The optimum number of clusters was determined by inspecting the dendrogram generated in the combination of the Ward minimum variance clustering algorithm and the squared Euclidean distance. This examination revealed that a 3-cluster solution would be optimal. To ascertain the reliability of the solution [48], the procedure was performed with different subsamples that were randomly selected (30%, 40%, and 60%). On the grounds of the preceding analysis, the 3-cluster solution was retained. It was the most meaningful and the one that best captured the patterns of the adoption of functional capabilities of EHR, HIE, PHR, and Telehealth among European GPs. The uncovered clusters formed significantly well-separated groups that had strong EHR, HIE, PHR, and telehealth functional capability adoption meanings. The 3 different patterns identified reveal how CIS capability priorities set at macrolevels (countries or EC), actually and empirically manifest at primary care levels.

It is worth recalling that cluster analysis was performed with and without the imputation of missing values. Of note is the fact that the results were similar with and without the imputation of missing values. As cluster analyses necessitate all variables to have nonmissing values, 740 observations were not classified in the analysis without the imputation of missing values. The two 3-cluster solutions were then compared to determine the degree of agreement among members of each cluster using Cohen kappa coefficient. The results reveal an almost perfect agreement between the two 3-cluster solutions with a kappa of 0.99 (kappa in the range of 0.80-1.00) [60].

Validation of the Cluster Solution and Multiple Discriminant Analysis

A multiple discriminant function analysis was performed following a cross-validation approach [37] to validate the 3-cluster solution and determine how the clusters differed on the 4 clustering variables portraying GPs based on EHR, HIE, PHR, and Telehealth functional capabilities [49]. Our discriminant analysis produced 2 functions with significant Wilks lambdas ($P < .001$). In addition, the hit ratios for the analysis and holdout samples were 95.90% and 94.70%, respectively. Two standard criteria were used to evaluate the accuracy of the hit ratios: the maximum chance criterion (C_{\max}) and the proportional chance criterion (C_{pro}) [45]. The last authors [45] underscored C_{\max} as the most conservative standard in that it will produce the highest standard of comparison. In this case, because the 3 clusters have different sizes, the C_{\max} is equal to 52.70%. Hair et al [45] suggested that the classification accuracy should be at least one-fourth greater than the accuracy of the classification achieved by chance ($1.25 \times C_{\text{pro}}$): $C_{\text{pro}} = 43\%$ and $1.25 \times C_{\text{pro}} = 53.75\%$. Overall, in a conservative view, both hit ratios are greater than maximum 1.25 (C_{pro} and C_{\max}). In conclusion, the null hypothesis (that the percentage correctly classified was not significantly different from what would be classified by chance alone) was rejected. Finally, from the distribution of the GPs along with the clusters' centroids in the plane of the 2 computed discriminant functions (ie, the scatter plot of GPs in the space of the 2 discriminant functions with the clusters' centroids), we were able to observe a complete separation of each one of the centroids from another along the 2 discriminant axes [61]. The evidence suggests that the discriminant functions performed very well in separating the 3 groups.

Although our empirically derived taxonomy appears to be meaningful, its quality is discussed in light of Rich [62] framework on requirements for a valid taxonomy: breadth, meaning, depth, theory, quantitative measurement, completeness, logic, and recognizability. Following the call by Dayer et al [63] to adapt the framework when applied to taxonomies created through cluster analysis, the assessment is based on 5 of the 7 initial criteria.

Breadth

The selection of clustering variables from which GPs were grouped was theory driven [37,42]. As stated earlier, the 18 clustering variables were selected based on their having a common theoretical foundation, that is to say, they pertain to the functional characteristics of 1 of the 4 CISs (EHR, HIE, PHR, or Telehealth), and previous studies have confirmed the influence of these clustering variables on the adoption of technologies [43,64,65].

Meaning

The resulting taxonomy is built on the broad foundations of the DOI theory [43], which acknowledges the complexity of the adoption of innovation and suggests that GPs should not be considered a homogeneous group when investigating the adoption of CIS capabilities. This theory supports the need for classification of the GPs adopting CIS based on the capabilities

they actually adopted. The resulting taxonomy highlights different clear priorities and routes to the adoption of the 4 major CIS capabilities.

Theory

The anchoring of the development of our taxonomy in the theory of DOI [43] provides a robust theoretical foundation that serves as a qualitative basis for GP grouping justification as well as variable selection and helps to describe and understand the adoption of the 4 major CISs (EHR, HIE, PHR, and Telehealth) at the medical practice level.

Quantitative Measurement

GPs were assigned to specific clusters or groups resulting from an inductive process based on empirical, multivariate data analysis as well as the application of ANOVA and post hoc analysis to enhance the validity of the results.

Recognizability

By deriving the taxonomy from the actual capabilities of the CIS circumscribed by each artifact (EHR, HIE, PHR, and telehealth technologies), we can claim that our taxonomy reflects the real world for both practitioners as well as theorists and depicts the actual landscape of EHR, HIE, PHR, and Telehealth adoption by GPs within the EU.

In a subsequent step, the 3 profiles (clusters) were compared according to 4 performance outcomes (quality of care provided to patients, efficiency of the practice, productivity of the practice, improvement of working processes) using an ANOVA and a Tamhane T2 post hoc test.

Statistical Analysis 2: ANOVAs With Tamhane T2 Post Hoc Tests

We used ANOVAs with Tamhane T2 post hoc tests to compare the 4 performance outcomes that were rated with a Likert scale: quality of care provided to patients, efficiency of the practice, productivity of the practice, and improvement of personal working practice.

Statistical Analysis 3: Regression Analysis

This analysis was performed in 4 steps. First, we used a regression model to identify the predictors of CIS adoption.

Second, for each of the following 6 characteristic variables, that is, 4 physician characteristics (gender, age, professional status, and years spent in general practice) and 2 practice characteristics (workplace location and practice size), a univariate multinomial logistic regression was conducted to analyze the effect of the characteristic variable on cluster membership.

Third, the multivariate multinomial logistic regression model was conducted with the 6 characteristic variables as independent variables and the 3-cluster solution as the outcome variable. This was used to analyze the effect of each characteristic variable on cluster membership, as shown in the first step, but controlling for the other 5 characteristic variables.

Fourth, the multiple multinomial logistic regression was performed to see if the cluster membership predicted the level of performance in terms of "the number of patients over the

past two (2) years” when controlling for the 6 characteristic variables.

Results

Characteristics of Adopters Versus Nonadopters of Electronic Storage of Patient Data

The logistic regression model indicates that compared with GPs who store patient data electronically, those who do not tend to be older in age, self-employed, working alone, with fewer years spent in general practice (Multimedia Appendix 1). Of note is

the fact that the odds ratios (ORs) for age and *years spent in general practice* are close to 1.

Empirical CIS Profiles of GPs

As shown in Table 3, the ANOVA *F* test is highly statistically significant for all 4 factors or groups of functional capabilities. In addition, the Tamhane T2 post hoc multiple pairwise comparison test revealed significant differences between the means of all 4 factors or groups of functional capabilities across the 3 clusters [66]. It is important to recall that, contrary to other tests such as the Tukey Honestly Significant Difference Test, the Tamhane T2 post hoc test does not assume equal variances.

Table 3. Capabilities profile and analysis of variance of clinical information systems.

Variables	Cluster			ANOVA ^a

^bN/A: not applicable.

^{c,d,e,f}Within rows, different superscripts indicate significant ($P<.05$) pairwise differences between means on Tamhane T2 post hoc test. *H*=high; *M*=medium; *L*=low.

Cluster I

The strong profile (n=1956) is the second largest of the 3 clusters and accounts for approximately 37% of the sample. Statistically, this cluster scored *high* in the pairwise difference between the means of all 3 groups for all 4 CIS capabilities. GPs within this cluster have a strong CIS capability profile and pay a great deal of attention to all 4 CISs, namely EHR, HIE, PHR, and telehealth. Thus, cluster I is named the *strong* CIS capabilities profile.

Cluster II

The moderate profile (n=2764) is the largest of the 3 clusters and accounts for approximately 53% of the sample. This cluster scored *medium* in the pairwise difference between the means of all 4 CIS capabilities. GPs within this cluster have an equally moderate emphasis on all 4 CIS capabilities. Thus, cluster II is named the *moderate* CIS capabilities profile.

Cluster III

The weak profile (n=524) is the smallest of the 3 profiles and accounts for approximately 10% of the sample. This cluster scored *low* in the pairwise difference between the means for 2 of the 4 CIS capabilities (EHR and HIE), whereas scoring *medium* for Telehealth and PHR capabilities. GPs within this cluster exhibit a focus on Telehealth and PHR capabilities, albeit with moderate strength. Thus, cluster III is named the *weak* CIS capabilities profile.

Predictors of CIS Profile Membership

Univariate and multivariate logistic regression analyses were performed (Multimedia Appendix 2) with CIS profiles as the outcome and 6 independent variables of physician and practice characteristics: gender, age, physician professional status, workplace location, years spent in general practice, and practice size). Of note is the fact that the outcome variable has 3 CIS profiles, and the odds in the Multimedia Appendix are to the *strong* profile as the reference.

Physician Gender

The multivariate model indicated that female GPs were more likely than their male counterparts to be in the *weak* (OR 1.52, 95% CI 1.24-1.87) or *moderate* profiles (OR 1.18, 95% CI 1.04-1.33) when controlling for other GPs' individual (age, physician status, and years spent in general practice) and practice (workplace location and practice size) characteristics.

Physician Professional Status

The multivariate logistic model indicated that the GPs working in a health center were less likely than the self-employed GPs working alone to be in the *weak* profile (OR 0.46, 95% CI 0.24-0.87) or *moderate* profile (OR 0.65, 95% CI 0.42-0.99) when controlling for other physicians and practice characteristics.

Similarly, self-employed GPs working in a group practice were found to be less likely than the self-employed GPs working

alone to be in the *weak* profile (OR 0.44, 95% CI 0.22-0.87). However, there was no association between the 2 professional status and membership in the *moderate* profile. The same result is obtained when comparing GPs working neither with a health center nor as self-employed GPs in a group practice with the self-employed GPs working alone in relation to membership with any of the nonstrong profiles.

Physician Age

The multivariate model indicates no association between physician age and membership in the *weak* profile. However, the multivariate model indicates that older GPs are less likely to be in the *moderate* profile, with the OR decreasing to 0.97 (95% CI 0.96-0.98) when controlling for other characteristics.

Years Physicians Spent in General Practice

The multivariate model indicates that senior GPs are less likely to be in the *weak* profile, with the OR decreasing to 0.97 (95% CI 0.96-0.99) when controlling for other characteristics.

The multivariate model also indicates that GPs with more years of practice are more likely to be in the *moderate* profile, with the OR increasing to 1.02 (95% CI 1.00-1.03) for each additional year spent in practice when controlling for other characteristics.

Workplace Location

The multivariate model indicates that GPs within a practice located in a medium- to small-sized city or in a rural town are less likely than those located in a large city to be in the *weak* profile, with OR 0.741 (95% CI 0.58-0.95) and OR 0.60 (95% CI 0.48-0.77), respectively. No significant relationship was found between GPs more or less likely to be in the *moderate* profile when comparing workplaces either between medium- to small-sized cities and large cities or between rural towns and large cities.

Practice Size

First, no association was found for membership to the *moderate* profile when comparing small practice groups with those working in a solo practice.

Second, between medium and solo, GPs working in medium-sized practice groups are less likely to be in the *weak* profile and the *moderate* profile than those in a solo practice, with OR 0.34 (95% CI 0.18-0.66) and OR 0.46 (95% CI 0.30-0.71), respectively.

Finally, between large and solo, GPs working in large practice groups are also less likely to be in the *weak* profile and the *moderate* profile than those in solo practice, with OR 0.37 (95% CI 0.19-0.69) and OR 0.37 (95% CI 0.24-0.56), respectively.

Comparison of CIS Profiles According to Practice Performance

As stated earlier, we used 5 measures of performance, including 4 based on a 4-point Likert-type scale (quality of care provided to patients, efficiency of the practice, productivity of the practice, improvement of working processes) and 1 variable of categorical type that is composed of 3 levels (1: decrease, 2: remain the same, 3: increase) related to the number of patients treated over the last 2 years.

The results in Table 4 indicates that the *strong* profile outperforms the other 2 in terms of the quality of care provided to patients, efficiency of the practice, productivity of the practice, and improvement of working processes. Surprisingly, however, the *moderate* and *weak* profiles do not differ from one another in terms of the quality of care provided to patients, efficiency of the practice, and productivity of practice, whereas the *moderate* profile outperforms the *weak* profile concerning improvement of working processes.

Table 4. Clinical information systems profiles and practice performance.

Variables	Cluster			ANOVA ^a	
	1	2	3	F test (df)	P value
Number of participants (n=5244), n (%)	1956 (37.30)	2764 (52.71)	524 (10.0)	N/A ^b	N/A
Performance^c					
Quality of care provided to patients	H: 0.18 ^d	M: -0.09 ^e	M: -0.20 ^e	53.7 (2)	<.001
Efficiency of the practice	H: 0.14 ^d	M: -0.07 ^e	M: -0.15 ^e	33.3 (2)	<.001
Productivity of the practice	H: 0.16 ^d	M: -0.09 ^e	M: -0.13 ^e	41.0 (2)	<.001
Working processes improvement	H: 0.18 ^d	M: -0.06 ^e	L: -0.37 ^f	73.1 (2)	<.001

^aANOVA: analysis of variance.

^bN/A: not applicable.

^{c,d,e,f}Within rows, different subscripts indicate significant ($P<.05$) pairwise differences between means on the Tamhane T2 post hoc test. H=high; M=medium; L=low.

A multinomial logistic regression model was used to test the association between the 3 profiles and the evolution of the number of patients treated over the past 2 years (a categorical-type variable with 3 categories, ie, 1: decrease, 2: remain the same, 3: increase) by controlling 6 characteristic

variables with *stable* level as the reference for the 3-category outcome variable (Multimedia Appendix 3). This model indicates that physicians in the *weak* profile are more likely to have experienced a decrease in the number of patients treated than those in both the *strong* and *moderate* profiles, with

OR 1.67 (95% CI 1.20-2.33) and OR 1.82 (95% CI 1.33-2.48), respectively.

Discussion

Over the past several years, scholars and policy makers have agreed on the unsustainable nature of the increasing trends of health care spending and investing in health information technologies is seen as a viable option in dealing with this threat. As a result, most countries of the Organisation for Economic Co-operation and Development have begun promoting and investing in CISs and making them one of their top priorities. In this context, 4 CISs have emerged as the most important: EHR, HIE, PHR, and telehealth. Although our knowledge of the 4 CISs has been advanced by several studies that have investigated their adoption and associated performance outcomes, the majority did so by considering the 4 CISs in isolation, which implies that our understanding of this complex phenomenon is still limited.

Using data collected by the EC through a survey of 5793 GPs conducted throughout the EU, this study sought to improve our understanding of the adoption of 4 CISs and the implications for performance outcomes. To the best of our knowledge, this study is one of the first to investigate the empirical configurations of the capabilities of the 4 most important CISs (EHR, HIE, PHR, and telehealth) in general practice settings. At the same time, we believe that the findings of this study provide several interesting insights for medical informatics research by confirming, extending, or challenging previous results, in addition to having important normative implications.

First, consistent with previous studies on the adoption of EHR [67,68] or HIE [69] in practice settings or ambulatory care, our results confirm that CISs are less prevalent among older GPs, working alone in solo practices. However, we found no association with gender, and our study revealed 2 surprising results that call for further investigations: (1) GPs with more years of experience are more likely to adopt electronic data storage. Of note is the fact that the prediction of *electronic storage of patients' data* by age and years spent in general practice was both weak, with ORs close to 1.0 of 0.97 and 1.02, respectively, and (2) GPs within a practice located in a medium-to small-sized city or a rural town are less likely than those in a large city to be in the *weak* profile.

Second, after measuring the capabilities associated with each of the 4 CISs, we empirically uncovered 3 theoretically meaningful and significantly well-separated configurations of profiles of CIS adoption by GPs. This result empirically confirms that CIS capabilities as organizational elements correlate in an understandable and stable way [31,70], and only a fraction of the theoretically conceivable configurations is viable and apt to be observed empirically [31].

Third, among the 3 profiles, one, the *strong* profile, outperforms the other two and leads to significantly high performance in terms of the quality of care provided to patients, efficiency of the practice, productivity of the practice, and improvement of working processes. Given that the *strong* profile scored high (H) and higher than the other 2 profiles on all 4 CIS capabilities,

the contrary would have been very worrying. Similarly, when compared in terms of *improvement of working processes* as a practice performance outcome, the *moderate* cluster that scored medium on all 4 CIS capabilities outperforms the *weak* profile. Although it seems obvious to expect the *moderate* profile to outperform the *weak* profile in certain ways, given the statistically significant differences in 2 CIS capabilities (of 4), the question remains as to why the expected performance gap manifests itself in exactly one performance indicator and why this indicator is *improvement of working process* and not the *quality of care provided to patients* or the *productivity of the practice* or the *efficiency of the practice*. Again, as expected, both the *strong* and *moderate* profiles outperform the *weak* profile in the number of patients treated over the past 2 years, but surprisingly, our results revealed no significant difference between the *strong* and *moderate* profiles (Multimedia Appendix 3).

Fourth, 2 counterintuitive pictures emerged from our results. First, when scrutinizing the *weak* profile, it can be noticed that this group displays a profile that seems to be reversed in terms of CIS capabilities. In fact, it exhibits a *low* score for EHR and HIE capabilities while exhibiting a medium score for telehealth and PHR. One would expect GPs to first build strong capabilities for EHR and HIE before considering the adoption of telehealth and PHR. Second, GPs in the *weak* profile deploy an overall set of CIS capabilities that seems to be inferior to the *moderate* profile, yet achieve *equifinal* performance outcomes [31,35]. More specifically, both profiles exhibit a *medium* score on 3 performance outcomes: *productivity of the practice*, *efficiency of the practice*, and *quality of care*. Following Gruber et al [71], who obtained similar results when linking small firms' capabilities to performance, we contend that these findings also suggest that configurations that lead to relatively higher performance outcomes for general practices in terms of the quality of care, efficiency of the practice, and productivity are not necessarily the inverse of those that lead to lower performance outcomes. It is important to remember that a general practice can be understood as a small firm.

This research contributes to the configuration literature by responding to a call for further empirical research on equifinality [35].

From a practical viewpoint, we contend that the resulting profiles of European GPs will assist policy makers to make sense of the general practice adoption of the 4 major CISs. As indicated in our study, GPs have been separated into "discrete and relatively homogeneous groups" [31] with different emphasis on EHR, HIE, PHR, and Telehealth capabilities, and unveiled associated practice performance consequences regarding five indicators. In particular, our results indicate that for a practice to maximize performance outcomes, it should develop high capabilities in all 4 CISs, because efforts to develop high capabilities on a selective subset may only be in vain, without any significant performance outcome to the point of being equivalent to developing inferior capabilities, at least concerning *quality of care provided to patients*, *efficiency of the practice* and *productivity of the practice*. Thus, policy makers should continue their efforts to stimulate the adoption of the 4 CISs among general practices while raising awareness

of the importance of achieving a *comprehensive profile*. In addition, given the laggardness of solo practices, it could be advised to define specific initiatives targeting this category of general practice.

By investigating the configuration of the 4 most important CISs and the associated implications for performance outcomes, this study explores a topic that has received limited attention until now. Hence, in interpreting our results, one should keep in mind some limitations. First, generalizability may be limited because our sample is composed of only European GPs. Second, there are intrinsic limitations due to the use of secondary data. In fact, we used a data set that was not collected to meet the specific objectives of this study. Third, even though the results of the

testing instrument reported in this study indicate high reliability for most scales, one out of the 4 scales measuring CIS capability (telehealth) has a reliability less than 0.6. In addition, even though the instrument has substantial face validity, it has not been subjected to formal psychometric assessment.

Given the paucity of studies that investigate the empirical configurations of the 4 CISs (EHR, HIE, PHR, and Telehealth) at either primary care practice or hospital settings, we encourage other researchers to build upon our results and investigate the configuration of these 4 CISs and the associated implications for performance outcomes in other regions, including hospital settings.

Authors' Contributions

The first author contributed to the conception and design of the study and drafted the first version of the manuscript. The third author performed the statistical calculations using SAS software. All authors reviewed and approved this study.

Abstract

Background: Information overload is affecting modern society now more than ever because of the wide and increasing distribution of digital technologies. Social media, emails, and online communications among others infuse a sense of urgency as information must be read, produced, and exchanged almost instantaneously. Emergency medicine is a medical specialty that is particularly affected by information overload with consequences on patient care that are difficult to quantify and address. Understanding the current causes of medical information overload, their impact on patient care, and strategies to handle the inflow of constant information is crucial to alleviating stress and anxiety that is already crippling the profession.

Objective: This study aims to identify and evaluate the main causes and sources of medical information overload, as experienced by emergency medicine physicians in selected National Health Service (NHS) trusts in the United Kingdom.

Methods: This study used a quantitative, survey-based data collection approach including close- and open-ended questions. A web-based survey was distributed to emergency physicians to assess the impact of medical information overload on their jobs. In total, 101 valid responses were collected from 4 NHS trusts in north England. Descriptive statistics, principal component analysis, independent sample two-tailed *t* tests, and one-way between-group analysis of variance with post hoc tests were performed on the data. Open-ended questions were analyzed using thematic analysis to identify key topics.

Results: The vast majority of respondents agreed that information overload is a serious issue in emergency medicine, and it increases with time. The always available culture (mean 5.40, SD 1.56), email handling (mean 4.86, SD 1.80), and multidisciplinary communications (mean 4.51, SD 1.61) are the 3 main reasons leading to information overload. Due to this, emergency physicians experience guideline fatigue, stress and tension, longer working hours, and impaired decision making, among other issues. Aspects of information overload are also reported to have different impacts on physicians depending on demographic factors such as age, years spent in emergency medicine, and level of employment.

Conclusions: There is a serious concern regarding information overload in emergency medicine. Participants identified a considerable number of daily causes affecting their job, particularly the traditional culture of emergency departments being always available on the ward, exacerbated by email and other forms of communication necessary to maintain optimal, evidence-based practice standards. However, not all information is unwelcome, as physicians also need to stay updated with the latest guidelines on conditions and treatment, and communicate with larger medical teams to provide quality care.

KEYWORDS

emergency medicine; information overload; physicians; national health care system

Introduction

Background

The concept of information overload has existed long before the term was first defined in the 20th century. The writer of Ecclesiastes 12:12 in the third century before Christ was complaining that “of making books there is no end.” In the first century, Anno Domini, the Roman philosopher Seneca noted how “the abundance of books is distraction” [1]. Hence, information overload has been experienced by people long before the appearance of today's digital gadgets and social media in the work environment and at home. Most people appreciate the freedom that comes with choice and the many channels of media that saturate the information world. However, a 2016 Pew Research Center survey [2] showed that around 20% of the American population experienced overload and unease in looking for information. According to this study, those with more access to the internet are more likely to express worries about information overload and report difficulty in finding the information they need. Moreover, many institutions such as government agencies, schools, banks, and health care services require a lot of data and information gathering from their customers to process their requests, which contributes to stress and anxiety [2]. In the United Kingdom, a recent survey conducted by TeleWare on 2000 employees revealed that 36% of employees admitted that they had wasted a lot of their working day attempting to resolve an issue where they have forgotten valuable information. A similar number (34%) explained that forgetting information has led them to deal ineffectively with customers, suppliers, or clients. Around a quarter have missed important deadlines (26%) or let their colleagues down (25%) because they did not have the necessary information in the front of their mind [3].

The idea of having every piece of information at hand in any given situation is undoubtedly tempting and, in critical working situations, mandatory [4]. However, this is becoming increasingly unrealistic because of the large volume of data and information. An understanding of the current situation may be gathered by setting information overload in the theoretical framework provided by Floridi [5], whose view entails the definition of 3 main periods in the advancement of humanity: *prehistory*, before recorded information; *history*, when society was aided by recorded information; and *hyperhistory*, where society is shaped and dependent on information and communication technologies. The spreading of the *onlife* human condition, whereby lives are lived both online and offline in an *infosphere*, mirrors the progression of society through hyperhistory. This drastic shift in how people perceive their existence has raised a number of issues, including information overload in a more contemporary, Information and Communication Technology (ICT)-centered lens.

This study aimed to explore the impact of information overload on emergency medicine physicians (EMPs) working across 4 National Health Service (NHS) trusts in north England. The

focus was to explore physicians' views on the impact of information overload, including the extent of the impact, whether it had increased, and whether any preventative measures were taken to address information overload. The cross-disciplinary research team included an EMP, 2 academics, and an NHS clinical effectiveness adviser who oversaw the study.

Literature Review

Information Overload in the Workplace

The concept of information overload became generally known in the early 1970s, after the publication of Toffler's book on society's deep organizational changes destined to cause shock and disorientation in people [6]. This initial idea of information overload refers to the difficulty a person can have understanding an issue and making errors caused by the presence of too much information. A later interpretation of the concept, in the 1990s, saw information overload defined as “occurring when the information processing demands on an individual's time to perform interactions and internal calculations exceed the supply or capacity of time available for such processing” [7].

Recent research has demonstrated how there cannot be a unifying definition of the concept, as the context in which it is used changes all the time [8,9]. There is however an agreement that information overload occurs when the information received becomes a burden rather than a help for users [10]. A survey conducted in 2016 by the Chartered Institute of Management Accountants showed how information overload was the main contributor to poor decision making in business globally [11]. Together with weakened decision making, information overload can also lead people to feel unnecessarily overwhelmed and stressed. Recent research has shown that people presenting with large amounts of information while performing search tasks tend to experience a sense of being overwhelmed and even display an increased heart rate, which leads to increased stress levels [12]. In the workplace environment, information overload can lead to a lack of engagement and loss of productivity [13-15]. The increase in mobile technologies has exacerbated this issue. The overload effects associated with the use of mobile information technologies in the workplace have become increasingly dominant and can translate into a considerable reduction in job satisfaction [16,17]. This is mostly because of the perception of immediacy that people have in connection with such devices. It is assumed that emails, text messages, and notifications should be read and answered quickly [18]. Several studies have demonstrated that training in an email or a social media protocol can be effective as a means to reduce information overload [9,19]. Interestingly, people of all ages and backgrounds are affected by this problem in every aspect of their working (and personal) life [9]. However, the same authors stated how the literature tends to focus on the workplace as a whole rather than on job specifications and particular skills required in certain occupations. The same view is shared by Kalman [20], who stated that “the workplace pressures attributed to information overload are very real, the concept itself is vague

and poorly defined.”. It is however worth noting that recent research has shown how information overload has the potential to enhance people’s cognitive abilities and help them process more information in less time, particularly if the right visualization tools (eg, charts and tables instead of text) are applied in the correct contexts [21]. There are benefits in assimilating larger amounts of information, and the human mind can adapt in time to the increased influx, but it is also bound to manifest side effects such as psychological disturbances and neurological problems along the way [22].

Information Overload and Health Care Professionals

When health care professionals experience information overload, at least one extra layer of concern must be taken into account: the consequence on patient care. Several studies have looked at the effects of information overload on nurses [23,24]; however, few have focused on information overload as experienced in general by health care professionals [25–27] and even less have approached the impact on patient care. Laker et al [28] argued how it could prevent practitioners from seeing the most important details while examining patients. Nevertheless, it is not the *right* information that is overwhelming, as that, if readily available at the point of care, would lead to effective patient care. It is the *background noise* information and other confounding factors (eg, multiple sources of information and conflicting or irrelevant information) that cause disruptions [29].

Klerings et al [27] agreed with this view and suggested solutions to overcome information overload and manage both health care information and patient care effectively. They mentioned different solutions based on the main overload trigger mechanisms, such as “technological solutions; creation or adaption of specific content types; improving health literacy; and creating or strengthening the roles of human intermediaries.”

Most likely, the situation is destined to get worse in this era of information expansion. As Yamamoto explained in 2016 [30], health care professionals are already overloaded by the information currently available, but the circumstances will worsen because of 3 key aspects: (1) the need to stay up to date from a technological and knowledge-based point of view; (2) the diversification of medical needs resulting in the growth of the medical practice; and (3) the rapid and constant changes in the health care environment. Digital technologies are proving to be both a curse and a blessing. On the one hand, they represent yet another source of—often unwanted information [31]—but, on the other hand, they can support physicians in the detection of adverse events and patients at risk of deterioration with the potential to improve health outcomes [32]. This is only achievable if, when planning and implementing digital information solutions in hospitals and clinics, factors such as the provision of clinical training, resources to cope with the additional workload, and optimization of algorithms to reduce superfluous alerts are taken into consideration [32].

In particular, emergency physicians are exposed to further burdens with the need for fast decision making [33], interruptions [34], multitasking [34], and highly variable workloads [35]. Emergency medicine is “a form of medical treatment and aid which seeks to treat unexpected, acute

illnesses that pose grave threats to life” [36]. The urgent dimension typical of emergency departments requires doctors to be constantly vigilant, highly reactive, and mentally lucid throughout often very long work shifts [37]. This highly pressurized environment leads to occupational stress, often with negative consequences for doctors’ mental and physical health and work efficiency, which can lead to mistakes in diagnoses and patient treatments [38]. Chronic workplace stress has been identified by the World Health Organization (WHO) as the leading cause of *burnout syndrome* [39]. According to the WHO, the syndrome is characterized by the following 3 main aspects: feelings of exhaustion, feelings of negativism toward one’s job, and reduced professional effectiveness [39]. A considerable body of literature has demonstrated that there is a higher prevalence of burnout among emergency physicians compared with other medical professions and specialties [36,40–42]. It is also evident that information overload plays a determinant role in exacerbating burnout in the medical profession [43,44]. However, only 1 study, conducted by Walton [45] on hospital doctors and pharmacists, has considered the impact of information overload beyond burnout on hospital medical staff. The complex setting in which emergency physicians act and operate requires a better understanding of the impact of information overload on their practice and its implications for both patient care, work efficiency, and work/life balance. To the authors’ knowledge, no empirical research has been conducted on information overload as experienced by EMPs specifically and according to different roles, age, and level of seniority; therefore, this paper hopes to serve as a pathbreaker for future studies.

Aim and Objectives

This study aimed to identify and assess the main causes and sources of medical information overload as experienced by EMPs. Specifically, the research objectives (ROs) were as follows:

1. RO1: Determine the extent to which EMPs experience medical information overload.
2. RO2: Establish the contributory factors to information overload and evaluate their impact on physicians’ working lives.
3. RO3: Identify the coping mechanisms adopted by EMPs to respond to information overload.
4. RO4: Explore whether EMPs at different career stages respond to information overload in different ways.
5. RO5: Determine the impact of physicians’ information overload on patient care.

Methods

Data Collection

The assessment of EMPs’ experience with information overload was undertaken using a survey-based primary data collection tool. This was a multicenter study covering 4 NHS trusts in north England, which had approached the staff in their emergency departments and asked them to complete a web-based survey over a period of 3 months in the summer of 2019. All eligible doctors from the trusts were sent an email inviting them to participate in the study. The opening page of

the survey included an information sheet and a consent form. Participants were not able to proceed with the survey unless they had ticked the consent option. The study followed the NHS Health Research Authority protocol and was granted both the NHS Research Ethics Committee and the University of Sheffield ethics approvals. The survey, designed using *LimeSurvey GmbH*, took approximately 10 min to complete and was divided into 2 main sections: the first related to demographics and the second addressing emergency physicians' views on medical information overload, opening with a definition of information overload to guarantee the homogeneity of interpretation. This section was composed of 42 Likert scale-like questions, comprising 2 overarching questions and 4 main aspects of information overload: (1) impact rating of individual information overload sources, (2) impact of information overload on specific work/life aspects, (3) preventative measures to manage information overload, and (4) useful sources of medical information. This part included statements such as "I feel that information overload significantly impacts on my work" and "E-mails I receive are a major contributing factor to my feelings of information overload" rated on a scale from 1 (completely disagree) to 7 (completely agree). There were also 7 open-ended questions to allow the respondents to elaborate on their opinions and perceptions. Most of the statements in the survey were extracted from a literature review conducted by Hall and Walton [8] and from a subsequent survey that one of the authors of this paper (GW) administered to hospital pharmacists and doctors in 2013 [45]. The remaining statements have been informed by 2 other authors (JW and JB) who are directly involved in emergency medicine and are aware of the current main sources of information overload in this sector. In total, the survey invite was sent to 263 physicians; 164 respondents participated with 101 recording full responses (38% response rate), which were then selected for analysis, as 63 records only contained partial demographic information and were deemed unusable.

Data Analysis

All data were saved in an IBM SPSS version 26 file for analysis. The dataset was initially inspected for errors and out-of-range values for each variable. The demographics were then produced

to profile the sample. Next, descriptive statistics were performed for the Likert-style questions in the main section of the survey; means and standard deviations were calculated for each of the statements. A principal component analysis (PCA) was performed on the survey statements related to the sources of information overload. Finally, independent samples *t* tests and one-way between-group analyses of variance (ANOVAs) with Hochberg GT2 post hoc tests were conducted to compare mean scores in relation to respondents' demographics (ie, the current level of employment, age, and the number of years in emergency medicine). The analyses performed in terms of gender and NHS trust did not show any differences between groups; hence, they are not reported here.

In addition, the open-ended questions and closing remarks were manually coded independently by 2 members of the research team using the 6-step approach to thematic analysis by Braun and Clarke [46].

Results

Sample Demographic Profile

This section provides a summary of the demographic characteristics of the respondents. The sample shows a relatively balanced distribution between doctors working as junior trainees (31/101, 30.7%), senior trainees (28/101, 27.7%), and consultants (29/101, 28.7%), whereas 12.9% (13/101) reported other types of working levels (Table 1). In terms of gender, 42.6% (43/101) were male and 56.4% (57/101) were female (only 1/101, 1%, did not indicate their gender). As for age, the majority (70/101, 69.3%) were between 20 and 39 years, with 30.7% (31/101) between 40 and 59 years. In terms of the period since respondents became EMPs, two-third (68/101, 67.4%) had been emergency physicians for 10 years or less. Finally, across the 4 NHS Foundation Trusts surveyed, 39.6% (40/101) of respondents were based at Leeds Teaching Hospitals, followed by Bradford Teaching Hospitals (24/101, 23.7%) and Airedale (23/101, 22.8%), whereas 13.9% (14/101) were based on North Tees and Hartlepool.

Table 1. Demographic data from the respondents to the survey.

Demographic characteristics	Values, n (%)
Age (years)	
20-29	24 (23.8)
30-39	46 (45.5)
40-49	18 (17.8)
50-59	13 (12.9)
Gender	
Male	43 (42.6)
Female	57 (56.4)
Prefer not to say	1 (1.0)
How long have you been an emergency medicine physician for? (years)	
<1	21 (20.8)
1-4	25 (24.8)
5-10	22 (21.8)
11-15	16 (15.8)
16-20	9 (8.9)
>20	8 (7.9)
What is your current level?	
Junior trainee ^a	31 (30.7)
Senior trainee ^b	28 (27.7)
Consultant	29 (28.7)
Other ^c	13 (12.9)
What NHS^d trust do you work for?	
North Tees and Hartlepool NHS Foundation Trust	14 (13.9)
Bradford Teaching Hospitals NHS Foundation Trust	24 (23.7)
Leeds Teaching Hospitals NHS Trust	40 (39.6)
Airedale NHS Foundation Trust	23 (22.8)

^aFoundation year, VTS, and ACCS.

^bST4-ST7, staff grade, and junior clinical fellow.

^cIncluding advanced clinical practitioner and associate specialist.

^dNHS: National Health Service.

RO1 and RO2: Emergency Physicians' Views on Medical Information Overload

Table 2 summarizes the responses to the Likert scale statements listed in the second section of the survey in terms of mean and standard deviation. The table reports the 2 general questions asked at the beginning of the survey, and the remaining statements were divided across the 4 main information overload aspects covered in decreasing order of importance. The results suggest that there is overall agreement among emergency physicians that information overload has an impact on their

work (mean 5.10, SD 1.25), and the problem has been increasing in time (mean 5.63, SD 1.34).

In terms of the sources that have the most impact on medical information overload, there is a wide range of mean values. Doctors listed the 24/7 culture (mean 5.40, SD 1.56), email handling (mean 4.86, SD 1.80), and, in equal measure, multidisciplinary communications (mean 4.51, SD 1.61) and local clinical guidelines (mean 4.50, SD 1.52). On the other hand, the information derived from patients (mean 3.29, SD 1.62), social media (mean 3.15, SD 1.88), and drug companies (mean 2.36, SD 1.50) does not pose particular concerns.

Table 2. Emergency clinicians' perspectives on information overload.

Statements ^a	VMean (SD)
To what extent does medical information overload impact your work?	5.10 (1.25)
To what extent do you agree that medical information overload has increased for you at work?	5.63 (1.34)
Impact of each of the following causes of medical information overload	
24/7 culture (ie, the <i>always available</i> workplace)	5.40 (1.56)
Email	4.86 (1.80)
Multidisciplinary communication	4.51 (1.61)
Local clinical guidelines	4.50 (1.52)
Info from employer/manager	4.43 (1.67)
Evidence-based practice	4.22 (1.57)
National clinical guidelines	4.21 (1.52)
Info to employer/manager (eg, as part of reporting activity)	4.14 (1.67)
Journal papers	3.41 (1.67)
Patients bringing information	3.29 (1.62)
Social media	3.15 (1.88)
Drug company information	2.36 (1.50)
How does medical information overload impact on the following aspects?	
Guideline fatigue	6.08 (1.56)
Stress and tension	5.25 (1.37)
Longer working hours	4.87 (1.70)
Impaired decision making	4.85 (1.57)
Imprecise clinical judgments	4.84 (1.45)
Tiredness/illness	4.81 (1.54)
Decrease in social life	4.26 (1.80)
What preventative measures do you adopt to combat information overload?	
Prioritization	6.07 (1.13)
Email handling skills (ie, ability to discriminate by importance)	5.39 (1.50)
Effective time management	5.30 (1.22)
Effective information management	5.23 (1.30)
Software/hardware	3.40 (1.81)
Information technology point of need delivery	3.13 (1.82)
Medical librarian	1.85 (1.32)
What sources do you find most useful when in need of medical information?	
Local clinical guidelines	6.13 (1.03)
National clinical guidelines	5.80 (1.09)
Colleagues	5.69 (1.34)
Evidence-based practice	5.14 (1.37)
Multidisciplinary communication	4.41 (1.49)
Journal papers	3.54 (1.39)
Patients bringing information	2.67 (1.56)
Social media	2.62 (1.65)
Medical librarian	2.60 (1.60)
Drug company information	2.17 (1.29)

^aAll statements were rated on a Likert scale from 1 to 7, and the values reported here are in decreasing order of importance.

Views on the consequences of information overload on different aspects of physicians' daily job and life show a more compacted set of values (less than 2 points difference between the top and bottom entries), indicating that all listed aspects are negatively impacted. Guideline fatigue is the leading consequence of information overload (mean 6.08, SD 1.56), followed by stress and tension (mean 5.25, SD 1.37). However, longer working hours, inaccurate decision making and clinical judgment, and chronic tiredness leading to illness also returned high mean values. Physicians also complained that information overload is detrimental to their personal and social lives (mean 4.26, SD 1.80).

RO3: Coping Mechanisms Adopted by Emergency Medicine Physicians to Address Information Overload

When it comes to the adoption of preventive measures to overcome information overload, prioritization is by far the most common approach (mean 6.07, SD 1.13), closely followed by email handling (mean 5.39, SD 1.50) and time (mean 5.30, SD 1.22) and information (mean 5.23, SD 1.30) management. Conversely, *external* support such as information technology (IT) and ICT and clinical librarians are not considered particularly effective.

In situations of actual need for medical information, both local (mean 6.13, SD 1.03) and national (mean 5.80, SD 1.09) clinical

guidelines are the 2 primary sources, which interestingly highlight the struggle doctors regularly experience. On the one hand, such guidelines are crucial to maintaining a critical level of medical knowledge, but, on the other hand, because of their sheer volume and constant updating, they represent the main cause of medical information overload. In this context, colleagues are also an important source of easily accessible and reliable medical information while on the ward (mean 5.69, SD 1.34). Patient information (mean 2.67, SD 1.56), social media (mean 2.62, SD 1.65), and drug companies (mean 2.17, SD 1.29) are considered irrelevant sources because of their unqualified or biased nature. However, medical librarians have also scored a low mean value (mean 2.60, SD 1.60), perhaps because their services were not considered to be of immediate relevance to emergency physicians' very fast case turnover.

PCA with direct oblimin rotation with Kaiser normalization was performed on the 12 statements addressing the main causes of information overload. The Kaiser-Meyer-Olkin value was 0.807, exceeding the recommended value of 0.6 [47], and the Bartlett test of sphericity reached statistical significance ($P<.001$), supporting the factorability of the correlation matrix. The analysis identified the presence of 3 factors explaining 42.2%, 12.2%, and 9.6% of the variance, respectively. Table 3 reports the factors and Cronbach α values calculated to assess the reliability of the scale.

Table 3. Exploratory factor analysis of factors relative to causes of information overload.

Factors/statements	Cronbach α
Factor 1: the dutiful physician	.800
24/7 always available culture	
Emails	
Information from employer/manager	
Information to employer/manager	
Multidisciplinary communications	
Factor 2: the informed physician	.842
Local clinical guidelines	
National clinical guidelines	
Evidence-based practice	
Factor 3: the current physician	.785
Journal papers	
Social media	

The first factor, named *the dutiful physician*, includes the potential sources of information overload that cannot be ignored or overseen as they form part of physicians' daily administrative tasks that must be undertaken in addition to direct patient care. These tasks are demanding and time-consuming. Regular reporting to and from line managers or employers and multidisciplinary communications are crucial to the smooth running of emergency departments and provide a more coordinated approach to patient care discharge planning [48]. Most of such communications are exchanged via email, which

becomes the main conduit of information overload, and are carried out at all times, hence exacerbating further the *always available* culture.

The second factor, named *the informed physician*, relates to physicians' need to stay up to date with the changes in guidelines, both at the local and national level and evidence-based practice on how health care professionals should care for patients with specific conditions, and which are based on best evidence practice. These guidelines help the standardization of care across NHS trusts and can be modified

to adjust to local needs to provide a cost-effective approach to care [49].

The third factor, named *the current physician*, includes additional sources of information overload that physicians experience on a regular basis in the form of notifications and which are mostly derived from scientific publications (eg, notifications of new articles, subscription invites, and electronic book updates) and social media. The respondents' comments on this aspect have shown how there appears to be an expectation that physicians, trainees in particular, cluster in online study groups and follow relevant Twitter handles such as #MedEd or #FOMed.

RO4: Information Overload Perceptions by Age and Years Spent in Emergency Medicine

Independent sample *t* tests have been undertaken on the bank of Likert scale statements in terms of age of respondents and

their experience in emergency medicine. All statistically significant results are reported in Tables 4 and 5. In terms of age (Table 4), younger physicians appeared less worried about their reporting activities (mean 3.89, SD 1.02) than older ones (mean 4.65, SD 1.11). Conversely, they are more affected by the loss in social activities because of information overload (mean 4.52, SD 1.31) as opposed to more experienced physicians (mean 3.68, SD 1.05). In addition, younger physicians reported a higher rate of impaired decision making (mean 5.19, SD 1.40) and imprecise clinical judgments (mean 5.12, SD 1.18) than their older colleagues (mean 4.07, SD 1.14 and mean 4.23, SD 1.37), who are still concerned about their performance but have greater experience to draw upon. Younger physicians also seem to rely more on local clinical guidelines (mean 6.28, SD 1.08) than older ones (mean 5.81, SD 1.23) to reduce decision fatigue.

Table 4. Independent samples *t* tests on the age of respondents.

Questions	<i>t</i> test (<i>df</i>)	<i>P</i> value	Mean difference	Age (20-39 years), mean (SD)	Age (40-59 years), mean (SD)	Total mean
Impact of info to employer/manager (eg, as part of reporting activity) on medical information overload	-2.109 (94)	.04	0.75	3.89 (1.02)	4.65 (1.11)	4.14
How does medical information overload impact on decrease in social life?	2.098 (51.011)	.04	0.84	4.52 (1.31)	3.68 (1.05)	4.26
How does medical information overload impact on impaired decision making?	3.304 (50.699)	.002	1.12	5.19 (1.40)	4.07 (1.14)	4.85
How does medical information overload impact on imprecise clinical judgments?	2.762 (49.767)	.008	0.89	5.12 (1.18)	4.23 (1.37)	4.84
What preventative measures do you adopt to combat information overload? Email handling skills (ie, ability to discriminate by importance)	-2.055 (70.489)	.04	0.61	5.19 (1.22)	5.81 (1.18)	5.39
What sources do you find most useful when in need of medical information? Local clinical guidelines	2.198 (60.325)	.03	0.47	6.28 (1.08)	5.81 (1.23)	6.13

In terms of years of experience in emergency medicine (Table 5), the only dissimilarity seems to relate to the impact and handling of work emails. Physicians with more than 10 years of experience identify the number of emails received as one of the main causes of information overload (mean 5.39, SD 1.19)

as opposed to physicians with less experience who scored a mean of 4.60 (SD 1.26) and hence attributed more importance to email handling skills as a way to manage the problem (mean of 6.03 and SD 1.15 against a mean of 5.06 and SD 1.13 reported for less experienced physicians).

Table 5. Independent samples *t* tests on the years spent in emergency medicine.

Questions	<i>t</i> test (<i>df</i>)	<i>P</i> value	Mean difference	Years of experience (0-10 years), mean (SD)	Years of experience (more than 10 years), mean (SD)	Total mean
Impact of emails on information overload	-2.134 (65.084)	.04	0.79	4.60 (1.26)	5.39 (1.19)	4.86
What preventative measures do you adopt to combat information overload? Email handling skills (ie, ability to discriminate by importance)	-3.166 (96)	.002	0.97	5.06 (1.13)	6.03 (1.15)	5.39

RO4: Information Overload Perceptions by Level of Employment

To conclude the quantitative assessment of the data collected, one-way between-group ANOVAs by the level of employment were also performed on the survey statements (Table 6). Across the 3 main levels populating emergency departments, senior

trainees and consultants are those acknowledging the increased information overload with time the most, possibly because of their longer service in hospitals. However, in relation to other aspects, senior trainees seem to experience the most difficulties. For example, in terms of the aspects of their work and life impacted by information overload, they complain about a decrease in social life and diminished decision-making abilities.

Table 6. One-way between-group analysis of variance on current level of employment.

Questions	<i>F</i> test	<i>P</i> value	Junior trainee, mean (SD)	Senior trainee, mean (SD)	Consultant, mean (SD)	Total mean
To what extent do you agree that medical information overload has increased for you at work?	5.798	.004	5.07 ^{a,b} (1.01)	6.07 ^a (1.02)	6.03 ^b (1.22)	5.63
How does medical information overload impact on decrease in social life?	3.249	.04	4.50 (1.27)	4.79 ^c (1.06)	3.72 ^c (1.36)	4.26
How does medical information overload impact on impaired decision making?	4.331	.02	5.17 (1.14)	5.36 ^c (1.14)	4.29 ^c (1.40)	4.85
What preventative measures do you adopt to combat information overload? Email handling skills (ie, ability to discriminate by importance)	9.223	<.001	5.47 (1.16)	4.67 ^c (1.18)	6.10 ^c (1.01)	5.39
What sources do you find most useful when in need of medical information? Social media	9.246	<.001	2.03 ^a (1.21)	3.59 ^{a,c} (1.02)	2.23 ^c (1.19)	2.62

^aJunior trainee versus senior trainee.

^bJunior trainee versus consultant.

^cSenior trainee versus consultant.

In addition, whereas for consultants, the ability to effectively manage work emails is crucial to handle, at least partially, information overload (mean 6.10, SD 1.01), senior trainees are the least concerned about this aspect (mean 4.67, SD 1.18). Finally, although the use of social media as a source of medical information is not a very popular choice among emergency physicians in general, senior trainees use them significantly more than the other 2 groups, with a mean of 3.59 (SD 1.02),

as opposed to 2.03 (SD 1.21) for junior trainees and 2.23 (SD 1.19) for consultants.

Qualitative Analysis of Open-Ended Questions

The survey contained several open-ended questions and, although they did not form part of the compulsory sections, still attracted a considerable number of spontaneous and insightful comments.

In terms of the length of time physicians have been experiencing information overload, 39.6% (40/101) claimed that the phenomenon had increased in the last 5/6 years; 10.9% (11/101) confirmed that it started before that, about 10 to 15 years ago; and 14.9% (15/101) did not specify a date but listed aspects such as progressing in their career, noting how the pressure shifted from night shifts only to an all-time problem and overload worsening once the email was firmly established within

the NHS. Around 3.0% (3/101) felt that they did not have enough experience to judge the problem, and the remaining respondents did not comment.

The remaining comments revolved around 2 main themes (Table 7), specifically, the ways in which medical information overload impacts physicians' work and various preventative measures to overcome information overload. The 5 subthemes identified within each of the 2 main themes are discussed below.

Table 7. Overview of the themes and subthemes emerging from open-ended questions.

Theme and subthemes	Strands
Ways in which medical information overload impacts on clinicians' working life	
1. Positive impact	
2. Direct causes leading to reduced patient care	Reverse views
	Impact on patients
	Distraction and forgetfulness
	Confusion
	Delayed decision making
	Tiredness, stress, and anxiety
3. Indirect causes leading to reduced patient care	
	Lack of time
	Email handling
	Information and communication technology systems
	Breadth of information
	Guidelines and evidence-based practice
	Ability to stay up to date
	Seniority
Preventative measures to combat information overload	
4. Personal attitudes	Avoidance
	Therapy
	Work-life balance
5. Workload management	Email and social media management

	Time management
	Prioritization
	Delegation

RO5: Ways in Which Medical Information Overload Impacts Physicians' Working Life

1. Positive Impact

A total of 3 respondents, all of them consultants, admitted that information overload was indeed present in their working life

but did not represent a hindrance to their performance (*reverse views* subtheme):

It doesn't. You do have to be discerning about where you get information from and use trusted sources though.

Increase in research is interesting and gives more confidence in decision-making. I find this is helpful rather than a hindrance.

The more information I have the better I can do my JOB!

The majority of respondents however did not agree with this view and listed a series of impeding aspects, which can be divided into direct and indirect causes leading to a reduction in patient care.

2. Direct Causes Leading to Reduced Patient Care

Among the direct causes, concerns for the well-being and quality of care of patients (*impact on patients strand*) were the most mentioned and most concerning for the physicians:

On a busy shift on the shop floor when there are competing priorities for my attention, increasingly feel that this means if I try to see my own patients then I either give them poor care or lose control of the department.

Slow decision-making, increased risk of errors.

This continuous feeling of apprehension and an impending sense of loss of control are accompanied by *distraction and forgetfulness*, which was the second most reported issue (strand) caused by information overload and can be summarized in the quote below:

I have a significantly higher background level of anxiety at work due to concerns about giving poor advice or forgetting something important due to the volume of information I am trying to process. I find the non-shop floor information much less of a problem.

Other strands, such as *confusion* with the information received, *delayed decision making* and *tiredness, stress, and anxiety* were mentioned in equal measure as contributing to a potentially reduced patient's quality of care:

Toward the end of the shift my answers take longer to arrive at, I feel like I am even more risk averse and at times feel like I am can become short with staff asking for help.

During busy environments if documents/protocols contain too much information I may struggle to pick up salient points.

3. Indirect Causes Leading to Reduced Patient Care

Among the indirect causes of information overload, leading to a reduced quality of patient care, *lack of time* to review the information properly was reported as one of the most serious problems:

Huge amount of information coming in and little time to process and implement any actions needed.

Not enough time to document all relevant information consistently.

Email handling and problems with ICT systems were reported as common, overpowering, and frustrating:

Email mainly - almost overwhelming.

Vast numbers of irrelevant or barely relevant emails containing information which will be forgotten immediately as it concerns rare circumstances or conditions never before experienced (and therefore poorly understood).

Multiple IT systems with different passwords and access. Constant emails - usually not relevant. Feel overwhelmed by the day to day IT so I don't want to access online resources to broaden my knowledge.

Moreover, 3 additional strands, namely *guidelines and evidence-based medicine, ability to stay up-to-date, and breadth of information*, are related to the need to be informed that physicians experience on a daily basis [50] and are difficult to address in an environment overloaded with what seems like irrelevant information:

I feel I am unable to keep up to date with the multitude of clinical guidelines from NICE, the college...only exacerbate by looking at Tweeter!

The number of guidelines/policies that now exist both locally and nationally - it is hard to keep track of all of these.

Finally, *seniority* was also mentioned as a hindering factor contributing to information overload, as more junior staff and nurses (and patients) tend to direct their queries and doubts to the more experienced physicians:

More difficult out of hours/weekends when I am the only senior decision-maker in the department. If working with a good registrar this can lessen the impact but if working with a less experienced middle grade all questions/information comes through me.

Questions from juniors and other colleagues.

Lots of questions asked throughout shift from nurses to other doctors.

Preventative Measures to Combat Information Overload

When it comes to addressing and solving the problem of information overload in effective ways, respondents suggested solutions that can be classified into 2 subthemes: *personal attitudes* and *workload management strategies*.

4. Personal Attitudes

As part of the individual attitudes observed, some physicians simply ignored the problem (*avoidance strand*). Some other physicians adopted a very pragmatic approach and had no difficulties recognizing their own limits:

When I am at work and feeling overloaded, I step away from the situation.

Learn to ignore.

Acceptance that you can't do everything.

Psychological stress is increasingly recognized within the medical profession, particularly in emergency medicine [51], and some respondents prefer to rely on formal support in the form of *therapy*:

Therapy - I have had CBT sessions and NLP sessions to help me deal with the stress and anxiety information overload gives me and to gain strategies regarding how to cope with this.

I take little steps and with the help of my therapist I try not to compare myself negatively to others.

Others preferred to self-manage and find a more balanced relationship between working and personal life (*work-life balance* strand), although often long shifts and complex working patterns make this option fairly difficult to attain:

My days off are for fun and time away - I do not work on days off. I avoid seeing colleagues on these days who talk about work when they are not there.

I feel a lot of the 'critical information' I need for my day to day job is limited - especially while trying to revise for exams, the need to switch off and rest is very important.

5. Workload Management

Physicians have also indicated a number of strategies to manage information overload that are more strictly linked to practical workload management and dealing effectively with emails and social media (*email and social media management* strand). This appeared to be a priority for many respondents:

When I am not at work or feeling overloaded I ignore my e-mails and mute my social media accounts.

Nil work emails on phone mute work WhatsApp groups when on leave no longer active on Facebook at all due to general overload but also work based groups.

This was followed by strategies to address *task and time management* in an effective and sustainable way:

Keeping a to-do- list booklet.

Summarising things. Writing things down properly helps consolidate my head.

Finally, *prioritization* and *delegation* were also mentioned as effective ways of managing information overload, particularly at times of crisis:

Prioritisation and having some "IT free" time is vital.

Delegation of clinical supervision.

Discussion

RO1: Determine the Extent to Which Emergency Medicine Physicians Experience Medical Information Overload

Both quantitative and qualitative data have shown that emergency physicians are deeply affected by an ever-increasing amount of medical information impacting every aspect of their job. The 24/7 (or *always available*) culture places itself firmly at the heart of the problem, as identified by Walton [45], and leads to problems with fatigue and, consequently, with performance, productivity, and safe decision making [52]. All these aspects have been highlighted by physicians in this study as being compromised not just by the very fast-moving pace

typical of their job, but by the constant and relentless information received and the information requested from them. What emerged very clearly from this study is the difficulty in striking a balance between the need to maintain an acceptable and current level of knowledge and the ability to sift and discriminate through large amounts of irrelevant information. There are valid arguments supporting both the benefits of information overload and its drawbacks. A small outlier group of respondents composed of 3 consultants claimed how there was no such thing as information overload as a negative attribute of their job. They see information as an opportunity to learn, as observed by Falschlunger [21], and increase their confidence in their decisions, in line with the *freedom of choice* described by Brehm and Brehm [53] and De Angelis [54]. However, the majority of physicians perceived information overload as a negative concept hindering their ability to process information effectively and accurately [55]. The migration toward *big data* handling by health care professionals because of the information expansion phenomenon described by Yamamoto [30] is also reflected in this study as physicians are faced with multiple evolving environments. The increasing number of emails and social media notifications received daily and regular updates in policies and evidence-based practice, coupled with new or updated IT systems to keep abreast of, will all contribute to feelings of inadequacy and frustration. Unless controlled and harnessed, such feelings, in the long term, can lead to *burnout syndrome*, which is very common among all types of health care professionals [43,44]. It is difficult to establish when physicians have started experiencing the burden of information overload in their careers. It appears that consultants and people working in emergency departments the longest have noticed a steady increase, made sharper since the ready access to internet-based resources and emails started over 20 years ago. This is in line with findings by Roetzel [56], who reported how the research around the 1980s and, particularly, the 1990s coincided with the rise and spread of information technologies. However, for most, the problem started to take shape with the advent of mobile platforms and the deployment of electronic health record systems in NHS trusts in 2005 [57].

RO2: Establish the Contributory Factors to Information Overload and Evaluate Their Impact on Physicians' Working Life

The leading causes of information overload in emergency physicians are multiple, and it is often difficult to discriminate among them because of their interlinked nature. The PCA conducted on the survey statements revealed 3 main factors contributing to information overload. The main factor leading to the concept of *the dutiful physician* is the administrative tasks physicians must carry out as part of their daily routine, such as reporting, responding to emails, and communicating with the other physicians forming a patient's care team. This study has reported an increased burden because of email handling compared with Walton's [45] research on hospital doctors, leading to the conclusion that, in the last 6 years, since that study was published, the number of emails has significantly increased as part of physicians' daily duties. It is also clear that administrative tasks are one of the main causes of physicians' burnout syndrome [58] because of their persistent and repetitive

nature. However, physicians are also aware of the importance of carrying out such tasks for the smooth running of the ward and the good care of patients [26]. A second set of causes deeply affecting physicians' perceptions of information overload is linked to the consultation of local and national clinical guidelines. Ironically, such guidelines, as important as they are to guarantee patients' consistency of care, are also a burden to health care professionals because of their frequent updates and notifications. On the one hand, physicians must remain current (ie, *the informed physician*) and follow the policies and directives reported in the guidelines to guarantee the quality of patient care, but on the other hand, the pressure of being up to date and making sure nothing is overlooked plays a considerable role in increasing physicians' stress [59]. A third factor contributing to information overload entails the number of notifications and alerts received mostly via social media, but also from journal editors and publishers and regarding new medical approaches, clinical trials, discoveries, and case studies (*the current physician*). These sources have registered a significant increase since Walton's study [45] in 2014, likely because of the current much wider diffusion of social media platforms in all aspects of society. Once again, physicians experience an internal dispute about when to start ignoring such alerts. Maggio and Artino [59] believe that medical librarians could help battle physicians' information overload and help them navigate through the various systems and social media, but they are not utilized as much as they should, a conclusion corroborated by this study, where librarians score among the least useful sources of medical information (Table 2). However, regardless of the causes of information overload, the consequences can be summarized as directly or indirectly leading to reduced patient care, which will be discussed further below.

RO3: Identify the Coping Mechanisms Adopted by Emergency Medicine Physicians to Respond to Information Overload

To help mitigate information overload, physicians have devised strategies for managing and filtering available medical information. The results of this study have shown similar results and led to the conclusion that information overload prevention and mitigation are left entirely in the hands of individuals and their personal views and preferences. A number of actions are taken from a pragmatic point of view (workload management) quite regularly, but with varying degrees of success. Among the most common approaches, email and social media handling skills are highly desirable, considering the steadily growing amount of communication, including patient information, passing through these tools [60]. Strictly linked to this is also the ability to prioritize tasks (including emails and social media), appearing very high in the list of possible solutions, particularly in situations of multiple concurrent demands [33], which are common practices in emergency departments. Prioritization is a skill developed with time and experience [61], in situations of high demand and variable workload [34], and is particularly popular in emergency departments. Task, time, and information management are other measures frequently adopted by physicians to overcome medical information overload and can take the form of simple actions, such as keeping daily and

weekly to-do lists, maintaining written records, timing actions, summarizing information, or key articles to help consolidate knowledge. Although most of the above points were identified by Walton [45], in this study, their importance is stressed further, and new approaches have emerged, including those dictated by personal attitudes. These play an important role in determining how people deal with information overload. This study has highlighted a few approaches, although not all adopted with the same conviction. A small group of respondents admitted that the easiest way is to ignore circumstances or demands when feeling overloaded, which is not necessarily a positive action to undertake, particularly in emergency care. This is symptomatic of the difficulty and pressure physicians are subject to and is a common self-preservation mechanism triggered by overwhelming situations [62]. Other people have mentioned formal therapy and a better work-life balance in which working and private life are kept separate, and personal time is seen as an opportunity to regain strength and stability. These approaches are not new, nor specific to emergency physicians, as they are common to most workplaces [11,19], but it would be advisable to integrate them with formal training on the job and regular sessions on developing coping skills.

RO4: Explore Whether Emergency Medicine Physicians at Different Career Stages Respond to Information Overload in Different Ways

This part of the study offers a new viewpoint of medical information overload drawn from physicians' experiences at different times in their careers and highlights deeply diverse perceptions and needs.

The study revealed an overall homogeneity of perceptions of medical information overload, in the sense that most respondents agreed on its increasing presence, size, and impact. However, some specific aspects showed differences in responses depending on the seniority of the physician. For example, people who have been in emergency care for 10 years or longer appeared to resent the increased number of emails received and attributed more importance to the ability to handle them than people who have been working in emergency care for less than ten years. This is also in line with the independent sample *t* tests conducted on the age of the respondents and with the ANOVA tests conducted on the level of employment. However, younger physicians and trainees appeared to be more worried about the loss in social life, impaired decision making, and imprecise clinical judgment than older colleagues and consultants. The literature demonstrates that junior clinicians have higher levels of anxiety because of uncertainty than senior clinicians [63,64], and this is reproduced in this study because of the additional stress of information overload. In particular, it appears that senior trainees are the most concerned about this problem and are the most affected by it, particularly with respect to impaired decision making. A recent study on Canadian emergency medicine residents [65] revealed how junior trainees are properly supervised and supported, but when they then become senior trainees, they lose most of that support and are left to fend for themselves. In addition, senior trainees are at a very demanding stage in their career, where they are preparing for independent practice [66] and are entrusted with more complex decisions

than ever before. This is bound to contribute to an increased sense of unease and frustration when it comes to information overload.

RO5: Determining the Impact of Physicians' Information Overload on Patient Care

Compromising the quality of patient care represents the ultimate consequence of medical information overload and rests at the forefront of physicians' thoughts. The qualitative responses in this study reported on the physicians' perceptions of the problem and showed how slow decision making because of information overload and frequent interruptions can lead to substandard care and errors in diagnoses and prescriptions. In addition, remembering patient diagnostics and medical history becomes difficult throughout a shift because of the large amount of information acquired about other cases and other confounding factors [28]. The fast turnover of emergency departments implies that there can often be a queue of people waiting to speak to a physician, who frequently does not manage to action one of these requests before others come in, hence compromising patient safety [32]. Among the effects of information overload mentioned by the respondents, distraction and tiredness play a key role. Physicians experience a higher background level of anxiety at work because of concerns about giving poor advice or forgetting something important because of the volume of information they are trying to process. This is exacerbated by long shifts, which can leave physicians both mentally and physically drained [43,44]. In critical situations, finding the right information fast is essential, but information overload can prevent this. Some respondents have been struggling with the correct information they should follow, as sometimes a lot of vague or unclear guidelines or advice can be worse than none at all, whereas others complained that documents and protocols contained so much information that it was difficult to discern salient points. In addition to this, other less obvious causes can still lead to poor patient care, particularly the ubiquitous nature of digital technologies, which provoke conflicting feelings among health care professionals. They are perceived as intrusive and time-consuming, but also as an important resource of clinical information, particularly when dealing with emergencies [31]. A recent study by Laker et al [28] introduced the concept of *emphasis framing* to aid health care professionals toward a more focused approach to decision making. This cognitive process could help in identifying the most relevant components of any piece of information while discarding the rest. For example, physicians could be directed toward article abstracts rather than full papers or be alerted to an incorrectly entered value for a medication prescription. The study reported an increase in clinical decision-making time through this approach, but also a significantly improved quality of medical decisions. Although a lot of work needs to be done to properly assess the real benefits of emphasis framing and how to implement it in real-world workflows, it is a research direction worth exploring further.

Conclusions

This study reported on the high and ever-increasing medical information overload in emergency medicine departments in the UK NHS trusts. Among the many factors listed by physicians

as influencing information overload, the historical emergency medicine culture of being constantly available throughout a shift (24/7 culture), email, and multidisciplinary communications have been mentioned as being the most severe. However, different levels of employment, experience in emergency medicine, and age also seem to influence physicians' perceptions of the leading causes of information overload. Nevertheless, some information is critical to guarantee high standards of patient care, particularly those derived from clinical guidelines.

This study advances previous research on information overload in 4 distinct ways: (1) by identifying the current causes affecting UK emergency medicine while also recognizing key information sources; (2) by offering insights on how information overload affects physicians in relation to demographic factors such as age, years spent in emergency medicine, and level of employment (ie, seniority); (3) by identifying mechanisms that emergency physicians put in place to manage information overload; and finally (4), by categorizing influencing factors in terms of their impact on patient care and reports on preventative measures currently in use to combat information overload.

However, this study is also subject to the following limitations: (1) although survey is an effective method to receive responses from a large number of participants and to explore relationships between variables, it might be less effective to answer complex questions such as user perceptions of information overload, contributing factors, and coping mechanisms, particularly when limited previous studies were conducted on this topic and with this particular user group; (2) the sample size is limited, although studies conducted on health care professionals are usually affected by this problem; (3) some of the variables listed as potential sources of information overload can be difficult to uniquely discriminate from each other (eg, emails may include clinical guidelines, employer information, and patient information), but the survey wanted to offer both information content aspects and information source channels; and (4) the study was only able to assess physicians' *perceptions* on the impact that information overload has on the quality of patient care. To attain an objective measure of such impact, different indicators would have been needed to allow for a direct correlation between patients' health outcomes and physicians' information overload.

This study has identified further research areas that could be worth taking forward to provide a more in-depth and more informed insight into information overload. The 24/7 culture, multidisciplinary interactions, and the pressure of following relevant guidelines are aspects specific to the emergency medicine profession and must be addressed to relieve physicians. Further investigation could determine the influence of professional boundaries on such aspects. A consistent thread in the findings was the contribution made by email in increasing information overload. This was an interesting outcome where it could be assumed that social media as a communication channel was taking the place of email. This would point to the value of a more detailed exploration, specifically on email and information overload. An area of concern that this study established was the interrelationship between clinical guidelines and information overload. By establishing how clinical guidelines make this contribution, it is possible to determine

how presentation, style, and format could be adapted to make them more accessible.

NHS trusts in the United Kingdom should consider some of the strategies adopted by the physicians participating in this study

to reduce the burden of information overload (eg, prioritization) and try to embed routine training or guidance on time and information management skills in staff development programs.

Abstract

Background: Over the last two decades, patient review websites have emerged as an essential online platform for doctor ratings and reviews. Recent studies suggested the significance of such websites as a data source for patients to choose doctors for healthcare providers to learn and improve from patient feedback and to foster a culture of trust and transparency between patients and healthcare providers. However, as compared to other medical specialties, studies of online patient reviews that focus on dentists in the United States remain absent.

Objective: This study sought to understand to what extent online patient reviews can provide performance feedbacks that reflect dental care quality and patient experience.

Methods: Using mixed informatics methods incorporating statistics, natural language processing, and domain expert evaluation, we analyzed the online patient reviews of 204,751 dentists extracted from HealthGrades with two specific aims. First, we examined the associations between patient ratings and a variety of dentist characteristics. Second, we identified topics from patient reviews that can be mapped to the national assessment of dental patient experience measured by the Patient Experience Measures from the Consumer Assessment of Healthcare Providers and Systems (CAHPS) Dental Plan Survey.

Results: Higher ratings were associated with female dentists ($t_{71881}=2.45$, $P<.01$, $g=0.01$), dentists at a younger age ($F_{7, 107128}=246.97$, $P<.001$, $g=0.11$), and those whose patients experienced a short wait time ($F_{4, 150055}=10417.77$, $P<0.001$, $g=0.18$). We also identified several topics that corresponded to CAHPS measures, including discomfort (eg, painful/painless root canal or deep cleaning), and ethics (eg, high-pressure sales, and unnecessary dental work).

Conclusions: These findings suggest that online patient reviews could be used as a data source for understanding the patient experience and healthcare quality in dentistry.

KEYWORDS

dental care; healthcare quality; consumer health informatics; patient online reviews; patient review websites; natural language processing

Introduction

Over the last few years, patient review websites have gained increasing interest among health consumers, academic communities, and healthcare providers [1,2]. A tremendous amount of online patient reviews were shared with the public through patient review websites, becoming a common source of information for patients choosing a doctor. Accordingly, a growing body of literature in online patient review studies has been developed using public health informatics methods to leverage the distribution and determinants of data for informing public health and public policy, coinciding with the Research Framework of Infodemiology and Infoveillance [3].

Despite debates on whether patient-generated reviews would be useful to improve healthcare quality [4-6], online reviews could serve as a valuable data source for understanding patient experience and the patient-provider relationship, and present unique values in improving dental care. Online reviews play an increasingly important role in health consumers' decision-making for choosing dental services [7,8]. A recent national survey reported that 59% of respondents recognized the importance of patient review websites, 35% selected a doctor based on good ratings, and 37% avoided selecting a doctor based on bad ratings. Nearly 90% of the respondents rated listings of accepted health insurance on review sites as high importance [2]. Online patient review studies also found strong associations between ratings and doctor characteristics, such as gender, age, years of practice, online presence, and medical education and training, with variations at specialties [1,9].

Online reviews are also rich in data on the patient experience, a critical measure of healthcare quality [10]. The notion of patient experience includes the entire scope of interactions, from appointment scheduling and access to information to communications with clinicians, cost, and payment. Positive patient experience is associated with better prevention and treatment adherence, safer healthcare outcomes, and better utilization of healthcare resources [11-15]. Incorporating data from the patient experience is also consistent with the principles of patient-centered care [10], as well as the goal of public reporting and the performance-based payment model set by the Centers for Medicare and Medicaid Services (CMS) [16].

Online patient reviews can inform better decision-making among patients and can be used to improve healthcare quality. As such, many studies on online patient reviews in a variety of medical specialties have been reported [1]. Nevertheless, analyses of online reviews of dentists are sparse. We only identified one study of online patient reviews in dentistry conducted in Germany [17]. In the United States, studies of dental patient reviews are missing. To address the literature gaps, we conducted a study with two aims. The first aim was to characterize the online reviews of dental patients in the United States by analyzing data extracted from patient review websites. In particular, we examined the association between dentist characteristics and patient ratings.

Our second aim was to understand to what extent online reviews can inform assessments of the patient experience by identifying semantic mentions of the patient experience in patient reviews.

Dental patient experience is traditionally assessed with the CAHPS (Consumer Assessment of Healthcare Providers and Systems) Dental Plan Survey, administered by CMS [18]. Using online reviews for patient experience assessment is feasible but challenging. For instance, information extraction from online patient reviews is labor-intensive because the reviews are written in free text. Content analysis frequently used in social science research could not be applied to this study, in which there were hundreds of thousands of reviews to assess. The identification of information relevant to the patient experience is also necessary to ensure research validity, yet there are no guidelines or empirical studies on how to identify patient experience content in online reviews. Patient reviews cover a variety of topics, but not all of them are related to the patient experience. For example, topics of patient satisfaction should not be identified as patient experience. The patient experience is comprised of the clinical encounters and has been frequently used as an indicator of patient safety [19], whereas patient satisfaction relates to whether patients' expectations about healthcare are met [20]. To overcome these challenges, we incorporated natural language processing [21] and human expert evaluation to identify relevant topics from online patient reviews. Natural language processing has extensive applications in health informatics and medical internet research, in which it has vastly improved the efficiency of processing free-text data using advanced statistical methods and automated computing [3]. Human expert evaluation mitigates the problem of misprocessed data typically produced by such a computerized method and improves the interoperability of the data analysis and results.

Methods

Data Acquisition

Publicly accessible online review data were obtained from HealthGrades, a well-known patient review website in the United States. Among many other sites, we focused on HealthGrades for two reasons. First, HealthGrades is widely used by patients who receive healthcare services from a full range of medical specialties in the United States. Second, HealthGrades provides a well-organized sitemap structure that facilitates data extraction. We analyzed data from a single review site because the data structure and measures of dentist demographics and performance vary, which will hinder data consolidation. In addition, data from multiple patient review sites would have little impact on representation and generalizability of this study because an active dentist typically has profiles on all popular patient review sites.

Online reviews for 204,751 dentists were extracted. This census approximates but does not fully match the workforce statistics (199,486 working dentists as of 2018) reported by the American Dental Association (ADA) [22] because some profiles are for recently inactive dentists and misclaimed or inappropriately captured profiles. The data contain the following attributes: state, city, specialty, gender, age, language, education, number of reviews, ratings, reviews, and wait time.

Data Preprocessing

There were 41 dental service listings in HealthGrades. We categorized these services into the 10 dental specialties defined by the ADA, general dentistry, and others (ie, unidentified and miscellaneous), resulting in 8 specialties (ie, dental anesthesiology, endodontics, oral and maxillofacial pathology, oral and maxillofacial surgery, orthodontics and dentofacial orthopedics, pediatric dentistry, periodontics, and prosthodontics), general dentistry, and others for downstream analyses. Public health dentistry and oral and maxillofacial radiology were excluded as they have only one entry at most. The data extraction was completed in September 2019. The study was identified as a nonhuman study by the Institutional Review Board of the University of South Carolina.

Statistical Analyses

We employed statistical analyses to assess the associations between ratings and dentists' characteristics using R Project for Statistical Computing. We used descriptive statistics to calculate proportions and mean distributions. Based on reported online reviews studies in general medical specialties, we hypothesized that (1) female dentists, (2) young dentists, and (3) short wait times would be associated with higher overall ratings. We also hypothesized that specialties are associated with overall ratings. An independent sample t-test was used to test whether ratings differ by gender. Analysis of Variance (ANOVA) was used to test whether ratings differ by specialties, age, and wait time, respectively. We used Hedges g to approximate the effect size because of unbalanced sample sizes in comparison groups.

Text Mining

Semi-automated natural language processing was used to identify concepts related to patient experience with limited

human labor required. [Figure 1](#) is a diagram of text mining procedures. We used Python for text processing and computation. Built on our pilot study of analyzing patient-generated reviews [23], we first extracted reviews from online sites, followed by standard data cleaning procedures, including tokenization and removal of stop words.

We then calculated bigram and trigram collocations. Collocations are habitual expressions of multiple words. In this study, we ranked using the "likelihood ratio" method [24], top 200 bigram and trigram collocations, respectively, from reviews associated with every rating category (ie, 1, 2, 3, 4, 5).

We observed a number of the collocations that are irrelevant to concepts of dental care and patient experience (eg, "phone call" and "many years ago") but were still ranked top 200 by likelihood ratio. Therefore, two raters (YL and CL) independently picked collocations related to patient experience using a 4-point Likert scale ("definitely relevant," "somewhat relevant," "somewhat irrelevant," "definitely irrelevant"). Inter-rater reliability was assessed using Cohen kappa. Two raters discussed on the collocations that received contrary opinions (relevant vs irrelevant) until a consensus was reached.

Next, we mapped patient-experience-related concepts onto a total of 17 composite measures from the Patient Experience Measures from the CAHPS Dental Plan Survey. [Table 1](#) shows the 17 measures categorized in three dimensions. Two reviewers (RS and JT), who are professors of dental medicine and licensed dentists, independently completed the mapping procedures. A consensus was reached after a discussion of the initial mapping results.

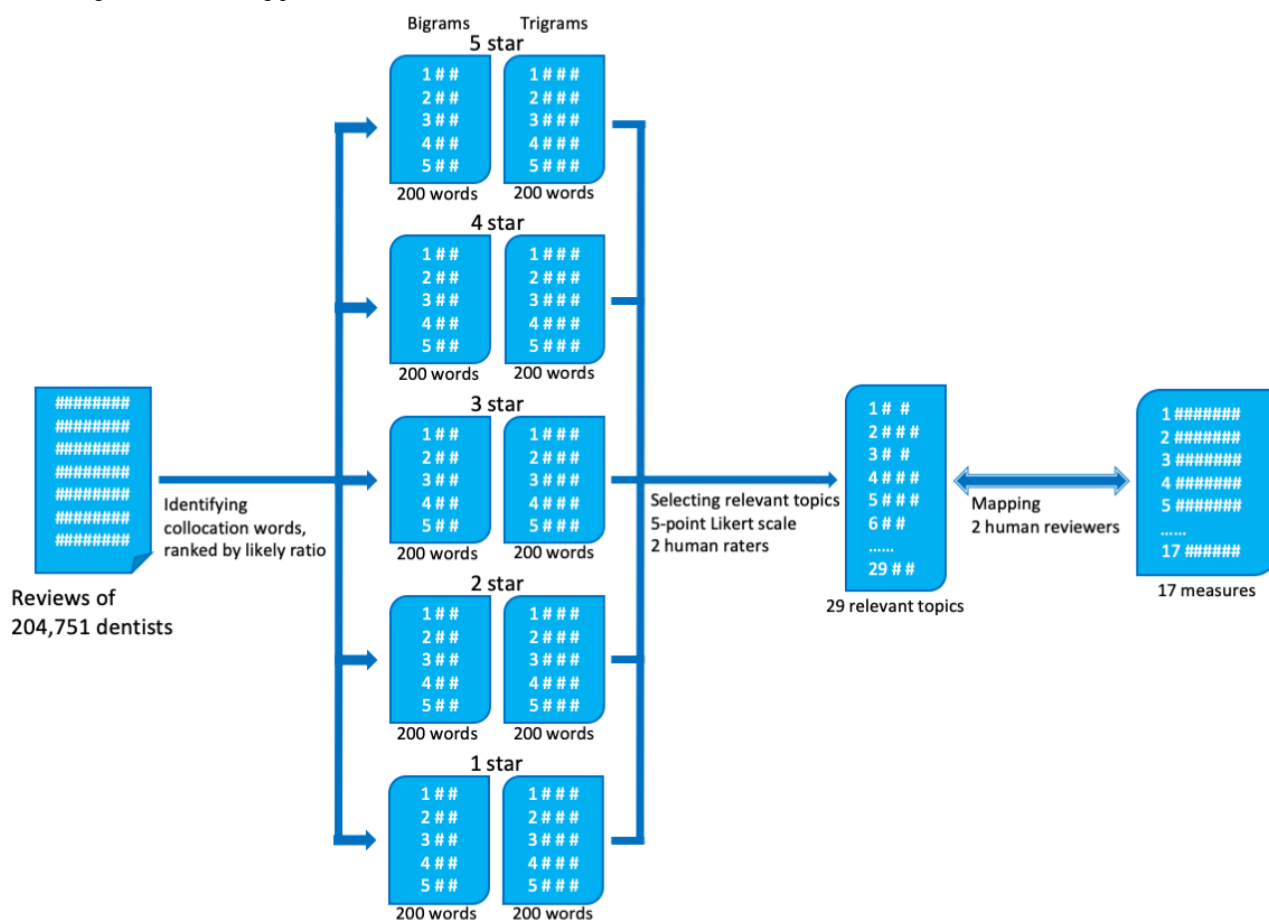

Figure 1. Diagram of text mining procedures.

Table 1. Composite measures from the Patient Experience Measures from the CAHPS Dental Plan Survey.

Dimensions, items	Composite measures
Care from dentists and staff	
Q6	How often did your regular dentist explain things in a way that was easy to understand?
Q7	How often did your regular dentist listen carefully to you?
Q8	How often did your regular dentist treat you with courtesy and respect?
Q9	How often did your regular dentist spend enough time with you?
Q11	How often did the dentists or dental staff do everything they could to help you feel as comfortable as possible during your dental work?
Q12	How often did the dentists or dental staff explain what they were doing while treating you?
Access to dental care	
Q13	How often were your dental appointments as soon as you wanted?
Q15	If you tried to get an appointment for yourself with a dentist who specializes in a particular type of dental care (such as root canals or gum disease) in the last 12 months, how often did you get an appointment as soon as you wanted?
Q16	How often did you have to spend more than 15 minutes in the waiting room before you saw someone for your appointment?
Q17	If you had to spend more than 15 minutes in the waiting room before you saw someone for your appointment, how often did someone tell you why there was a delay or how long the delay would be?
Q14	If you needed to see a dentist right away because of a dental emergency in the last 12 months, did you get to see a dentist as soon as you wanted?
Dental plan costs and services	
Q19	How often did your dental plan cover all of the services you thought were covered?
Q22	How often did the 800 number, written materials, or website provide the information you wanted?
Q27	How often did your dental plan's customer service give you the information or help you needed?
Q28	How often did your dental plan's customer service staff treat you with courtesy and respect?
Q20	Did your dental plan cover what you and your family needed to get done?
Q24	Did this information (from your dental plan) help you find a dentist you were happy with?

Results

Descriptive Statistics

Table 2 shows the demographics of these dentists. Among the collected data, 154,683 (75.55%) dentists received at least one rating or review. The number of reviews ranged from 1 to 1789. There were more male dentists than females with a percentage difference of 85.87%. The majority of dentists (78.55%) were

general dentists, followed by dentists specialized in orthodontics and dentofacial orthopedics (9.23%), pediatrics (4.76%), and endodontics (3.81%). The majority of dentists (91.83%) did not specify any second languages other than English. Among those who indicated speaking a second language, Spanish, Hindi, Arabic, French, and Chinese were most common. There were 150,571 (73.54%) dentists who received an overall rating of ≥ 3 out of 5, and 50,068 (24.45%) of all dentists received no ratings.

Inferential Statistics

ANOVA showed no significant effect of specialties on ratings ($F_{9,154673}=58.74$, $P=1.37$, $g=0.06$). However, the average rating was higher for female dentists ($M=4.58$) than male dentists ($M=4.57$) ($t_{71881}=2.45$, $P<.01$, $g=0.01$). See [Figure 2](#).

We also found a significant effect of age on ratings ($F_{7,107128}=246.97$, $P<.001$, $g=0.11$) with younger age associated with higher ratings. The Tukey Honestly Significant Difference (Tukey HDS) test showed a significant difference in ratings

between each pair of age groups except “30-39” vs “Over 89” ($P=.15$, $g=0.01$), “Under 30” vs “30-39” ($P=.10$, $g=0.01$), “40-49” vs “Over 89” ($P=.95$, $g=0$), “50-59” vs “60-69” ($P=1.00$, $g=0$), “50-59” vs “Over 89” ($P=1.00$, $g=0$), “60-69” vs “Over 89” ($P=1.00$, $g=0$), and “80-89” vs “Over 89” ($P=1.00$, $g=0$). See [Figure 3](#).

There was also a significant effect of wait time on ratings ($F_{4,150055}=10417.77$, $P<.001$, $g=0.26$) with shorter wait times associated with higher ratings. Tukey HDS showed statistical significance in comparing the mean difference of ratings in each pair of wait times (all $P<.001$, $g=[0.01, 0.18]$). See [Figure 4](#).

Figure 2. Overall ratings by gender.**Figure 3.** Overall ratings by age group.

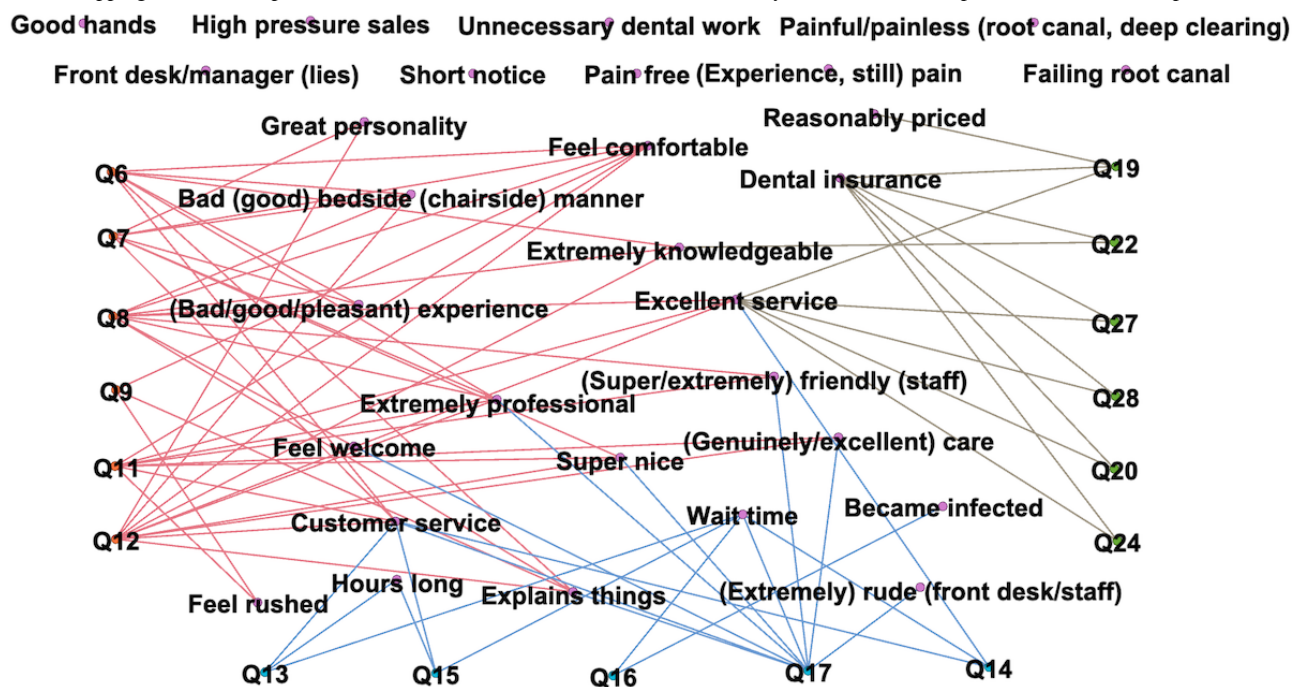

Figure 4. Overall ratings by wait time.

Identification of Concepts Relating to Dental Patient Experience

Cohen kappa (equally weighted) was 0.95 between the two raters who independently identified patient experience-related words and phrases from 2000 automatically extracted collocations. After discussion, they identified 29 words and phrases, then two other reviewers of dental experts independently mapped the 29 words and phrases onto the 17 composite measures in the Patient Experience Measures from the CAHPS Dental Plan Survey. Figure 5 shows a map of links. Each composite measure has 2-10 representing words and phrases. Out of the three dimensions of the patient experience,

there were more topics representing “care from dentists and staff” and “access to dental care” compared to “dental plan costs and services.” Patients were more likely to discuss their experience with dentists and staff than health insurance providers. There were eight words and phrases related to the patient experience that did not correspond to any composite measures. Some of these topics were specific to dental care. For example, discomfort (eg, painful/painless root canal or deep cleaning) is a common type of feedback from dental patients. Topics relating to ethics (eg, high-pressure sales and unnecessary dental work) have received little attention in dentistry but merits further research.

Figure 5. Mapping of Patient Experience Measures from the CAHPS Dental Plan Survey and the words and phrases extracted from patient reviews.

Discussion

Principal Findings

Over the last few years, researchers have begun a systematic analysis of online patient reviews. In the United States, several empirical studies investigating online reviews of general healthcare services and specialties are well documented, but such studies have not been performed in dentistry [1]. To the best of our knowledge, this study represents the first study of online reviews of dental care in the United States. In particular, this study demonstrated that online patient reviews are an essential data source for studying dental patient experience. This study also characterized patient feedback to dental care, which can inform dental care quality improvement.

We found several factors associated with overall dentist ratings. In particular, female dentists were rated slightly higher than their male counterparts, although this should be interpreted with the understanding that the effect size is small ($g=0.01$), and the sample size was small for senior dentists. The gender and age differences we found in this study were similar to a study of online reviews of dentists in Germany [25] as well as reviews of surgeons [26,27], but such a statistical significance was not consistent in other studies. Earlier studies on patient-provider communication suggested that female healthcare providers engage in significantly more active partnership behaviors, positive talk, and building trust with patients [28]. Female providers were also found associated with lower mortality and readmission as compared to their male counterparts [29]. The literature on healthcare quality suggests that younger physicians in acute care hospitals report lower mortality rates [30]. Our data also showed that higher overall ratings were associated with shorter wait times ($g=0.26$). This finding has been reported and discussed in several studies of online patient reviews [1]. Patient review websites such as HealthGrades and RateMDs

have included “wait time/punctuality” as a default measure for healthcare providers.

The proliferation of patient review websites represents a wealth of patient-experience data, but these data remain understudied. In this study, we identified unstructured descriptions of patient experience using a method integrating quantitative text mining and qualitative human evaluation. Our method recognizes the role of automated textual data analytics in harnessing information from online reviews, consistent with other recent studies [31-37], although some researchers argued the limitations of text mining because it involves limited supervision by human experts [31]. To minimize the impact of this lack of human oversight, we incorporated human evaluation procedures into the automated natural language processing effort. Our findings showed that patient reviews covered a full range of topics measured by the Patient Experience Measures from the CAHPS Dental Plan Survey and demonstrated a high level of correlation. Among the eight topics not corresponding to any measures from the survey, some topics may have provided a nuanced view of dental care as compared to patient survey responses [36]. These findings suggest that online patient reviews can be used to assess patient experience during dental care.

Limitations

Our study has the following limitations. First, data from Healthgrades, like data from any other patient review website, may be incomplete and biased. Not all dentist profiles have been claimed. Although authentication is required for dentist profile information, inaccuracies may still exist. The overall ratings may be biased because patients who are happy with health services are more likely to leave ratings and reviews [2]. Second, although there are good reasons for using data from a single review site, this limitation may still weaken the reliability of the study. Repeated measures and follow up studies are needed to evaluate the findings of the this study. Third, it is challenging to differentiate the descriptions of the patient

experience from patient satisfaction as patients often write about their satisfactory or unsatisfactory experience with emotions and personal preferences. In this study, we only analyzed words and phrases at a semantic level, while contextual information is limited. Third, text mining is efficient for big data analyses but falls short in domain-specific and context-based analyses, in which traditional qualitative approaches should be considered as an essential complement of text mining [31].

Despite these limitations, this study analyzed an extensive dataset and found an association between dentists and online patient reviews. The thematic analysis also identified themes

of patient experience similar to those of CAHPS, suggesting that online patient reviews can inform improved quality in dental care.

Conclusions

This study demonstrated that PORs are a potential data source that can supply rich performance data from the patient perspective, based on which assessments of dental care quality and the patient experience is feasible. We also identified several factors associated with dentists' overall ratings, which could be used to inform dental care quality improvement.

Acknowledgments

We thank Dr Jenny S Tjahjono for the contribution to the expert evaluation. This study is supported by a seed grant from the University of South Carolina.

Abstract

Background: An OHC online health community (OHC) is an interactive platform for virtual communication between patients and physicians. Patients can typically search, seek, and share their experience and rate physicians, who may be involved in giving advice. Some OHC providers provide incentives in form of honorary titles to encourage the web-based involvement of physicians, but it is unclear whether the award of honorary titles has an impact on their consultation volume in an OHC.

Objective: This study is designed to identify the differential treatment effect of the incentive policy on the service volumes for the subgroups of treatment and control in an OHC. This study aims to answer the following questions: Does an honorary title for physicians impact their service volumes in an OHC? During the period of discontinuity, can we identify the sharp effect of the incentive award on the outcomes of physicians' service volumes?

Methods: We acquired the targeted samples based on treatment, namely, physicians with an honorary title or not and outcomes measured before and after the award of the 2 subgroups. A regression discontinuity design was applied to investigate the impact of the honorary titles incentive as a treatment in an OHC. There was a sharply discontinuous effect of treatment on physicians' online health service performance. The experimental data set consisted of 346 physicians in the treatment group (with honorary titles). Applying the propensity score matching method, the same size of physicians (n=346) was matched and selected as the control group.

Results: A sharp discontinuity was found at the time of the physician receiving the honorary title. The results showed that the parametric estimates of the coefficient were significantly positively ($P<.001$) associated with monthly home page views. The jump in the monthly volumes of home page views was much sharper than that of the monthly consultations.

Conclusions: The changes in the volumes of monthly consultations and home page views reflect the differential treatment effect of honorary titles on physicians' service volumes. The effect of the incentive policy with honorary titles is objectively estimated from both the perspective of online and offline medical services in an OHC. Being named with honorary titles significantly multiplied monthly home page views, yet it did not significantly impact monthly consultations. This may be because consultation capacity is limited by the physician's schedule for consultations.

Introduction

Background

Online health communities (OHCs) are an essential channel for creatively allocating health care resources among widely distributed patients in modern life. An OHC is usually referred to as an interactive platform between patients and physicians for virtual communication. Patients can search, seek, and share their experience of medical advice and rate the physician as social returns in an OHC. Meanwhile, physicians can share their medical knowledge and provide online medical services. An OHC is a convenient, real-time supplement for physician-patient interaction (PPI) without limitations on time and space [1]. Physicians' web-based involvement (ie, the service volumes) is a determinant factor of OHCs' success in health service delivery [2]. The platform management provider of an OHC often provides incentive policies (ie, honorary titles) to encourage physicians' web-based involvement. For example, 346 physicians on the *Good Doctor* platform were awarded the honorary title *2017 Annual Good Doctor* in January 2018. According to a survey of large OHC firms by the Towers Watson/National Business Group on Health [3], 69% reported that they offered wellness incentives and that the size of the incentives increased with time. However, it is still unclear whether the award of honorary titles has an impact on their consultation volume in an OHC.

With the quick development of OHCs, the physician-patient online interaction has gained more attention from scholars all over the world, especially regarding what incentive mechanisms and strategies can be designed to prompt sustained PPIs in OHCs [4]. In the bidirectional process of PPIs [5], patients seek information and make the decision to select a physician for consultation, and then, the physicians share their medical knowledge and provide medical services. Patients could also provide returns (rate, vote, and share experience online) for physicians. After receiving feedback and returns, physicians could balance their efforts for the subsequent PPI process. A good PPI can benefit both patients and physicians. It can provide patients with a truly information-based selection process and good outcome of the consultation process. In addition, a good PPI can provide physicians with returns that can also affect their reputation. Incentive policies have been widely developed to encourage PPI [3]. The high rating or award of good doctors online is thought to be a good indicator. This indicator not only represents the praise of the physician but can also predict the following process of PPI theoretically. Recently, there have been more studies focusing on the impact of incentive policies (high rating or honorary title of *Good Doctor*) in OHCs [1]. A previous study reported that physicians' online contributions and reputation were closely associated with patients' decision-making process when seeking medical consultation [6]. Due to the cross-sectional study design, the conclusion can only be explained in terms of association [7]. To evaluate the causal impact of incentive policy on physicians' consultation

volumes, a sequential occurrence needs to be considered and analyzed in causal design, as appropriate.

In this study, we intend to estimate the causal effect of an incentive strategy on the PPI process of an OHC. Our analysis uses the information from the biggest OHC in China (*Good Doctor* website) [1], which provides reliable information on more than 10,000 hospitals and more than 640,000 physicians across the country. The specific treatment in our study is the award of the honorary title of *Annual Good Doctor*, which is assigned by a threshold of a weighted score summarizing the hospital level, the professional capital, number of votes, and the experience of health care service of patients. The dimensions of treatment included both temporal (pre- and post-treatment) and treatment (treated and untreated group) effects. The outcome contained 2 aspects [8]: the home page view frequency and the online consultation frequency. The home page view frequency mainly represents the physicians' reputation and effort from the patients' side. The online consultation frequency further includes the accessibility and efforts of physicians when chosen for online services. The 2 indicators together represent the performance of the continuous PPI process in OHCs.

Literature Review

Although the natural experiment design is widely adopted to evaluate the policy's causal effects in empirical research [9], the experiment remains difficult or impossible to implement because of ethical, political, and financial reasons. A large share of the empirical work on policy evaluation relies on observational data, in which policies are determined in a way other than through randomization assignment. Drawing the inference of a policy's causal effect based on observational data is quite challenging, especially for incentive policy evaluation in an OHC setting. Several methodological issues need to be overcome by adopting causal methods creatively because of the various weaknesses of classic methods.

The counterfactual impact of the treatment needs to be estimated in causal inference. *Treatment* is a general term referring to certain interventions of interest, for example, the incentive policy in our study. An important prerequisite is that the treated and untreated groups are comparable and balanced to draw unbiased causal effects, which can be achieved by randomization in an experimental setting. However, in an observational study, treated and untreated groups may differ in observed and unobserved characteristics, which can affect the assignment of treatment and outcome. Several techniques such as multiple linear models and extensions, widely adopted in previous studies to identify the association between rewards and physicians' contribution [1], only control for observed confounders. Propensity score matching (PSM) [10,11] mimics the randomization process, reduces the confounding on the treatment assignment, and reaches a balanced group sample (with simulated counterfactual control units) in an observational setting. With the propensity score defined [12] as a conditional probability of assignment to treatment based on covariates, PSM largely reduces the matching process from multiple dimensions

to a single dimension [13]. The matching process is also appropriate for temporal case matching [14] and the classification of medical cases [15].

To mimic the experimental design with observational data, both *treatment* and temporal effects need to be considered. With the treated samples, a simple comparison of outcomes between pre- and post-treatment could be contaminated by the effects of other events (except the treatment) that occurred during both periods. For example, the seasonable factor may affect the change in the outcomes of OHCs [1]. With both treated and control groups, the comparison of post-treatment outcomes could capture more than the treatment effect, even after controlling for observed confounding [16]. The reason lies in the difference in unobserved attributes between the treated and untreated groups. Difference-in-differences (DID) [17], combined with PSM to achieve a parallel trend assumption (2 groups would show a parallel trend if neither of them experienced the treatment effect), is a useful method to reduce the impact of extraneous factors and selection bias. DID compares the average change over time in the outcome of the treated group with that of the control (untreated) group [18].

In many practical cases, the treatment assignment is (partially) determined by a cutoff or a threshold. This advanced design, known as a sharp regression discontinuity design (RDD) [19], is an extension of DID. Despite comparing the observations of the pre- and post-treated outcomes available in both groups, RDD also shows a good capacity for causal inference when the treatment assignment is deterministic and discontinuous at the cutoff. Comparing the observations close to the cutoff (local treatment effect) would achieve local *randomization* near to the threshold.

This study aims to estimate the causal effect of an incentive strategy on the PPI process of an OHC. In accordance with the previous discussion on methodology, PSs were estimated as the predicted probabilities of treatment (being awarded honorary

titles based on covariates). Score matching was then conducted to reach a comparable control sample with the treatment group. Considering both the temporal and treatment dimensions of the policy, the DID idea was applied to compare the average pre- and posttreatment changes in the treated group (with the honorary title) with those in the untreated group. If the relationship between the covariates and the potential outcomes is *smooth* around the threshold (in covariates), the discontinuity (sharp jump) created by the treatment can provide local randomization. RDD would then be implemented appropriately to evaluate the causal effect of treatment (receiving the honorary title) on both outcomes (home page view and online consultation frequency) at the threshold.

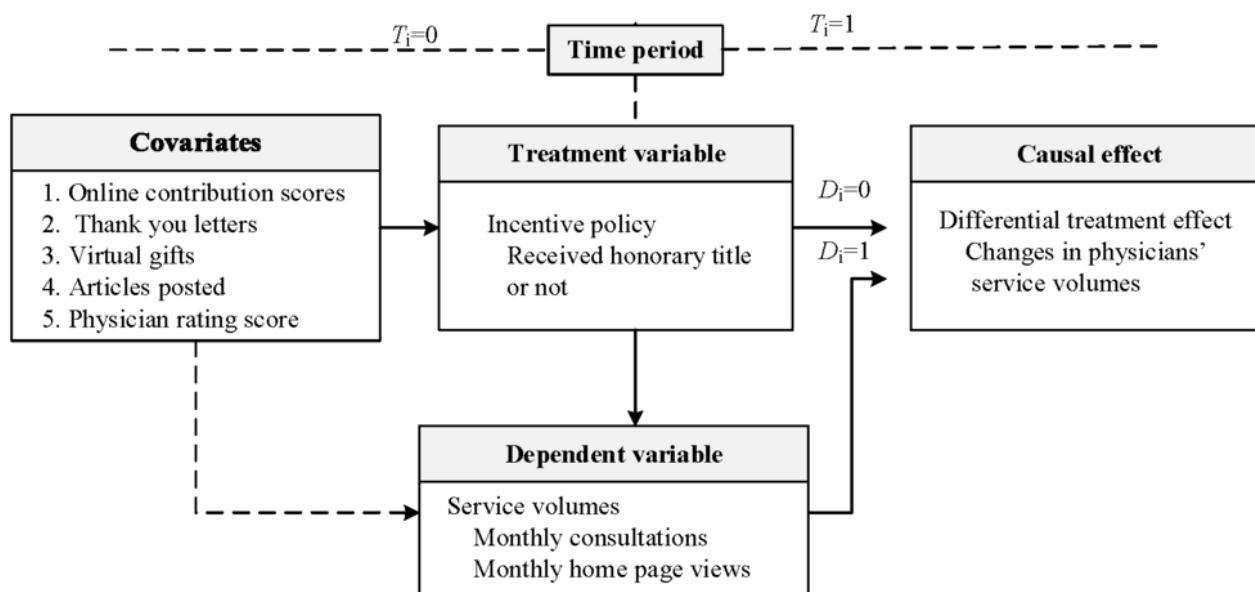

In summary, this study aimed to identify the average change in home page views and online consultation volume for physicians with the honorary title versus those without the honorary title. The investigation attempts to answer the following questions: (1) Does there exist the average treatment effect (ATE) of the honorary title on changes in outcomes (physicians' home page views and consultation volumes) in an OHC? (2) At the discontinuity of the *treatment* assignment, does the sharp effect of the incentive award exist on the outcomes, and can it be identified?

Methods

Research Models

This section demonstrates the research framework of this study. To investigate the differential treatment effect, the incentive policy was regarded as the treatment in the research design. The research framework was demonstrated to investigate the differential treatment effect of the incentive policy on physicians' service volumes, as illustrated in Figure 1. This service volume also reflected the patients' choice of physicians online.

Figure 1. Framework of the causal effect study on the outcome of physicians' service volumes, with $D=1$ indicating that physicians received honorary titles (in the treatment group), $D=0$ indicating the control group, $T=1$ indicating the postaward period, and $T=0$ indicating the preaward period.

First, 5 covariates were considered in this observational study. These variables are the physician rating score (PRS), the number of thank you letters, the number of virtual gifts, the number of online contribution scores, and the number of articles posted. The covariates represent the doctor's characteristics at a specific time point. Second, the honorary titles of the physician awarded from the OHC were viewed as the treatment. Within the causal inference mechanism, the objects of interest were those physicians assigned as the award recipient or not (D_i). This time factor helped in distinguishing the factors of the cause and effect among those variables. Third, to further investigate the dynamism of the effect on the changes in their service volumes, the time periods (T_i) were divided into those before awarding and after awarding. Fourth, the service volume is measured by 2 factors: the number of monthly consultations and the number of monthly home page reviews. These 2 factors reflect the online service (home page reviews) and the offline service (serviced patients of medical consultations), respectively. The number of patients that physicians serviced monthly (Patients #) and the number of their home page views monthly (Views #) [20] can

be viewed as the proxies of the outcomes. Thus, these 2 proxy variables were set as the dependents. Moreover, the initial states of the numbers of those 5 covariates are measured as their cumulative before the examined period (June 25, 2017).

The definitions and measurements of all variables are presented in Table 1. $Patient_i(t)$ is measured as the number of online consultations (for patients) provided by the physician i in month t . $Views_i(t)$ is measured as the number of online home page views of the physician i in month t . The covariates were considered for case-control matching. PRS_i is measured as the PRS (by patients), which refers to the star scores listed on the OHC website. $Thank_i(t)$ is measured as the mean of the number of thank you letters of the physicians. $Gift_i(t)$ is measured as the mean of the number of gifts received by the physician i in month t . $Contr_i(t)$ is measured as the mean of the contribution score of physician i in the month t , which refers to the contribution scores listed on the website. $Article_i(t)$ is measured as the mean of the number of physician articles. N is the number of physicians in the experimental data.

Table 1. Variable definitions and measurements.

Variables	Definitions	Measurements
Causal effect		
RDD_{effect}	Differential treatment effect	The causal effects of honorary titles incentives (treatment) in OHC ^a with RDD ^b
Dependent variable Y		
$Patient_i(t)$	Number of monthly consultations	Number of online consultations (for patients) provided by the physician i in the month t
$Views_i(t)$	Number of monthly home page views	Number of online home page views of the physician i in the month t
Treatment variable		
D_i	Receive honorary title or not	$D_i=1$ indicates physician i was titled as 2017 Good Doctor in OHC, otherwise $D_i=0$
Time periods		
T_i	Preaward or postaward period	$T_i=0$ indicating the period before January 2018 (date of the honorary title), otherwise $T_i=1$
Covariates		
$Contr_i(t)$	Contribution score	Total online contribution score calculated by OHC for physician i in the month t
$Thank_i(t)$	Number of thank you letters	Total number of online thank you letters physician i received in the month t
$Gift_i(t)$	Number of virtual gifts	Total number of online virtual gifts physician i received in the month t
$Article_i(t)$	Number of articles posted	Number of articles posted by physician i in the month t
$PRS_i(t)$	PRS ^c	Mean of the rating scores by patients for physician i in the month t

^bRDD: regression discontinuity design effect.

^cPRS: physician rating score.

Data Collection

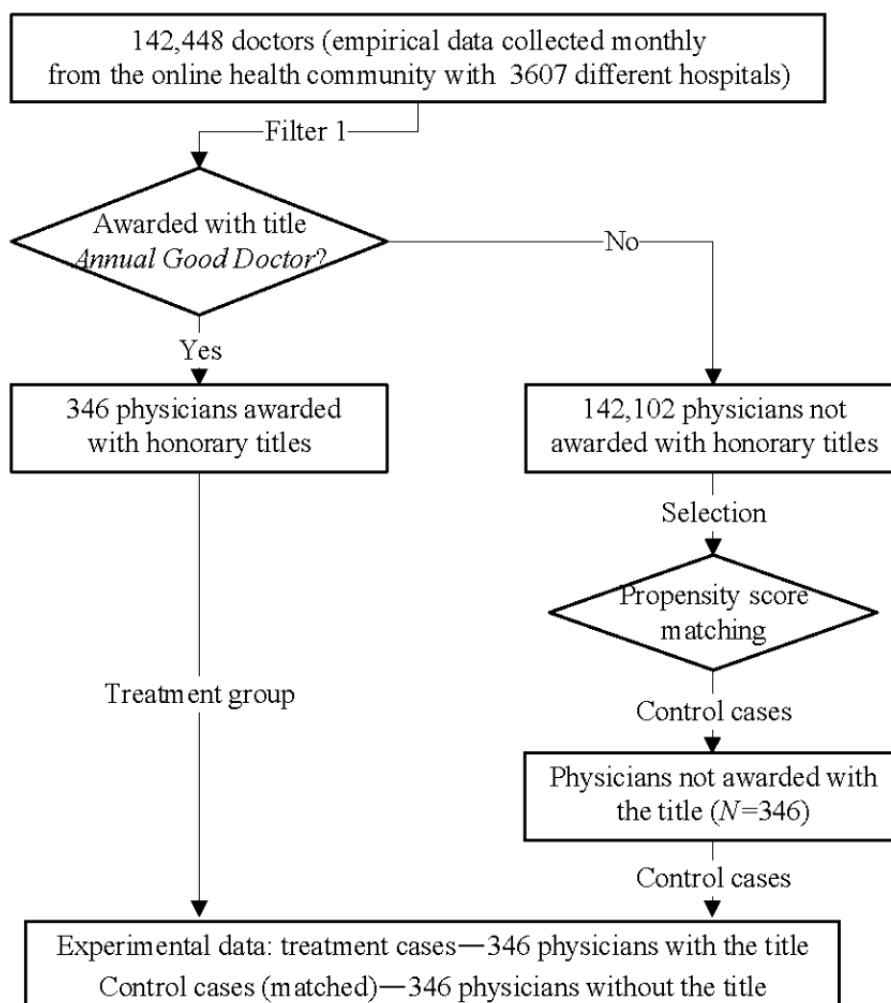

This study used existing records to conduct a retrospective study. The requirement for individual doctor consent was waived as the study did not impact clinical care and all data were deidentified. None of the data collected for the study were related to private information about the physicians.

Through the web crawler technology, a longitude data set from July 26, 2017, to June 26, 2018, was collected and filtered

monthly from the Good Doctor website for the study. The collected data set contained the variables used in this study and other deidentified information. Among the online physicians, over 140,000 were involved and participated in OHC [1] with their personal profiles (including personal home pages). In January 2018, 346 of them were awarded the honorary title 2017 Annual Good Doctor. Honorary titles were rated based on the number of consultations, the number of appointment referrals (patients), patient satisfaction with online services (the review

rating score), and other factors. The flowchart of data acquisition and filtering process is shown in Figure 2.

Figure 2. Data collection and preprocessing procedures.

During the preprocessing, outliers were removed from the original data. The design of the study is based on the propensity score matching (PSM) with 1:1 matching. The distribution of the logarithm of monthly consultations and that of the monthly

home page views are illustrated in Figures 3 and 4. In these figures, 0 indicates the control group and 1 indicates the treatment group. The distribution results suggest that the causal effect cannot be estimated with the distributions directly.

Figure 3. Distribution of the logarithm of monthly consultations, with 0 indicating the control group and 1 indicating the treatment group.

Figure 4. Distribution of the logarithm of monthly home page views, with 0 indicating the control group and 1 indicating the treatment group.

Estimation of RDD Effect

Through the RDD model, this study attempted to identify the ATE [21] of honorary titles for physicians on the changes in their service volumes. The theoretical contributions of this study not only lie in the design for estimating the RDD effect but also in combining it with the DID model through prediction of the counterfactual outcomes of the matching samples. The prediction of the RDD effect can be modeled as [22] follows:

$$E(y_i | x_i) = \beta_0 + \beta_1 x_i + \beta_2 x_i^2 + \dots + \beta_j x_i^j + \epsilon_i$$

Where $E(y_i | x_i)$ and $E(y_i | x_i)$ are the estimated expectation of the treatment group and the control group with the covariates x (ie, time period) and the outcomes y (ie, $Patient_i(t)$ and $Views_i(t)$), respectively.

To derive a balanced control-treatment case data set, we trained the logistic regression to estimate the PS [23].

$$PS_i = \frac{1}{1 + \exp(-(\beta_0 + \beta_1 x_i + \beta_2 x_i^2 + \dots + \beta_j x_i^j))}$$

where β_0 is the coefficient of the constant term and $\beta_j, j=1, \dots, 5$, are the coefficients of the covariates, as detailed in Table 1.

The error term ϵ_i obeys a normal distribution with mean and variance σ^2 .

We then matched control-treatment cases on pretreatment covariates with the PS. In the matching process, the scalar (N)

can be preset for the number of matches needed (ie, the default value 1 is for one-to-one matching). More similar units are more likely to experience similar trends to meet the parallel path assumptions. Thus, the bias of the RDD effect can be reduced with such data sets of control-treatment pairs.

Results

In this section, we describe the results with descriptive statistics, the overlap assessment, and the differential treatment effect of honorary titles. Our findings provide empirical evidence that a regression discontinuity exists at the cutoff of the period.

Descriptive Statistics

The statistics of the empirical experimental data for each month are shown in Table 2. The state column illustrates the initial mean value of the experimental period, and the following 11 columns show the marginal changes per month. For example, PRS in August 2017 was 0.01, which means that it increased by 0.01 on average from the mean value (4.58) in the last month (July 2017). As the certification date of honorary titles (award) was January 20, 2018, the examined periods of treatment were from January 2018 to June 2018 (6 months).

From Table 2, the results show that for D=1 (award), monthly changes of preaward PRS were positive, whereas for D=0 (nonaward), there were negative changes. In terms of the thank you letters, the monthly data of D=1 (award) was higher than that of D=0 (nonaward). Similar trends were observed for virtual

gifts, posted articles, contribution scores, consulted patients, and home page views.

Overlap Assessment

The first step in analyzing the experimental data was to estimate the PSs using a logistic regression model with one main effect (on treatment) for each covariate. In the estimation of PS, the dispersion parameters for the binomial family were taken to be 1. With many covariates, it is difficult to examine the numeric diagnostics carefully for each covariate. As usual [24,25], graphical diagnostics are helpful for quickly assessing the covariate balance. Although the densities of raw treated and matched treated cases did not change, those of raw controls and matched controls changed significantly. The absolute standardized difference is defined as follows [26]:

where $mean(x_{treat})$ and $mean(x_{control})$ denote the sample mean of the covariate in treated and control units (physicians), respectively, and s^2_{treat} and $s^2_{control}$ denote the sample variance of the covariate in treated and control units, respectively.

Figure 5 shows the weighted dots by their proportional size, which is also useful for stratification. Meanwhile, the absolute standardized difference is helpful for comparing the mean of continuous variables between the 2 groups, as illustrated in Figure 5 (right). The results show an adequate overlap of the PSs, with a good control match for each treated unit.

Figure 5. Distribution of propensity scores with experimental data. The left subfigure illustrates the distribution of propensity scores, and the right subfigure illustrates the absolute standardized difference in means of all data and matched data. Contr: Contribution score; PRS: physician rating score.

Differential Treatment Effect of Honorary Titles

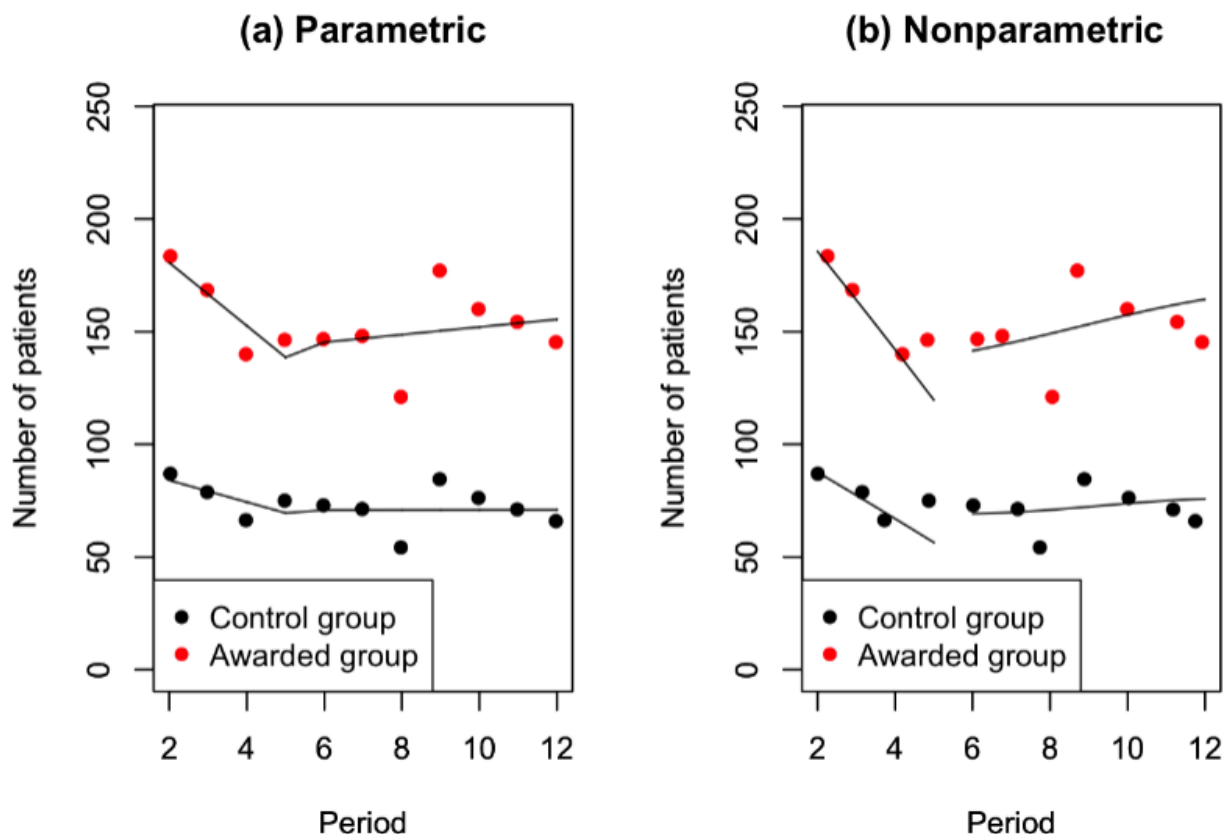

This treatment effect illustrates the impact of honorary titles on the changes in physicians' service volumes. Two tests for the estimation of the impact of honorary titles were carried out with the panel data of 12 months. The period of control was investigated from July 2017 to December 2017, and the period of treatment was from January 2018 to June 2018. Among them, the first month of control was used to acquire the initial state

of the system. The marginal quantity of the sequential periods was then acquired accordingly. The impacts of honorary titles on monthly consultations and home page views were analyzed using the panel data, as demonstrated in Table 3. The estimation of the number of monthly consultations before and after doctors receiving honorary titles is also visually illustrated in Figure 6. Similarly, this study also investigated the estimates of the number of monthly home page views, and the results are shown in Figure 7.

Table 3. Parametric and nonparametric estimates of the coefficient (the treatment effect).

Group and methods	Estimate	SE	N ^a	P value
Monthly consultations				
Control				
Parametric	6.113	5.970	3696	.31
Nonparametric	-9.286	8.087	1680	.25
Treatment

^aN: number of physicians in the experimental data.

Figure 6. Estimation of the number of monthly consultations before and after physicians receive honorary titles.

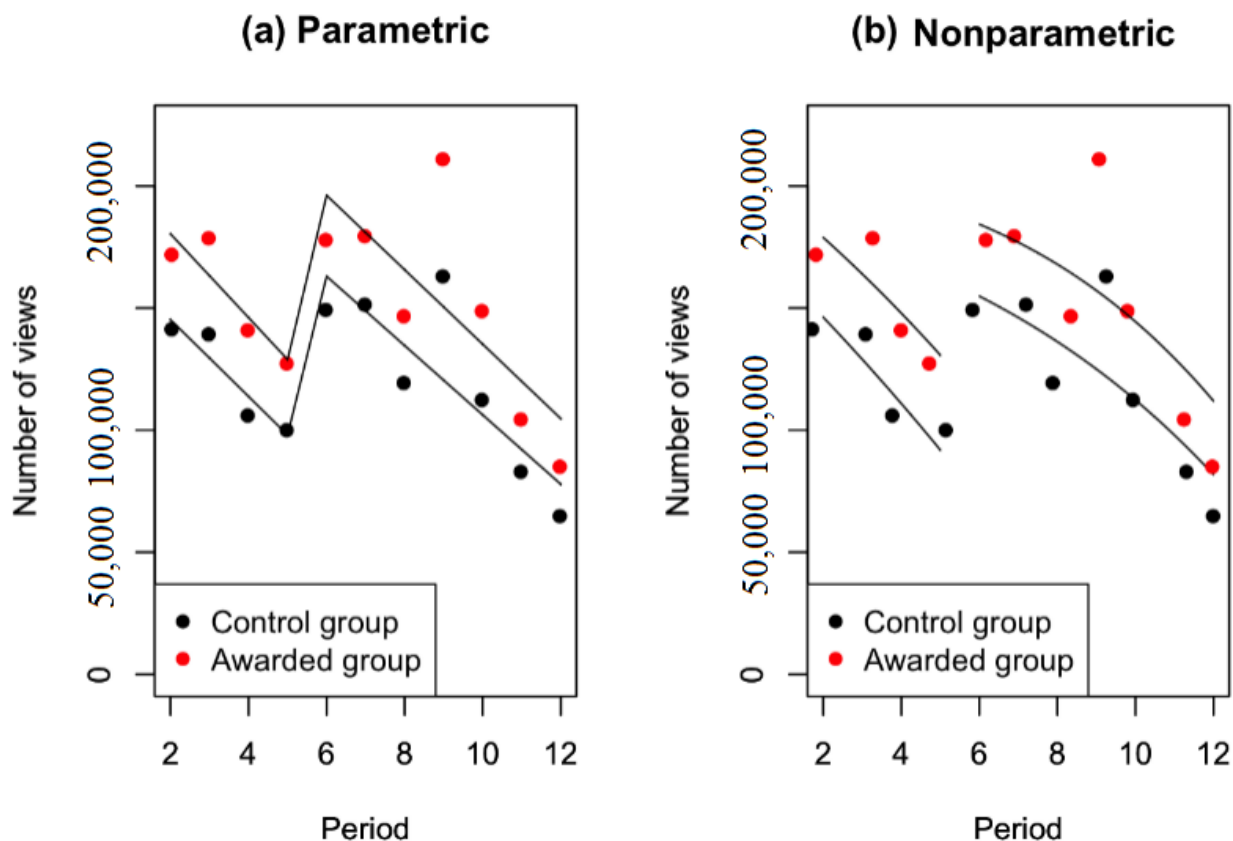

In Table 3, the results show that the parametric estimates of the coefficient (the treatment effect of the honorary title) are significantly positive ($P < .001$) on monthly home page views. The estimates were 80,666 for the control group and 84,340 for the treatment group. Similar results were obtained for the nonparametric estimates of the coefficients, which were 66,814 for the control group and 73,351 for the treatment. These results indicate that the physicians with honorary titles had more monthly home page views than their counterparts. Meanwhile, honorary titles highlighted the physicians, accelerating the increase of the monthly home page views more greatly than the others. The number of monthly consultations of the physicians with the honorary titles was larger than those without the titles.

However, the parametric estimates of the effect on monthly consultations are positive (6.113 for the control and 20.699 for the treatment group) but not significant. The nonparametric estimates of the effect on monthly consultations were negative (-9.286) for the control and positive (5.133) for the treatment group (also insignificant). These results support our argument

that the effect of honorary titles for physicians can significantly multiply the increases in the monthly home page views, yet they cannot significantly impact the monthly consultations.

In Figure 6, despite the decreasing trends, there was also a jump for monthly consultations during the period of receiving honorary titles. The results also indicated that 2 months of lag existed in the RDD. However, the jump in the volume of monthly consultations was insignificant or did not occur instantly. The honorary titles of physicians were awarded in January 2018, whereas a sharp regression discontinuity occurred in March 2018.

In Figure 7, the results show that honorary titles caused a jump in the monthly volume of home page views, that is, a sharp regression discontinuity. Moreover, the trends of the period before the jump were decreasing, which illustrated that the counterfactual observations of monthly volumes would be much less than those before this jump. Therefore, these results provide empirical evidence that regression discontinuity existed at the cutoff of the period.

Figure 7. Estimation of the number of monthly home page views before and after physicians receive honorary titles.

Discussion

Principal Findings

In this paper, we investigated the causal effect of honorary titles for physicians in terms of the changes in their service volumes in online health care communities. Monthly home page views and consultations were chosen as the 2 proxy variables for the outcomes. To identify the causal effect, multiple covariates, including physicians' rating scores, thank you letters, virtual gifts, online contribution scores, and posted articles, were considered for PS estimation. With pure randomization, the bias of effect estimation was reduced with the assigned samples. Through PSM, the results showed an adequate overlap of the PSs, with a good control match for each treated case. The results showed that honorary titles caused a jump in the monthly volumes of monthly consultations and home page views, specifically a sharp regression discontinuity.

Compared with the discontinuity regressions, the jump in monthly consultations is not as sharp as that of home page views. There may be many reasons for these sharp regression discontinuities. For example, if honorary titles are implemented for ranking and deploying physicians to users, then entitled physicians get more clicks because they appear first. However, consultation capacity is limited by the physician's schedule. This leads to the limit of the increase in monthly consultations for physicians. In contrast, there is no limit to the increase in home page views, which causes the jump in the monthly volumes of home page views to be much sharper than that of the monthly consultations. In total, changes in the monthly

volumes of monthly consultations and home page views reflect the differential treatment effect of honorary titles on physicians' service volumes. The effect of the incentive policy with honorary titles is objectively estimated from the perspective of both online and offline medical services.

Although the causal study design was performed rigorously with the PSM method, this study still has some limitations. The number of articles posted by physicians was collected monthly for this study, with potential seasonable noise data. Meanwhile, the historical monthly data of the home page views and the online consultation frequency may be a cause of the honorary title for physicians in the current period. In this study, we introduced the time factor to distinguish the factors of the cause and effect among these variables. In future studies, their historical data can also be implemented as covariates to improve the balance of the comparing groups in the causal inference. To further investigate the proxy of physicians' service volumes, more characteristics could be abstracted from physicians' articles. In addition, falsification checks could also be implemented in future studies, including investigating whether covariates jump during the period of honorary titles (when jumps occur at cutoff thresholds) and what are the most reasonable time lags.

Conclusions

In OHCs, the platform management provider offers incentive policies (eg, honorary title) to encourage physicians' web-based involvement. However, the impact of the incentive policy on patients' online choice of physicians is still unclear. In this study, we investigated the causal effect of honorary titles for

physicians on changes in their service volumes, including monthly home page views and consultations. By stratifying the samples with the treatment (honorary title) and the period (pre- vs postaward), the RDD method was applied to identify the impact of the incentive policy on the service volumes of physicians. A sharp discontinuity was found at the time of the physician receiving the honorary title. The results showed that both parametric and nonparametric estimated coefficients were

significantly positive ($P < .001$) for monthly home page views. The effect of honorary titles for physicians can significantly multiply the increases in the monthly home page views, yet its impact on monthly consultations was insignificant. Therefore, these results provide empirical evidence for our claim that regression discontinuity existed at the cutoff of the period. In the future, more investigations can be conducted to identify the time lag of the RDD effect.

Abstract

Background: Online physician reviews are an important source of information for prospective patients. In addition, they represent an untapped resource for studying the effects of gender on the doctor-patient relationship. Understanding gender differences in online reviews is important because it may impact the value of those reviews to patients. Documenting gender differences in patient experience may also help to improve the doctor-patient relationship. This is the first large-scale study of physician reviews to extensively investigate gender bias in online reviews or offer recommendations for improvements to online review systems to correct for gender bias and aid patients in selecting a physician.

Objective: This study examines 154,305 reviews from across the United States for all medical specialties. Our analysis includes a qualitative and quantitative examination of review content and physician rating with regard to doctor and reviewer gender.

Methods: A total of 154,305 reviews were sampled from Google Place reviews. Reviewer and doctor gender were inferred from names. Reviews were coded for overall patient experience (negative or positive) by collapsing a 5-star scale and coded for general categories (process, positive/negative soft skills), which were further subdivided into themes. Computational text processing methods were employed to apply this codebook to the entire data set, rendering it tractable to quantitative methods. Specifically, we estimated binary regression models to examine relationships between physician rating, patient experience themes, physician gender, and reviewer gender).

Results: Female reviewers wrote 60% more reviews than men. Male reviewers were more likely to give negative reviews (odds ratio [OR] 1.15, 95% CI 1.10-1.19; $P<.001$). Reviews of female physicians were considerably more negative than those of male physicians (OR 1.99, 95% CI 1.94-2.14; $P<.001$). Soft skills were more likely to be mentioned in the reviews written by female reviewers and about female physicians. Negative reviews of female doctors were more likely to mention candor (OR 1.61, 95% CI 1.42-1.82; $P<.001$) and amicability (OR 1.63, 95% CI 1.47-1.90; $P<.001$). Disrespect was associated with both female physicians (OR 1.42, 95% CI 1.35-1.51; $P<.001$) and female reviewers (OR 1.27, 95% CI 1.19-1.35; $P<.001$). Female patients were less likely to report disrespect from female doctors than expected from the base ORs (OR 1.19, 95% CI 1.04-1.32; $P=.008$), but this effect overrode only the effect for female reviewers.

Conclusions: This work reinforces findings in the extensive literature on gender differences and gender bias in patient-physician interaction. Its novel contribution lies in highlighting gender differences in online reviews. These reviews inform patients' choice of doctor and thus affect both patients and physicians. The evidence of gender bias documented here suggests review sites may be improved by providing information about gender differences, controlling for gender when presenting composite ratings for physicians, and helping users write less biased reviews.

KEYWORDS

reviews; physician-patient relationship; gender; soft-skills

Introduction**Background**

Physician review sites are relatively new and were initially greeted with concern by some in the medical community. In particular, some physicians were critical of the lack of transparency in composite statistics [1] and were concerned that online reviews could harm their careers [2]—perhaps unfairly [3,4]. Although ratings are generally high [2,3,5,6], negative ratings undoubtedly influence patient behavior [7] and impact doctors [1,8]. Some doctors have attempted to *gag* patients by contractually prohibiting them from writing online reviews [9].

Most studies of online physician reviews have focused on portals such as HealthGrades [10], RateMDs [11], Vitals [12], and Yelp [13]. Studies tend to have a small sample size, analyzing approximately 5400 reviews [6]. Many studies aim to understand the factors that influence quantitative physician ratings. The qualitative analysis of 712 reviews by López et al [5] established thematic categories that tended to appear in reviews. Paul et al [14] replicated and expanded this work with a natural language processing (NLP) approach, which they applied to the text of 50,000 online reviews downloaded from RateMDs [11]. Their novel joint topic–sentiment modeling approach found that certain textual accounts of interpersonal skills such as *rude*, *arrogant*, and *condescending* are strongly associated with negative reviews, and drew attention to the role of patient experience of bureaucratic process in reviews, noting that these experiences were often reflected in reviews. Wallace et al [15] expanded on the work by López et al [5] and Paul et al [14] by analyzing 60,000 reviews to identify relationships between overall rating, health outcomes, and cost of care. To date, the only study to investigate the relationship between physician reviews and gender is that by Nwachukwu et al [16] on surgeon quality in sports medicine. They found that communication style influenced the valence of ratings for top- and bottom-tier surgeons and that female surgeons typically had higher ratings [16]. These and other studies of online reviews endeavor to understand how clinical experiences influence patient satisfaction and health outcomes. However, they tend to overlook or minimize questions about whether online review data reflect real experiences of medical care. Reviews may not be representative of the public or reflect demographic variation in health care utilization; indeed, doctor reviews are typically written by educated, younger, affluent, and healthier people [5]. However, a study comparing ratings of over 3000 physicians with licensing data showed a clear relationship between doctor quality and ratings [3].

Little research has studied the impact of gender or other demographic factors on the content and ratings of online physician reviews. Although qualitative studies of doctor-patient relationships have considered both negative and positive experiences [5], including the impact of demographics [17–19], the nature of these studies makes it difficult to estimate the size or scope of gender and other demographic variation in online

physician reviews. Furthermore, gender differences, in particular biased interpretations of clinical experiences based on gender stereotypes, may impact online review content, which in turn may negatively impact both patients and physicians and perpetuate false gender stereotypes. The large-scale systematic study we present here documents gender differences in patient reviews with respect to both patients and doctors and proposes improvements for online review systems that could help reduce these disparities, thus improving information quality.

Gender and Health Care

Although we know little about gender in the context of online reviews, gender has been studied extensively in the social sciences for over half a century. Much of this work investigates the role of gender in medical care and health systems more generally.

Gender is a cultural construct that affects people's expectations and actions [20]. In social contexts and practices [21], gender is *assessed* independently of one's identity [22]. Thus, any name appearing in online text is likely to be interpreted in terms of the man/woman binary, which is reflected in the use of gender in the current doctor review literature.

The expectations of one's behavior differ depending on one's assessed gender. Indeed, leadership traits praised in men are penalized in women, while traditional *feminine* behavior is seen as ineffective [23]. When writing references, men are described with more standout and ability-based words and fewer *grindstone* words (eg, *hardworking*, *conscientious*) [24], and women are described with more communal words [25]. Even when all factors are controlled, people rated teachers differently on hard skills (eg, *promptness*, *fairness*) and soft skills depending on the gender portrayed by the instructor [26]. Thus, bias may influence review content even when performance is identical.

In health care, gender differences influence doctors' communication with patients [27–29], doctor and patient trust [30], and even diagnosis error rates [27]. Female *doctors* are seen as partners and more involved in the patient-doctor relationship, whereas female *patients* are treated with more condescension [27,29,31], have their concerns dismissed [29] and credibility doubted [27]. Conversely, patient satisfaction is dependent on more caring communication styles for women than for men [32]. However, many studies documenting these trends are small in scale or have weak evidence [33]. One exception is a study of over 10,000 people experiencing long-term illness in Sweden, where women reported being blamed, interrupted, disbelieved, doubted, and regarded as stupid [19]. These gender differences are likely to impact review scores, as lower patient satisfaction is correlated with high physician dominance, which can manifest itself in gendered actions (eg, poor information sharing and use of medical jargon) [34]. In this study, we investigate how these gender biases are represented in online reviews, which affect patients, physicians, and people using the reviews.

Study Design and Motivation

The goal of this study was to broaden and deepen our understanding of the impact of gender bias and other gender differences on online physician reviews. We leveraged reports of patient sentiments about their doctors through a large-scale analysis of online reviews. The Google Place review data analyzed here allowed us to identify patient and reviewer gender and characterize patient sentiment or experience in terms of both overall quality (a reviewer-entered Likert-type scale) and thematic content. Specifically, we formulated the following hypotheses (H):

- H1a—Physician ratings and physician gender: female physicians are more likely to receive negative reviews than male physicians.
- H1b—Physician ratings and reviewer gender: Female reviewers are more likely to report negative experiences with doctors.
- H2a—Soft skills and physician gender: Female physicians are more likely to receive criticism mentioning soft skills than male physicians.
- H2b—Soft skills and reviewer gender: Female reviewers are more likely to mention soft (interpersonal) skills in negative reviews.
- H3—Reviewer gender and physician gender: Female reviewers are more likely to report negative experiences with male doctors.

Hypotheses H1a and H1b relate to physician gender and reflect the findings of prior work on gender inequalities in reviewing in other fields [24–26]. Hypotheses H2a, H2b, and H3 are based on prior work documenting gender differences in clinical encounters [27,28].

Our approach comprised both qualitative and quantitative perspectives on review content that mutually informed one another throughout the research process. We collected and analyzed a corpus of 154,305 reviews of doctors that constitutes a large nationally representative sample of physician reviews across all medical subfields and clinical contexts. Our focus was specifically on characterizing the differences in experience quality and content as they relate to reviewer and doctor gender.

This study contributes to the larger body of work on the impact of gender on clinical interactions and provides insight into what patients value in their doctors. Furthermore, we add to the small but growing body of literature that seeks to develop a general understanding of online reviews and the systems that collect and display them. Our results must be interpreted with caution due to the unstructured and often short nature of the patient narratives in reviews, the relative crudeness of the NLP techniques employed (as compared with human interpretation), and selection biases introduced by nonrepresentative variation in demographic characteristics of reviews and the types of experiences that motivate patients to write reviews. Such selection biases are almost unknown although we make a novel contribution here.

Online reviews provide an opportunity to learn, at scale, about patients' perceptions of their doctors. Our findings have direct implications for the design of review sites and the presentation

of search results. We argued that there are a number of useful ways in which gender differences can be reflected and potentially corrected in the presentation of information on the internet.

Methods

This study is a large-scale ($N > 10^5$) text analysis of reviews of US physicians in the form of social media trace data. Social media trace data have the advantage of feature richness, (often) wide availability, and relation to genuine human social behavior outside of an experimental or survey context. The analytic approach we pursued in this study followed a similar process to the hybrid ethnographic and NLP approach advocated by Nelson [35]. The methodological framework is a recursive process whereby qualitative text analysis (sometimes called *deep reading* or *content analysis*) informs computational feature extraction, which is then evaluated through further qualitative analysis. This refinement process continues until the patterns in the computationally derived features match the intuitions and examples accumulated through qualitative analysis fairly well. Ultimately, a quantitative analysis, in this case regression modeling, is applied to validate large-scale patterns in the data. The rest of this section details the specifics of this approach, the review sampling process, inference of reviewer and physician gender, and modeling of associations and interactions among the variables of interest.

Physician Review Collection

To examine how gender influences patient experience at scale, we sought a representative sample of reviews of US physicians. As gender and other demographic variables are rare in social media, we sought data that contained physician and reviewer names, which we used as a proxy for gender.

Review Collection Application Programming Interface

After exploring possible sources of physician reviews considering various application programming interface (API) features and use in prior work, we selected the Google Places API [36]. The API provides access to patient and physician names, which we leveraged to infer gender, as well as a broad range of areas and specialties. The Google My Business API has a 5-review limit for any particular doctor. Unfortunately, the API documentation does not provide information on how these reviews are selected. We can be fairly confident, however, that reviewer gender is not a factor. Thus, it is unlikely that this introduces bias into the sample with regard to the variables of interest. Furthermore, we took measures to ensure that our personal search histories did not influence review collection.

Geographical Sampling

Reviews, physicians, and practices are likely to vary by location. Differences in locale, such as ruralness or urbanity, can influence health outcomes and care options, as can regional differences. For instance, in the United States, mortality rates of particular conditions have been shown to differ greatly from state to state [37]. Samples were taken across states from multiple regions of the United States using the Google Places API to control for the effect of locale. We steadily increased latitude and longitude

intervals throughout each state with a 10,000-m radius to capture both urban and rural regions.

Data Summary

Reviews returned by the Google My Business API were either for a *place* (such as a practice with multiple doctors) or a *physician*. The API provided additional *review-specific* data for each review: a 5-point Likert-type rating assigned by the reviewer to the doctor or practice, doctor name, reviewer name, the location of the practice, and the text content of the review. The reviewer and physician gender were determined

automatically using third-party software described in the following section.

The collection strategy described in this section yielded 154,305 reviews of physicians across the United States. These reviews spanned 2007 to 2017. Doctor ratings were highly polarized, exhibiting a U-shaped distribution (Figure 1). Of the reviews collected, 46,605 were rated 1 star or 2 stars (*negative* reviews) and 107,700 were rated 4 stars or 5 stars (*positive* reviews). Another 3,208 reviews were rated 3 stars and were omitted from our analyses. We did not screen for particular specialties.

Figure 1. Left: Gender distribution in the complete data set (N=154,305). The unknown category represents clinics and names that were androgynous or unknown to the gender classifier. Middle: Distribution of physician ratings by physician gender (N=137,329). Right: Distribution of physician ratings by reviewer gender (N=129,985).

The mean length of positive reviews was 50 words, while the mean length of negative reviews was 100 word (both follow heavy-tailed distributions). The distribution of inferred gender for both doctors and reviewers is shown in Figure 1. Note that we expected to see a fairly high rate of unknown gender in these data because some reviews are for medical practices that include multiple physicians. In addition, some physicians' gender could not be identified. Given the presence of nonperson entities among *physicians*, it is perhaps surprising that reviewers have a greater rate of gender ambiguity. This likely reflects typos and pseudonyms among reviewers, who have a weaker incentive to use the correct name. However, the high rate of gender detection suggests that this should not be a great concern, as almost all reviewers use *real* names, not screen names. We were less certain about the rate of pseudonymous users but proceeded on the assumption that even when pseudonyms are used, they accurately reflect the reviewer's gender.

Qualitative Coding

Sampling Strategy

To guide our quantitative analysis and support the validation of our approach, we additionally selected a small sample of reviews for hand coding. A total of 200 reviews were selected for hand coding using stratified sampling for a distribution of 60% negative (3/5 from each state) and 40% positive (2/5 from each state) reviews because our initial read-throughs indicated that negative verbiage was less prevalent than positive verbiage in our sample.

As this sample was relatively small in comparison with the number of total reviews collected, we used search terms intended

to select for specialties that would help us focus on specific patient genders. We selected 50 reviews by mostly female reviewers using *maternal, fetal, fertility, natal* as search terms for clinic name and *maternity, fetal, miscarriage, trimester, fertility, natal, birth, pregnancy, delivery, baby*, midwife, *Ob/Gyn* in the review. We also selected 50 reviews by mostly male reviewers using *cancer, prostate* in the review itself, along with 100 reviews of both male and female urology reviewers. All of these reviews were manually assessed to ensure that they represented the assigned group. Although pregnancy and prostate cancer are not comparable medically, we chose them because they selected for patients by biological sex. They are the only common conditions that affect only one biological sex. This reduces uncertainty in our interpretation of the qualitative data.

We analyzed these reviews to construct a codebook (Multimedia Appendix 1) and develop an intuition for the patterns of thematic content and gendered interaction in physician reviews. Throughout this paper, we reflect on these patterns or illustrate particular situations by quoting largely from the reviews in this sample. The intuitions we developed through our qualitative and quantitative analyses have led us to conclude that situations reported in exemplar quotations generalize beyond the women's health or urological contexts. Accordingly, our quantitative analysis and some follow-up quantitative investigations span the entire data set.

When we quote reviews, they will be cited with the following descriptors: physician gender (Male; Female; Unknown), star rating (1-star, 2-star,..., 5-star), doctor type (O=OBGYN; U=UROLOGY). For example, (Male; 5-star; O5654) is an

OBGYN review of a male physician with a 5-star rating. Quotes are exemplary of many similar statements found in the reviews, with some synthesis and paraphrasing to support anonymization.

Codebook Construction

We developed a codebook to regulate our analysis of the reviews. These codes were divided into 2 parts: regular codes and context codes. Context codes relate to demographic information, doctor gender, or specialty, while regular codes reflect the content of the review, for example, *professional* or *rude*.

We began with codes identified by López et al [5]. We also used iterative open coding to identify common categories of statements in the data. After coding each of the qualitative

samples in Text Analysis Markup System [38], we took each coded section and created an affinity diagram, grouping similar segments independent of the initial codebook to represent the content of the reviews most accurately. These were then grouped into overarching categories that could be used for the analysis of the full data set. The process resulted in 7 main thematic areas: *process*, *candor*, *trust*, *investment*, *amicability*, *indifference*, and *disrespect*. The themes represented 2 general categories: those pertaining to nursing and administrative *process* (process) and those pertaining to soft skills. The latter group was further subdivided into *positive* (candor, trust, investment, amicability) and *negative* (indifference, disrespect) soft skills. After developing the codebook, 3 authors coded 20 reviews to assess interrater reliability using Cohen kappa (Table 1) and then refined the categories to improve agreement.

Table 1. Themes that emerged in affinity diagramming and examples of the associated terms in the dictionaries used in the quantitative analysis.

Theme	Sample terms	Kappa ^a	Count	Accuracy ^b	Precision	Recall
Positive soft skills		0.61	113	0.77	0.74	0.90
Candor	Honest, explain, answer, direct	0.95	41	0.84	0.57	0.76
Trust	Support, safe, reassure, comfort	0.98	27	0.42	0.41	0.63
Investment	Respect, care, compassion, listen	0.93	65	0.42	0.60	0.74
Amicability	Warm, friendly, personable, funny	0.94	31	0.82	0.46	0.84
Negative soft skills		0.53	25	0.87	0.44	0.16
Indifference	Cold, dismiss, ignored, abandoned	0.74	16	0.87	0.50	0.16
Disrespect	Rude, harass, condescending, arrogant	0.40	25	0.92	0.50	0.44
Process	Cost, nurse, staff, wait	0.83	115	0.87	0.84	0.96

^aKappa represents interrater agreement (on 20 reviews).

^bAccuracy, precision, and recall, respectively, on a random sample ($N=100$) of 200 total reviews. A review is labeled as pertaining to a theme if at least one of the words in the theme in dictionary is presented in the review. Note the infrequency of negative soft skills (16 and 25 for indifference and disrespect, respectively), contributing to low precision and recall.

Computational Feature Extraction

Gender Detection

A third-party Python library [39] was used to infer the probable gender of physicians and reviewers based on their name. Although not everyone identifies within the female-male gender binary [22], currently, gender is typically assessed and reacted to with respect to this binary [21], so a binarized gender of reviewers and physicians was extracted using the names provided. Although a binary definition of gender does not capture the spectrum of gender and gender relations, capturing a more complex understanding of gender is infeasible given the scope of our data and the lack of identifying information for reviewers and doctors beyond name.

To verify the accuracy of the gender inference procedure, we took a random sample of 200 reviews and compared automatically inferred gender with our human-coded gender determinations informed by close reading of the reviews informed by name and gender pronouns. Automated physician gender inference was 98% accurate. The accuracy of reviewer gender was not examined because the only available measure was the reviewer's name.

The distribution of genders is shown in Figure 1 (left). Gender could not be inferred for 12.8% of physicians and 17.5% of patients. A logistic regression model (not shown) estimated with high confidence that female physicians are 1.41 times more likely to be reviewed by female patients ($P<.001$). A second model (also not shown) indicates that physicians are 4.36 times more likely to be reviewed by patients of the same gender ($P<.001$). These figures do not necessarily represent the actual gender distribution of patients *seen* by doctors, as there may be selection bias for or against intragender reviews.

Thematic Content of Reviews

Informed by the qualitative analysis, dictionaries were developed relating to the 7 themes (*process*, *candor*, *trust*, *investment*, *amicability*, *indifference*, and *disrespect*) identified in the qualitative coding. Review text was stemmed using Porter stemmer and tagged with a binary label for each theme if the review mentioned a word in the theme's dictionary. Working separately, we coded 200 reviews to assess the ability of the codebook to identify each of the themes. Table 1 presents summaries of the themes, their kappa statistics, and the performance of the binary variables when applied as a single-feature classifier against a random test set of 100 hand-coded reviews that were not used to inform the codebook.

Tables 2 and 3 display the frequencies with which the terms appear in the corpus and the proportion of reviews for each combination of gender/physician rating for physician gender and patient gender separately.

Table 2. Prevalence of themes by physician gender.

Theme	Doctors (female, n=36,847; male, n=74,189) ^{a,b}			
	Female (negative; n=13,874), n (%) ^c	Female (positive; n=22,973), n (%) ^c	Male (negative; n=17,906), n (%) ^c	Male (positive; n=56,283), n (%) ^c
Positive soft skills	7403 (53.36)	16,984 (73.93)	7530 (42.05)	37,993 (67.50)
Candor	2756 (19.86)	3531 (15.37)	2227 (12.44)	8431 (14.98)
Trust	754 (5.43)	2725 (11.86)	745 (4.16)	5566 (9.89)
Investment	4724 (34.05)	12,266 (53.39)	4830 (26.97)	26,032 (46.25)
Amicability	1928 (13.90)	7481 (32.56)	1621 (9.05)	16,047 (28.51)
Negative soft skills	4629 (33.36)	488 (2.12)	4505 (25.16)	721 (1.28)
Indifference	868 (6.26)	163 (0.71)	836 (4.67)	298 (0.53)
Disrespect	4112 (29.64)	343 (1.49)	3942 (22.01)	442 (0.79)
Process	9330 (67.25)	10,099 (43.96)	9981 (55.74)	23,837 (42.35)

^aMany reviews contain multiple themes, so the overall rows (bold) have smaller numbers than the sum of themes would indicate. This table includes only those reviews for which a gender was assigned (n=111,036).

^bThe physician rating is denoted as negative/positive.

^cPercentages represent the proportion of reviews containing the theme for that particular gender/rating combination.

Table 3. Prevalence of themes by reviewer gender.

Theme	Reviewers (female, n=67,857; male, n=43,179) ^{a,b}			
	Female (negative; n=18,780), n (%) ^c	Female (positive; n=49,077), n (%) ^c	Male (negative; n=13,000), n (%) ^c	Male (positive; n=30,179), n (%) ^c

Indifference	1101 (5.86)	305 (0.62)	603 (4.64)	156 (0.52)
Disrespect	5178 (27.57)	513 (1.05)	2876 (22.12)	272 (0.90)
Process	11,469 (61.07)	21,728 (44.27)	7842 (60.32)	12,208 (40.45)

^aMany reviews contain multiple themes, so the overall rows (bold) have smaller numbers than the sum of themes would indicate. This table includes only those reviews for which a gender was assigned (N=111,036).

^bThe physician rating is denoted as negative/positive.

^cPercentages represent the proportion of reviews containing the theme for that particular gender/rating combination.

Dictionary-based text analysis is crude in that it cannot determine valence, that is, the dictionary approach cannot distinguish between the phrase “Dr. X listens,” for example, “Great bedside manner. She was kind and listened to everything I had to say” (Female; 5-star; 15180), and the many variants of its negation, for example, “I never felt like she truly listened” (Female; 1-star; 25068). Positive soft skills are more likely to be negated than negative ones, largely because double negatives are far less common than single negatives in English. This is borne out by the associations between each theme and *negative reviews* in the set of models summarized in Table 4. Determining

valence is further complicated by constructs that contradict a negative, such as “If you want a doctor who knows what’s best after not listening to you for 5 minutes, don’t see him. This quality of care is almost impossible to find” (Male; 5-star; 40558). As reviewers have assigned a general valence to their experience, we leveraged physician ratings to distinguish positive from negative sentiment. However, this applies only in analyses where positive reviews are considered in isolation from negative reviews and vice versa. In the quantitative analyses below, we typically controlled for interactions between gender and physician rating. Therefore, when considering a soft

skill in the context of reviews with ratings of the opposite valence, the soft skill should be interpreted as the negation of that interpersonal trait. For instance, when *amicability* appears

in a negative review, the reader should interpret this as the *absence* of amicability, whereas *disrespect* in the same review should be regarded as the *presence* of disrespect.

Table 4. Logistic regression on the presence of a theme in review (n=106,325).

^aRows represent distinct logit models for each of the 7 themes. Each cell reports the log-likelihood that a variable is associated with the given theme. Sentences containing terms related to the process have been removed from the reviews.

^bFemale=1, male=0.

^c $P < .001$.

^dMissing value indicates that no coefficient was estimated for the given endogenous variable.

^e $P < .01$.

Quantitative Analysis

A total of 3 sets of logistic regression models were fitted to these data. Reviews for which either reviewer or physician gender could not be identified were removed from the analysis in all of the models presented in the Results section. This reduced the data set by 28% from 154,305 reviews to 111,036.

The set of models we present investigated the association between negative reviews and reviewer/doctor gender. The second set comprised models examining the likelihood that a review mentions a soft skill. As our primary variables of interest are binary, and we are interested in interactions among those binary variables, the interpretation of the logistic regression variables is complicated. All interaction terms disrupt the interpretation of their component variables, but this

interpretation is even more difficult when estimating all pairwise interactions of a set of variables (in this case, 3). Effectively, this decomposes each main effect coefficient into different components, which must be carefully interpreted and summed to construct odds ratios (ORs) for various conditions. We present one set of regressions on each review theme for each interaction rather than estimating all 3 interactions in a single model for readability. Through these sets, we tested *physician gender*, *reviewer gender*, and *physician rating* for pairwise interactions. The intercept and noninteracting effects are only marginally altered between these models, if at all. An additional set of models estimates the main effects of each dependent variable. When reporting these results, models are grouped by these model classes rather than by the dependent variable, as the relation between the independent variables takes priority over the particulars of the review themes. Finally, a pair of models

estimates how administrative process correlates with gender, physician ratings, and soft skills.

Results

This section discusses the statistical models fit to the review data. The report and discussion of these results is supplemented with excerpts of real reviews examined in the qualitative component of this study. We present these reviews to illustrate and contextualize the quantitative findings and the computational method of feature extraction.

Physician Ratings and Gender

Owing to the possibility that reviews could be influenced by clinical processes outside of physician control, we first fit a pair of models with and without mentions of bureaucratic *process*. The logit models summarized in Table 5 indicate that physician ratings are extensively influenced by gender, irrespective of mentions of *process*. Four models examine the correlation between sets of independent variables and the probability of a

negative review. The A models were fit on all reviews for which we were able to infer both doctor and reviewer gender ($N=111,036$). In the data set on which we regressed the B models, we stringently controlled for mentions of *process*, which refer not to the physician but instead to the clinical aspects beyond the patient-physician relationship. The data set for the B models is the result of filtering sentences that mention terms associated with *process* from the reviews and then removing any reviews that were left without text. This process yielded a slightly smaller data set ($N=106,325$). Models 1A and 1B present a base model that includes only physician and reviewer gender and an interaction term. Models 2A and 2B control for soft skills, with Model 2A controlling for *process*. The overlapping coefficient estimates do not differ substantially between the 4 models, suggesting that mentions of *process* do not substantially alter the correlations captured by the variables of interest in these data. However, we conservatively controlled for them in the remainder of this section, except in models that consider *process* explicitly.

Table 5. Logistic regression on rating negative (A: $n=111,036$; B: $n=106,325$). Models 1 and 2 differ in the inclusion of review content themes. The B variants show the effects of filtering sentences mentioning process from each review.

Variable	Model 1A	Model 1B (no process)	Model 2A	Model 2B (no process)	P value
Intercept	-1.05	-1.08	-1.12	-0.80	<.001
Doctor _F ^a	0.67	0.69	0.63	0.71	<.001
Reviewer _F ^a	-0.16	-0.14	-0.14	-0.11	<.001

^cNot applicable.

Although the dictionaries that contain terms related to review themes were developed in conjunction with our qualitative analysis and were thus thoroughly vetted, there remained concerns that these term lists do not adequately capture the themes they purportedly represent. As discussed in the Methods section, dictionary-based or *bag of words* (presence or absence of terms) approaches to natural language understanding often struggle to overcome or capture nuance in word use, notably suffering an inability to distinguish positive use from negation. We fit 2 models (2A and 2B) to verify that the soft skill dictionaries are correlated with negative reviews, as expected. The coefficients for the themes indicate that our dictionaries capture the basic tendency we anticipated: 3 of 4 positive soft skills, *trust*, *investment*, and *amicability*, are correlated with positive reviews (negative coefficients; $P<.001$), and 2 negative

soft skills, *indifference* and *disrespect*, are correlated with negative reviews ($P<.001$). Notably, *candor* is not associated with either positive or negative reviews. This suggests the possibility that *candor* was mischaracterized by its dictionary. However, the intercoder agreement and classifier performance in Table 1 imply that the dictionary for *candor* captures the theme equally well as the other positive soft skills. Rather, it seems that *candor* was misclassified as a *positive* soft skill and, as defined by its dictionary, is perhaps better understood as a *neutral* soft skill, appearing equally in positive and negative reviews. The models estimate large absolute effects for the three other positive soft skills. A negative soft skill, *indifference*, fits a considerably greater effect than any positive soft skill, and *disrespect* fits an even greater effect. This is consistent with the descriptive statistics in Tables 2 and 3, which suggest that

although positive soft skills are more strongly associated with positive reviews, they also appear often in negative reviews. Negative soft skills by contrast occur overwhelmingly in negative reviews. Generally, these findings further suggest that our dictionaries accurately represent the themes they attempt to capture.

H1a: Female Physicians Are More Likely to Receive Negative Reviews Than Male Physicians

She was harsh and short. I always felt rushed and uncomfortable... it was like she was just making sure she did what was required. No sympathy at all.
[Female; 1-star review; O6198]

The logit models on physician ratings (Table 5) indicate that female doctors are considerably more likely to receive negative reviews. Model 1B, which includes only physician and reviewer gender and an interaction term, estimates that female physicians' reviews are 2.00 (95% CI 1.90-2.10) times as likely to be negative than the reviews of male physicians (log OR 0.69, 95% CI 0.65-0.74; $P<.001$). Model 2B, which controls for mentions of soft skills, estimates a slightly larger coefficient.

H1b: Female Reviewers Are More Likely to Report Negative Experiences With Doctors

Contrary to our hypothesis, Model 1B estimates that men write negative reviews at 1.15 (95% CI 1.08-1.16) times the rate of women ($P<.001$). Controlling for review content themes (Model 2B) fit a slightly smaller estimate. There was no interaction between physician gender and reviewer gender, indicating that female patients are no more likely to give a doctor of a particular gender a negative review than men are.

Patient Experience, Physician Ratings, and Gender

Several batteries of logistic regression models were fit to investigate how specific aspects of the patient experience (review themes) interact with gender and overall patient experience (physician rating). The coefficients estimated by these models are listed in Table 4. As described in the Methods section, we fit separate models for each of the interaction terms, as the interpretation of multiple interaction terms is complicated, and separating them into distinct models does not significantly alter the results. We fit models that interact for gender and physician ratings for positive soft skills only, as negative soft skills are almost exclusively found in negative reviews. Furthermore, we report the gender \times gender interaction model for disrespect only, as no other model estimated a significant interaction.

As comments about *process* may be wrongly ascribed to a doctor's soft skills, the model for each theme controls for mentions of *process*. We found that *process* was significantly associated with all soft skills ($P<.001$), including a strong correlation with *amicability* and *disrespect* (see Table 6 and *Process and Gender* section for a more detailed treatment of this model). The model estimates that *process* is 2.73 (95% CI 2.65-2.86) times as likely to co-occur with *amicability* and 2.02 (95% CI 1.92-2.13) times as likely to co-occur with *disrespect*. This is unsurprising given our qualitative investigation, which found that the reviewers commonly commented on the friendliness or rudeness of the staff. For instance, when positive

reviews mentioned both *process* and *disrespect*, it almost always contrasted a positive experience with a physician with a negative process experience. Reviewers seemed to be fairly capable of separating feelings about bureaucratic process from their experience with a physician, setting their dissatisfaction with, for example, staff, insurance, or booking aside when assigning a rating to a doctor who otherwise provided a good clinical experience.

Physician Ratings and Soft Skills

In our qualitative analysis, we observed that reviews mentioning positive soft skills were primarily associated with high scores for male and female doctors. Reviewers wrote positively about physicians who were candid and direct, "Ladies this doctor listens and responds with respect, she does not talk down to you either" (Female; 5-star; U940); who were trustworthy and supportive, "The delivery would've been terrifying without him" (Male; 4-star; O7390); invested, "She asks questions and listens. She makes me feel like I am important" (Female; 5-star; U933); and amicable, for example, "She is an amazing doctor. Kind, caring, empathetic, warm, knowledgeable, quick thinking, funny, and honest" (Female; 5-star; O679). As stated in the discussion of the logit models in Table 5, positive soft skills are more likely to appear in positive reviews ($P<.001$). These models also estimate large effects for positive soft skills except *candor*, being at least 2.4 times as likely to appear in positive reviews than negative ones.

We also coded for 2 negative soft skills, *indifference* and *disrespect*. *Indifference* was relatively rare, appearing in only 2% of the reviews. *Disrespect* was more common, occurring in 8% of all reviews. Unlike positive soft skills, which appeared in both positive and negative reviews, negative soft skills were almost exclusively found in negative reviews. When they did appear in positive reviews, it almost always referred to bureaucratic process, not the physician. Typical reviewer comments coded for negative soft skills relate experiences with doctors who lack courtesy, patience, and warmth toward their patients, for example, "I could not believe how condescending and snippy she was!" (Female; 1-star; O8376); "He was very rude, condescending, arrogant, and appeared angry" (Male; 1-star; U1122). Reviewers also described feeling ignored, "I felt passed around and ignored" (Female; 1-star; O10061), or that their concerns were dismissed, "...brushed it off" (Female; 1-star; O10100) and "I was in tears because he was too stubborn to listen" (Male; 1-star; U1047). Other complaints included ignoring patients' understanding of their own medical condition and lack of inclusion in decision-making. As reviewers mentioned, "The doctor does not listen to you and forces his opinion down your throat without considering your view. Do not visit here" (Male; 1-star; U398) and "He did not want to listen to anything I had to say and he definitely didn't want me getting a second opinion. He got defensive and standoffish at the mention of any other opinion which says SHADY all over it" (Male; 1-star; U198).

The logit models for negative soft skills indicate that negative soft skills are far more likely to appear in negative reviews than positive ones. The log-likelihood coefficients are considerably stronger for negative than for positive soft skills. This is because

positive soft skills can be negated to note the absence of a positive quality, whereas negative soft skills are rarely negated to indicate a positive quality.

H2a: Female Physicians Are More Likely to Receive Criticism Mentioning Soft Skills Than Male Physicians

I feel 100 percent comfortable telling her anything because I know she holds no judgment and treats everybody with fairness and kindness. [Female; 5-star review; O8982]

The coefficients in the $Doctor_F \times Rating_{Neg}$ indicate that positive soft skills are more likely to occur in reviews of female physicians. In positive reviews, *trust*, *investment*, and *amicability* were more strongly associated with the reviews of female doctors than those of male doctors ($P < .001$). Trust and investment show no significant interaction between physician gender and physician rating, indicating that all reviews of female physicians are more likely to mention *trust* and *investment* than those of men. The models estimate that *trust* occurs 1.20 (95% CI 1.15-1.26) times and *investment* 1.31 (95% CI 1.27-1.34) times as often in reviews of female physicians than in those of male physicians. *Amicability* is estimated to have a significant effect on positive reviews and an additional amplifying effect in negative reviews. Positive reviews of female physicians reported *amicability* more often than those of male physicians (log OR 0.20, 95% CI 0.17-0.24; $P < .001$). To calculate the probability of mentions of *amicability* in female doctors' negative reviews, we summed the *base* (that of positive reviews) log OR (0.20) with the log OR (0.29, 95% CI 0.19-0.38; $P < .001$) from the interaction term. The model estimates that *amicability* is much more likely to be mentioned in negative reviews of female physicians than in reviews of male physicians (log OR 0.49, 95% CI 0.36-0.62). Similarly, *candor* is much more likely to appear in negative reviews of female physicians (log OR 0.48, 95% CI 0.35-0.60; $P < .001$), although it is equally likely to appear in male and female physicians' positive reviews.

Negative soft skills are more easily interpreted than positive ones, as they are less likely to be negated and thus occur predominately with negative valence. As discussed earlier, this is supported by the stronger associations of negative soft skills with negative reviews than those of positive soft skills and positive reviews. Qualitative analysis of reviews indicated that *disrespect*, when it occurs in positive reviews, usually refers to *process*. However, occasionally, reviewers will contradict or justify negative soft skills when referring to positive experiences with physicians, for example, "Some may misinterpret her candor as rudeness, but I appreciate that about her - she always gets right to the point" (Male; 5-star; 951) and "He can seem somewhat arrogant, but I've been seeing him for a while now, and he really knows his stuff and takes his patients very seriously. He has a right to think highly of himself!" (Male; 5-star; 7181).

Given their overwhelmingly negative valence, it is sufficient to model negative soft skills without interactions for gender and overall review quality (the *No Interactions* section of Table 4). However, it is important to control for physician ratings given the much higher rate of negative reviews in women's reviews. Both *indifference* (log OR 0.29, 95% CI 0.20-0.37; $P < .001$) and

disrespect (log OR 0.35, 95% CI 0.30-0.41; $P < .001$) are more likely to be mentioned in reviews of female physicians than in reviews of male physicians.

H2a: Female Reviewers Are More Likely to Mention Soft Skills in Negative Reviews

Our qualitative analysis did not reveal consistent patterns of association between mentions of soft skills and reviewer gender. As this investigation was limited to a small sample of reviews, we expected the quantitative results to yield patterns consistent with observations of gender differences in patients' clinical experience reported in the literature. The logit models of soft skills offer 2 advantages in detecting gender bias in clinical settings. First, the high volume of observations may detect a pattern that was too rare to emerge from the qualitative analysis. Second, it may be that gender bias is not explicitly identified in most reviews but rather emerges when looking at the reviews in aggregate. The logistic models of soft skills demonstrate several associations between reviewer gender and soft skills, including interesting interaction effects.

The $Doctor_F \times Rating_{Neg}$ models in Table 4 find that all positive soft skills are more likely to occur in reviews written by women than those written by men ($P < .001$). *Candor* is roughly 1.17 (95% CI 1.13-1.21) times more likely to appear in all reviews written by women. The other 3 positive soft skills demonstrate a higher rate among women in positive reviews and a compensatory effect in women's negative reviews. However, this effect merely dampens the greater probability of occurring in reviews written by women, not equalizing it. In the models that did not fit coefficients for gender and rating interactions (*No Interactions*), both *indifference* (log OR 0.18, 95% CI 0.09-0.27; $P < .001$) and *disrespect* (log OR 0.24 95% CI 0.18-0.30; $P < .001$) were more likely to appear in reviews written by women.

H3: Female Reviewers Are More Likely to Report Negative Experiences With Male Doctors

I have hunted for a female Urologist for several years. I was dealing with a male doctor who kept blowing off my concerns as a woman and telling me what women think they feel or know. [Female; 5-star review; U940]

When women mentioned soft skills, they occasionally related difficulties with their doctor to physician gender. However, female reviewers rarely attributed poor treatment to their womanhood or to male physicians treating women poorly. It was also rare that women commented on the absence of bias in settings where they might have expected it, for example, "While he treats women and men, I think his sensitivity makes him especially good with women" (Male; 5-star; U1081).

To examine whether women or men report differential treatment depending on the gender of their doctor, each model tested an interaction effect between physician gender and patient gender. Only *disrespect* produced a highly significant gender \times gender interaction. The model for *disrespect* estimates log OR of -0.16 (95% CI -0.28--0.04; $P = .008$) for women who review female doctors. The reader may be inclined to interpret the negative coefficient for gender \times gender interaction as evidence that

women are less likely to report *disrespect* when seeing a female physician. This is true, but it must be qualified when we ask the question, *less likely relative to what?*

The odds ratio for the $\text{gender} \times g$ interaction indicates that the discrepancy in reports of disrespect between women and men is not so great when seeing a female doctor as we would have expected given the difference between women and men when seeing a male doctor. Female reviewers would seem to benefit from seeing female doctors, as we cannot reject the null that men and women report *disrespect* from a female doctor at equal probability. The $\text{Doctor}_F \times \text{Reviewer}_F$ model of *disrespect* estimates women to be 1.37 (95% CI 1.26-1.49) times as likely (log OR 0.31, 95% CI 0.23-0.40; $P < .001$) as men to report *disrespect* when seeing a male doctor (the Reviewer_F column). Given the interaction term, this probability represents the OR that a woman (compared with a man) reports *disrespect* from a *male doctor*. Summing this *base* probability with the interaction coefficient (log OR -0.16) estimates that female reviewers are 1.16 (95% CI -0.05 -0.36) times (log OR 0.15) more likely to report *disrespect* when seen by a female doctor than a *man* seeing a female doctor. As the 95% confidence

interval overlaps 0; we cannot reject the null hypothesis, that men and women report disrespect with the same probability when seeing women doctors. Similarly, when a man reviews a female physician, he is 1.58 (95% CI 1.43-1.74; log OR 0.46, 95% CI 0.36-0.55) times more likely to associate her with *disrespect* than he would a male doctor. The compensatory effect of the $\text{gender} \times \text{gender}$ interaction coefficient diminishes, but does not dissolve, the probability that a female doctor is reported to be disrespectful. When reviewed by female patients, female doctors are 1.35 (95% CI 1.08-1.67) times more likely to be associated with *disrespect* than a male doctor.

Process and Gender

Although we made no predictions about administrative *process*, it is worth noting several patterns that emerged from the logistic models on mentions of *process*. We fit 2 models of *process* reported in Table 6 in the reviews for which gender could be inferred and which did not filter out mentions of *process* ($N=111,036$). Model 1 parallels the models of themes in Table 4 and accordingly reports interaction effects as separate models. Model 2 estimates correlations between each theme and *process*, controlling for rating and gender.

Table 6. Logistic regression on the presence of process in review ($N=111,036$).

Variable	Model 1			Model 2
	$\text{Doctor}_F^a \times \text{Rating}_{\text{Neg}}$	$\text{Reviewer}_F^a \times \text{Rating}_{\text{Neg}}$	$\text{Doctor}_F \times \text{Reviewer}_F$	Themes
Intercept	-0.37^b	-0.41^b	-0.43^b	-0.84^b
Doctor_F	0.06^b	0.20^b	0.19^b	0.12^b
Reviewer_F	0.11^b	0.11^b	0.14^b	0.04^c
$\text{Rating}_{\text{Neg}}$	0.54^b	0.70^b	0.78^b	0.83^b
$\text{Doctor}_F \times \text{Rating}_{\text{Neg}}$	0.42^b	— ^d	—	—
$\text{Reviewer}_F \times \text{Rating}_{\text{Neg}}$	—	-0.02	—	—
$\text{Doctor}_F \times \text{Reviewer}_F$	—	—	-0.13^b	—
Candor	—	—	—	0.26^b
Trust	—	—	—	0.34^b
Investment	—	—	—	0.22^b
Amicability	—	—	—	1.01^b
Indifference	—	—	—	0.00
Disrespect	—	—	—	0.70^b

^aFemale=1, male=0.

^b $P < .001$.

^c $P < .01$.

^dMissing value indicate that no coefficient was estimated for the given endogenous variable.

Process is much more likely to be mentioned in negative reviews ($P < .001$). This is consistent across all models. This may be because when process is smooth, it is more likely to go unnoticed, whereas poor experiences with process are more likely to color the overall experience. Parallel to the trend observed in soft skills, *process* more often occurs in reviews written by and about women ($P < .001$). The $\text{Doctor}_F \times \text{Rating}_{\text{Neg}}$

model estimates that negative reviews of female physicians are 2.61 (95% CI 2.41-2.88) times as likely to mention process than negative reviews of male physicians (log OR 0.96, 95% CI 0.88-1.06; $P < .001$). By contrast, female and male reviewers mention process in negative reviews at equal rates. Women who see female doctors are less likely to mention *process*, which

produces an equalizing effect that offsets the greater rate of reports of *process* for both female reviewers and physicians.

We also examined the association of *process* with soft skills. Model 2 demonstrates a positive correlation between mentions of *process* and soft skills. The correlations with *amicability* and *disrespect* are sizable (log OR 1.01, 95% CI 0.98-1.04 and 0.70, 95% CI 0.65-0.76, respectively; $P < .001$), indicating that patients value the ease of interpersonal interactions with staff, that is, whether they are *friendly* or *rude*, and likely interpret bureaucratic competence through the framework of how *nice* the staff are. In our qualitative analysis, we found that positive reviews expressing *disrespect* overwhelmingly do so with regard to *process*, indicating that reviewers are able to separate relationships with their doctor and the overall clinical experience as reflected in the final review. This compartmentalization is well illustrated by a patient who reported a positive experience with a doctor but faced problems with poor administration such that the patient ultimately severed their relationship with the clinic:

Terrific bedside manner!! Really dedicates time to patients and will even follow up by phone. The staff are rude and incompetent though. They repeatedly failed to file paperwork with my insurance. I got fed up with it and had to find a new doctor. [Unknown; 5-star review; 3686]

Discussion

Interpreting These Results

Our results provide compelling evidence for a number of effects of gender on patient experience, as reported in physician reviews. These findings may be interpreted through 2 distinct frames. First, a *patient experience* frame attempts to interpret gender dynamics in the context of the patient-physician relationship. This frame should be familiar to readers versed in the literature on gender and clinical experience. The second frame, the *online review system* frame, seeks not to understand or improve the clinical aspects of health care but rather considers how gender differences may subvert or be leveraged to improve reviews as a valuable public resource that informs decisions about care-seeking.

The following discussion of the results in context of the hypotheses of this study assumes the *patient experience* perspective. The Summary and Recommendations section, however, largely reflects the *online review system* perspective, which is less concerned with controlled statistical inference than it is how the descriptive statistical patterns in [Tables 2](#) and [3](#) might affect public perception of physician quality and how we might design online review systems to improve physician-patient matching and offset bias.

H1a: Physician Ratings and Physician Gender

We hypothesized that female physicians would be more likely to receive lower ratings. This hypothesis was supported by our study. These data indicate that there is considerable reviewer bias against female physicians. This is consistent with well-documented patterns of bias against women in other fields,

notably when reviewing instructor performance in a controlled online classroom [26].

H1b: Reviewer Gender and Rating

We hypothesized that female patients would report overall worse clinical experiences than men. The results here support the opposite hypothesis. We found that men are slightly more likely to report negative experiences than women.

There are several valid interpretations of these findings. Men may receive worse care than women, as captured by patient experiences (rather than health outcomes). Alternatively, it could be that men have higher expectations for care than women or are less competent at navigating the clinical setting. Both are plausible given that men less frequently utilize health services [40,41]. Finally, we might attribute the discrepancy to women's greater propensity for agreeableness [42,43], and for forgiveness [44] and compromise [45] in interpersonal conflict. These interpretations are not mutually exclusive, and further research is warranted to account for this trend.

H2a: Soft Skills and Physician Gender

We hypothesized that reviews of female physicians would be more likely to critique their soft skills. Our results indicate that this is true of all soft skills. All soft skills were more often mentioned in the reviews of female physicians. In negative reviews of female physicians, reviewers were considerably more likely to mention *candor* and *amicability*.

The results supporting this hypothesis indicate that female physicians' soft skills are more likely to be critiqued and that female physicians are much more likely to be associated with *disrespect*. We also present evidence that women may be penalized for lacking *candor* and *amicability* to a much greater degree than men. This may be attributed to failure to live up to a positive stereotype, as women are generally expected to be more open and personable, and female physicians in particular are expected to be more caring [46]. Furthermore, the physician role is one of authority, and research has extensively documented that women are punished for leadership styles that men are rewarded for [47,48].

H2b: Soft Skills and Reviewer Gender

We hypothesized that female reviewers are more likely to reflect on their doctor's soft skills. This hypothesis was supported by our study.

In positive reviews, women mentioned all positive soft skills with greater probability. However, the magnitude of these effects was diminished in negative reviews. These patterns suggest that women may be more inclined to value a physician's soft skills. However, it also indicates that men may be more sensitive to a lack of positive soft skills than their presence.

We found that women were more likely to mention the negative soft skills, *indifference* and *disrespect*. This likely reflects the wealth of literature documenting the tendency for physicians to take women's concerns less seriously and treat them with condescension [27,29,31].

H3: Reviewer Gender and Physician Gender

We expected that female patients would report more negative experiences with male doctors. Our results support this hypothesis. Although there was no significant interaction effect of reviewer and physician gender on the probability of a negative experience, we found a significant interaction between reviewer and physician gender on the likelihood of reporting *disrespect*, which overwhelmingly occurs in negative reviews. Female reviewers apparently benefit from seeing female doctors, as they are less likely to mention *disrespect* when reviewing female physicians than when they review men. This compensating effect neutralized the overall greater association of *disrespect* with female reviewers, but not female doctors.

Given the literature and our previous finding that female physicians are subject to biased reviews, these results suggest that even women harbor bias against female physicians. However, this bias is considerably smaller among women than it is among men and is complicated by physician-gender/patient-gender preferences for different communication styles [32].

Process and Physician Gender

We made no predictions regarding the relationship between *process* and soft skills or reviewer/physician gender. However, we found that both *amicability* and *disrespect* were highly correlated with *process*, suggesting that the ease of social interaction with staff is important to reviewers. Importantly, negative reviews of female physicians are considerably more likely to mention aspects of the clinical experience beyond experiences with the doctor.

The strong association between *process* and negative reviews of female doctors may reflect a tendency for patients to assess male doctors “on their own merits,” whereas women are more likely to be held accountable for poor process. This reflects a *bias against women* interpretation. A *realist* account might hypothesize that female doctors are more likely to work in clinics with less competent or accommodating staff.

Limitations

This work is complementary to previous qualitative studies on the influence of gender on the doctor-patient relationship. We acknowledge that it is unclear whether gender differences reflect patient perception or the reality of physician behavior. For example, given the ample evidence in other contexts on bias against women, the high rate of negative reviews for female physicians likely reflects reviewer bias against physicians rather than genuine differences in treatment. However, our approach does not allow certainty in this regard. The Discussion section provides a more detailed explanation of the interpretation of gender differences in the context of the findings of previous studies. We also recognize that the data do not contain information related to patients’ health outcomes. Although the health outcome of each patient is not represented in our data, other studies have shown that reviews can reflect real health consequences [14]. Similarly, treatment noncompliance, unwarranted recalcitrance, and other patient characteristics beyond the reviewer’s narrative are not captured in the reviews.

In this paper and similar research, gender representation is reported as binary, which does not capture the full spectrum of gender or gendered interaction. Even though gender is likely to be interpreted in a binary fashion by most review readers [21], the doctor-patient relationship is more complex, and other data could offer more nuanced and richer perspectives. Furthermore, our work does not consider the intersection of gender and other identities, such as race [49,50].

As noted in the Methods section, the Google Places API limits data collection to 5 reviews per physician or practice. Google provides no documentation on how these reviews are chosen from all the reviews written. We acknowledge that the small sample may not be fully representative of a doctor or practice; however, our contribution is more focused on the biases within the reviews and not on the doctors themselves. We also note that the Google Places reviews are subject to selection biases. Demographics undoubtedly play a role in determining who writes physician reviews (eg, consider the high proportion of female reviewers in our data set). However, the data likely suffer selection biases, irrespective of demographic differences. For instance, it is probable that the U-shaped distribution of physician ratings is both a product of overall polarized attitudes and strong experiences providing greater motivation to write a review. It seems likely that other such selection biases were present in these data but were unknown to us as we performed our analysis.

Summary and Recommendations

The increasing prevalence of online reviews of physicians affects both medical practices and patient choices. However, little is known about biases that may be present in these reviews or whether they reflect the real biases documented in doctor-patient interactions [27,28]. Conversely, most studies of gender bias in doctor-patient interactions to date have been limited to qualitative analyses, smaller-scale data sets, or specific medical conditions.

This study is the first to provide evidence that gender biases and other gender differences are observable at scale in physician reviews. We provide extensive evidence of differences in physician ratings and review content with respect to both physician and reviewer gender. Our statistical inference indicates that these differences are robust when controlling for possible confounding relationships and therefore are likely to reflect gender differences and biases in the patient-physician relationship.

It is difficult to disentangle which aspects of these gender differences may be attributed to review selection bias, gender bias, or gender behavioral variation. However, these patterns undeniably affect prospective patients as they peruse online reviews to select a doctor. Thus, it is important to consider how we might educate the public about the effects of gender bias on physician ratings and how online review systems could be improved to control for bias. We propose several concrete steps that could be taken to better support patients.

Review systems can draw attention to gender differences in reviews to aid prospective patients in building their own understanding of a physician’s potential gender biases. One

way to do this is to organize reviews by gender. This could either be the default presentation or a special gender-separated view. Alternatively, reviewer gender might be indicated explicitly only in automatically generated summaries of physician reviews. Additionally, prospective patients might benefit from a panel that provides a sense of how a particular physician compares with other physicians on gender. For example, if there is a discrepancy between men's and women's ratings for a physician that differs greatly from the gender discrepancy of other similar physicians, a prospective patient might benefit from reading their reviews with this information in mind.

An online review system could also help to correct for gender differences that generally affect reviews. As female physicians receive many more negative reviews on average, a prospective patient might find it easier to select among physicians if ratings are adjusted to control for the physician's gender or if ratings are reported relative to physicians of the same gender. On the other hand, online review systems could implement measures to reduce bias in the reviews. For instance, when writing a review and using a word that is commonly used to critique

female physicians, the system could prompt the reviewer about gender stereotyping in word choice or alternative terms that are gender neutral. This might encourage a more balanced approach to review writing and help reviewers recognize their own biases. Alternatively, information can be solicited from the reviewer in such a way that greatly reduces the effects of gender stereotypes on performance evaluation [51].

These approaches would ideally lead to reviews that more accurately reflect the quality of care provided by physicians. Finally, this study draws attention to several important areas for future work. We advocate researchers adopt mixed methods approaches similar to the one presented here when pursuing quantitative analyses of text. Furthermore, this study raises questions specifically related to online review systems as objects of study in their own right. Little is known about how readers interpret online reviews, notably in the context of health care and gender. It also highlights the need to study how review systems can be designed to improve review accuracy and inform review readers and writers on gender bias in online reviews. We propose that experimental studies in review cognition and system design will be most fruitful to these ends.

Abstract

Background: During the last few decades, preventing the development of cardiovascular disease has become a mainstay for reducing cardiovascular morbidity and mortality. It has been suggested that interventions should focus more on committed approaches of self-care, such as electronic health techniques.

Objective: This study aimed to provide evidence to understand the financial consequences of implementing the “Do Cardiac Health: Advanced New Generation Ecosystem” (Do CHANGE 2) intervention, which was evaluated in a multisite randomized controlled trial to change the health behavior of patients with cardiovascular disease.

Methods: The cost-effectiveness analysis of the Do CHANGE 2 intervention was performed with the Monitoring and Assessment Framework for the European Innovation Partnership on Active and Healthy Ageing tool, based on a Markov model of five health states. The following two types of costs were considered for both study groups: (1) health care costs (ie, costs associated with the time spent by health care professionals on service provision, including consultations, and associated unplanned hospitalizations, etc) and (2) societal costs (ie, costs attributed to the time spent by patients and informal caregivers on care activities).

Results: The Do CHANGE 2 intervention was less costly in Spain (incremental cost was –€2514.90) and more costly in the Netherlands and Taiwan (incremental costs were €1373.59 and €1062.54, respectively). Compared with treatment as usual, the effectiveness of the Do CHANGE 2 program in terms of an increase in quality-adjusted life-year gains was slightly higher in the Netherlands and lower in Spain and Taiwan.

Conclusions: In general, we found that the incremental cost-effectiveness ratio strongly varied depending on the country where the intervention was applied. The Do CHANGE 2 intervention showed a positive cost-effectiveness ratio only when implemented in Spain, indicating that it saved financial costs in relation to the effect of the intervention.

Introduction

Background

In the last few decades, prevention at both population and individual levels in patients with established cardiovascular disease (CVD) has become a mainstay for reducing cardiovascular morbidity and mortality [1]. However, CVD remains the leading cause of death globally [2].

One of the cornerstones of CVD prevention is the promotion of lifestyle changes, including physical activity, a healthy diet, and avoidance of unhealthy behaviors such as smoking and drinking alcohol [1]. However, providing patients with relevant information regarding the importance of lifestyle habits seems to be insufficient to prompt these changes and maintain them over time [3]. Instead, it has been suggested that the preventive paradigm should shift from passive to more committed approaches of self-care based on the following three core elements: self-care maintenance, self-care monitoring, and self-care management [4-6].

The emergence of solutions based on information and communication technologies (ICTs), such as telemedicine, has greatly contributed to filling some of the gaps of effective self-care. One of the most classical ICT solutions has been the use of self-monitoring devices in patients with high cardiovascular risk to facilitate successful blood pressure (BP) control [7]. The expansion of mobile apps and their peripheral devices has raised the number of ICT-based interventions aimed at improving not only self-monitoring but also behavior changes in various patient profiles, including older people with high cardiovascular risk [8-10]. The emergence of lifestyle data-driven apps illustrates the increasing interest in this approach in various health care areas [11].

To date, evidence regarding the efficacy of these interventions is still evolving. Clinical guidelines for the prevention of CVD highlight that cost-effectiveness data from randomized controlled trials (RCTs) are scarce, and most data regarding the cost-effectiveness of cardiovascular prevention strategies combine clinical evidence with simulation approaches [1,12,13]. Simulation modeling is currently used to address important issues in clinical practice and health policy that have been very difficult to study within high-quality clinical trials but provide necessary insights for making health care decisions. Nonetheless, assumptions and personal choices are required to conduct simulation modeling, leading to potentially biased outcomes. Transparency in decision-making is therefore critical to

adequately understand the observed outcome [14]. In this regard, there is a need for providing the various stakeholders, particularly policy makers, with evidence from nonsimulated research trials to understand the financial consequences of scaling up ICT solutions for health care systems [15]. In this study, we aimed to determine whether the Do Cardiac Health: Advanced New Generation Ecosystem (Do CHANGE) 2 preventive intervention is a cost-effective alternative for patients with CVD in Spain, the Netherlands, and Taiwan.

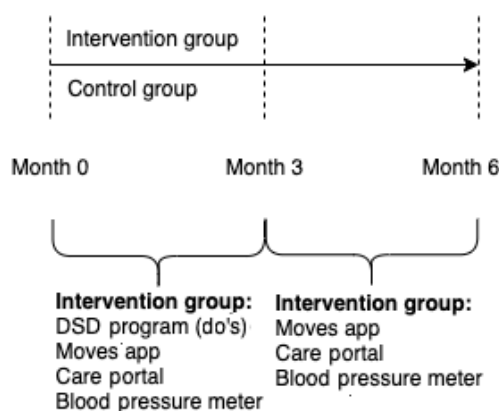

The Do CHANGE Project

The Do CHANGE program was developed as an ICT-based alternative for providing health education, which leads to behavioral changes in care recipients [16,17]. The Do CHANGE program consists of a 6-month intervention with a set of devices that include self-monitoring tools and the Do Something Different (DSD) behavior change program (only available during the first 3 months of the intervention), which has been shown to be effective in changing health behaviors in previous studies targeting different populations [18]. The Do CHANGE program included the following two phases: Do CHANGE 1 and Do CHANGE 2, which were assessed in two consecutive RCTs (Figure 1).

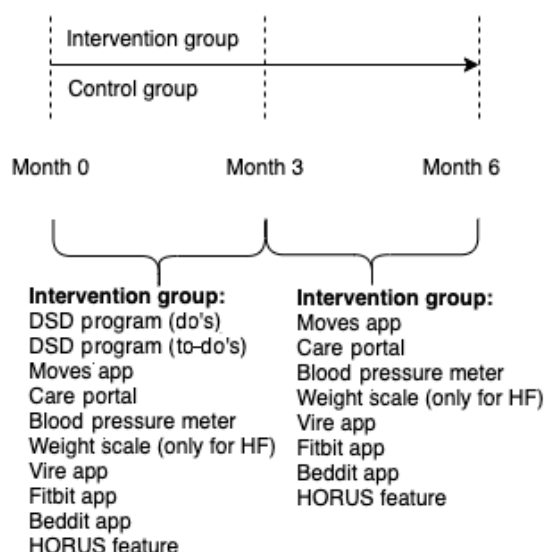

Patients included in the Do CHANGE 1 study received the DSD behavior change program, which was provided via text messages on patients' mobile phones. Behavioral flexibility is associated with a broad range of behavioral repertoires, making people more open to experience and adopt new behaviors [19]. This is achieved by disrupting patients' daily behavioral routines for a short period (eg, a few seconds) with behavioral prompts (referred to as "do's") delivered through patients' mobile phones. These messages challenge patients to do something different and get out of their comfort zone. Do's have been developed by a multidisciplinary team including cardiologists and psychologists, ensuring that they apply to the target population and are thus related to daily behaviors or needs. Patients received a total of 32 do's during the 3-month intervention period (2-3 do's per week). The program was tailored to the cardiac population with slight differences in the program depending on patients' primary diagnosis (coronary artery disease, heart failure, and hypertension), as the preferred health behaviors may vary depending on the diagnosis [20]. In order to obtain objective measures on patients' physical functioning, all participants received a BP monitor, the Moves app (Facebook Inc; to register GPS location), and the Careportal (Docobo Ltd, home monitoring device measuring daily symptoms and an electrocardiogram).

Figure 1. Do CHANGE 1 and 2 randomized controlled trial design including intervention details. Do CHANGE: Do Cardiac Health: Advanced New Generation Ecosystem; DSD: Do Something Different; HF: heart failure.

Do CHANGE 1 Randomized Controlled Trial

Do CHANGE 2 Randomized Controlled Trial

The main additional features of the Do CHANGE 2 compared with the Do CHANGE 1 trial were the greater number of devices for self-monitoring and collecting behavioral information, and the capacity of the DSD program to tailor the behavioral prompts to the actual behavior of the care recipient, thus allowing for a personalized approach. Do CHANGE 2 integrates the principle of theory-driven behavioral change techniques, which can guide behavior change, within the offered interventions [21]. As a natural evolution from the Do CHANGE 1 trial, the second phase aimed to increase the ability of a person to express behavior in a more context-dependent way [22], thus being more open to experience and increasing the likelihood of adopting new behaviors [19].

Care recipients perceived the Do CHANGE 1 program as helpful and easy to use; however, it failed to prompt relevant lifestyle changes (measured with the Health Promotion Lifestyle Profile-II questionnaire) compared with treatment as usual (TAU) [20]. The Do CHANGE 2, based on a more personalized approach, resulted in a relevant change in lifestyle behavior over time in the intervention group. In addition, the intervention was perceived as useful and feasible by patients and health care professionals [23]. In order to provide a broader perspective of the effects of this program, we present herein the results of the cost-effectiveness analysis of the Do CHANGE 2 compared with TAU.

Methods

Trial Design and Patients

This was a multisite RCT to assess the cost-effectiveness of an ICT-based program to change behavior in patients with CVD compared with TAU. Local clinical specialists and research assistants recruited adult patients treated in the following three hospitals in three different countries: *Badalona Serveis Assistencials* (Spain), *Elisabeth TweeSteden Ziekenhuis* (the

Netherlands), and *Buddhist Tzu-Chi Dalin General Hospital* (Taiwan). The planned sample size based on the available project resources was 75 patients for Spain, 75 for the Netherlands, and 100 for Taiwan. Once accepted to participate in the study, patients at each study site were randomized to receive either the TAU or the Do CHANGE 2 intervention. The primary outcomes were lifestyle change and quality of life. Additionally, behavioral flexibility was considered a mediator variable in this relationship. As the project aimed to provide proof of concept and examine the feasibility of the intervention, no sample size calculation was performed a priori. Recruiting a comparable number of patients across the countries was considered relevant to provide proof of concept. The details regarding the study patients and trial design are described in the report by Habivovic et al [16].

The most remarkable changes from the original study protocol (Do CHANGE 1) were the changes in the DSD program (moving from predefined messages according to the patient psychological profile to nudges tailored according to their behavior as gathered by the measurement devices), the addition of two new wearable devices (Beddit [Apple] and Fitbit [Fitbit Inc]), and the Vire app (Do CHANGE app). Considering the importance of weight in heart failure (HF), patients with this diagnosis also received a weight scale.

Inclusion Criteria

Participants were screened from adult patients (aged 18-75 years) who had been primarily diagnosed with either hypertension (ie, systolic BP [SBP]/diastolic BP [DBP] $\geq 140/90$ mmHg in two consecutive measurements), coronary artery disease (ie, occurrence of myocardial infarction or angina pectoris, or previous percutaneous coronary intervention and/or coronary artery bypass graft surgery), or symptomatic HF (ie, New York Heart Association class I-IV). Patients also had to have two or more of the following risk factors: increased

cholesterol, smoking, diabetes, sedentary lifestyle, and psychosocial risk factors. The presence or absence of each of the risk factors was assessed following the local guidelines in each participant country. For HF patients, additional inclusion criteria were a diagnosis of systolic or diastolic HF and the presence of HF symptoms (eg, exhaustion, shortness of breath, and chest pain). Other general inclusion criteria were an adequate level of the native language, access to the internet at home, having a smartphone compatible with the apps used in the study, and having the skills necessary to use a personal computer and a smartphone.

Exclusion Criteria

Patients with life expectancy less than 1 year, life-threatening comorbidities, a history of psychiatric diseases other than anxiety and depression, and relevant cognitive impairments and those on the waiting list for heart transplantation were excluded from the study.

The reasoning for establishing the exclusion criteria was to prevent the inclusion of patients whose disease severity may critically increase during the intervention. These patients may perceive participation as an extra burden, are more likely to drop out due to illness-related complaints or early mortality, and may be less likely to benefit from a lifestyle intervention owing to severe comorbidities. Patients with mental illness were also excluded because the intervention might become stressful and trigger symptoms in these patients. The selected exclusion criteria are in line with the DO CHANGE 1 trial, safeguarding that the study is not perceived as a burden and meets patients' needs as much as possible.

Intervention

The Do CHANGE 2 program implemented in this trial was similar to that described by Broers et al for Do CHANGE 1 [20]. Patients randomized to the intervention group received devices for measuring key clinical parameters needed for monitoring their CVD, such as a BP monitor, weight scale (in HF patients only), and the Careportal, which allowed monitoring of daily symptoms and an electrocardiogram. The patient's location was monitored by the Moves app. In addition to the aforementioned ICT solutions (also used in the Do CHANGE 1 program), the Do CHANGE 2 program included the Vire app, a purpose-designed app to integrate the input from all the monitoring devices, so that the patient could interact with a unique easy-to-use source of information. The app integrates the information coming from the following apps: the Beddit app (provided with the device under the mattress cover sheet) aimed at monitoring sleep efficiency, the Fitbit app (with the wristband) aimed at measuring physical activity through step count, and the HORUS feature embedded in and aimed at collecting pictures of the different meals of the patients in order to provide diet recommendations. Study participants in the Do CHANGE 2 intervention group were also provided with leaflets

([Multimedia Appendix 1](#)) and multimedia resources explaining the use of the Do CHANGE environment.

Like in the Do CHANGE 1 program, patients in the intervention group received a 3-month behavior change program. The program was based on providing care recipients with short messages aimed at disturbing daily routines. Messages were delivered through their mobile phones and suggested them to "do something different." However, unlike the Do CHANGE 1 program, in the Do CHANGE 2 program, behavioral nudges were not only predefined according to the patient's personality profile but also tailored to the patient's behavior, as recorded by the monitoring devices. These behavior-driven messages called to-do's were delivered to the patients based on their current functioning. Patients receive their do's and to-do's through the Careportal or the Vire app, or via SMS, depending on patients' preferences [16].

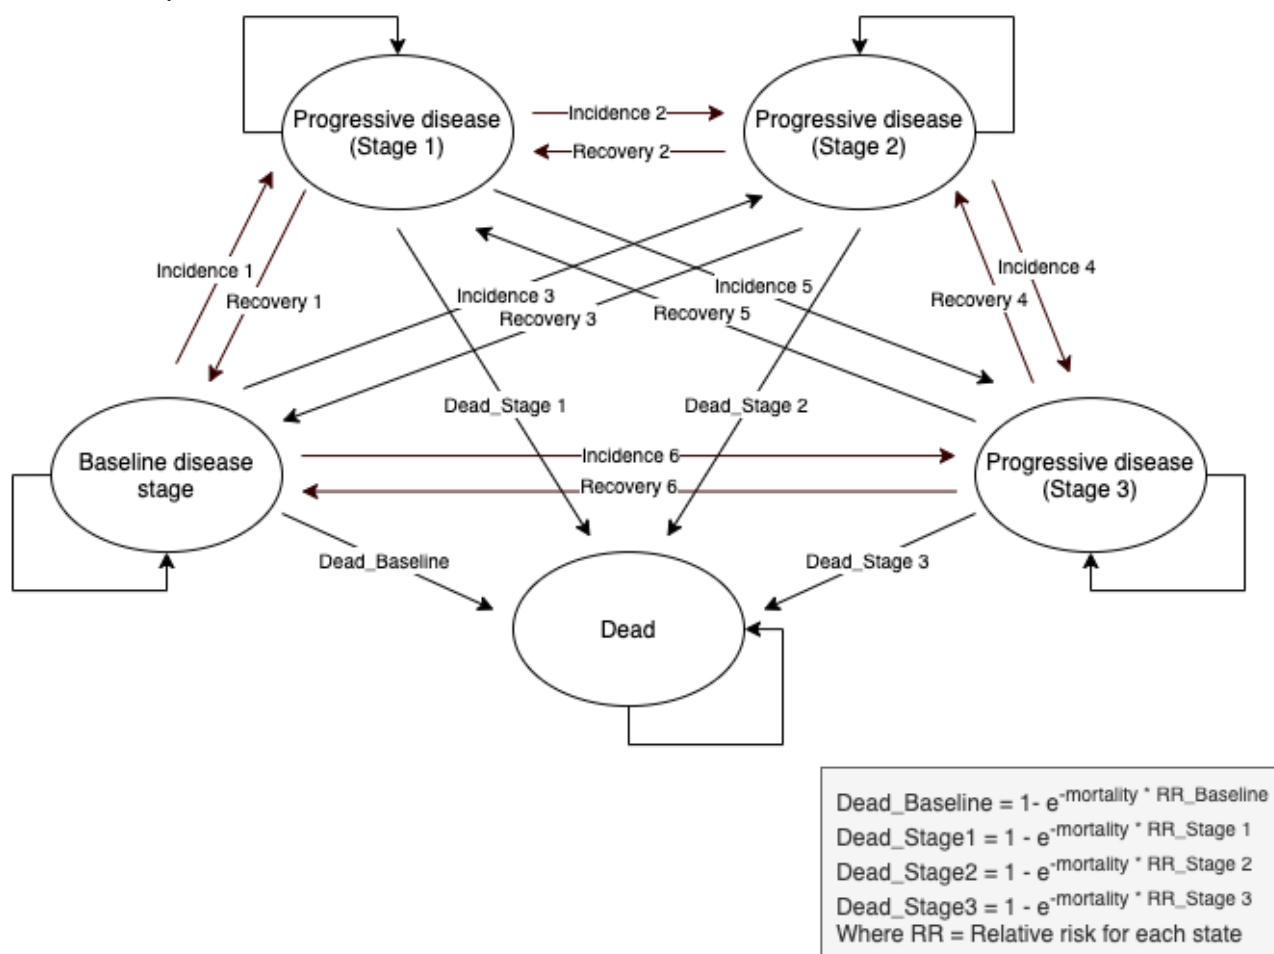

The GPS data from the Moves app and activity data from the Fitbit device were used to calculate higher abstraction scores called *activity*, *variety*, and *social opportunities*. The to-do's were tailored based on the trends of these scores over time (eg, a patient with declining activity would receive a message that focuses on increasing activity). The granularity of this system is not restricted to one score; alternatively, new scores are calculated for each update of data, and the system determines whether the score is a "target" for a message. Multiple combinations of targets are possible; therefore, a to-do can tackle both *variety* and *social opportunities* if needed based on the scores. A detailed description of the construction process of to-do's can be found in previously published work [23,24].

Besides receiving personalized prompts (eg, based on activity levels), patients were contacted each week by the research assistant to check how everything was going and to provide dietary coaching. This might have greatly contributed to the high adherence rate during the first 3 months, as they received personalized feedback. After this period, patients were not contacted in person anymore; however, they were allowed to keep all the devices (eg, Fitbit, Beddit, etc) in order to monitor their behavior for the remaining 3 months.

Cost-Effectiveness Analysis

The cost-effectiveness analysis of the Do CHANGE 2 RCT was conducted using the Monitoring and Assessment Framework for the European Innovation Partnership on Active and Healthy Ageing (MAFEIP) tool [25]. The MAFEIP tool performs a cost-utility analysis through a web app that analyzes incremental costs and effects. The cost-effectiveness estimates are based on the principles of decision analytic modeling and Markov models that assess the impacts that health-related innovations have in terms of health outcomes and resource usage. For Do CHANGE 2, we parametrized the tool on a Markov model of five health states from the perspective of the three service providers ([Figure 2](#)) [26].

Figure 2. Markov model of five health states applied for the Do CHANGE cost-effectiveness analysis. Do CHANGE: Do Cardiac Health: Advanced New Generation Ecosystem.

The MAFEIP tool requires the user to provide the following three main types of inputs: (1) the health states and the corresponding transition probabilities between them, (2) the costs, and (3) the utility, for which the EuroQol five-dimension three-level (EQ-5D-3L) questionnaire was used as recommended by the National Institute for Health and Care Excellence [27].

In order to estimate the incremental health gain from a particular intervention delivered, the defined model needs to be run twice. Once with parameter estimates for the respective intervention under assessment (ie, Do CHANGE 2), and once with parameters corresponding to the standard care scenario (ie, TAU). In the model, these two scenarios may differ in terms of transition probabilities (disease incidence, recovery, and mortality), as well as the utility weight and health care and societal costs related to the health states. When the model simulates a hypothetical cohort of patients moving between these health states over time, the differences in survival, utility, and cost accumulate until reaching an estimate of the incremental costs (ΔC) and health effects (ΔE) that can be expected from the intervention under evaluation. Therefore, the tool can be used to estimate the incremental cost-effectiveness ratio ($\text{ICER} = \Delta C / \Delta E$) or the incremental net monetary benefit ($\Delta E \times \lambda - \Delta C$) of one intervention compared with another, where λ is defined as the willingness-to-pay (WTP) threshold for an additional unit of health gain.

Besides the transition probabilities among health states, the utility, and the cost, the tool allows the user to include the relative risks for mortality, the discount rates, and the time horizon for the analysis (cycle length). The parameters included in this analysis and their assessments during the study are explained in detail below.

Definition of Health States

The first stage in the construction of a Markov model is defining the different states of the disease in relation to the important clinical and economical effects of the disease. Evidence suggests that high BP is the predominant risk factor for CVD [28]. Following the scientific evidence and for the purpose of the Do CHANGE assessment, the health states were established based on SBP and DBP, according to the classification of the American Heart Association [29] as follows: baseline disease stage (SBP <120 mmHg and DBP <80 mmHg), progressive disease stage 1 (SBP 120-129 mmHg and DBP <80 mmHg), progressive disease stage 2 (SBP 130-139 mmHg or DBP 80-89 mmHg), progressive disease stage 3 (SBP ≥140 mmHg or DBP ≥90 mmHg), and death. On a side note, the latest stage was not included, as it is considered to be a hypertensive crisis (SBP >180). The transition probabilities were calculated based on the changes between the initial health states (at baseline) and those at 3 months. These transitions can be of incidence (ie, the annual probability for an individual to move from baseline to each

progressive stage of the disease) and recovery (ie, the annual probability of improving).

Cost Estimate

The following two types of costs were considered for both study groups: (1) health care costs (ie, costs associated with the time spent by health care professionals on service provision, including consultations, unplanned hospitalizations, etc) and (2) societal costs (ie, costs associated with the time spent by patients and informal caregivers on care activities).

The data collected by the research team in each country were provided in local currency units (Euro for both Spain and the Netherlands and New Taiwan Dollars for Taiwan). Taiwan prices were converted into a common basis of 2018 Euros using simple exchange rate conversion factors, reflecting the average market exchange rate between New Taiwan Dollars and Euros during the year in question (NT \$1=€0.02862). A currency exchange rate of €1=US \$1.12 is applicable (average exchange rate for 2018).

For computing the time spent by health care professionals, we considered an average duration of 15 minutes and 25 minutes for a visit to a general practitioner and specialist, respectively. The personnel cost was established based on the average cost for one full - time employee, including employer contributions to social security. The average hourly costs were €29.23 (Spain), €59 (the Netherlands), and €16.88 (Taiwan) for a general practitioner; €20.79 (Spain), €40 (the Netherlands), and €6.33 (Taiwan) for a nurse; and €34.81 (Spain), €13.50 (the Netherlands), and €4.91 (Taiwan) for a specialist. The estimations of cost per bed - day for hospitalizations were €733.56 (Spain) and €1853.57 (the Netherlands), which were obtained by dividing the expenditure for inpatient curative care in hospitals by hospital bed - days for services of curative care (both publicly available) [30]. The corresponding costs for Taiwan were calculated by dividing the average expenses of hospitalization by the number of hospital days, which was €342.50 [31].

Societal costs differed according to the study group. For patients allocated to the control group, we considered the extra travel time spent by patients and caregivers in usual care compared with Do CHANGE 2, whereas for those allocated to the intervention group, we considered the time spent by patients using the service.

Additionally, for patients in the Do CHANGE group, the following costs were added: time spent by professionals in service development and training (4 hours per professional, divided by the number of randomized subjects), time spent by nurses in training patients (30 minutes per participant) and installing the Do CHANGE service ecosystem (45 minutes per patient), and the cost of the devices (including taxes). Data are provided in Euro (2018).

Utility Calculation

Utility was estimated using the EQ-5D-3L tool [32]. The EQ-5D is a standardized questionnaire-based measure of self-rated health-related quality of life developed by the EuroQol Group to provide a simple and generic measure widely used for both

clinical and economic appraisals. In the case of the Do CHANGE 2 project, we used the EQ-5D-3L version, which was administered at baseline and at 3 and 6 months.

The resulting scores of the questionnaire were weighted using the trade-off method previously described for Spain [33], the Netherlands [34], and Taiwan [35]. The EQ-5D health states, defined by the EQ-5D descriptive system, were subsequently converted into a single summary index by applying specific weights to each of the levels in each dimension of quality of life. The index was calculated by deducting the appropriate weights from 1, which was the value assigned to full health. In the case of the cost-effectiveness analysis of the Do CHANGE intervention, our interest was to measure the change over time, rather than the absolute values. Therefore, we calculated the changes in utility for each of the five health states and for each of the study conditions and added a common initial measure for the whole sample to each of them. The MAFEIP requires EQ-5D utility scores combined with time indicators to compute quality-adjusted life-years (QALYs) automatically.

Relative Risks of Mortality, Discount Rates, and Time Horizon

The MAFEIP tool allows mortality rates to be internally calculated by using the all-cause mortality rates (age- and sex-dependent) extracted from the Human Mortality Database. The relative risk of mortality is a measure that estimates the mortality in a specific population (eg, people who participated in the Do CHANGE 2 study) compared with (ie, divided by) the mortality in a reference population or condition (in this case, from the Human Mortality Database). The reference condition considers CVD mortality for the population of the specified country (ie, Spain, the Netherlands, and Taiwan).

The discount factors for costs and effects are used to estimate outcomes while taking into account the future costs and health effects, that is, adjusting for differences in the timing of costs (expenditure) compared with health benefits (outcomes). Therefore, adequately applied discount factors express future costs or benefits at today's equivalent value. In Do CHANGE 2, we followed the recommendations from the Health Technology Assessment authorities in each country [36-40]. The discount factors for costs and health outcomes applied in Do CHANGE 2 were 3% for both costs and health outcomes in Taiwan and Spain, and 4% for costs and 1.5% for health factors in the Netherlands.

Finally, the MAFEIP framework allows specifying the number of cycles that the model will run, which represents the timeframe in which the impact of the intervention will be evaluated. Markov models are used to simulate both short-term and long-term processes (ie, CVDs) [41]. In the case of Do CHANGE 2, we wanted to see estimates of the incremental costs (and effects) of the intervention in a time horizon of 5 years. The cycle length we selected is not in line with CVD's etiology (ie, a long disease development process) [41] but considers the nature of the intervention and the maximum time frame it can be sustained in light of the depreciation of the wearable and medical device technology that was used.

WTP Threshold

The balance between the economic benefit and clinical effectiveness varies and is entirely dependent on the relationship between the ICER and the threshold value the society is willing to pay at a specific point of time, which is known as the WTP threshold. The fact that WTP thresholds can be specified after the ICER is calculated raises concerns about researchers selecting WTP thresholds that suit their hypothesis, hence compensating for technology of relatively lower value [42].

While there is an agreement about CVDs being preventable to a certain extent, there has also been a discussion as to whether prevention interventions offer good value for money. Previous research has shown a positive relation between lower lifetime risk for CVD mortality and increased survival and quality of life [43]. Prevention strategies can bring relevant benefits at lower costs relative to most treatment options provided that their cost-effectiveness value is almost always below the accepted societal WTP [44].

For the Do CHANGE 2, we selected a WTP threshold of €15,000/QALY for the three countries, not corresponding to the value recommended by local Health Technology Assessment guidelines. The WTP threshold is lower in all cases. We set a lower WTP threshold in order to avoid the concerns mentioned above and to fit the results of the technology, and considering comparisons with other preventive interventions.

Data Collection and Analysis

The questionnaires, as defined in the study protocol, were loaded into the web tool LimeSurvey [45] and collected by local research assistants. Data from the medical devices (built-in electrocardiogram monitor, blood pressure meter, and weight scale) were collected through the Careportal. The data generated by the wearable devices (Fitbit and Beddit) were continuously monitored and integrated through the Vire app. Information regarding resource consumption (eg, hospitalization costs) was collected by local research assistants from the local electronic medical records.

IBM SPSS Statistics for Windows Version 21.0 (IBM Corp) was used to perform the statistical analyses of the effectiveness study, and R (R Core Team 2018) and RStudio (RStudio Team 2016) were used to calculate the transition probabilities and utilities. We used the MAFEIP tool to perform the cost-effectiveness analysis.

Results

Study Participants

Figure 3 shows the overall flow chart of participant recruitment in the Do CHANGE 2 project. Of the 4540 patients assessed for eligibility at all three sites, 238 were enrolled in the study

(120 in the intervention group [Do CHANGE] and 118 in the control group).

Owing to relevant differences in patient recruitment strategies between sites, most patients screened in Spain and the Netherlands agreed to participate, whereas many patients in Taiwan refused to participate. Based on retrospective investigation, it appeared that all inclusion criteria in Taiwan were checked after the patients were approached for participation. Hence, the number of patients that were approached appeared to be much higher. In Spain and the Netherlands, patients who fulfilled the basic inclusion criteria were offered to participate. If the same strategy was applied in Taiwan, the refusal rate would have been much lower. Both Spain and the Netherlands met the target number of participants as defined in the project plan, whereas Taiwan did not reach the planned number of participants.

Eighteen patients dropped out before the end of the 6-month follow-up, demonstrating a very high adherence rate. Owing to the personalized nature of the intervention (eg, relevant behavioral prompts and personalized feedback), we expected the adherence to be high. We believe that the nature of the 3-month intervention, where blended and personalized care was provided, combined with the monitoring devices after that period contributed to the high adherence. Patients were engaged in their health management, and therefore, they might be more willing to proceed with monitoring.

Of the 114 participants who were in the program for at least 3 months, 72 (60%) claimed to have carried out all the nudges provided by the DSD and 86 (72%) reckoned the program was useful. Reasons for not adhering to the program were mainly having no time (8/84, 6.7%), not feeling like it (2/84, 1.7%), and falling ill (2/84, 1.7%). One of the participants who quit the program disclosed that being confronted with the illness on a daily basis became too stressful. Moreover, in some cases, the confrontation for some partners to deal with the illness of their husband or wife caused anxiety.

Table 1 summarizes the main demographic characteristics of the three participating countries. None of the variables collected showed relevant systematic differences between study conditions at baseline, except for Spain, with participants in the Do CHANGE 2 group being younger (Do CHANGE 2 group vs TAU group: mean 53.8 years, SD 15.8 years vs mean 67.4 years, SD 7.5 years), having a higher education (mean 14.5 years, SD 6.3 years vs mean 9.1 years, SD 5.5 years), and showing a higher employed proportion (17/37, 45.9% vs 4/37, 10.8%). Multimedia Appendix 2 presents the clinical characteristics of the study sample, medication, and psychological symptoms. The only significant difference at baseline was observed in psychotropic medication for participants in the TAU group in Spain ($P=.03$), which is consistent with the population in the control group being older.

Model Input

The model input for the MAFEIP tool included data regarding the health states (and transition probabilities) of study participants, the costs associated with each study group, and the utility estimate. [Table 2](#) summarizes the distribution of study participants across the MAFEIP health states at study start, as well as the transition probabilities between these states, computed by considering data recorded at month 3. [Table 3](#) summarizes the total health care and societal costs for each group and each state. The detailed amounts for each type of

health care and societal cost are provided in [Multimedia Appendix 3](#). The specific costs associated with the implementation of the Do CHANGE environment are presented in [Table 4](#). The utility values calculated from the EQ-5D-3L scores and the estimated utility computed by adding the initial common measure are described in [Table 5](#). No systematic differences were observed between study conditions at baseline. The utility values for the whole study sample in Spain, the Netherlands, and Taiwan were 0.897, 0.842, and 0.854, respectively.

Cost-Effectiveness

After cleaning the data, 207 participants were included in the cost-effectiveness analysis (92 in the intervention group and 115 in the control group). The Do CHANGE 2 intervention was less costly in Spain (incremental cost was −€2514.90) and more costly in the Netherlands and Taiwan (incremental costs were €1373.59 and €1062.54, respectively). Figure 4 shows the cost-effectiveness plane for the three countries. The cost-effectiveness plane plots the incremental cost of the intervention on the y-axis and the incremental health outcome (measured in QALYs) on the x-axis. The diagonal line

represents the WTP per additional QALY gained, which is the maximum amount that the society is willing to give in exchange for a better quality of life. Different thresholds may also be selected. Depending on the location of the ICER point in this plane, one would be able to interpret whether an intervention is cost-effective. When the ICER point is within the lower-right quadrant, it means the intervention is accepted (it is more effective and cheaper), and when it is within the upper-left quadrant, it means that the intervention is not accepted (it is less effective and more expensive). If the ICER point lies in the other two quadrants, then the intervention may or may not be accepted depending on the ICER and WTP threshold values.

Figure 4. Cost-effectiveness plane for the Do CHANGE intervention in Spain, the Netherlands, and Taiwan. The dotted line shows the willingness-to-pay threshold of €15,000 per QALY. Do CHANGE: Do Cardiac Health: Advanced New Generation Ecosystem; ICER: incremental cost-effectiveness ratio; QALY: quality-adjusted life-year; WTP: willingness to pay.

Compared with usual care, the effectiveness of the Do CHANGE 2 program in terms of QALY gains was slightly higher in the Netherlands (incremental effect of 0.011) and lower in Spain and Taiwan (incremental effects of -0.134 and -0.094 , respectively). Even though the Do CHANGE program was more effective than usual care in the Netherlands, the relative costs for gained utility (€124,489.27 per QALY) were too high to accept this intervention. Taken together, the Do CHANGE intervention would only be accepted in Spain, where it would help save €8,769.05 per QALY.

We also calculated the incremental cost and health-related quality of life for every age-gender combination in the specified target population. The data are presented in [Multimedia Appendix 4](#).

Discussion

Principal Findings

In this cost-effectiveness analysis of an ICT-based intervention to change the health behavior of patients with CVD (the Do CHANGE program) assessed in a multicenter RCT, we found that the ICER strongly varied depending on the country where the intervention was applied. The Do CHANGE 2 program was slightly more effective than usual care in the Netherlands only, albeit at an incremental cost too high to accept the intervention at the selected WTP threshold (€15,000 per QALY). The same intervention was less effective but less costly than usual care in Spain. In Taiwan, the intervention resulted in the dominated option (less effective and more expensive). Therefore, implementation of the Do CHANGE 2 intervention is only recommended in Spain, where it could allow saving financial costs taking into account the costs and effects of the intervention.

We further tested the results with higher WTP thresholds (ie, €30,000 per QALY), with results remaining in the same line.

Contextualization With Previous Work

There is a large body of evidence showing that ICT solutions, including mobile-based telemonitoring, improve the quality and outcomes of care in patients with CVD [46]. Unfortunately, the cost-effectiveness assessment is often disregarded, and many studies reporting cost information do not meet a quality standard high enough to determine the cost-effectiveness or cost-utility of the intervention [46,47].

Regardless of the quality in reporting of individual studies, evidence on the cost-effectiveness of ICT-based lifestyle interventions is rather controversial, and many authors have acknowledged difficulties in drawing strong conclusions in this regard [48-50]. Overall, cost-effectiveness evaluations of secondary and tertiary prevention strategies for patients with CVD are challenged by the multiple factors influencing the outcomes and costs, such as baseline cardiovascular risk, the cost of drugs or other interventions, reimbursement procedures, and implementation of preventive strategies [1]. In the case of telemedicine approaches, it has been recognized that cost-effectiveness depends largely on local aspects of the individual service (and care as usual) being evaluated, and a service may be highly cost-effective in one context but highly ineffective when transferred to another context [47]. This was the case in our analysis, which yielded controversial results regarding the cost-effectiveness of the intervention in the different countries involved. Importantly, the success of an ICT-based lifestyle intervention strongly depends on the willingness of individuals to adopt the intervention, which is likely to be associated with cultural constraints and, therefore, to be country specific.

These differences were particularly pervasive between the Netherlands and Taiwan, where the cost-effectiveness planes showed an almost opposite profile, although the same intervention was implemented. We associate this situation with the majority of patients recruited in Taiwan having hypertension as the primary diagnosis and medical consultations involving health care professionals (ie, physicians) in the Netherlands being too expensive for them to devote time to a prevention intervention that could perhaps be conducted by nurses. This finding supports the need to evaluate the cost-effectiveness of these types of interventions within each context in order to provide the various stakeholders with evidence to understand the financial consequences of scaling up ICT solutions for health care.

Limitations

The main limitation of our trial was the sample size, which was constrained by budget restrictions. The discrepancy between the target and the actual sample size was mainly due to technical difficulties in recruiting participants, who had to enroll in the trial for a minimum duration of 6 months. The low sample size might have constrained the representativeness of the results and made them more sensitive to biases associated with patients with extreme behaviors (ie, outliers). Actually, the extremely low number of participants within, for instance, the states “baseline” and “progressive disease stage 1,” might explain the unrealistic utilities of these patients before the intervention (eg, 0.962 and 1, respectively, for the control group), which were considerably higher than the average reported in larger RCTs involving HF (utility 0.84) [51]. Another example associated with this limitation is the relevant differences for patients allocated to the intervention group in Spain, who were younger and had higher education.

Second, an acknowledgment must be made regarding the limitation associated with the heterogeneous characteristics of the study sample for the primary diagnosis and cultural setting (ie, Spain, the Netherlands, and Taiwan), which may have contributed to the heterogeneous results across countries.

Unlike other cost-effectiveness analyses, we did not consider the contribution of medication to the health care costs. Although this might have increased the accuracy of the absolute costs, from a clinical point of view, it is unrealistic that the prescribed medicines would change throughout a 3-month time lapse. Since our main interest was assessing the change in costs rather than describing the actual values, we considered that it was more appropriate to exclude this concept from the cost-effectiveness analysis.

Finally, although RCTs are considered the gold standard for assessing cost-effectiveness, some authors criticize that they might miss information regarding how the intervention fits into routine practice [15].

Conclusions

Our results suggest that the Do CHANGE 2 environment may help reduce health care costs associated with the management of patients with CVD in certain settings. However, changing health behavior and assessing the impact of this change on health care and societal costs remain big challenges. In line with previous research in this field, our assessment does not allow drawing strong conclusions in this regard. Irrespective of the specific cost-effectiveness of the Do CHANGE 2 program, our results highlight the high heterogeneity that ICT-based interventions might show depending on the country where they are implemented and stress the need for assessing each intervention in all areas before scaling up implementation.

Acknowledgments

The continuous development of the MAFEIP tool is funded by the European Commission's Horizon 2020 program under the projects WE4AHA (grant number: 769705) and DigitalHealthEurope (grant number: 826353). The Do CHANGE study was funded by the European Commission's Horizon 2020 program (grant number: 463735). The funder had no role in data collection or analysis, the decision to publish, or the preparation of the manuscript. The Do CHANGE team received funding for Research and Innovation from the European Union for the project. Within the consortium, two small- and medium-sized enterprises (Docobo and Do Something Different) and one start-up (Onmi) were financially supported to develop their products. The authors would like to acknowledge all the patients who were willing to participate in this study within the three countries and were willing to share their data, thus making this work possible. Moreover, the authors would like to thank all students and health care professionals for their support in recruitment and data management. The authors also want to acknowledge the inestimable work conducted by the Do CHANGE consortium members (www.do-change.eu). Lastly, the authors would like to thank Gerard Carot-Sans (PhD) for providing medical writing assistance during the preparation of the manuscript and Leah Bührmann (MSc) for her help with SPSS analysis.

Authors' Contributions

JPJ, JWMGW, MH, EB, and DVB contributed to the study design and data collection. JPJ, MW, and DVB conducted the statistical analyses. JPJ drafted the manuscript. All authors critically revised and approved the final version of the manuscript. FLV and FF supervised the study.

Conflicts of Interest

None declared.

Abstract

Background: Research on problematic internet use has focused on devising diagnostic criteria or describing the factors that influence internet overuse. However, a paradigm shift is necessary in studying the phenomenon of increased internet use not just from a pathological point of view but also from a developmental point of view that considers children's behavior of adapting to a technology-oriented society.

Objective: In this paper, we propose the Cyclic Value-Context Reinforcement Model (CVCRM) to understand problematic internet use behavior. The purpose of our study was to construct a developmental process model that provides a holistic understanding of problematic internet use behavior of children and to empirically validate the proposed model by conducting a thematic analysis on actual counseling data.

Methods: To validate the CVCRM, we conducted thematic analysis using the counseling data from 312 Korean children aged 7-18 years. For the coding process, 7 master's and doctoral student researchers participated as coders, and 2 professors supervised the coding process and results.

Results: This project was funded from October 2015 to September 2019 to analyze counseling data from 312 children who participated in counseling sessions during January 2012 to May 2014. Based on the data analysis, we present the CVCRM, which integrates existing theoretical approaches and encompasses the 3 interacting aspects that induce and reinforce problematic internet use in children: psychosocial value, environmental context, and internet utility. Specifically, using counseling data, we empirically ascertained that problematic internet use behavior feeds into children's psychosocial values and environmental contexts, which in turn facilitates problematic internet use in a cyclical manner.

Conclusions: Through this empirical validation, the CVCRM can provide a theoretical framework and an integrated perspective on the developmental mechanism of problematic internet use behavior of children.

problematic internet use; children; cyclic value context reinforcement model; psychosocial value; environmental context; internet utility

Introduction

Background

The internet is pervading every aspect of daily life, even for children. Based on the European Union Kids Online Model of Children, Livingston et al [1] argued that the research agenda on children's internet usage needs to shift direction from "how children engage with the internet as a medium" to "how children engage with the world mediated by the internet." Furthermore, they raised a critical research question: "For which children under which circumstances does internet use lead to risk and why?" This question redirects our attention from the internet itself to children as active agents, to the environmental context in which children are located, and to children's developmental process of adaptation.

With the widespread use of the internet, problematic internet use is an important social issue in the global society. Compared to the term internet addiction or dependency, problematic internet use is broad enough to cover the negative consequences of the varying degrees experienced by an individual without the risk of social stigma as a pathological person [2-4]. Problematic internet use is defined as "use of internet that creates psychological, social, school, and/or work difficulties in a person's life" [5]. Until now, most research on problematic internet use has focused on devising diagnostic criteria or describing the factors that influence internet overuse. However, a paradigm shift in the study of the phenomenon of increased internet use is necessary, not just from a pathological point of view but also from a developmental point of view that considers children's behavior of adapting to a technology-oriented society.

In this study, we propose the Cyclic Value-Context Reinforcement Model (CVCRM) to explain problematic internet use behavior. The purpose of our study was to construct a developmental process model that provides a holistic understanding of problematic internet use behavior of children and to empirically validate the proposed model by conducting a thematic analysis of counseling data collected from 312 Korean children, aged 7 to 18 years. We explored the adaptive functions of the internet-mediated environment in achieving children's developmental tasks and satisfying their psychosocial values as well as their environmental needs.

Problematic Internet Use Behavior: Need for an Integrated Process Approach

Research topics on problematic internet use behavior have changed from a predominantly symptom-centered approach to a cause-centered approach and from individual factors to environmental contexts that impact internet use. Using the symptom-centered approach, researchers developed diagnostic criteria based on the investigation of symptoms of internet overuse and designed intervention methods to relieve the corresponding symptoms [6-10].

However, a symptom-centered approach is not enough to change the causal context and prevent symptom development. To address this issue, a cause-centered approach has been established to identify factors affecting problematic internet use. Early cause-centered studies examined individual internal

factors, including comorbidity [11-13] or psychological vulnerabilities, such as loneliness and shyness [14-16], as the cause of problematic internet use. In addition to the individual internal factors, research on external variables and environmental contexts, which include the influences of family, school, and society, has begun recently. Family function, communication, and family conflicts are important factors that affect problematic internet use [17-20]. Additionally, people with internet-related problems tend to experience more real-life problems in social relationships and school life [21,22]. Considering these results, in order to gain a more comprehensive understanding of the phenomenon, we need to examine environmental contexts as important factors in models that examine problematic internet usage.

Although existing work has identified a correlation between specific individual and environmental factors and internet use, we need to look beyond individual relationships between specific factors and consider the overall development of problematic internet use behavior. In particular, certain individual factors transact cyclically with other factors, usage behavior, and problematic symptoms. For example, depression, loneliness, and self-control have been found to interact with other factors that affect problematic internet use [14,23-25]. Thus, comorbidities and psychological vulnerabilities are causes, as well as consequences, of problematic internet use [26,27]. Kardefelt-Winther [27] also reported that the correlations of loneliness and social anxiety with excessive online gaming were no longer present when controlling for stress. In addition, symptoms of psychopathology mediate irrational beliefs and internet gaming addiction [28]. Therefore, the relationship between internet use behavior and factors influencing it can be transactional and cyclic, rather than a one-way causal relationship.

Given the expanded research interest, from symptoms to causes of problematic internet use behaviors and from individual factors to environmental contexts, a process-centered approach integrating these factors is necessary to increase an overall understanding of problematic internet use. In other words, from a holistic perspective, we need to understand the intersection between the environmental context and personal characteristics and to reveal the mechanism underlying how these factors transact with each other and reinforce problematic internet use behavior.

Previous Theoretical Models on Problematic Internet Use Behavior

In order to construct an integrated developmental model and to guide our understanding in a qualitative thematic analysis, we selected 7 related theoretical models: (1) cognitive-behavioral model of pathological internet use [10], (2) a new model of media attendance [29], (3) model of compensatory internet use [30], (4) basic model of problematic internet use in youth [31], (5) differential-susceptibility to the media effects model [32], (6) reinforcing spirals model [33], and (7) player's value structure in digital games [34]. In this section, we compare these 7 models and discuss the insights gained in relation to problematic internet use behavior.

Davis [10] introduced the cognitive-behavioral model of pathological internet use. This model described the following 3 categories of factors contributing to behavioral symptoms: individual psychopathology, internet exposure experience, and social deficits. The core factor of this model is “maladaptive cognitions.” Accordingly, the model suggests that individuals who have maladaptive cognitions have a negative view of themselves and use the internet to gain positive responses from others. Based on the cognitive-behavioral approach, this model was an early attempt to explain the etiology of pathological internet use. However, this model has limitations in that it focuses on the vulnerability of the individual by regarding internet use behavior as a pathological symptom. Another limitation of the model is that it considers the individual as a passive and socially deficient being that simply responds to situational cues.

LaRose and Eastin [29] proposed an internet use process model that combines the concepts of use and gratification with the social cognitive theory, by matching similar dimensions in both models. The following 6 expected internet outcomes were identified: novel, social, activity, monetary, self-reactive, and status. This model also added the factors of self-efficacy and self-regulation to broaden the understanding of use and gratification. The internet use process model explains internet use behavior using the expected outcomes of internet use, rather than focusing on problematic symptoms or individual vulnerabilities. In addition, the model regards users as active subjects that select media according to expected outcomes (ie, gratification). However, this approach does not consider the preceding factors that lead to the expected outcomes of internet use behavior.

Kardefelt - Winther [30] presented a model of compensatory internet use and explained internet use behavior through motivation that stems from unmet real-life needs. This model suggests that people use the internet as a stress-coping strategy. Furthermore, the model considers the real-life context of internet usage by introducing the concept of “coping motivation,” which regards reality-based difficulties as an important factor for inducing internet use. However, this model can only explain internet use behavior as a coping strategy for people who experience problems in a real-life context. Additionally, because motivation is relatively temporary and limited to a specific situation, the model is not suitable for explaining persistent internet use behavior.

As a more comprehensive model, Tam and Walter [31] suggested a basic model of problematic internet use for youth that is based on the literature from the past 10 years. They argued that problematic internet use is conceptualized, not as a unitary mental health condition, but rather as complex pathways of underlying psychological, developmental, ecological, and intrafamilial factors. This model distinguishes between regular internet use, problematic or heavy internet use, and pathological internet use or gaming addiction. Additionally, it separates the predisposing and protective factors that affect each state. However, while this model describes each of the subfactors affecting problematic internet use in detail, it has a limitation that it does not account for the interrelationships between the different factors.

In the literature on the effects of media, Valkenburg and Peter [32] introduced the differential-susceptibility to the media effects model. The model proposed that media effects are conditional and depend on the following 3 types of differential-susceptibility variables: dispositional, developmental, and social. These 3 differential-susceptibility variables affect the choice of media use. Additionally, the model distinguished the following 3 media response states: cognitive, emotional, and excitative. These 3 response states mediate the relationship between media use and media effects. Finally, this model adopted the transactional proposition, which suggests that media use, media response states, and differential-susceptibility variables are influenced by media effects. This model also provided insights regarding the relationship between media and nonmedia variables. However, because it deals with a microlevel analysis focused on individual media users, it is difficult to apply to design intervention methods of behavioral change on the level of user activity or environmental affordance.

Based on a system-theory perspective [35] and the social identity theory [36], Slater [33] elaborated the reinforcing spirals model. It recognized that media use serves as both an outcome and a predictor in many social processes and that media use in the contemporary society is a principal means to maintaining personal and social identities. One premise of this model is that the process of media selection and the effect of exposure to selected media are dynamic and ongoing. Therefore, this model considers that users tend to select certain types of media contents according to their social context, social identity, and prior attitudes. In addition, certain media content exposures have a subsequent impact on the strength and accessibility of social group identification, attitudes, and behaviors. In turn, the influence of subsequent media use continues to reinforce those associated elements of social identity, attitude, and behavior over time. The virtue of this model is highlighting the ongoing dynamic social process of media use behavior. However, social identity is not static and could vary according to the function of the environmental contexts and values of users.

Recently, in the domain of game studies and consumer research, Lin et al [34] proposed the structure of attribute-consequence-value chains of digital game players. Using soft-laddering interviews and a theoretical framework of means-end chains, they revealed game attributes that players direct their attention to, including attributes such as the connection system, popularity, graphic design, and diverse game genres. Depending on these attributes, players experience certain consequences, such as improved interactivity, cultivated logic and reflex, acquisition of an authentic experience, enhanced pleasure of senses, and utilized imagination. This model also identified the values that game players pursue, such as fun and enjoyment of life, sense of accomplishment, warm relationships, and excitement. This study provided us with insights in terms of the sequential process of users' values, media attributes, and experiential consequences.

Insights for Developing the Integrated Model of Problematic Internet Use Behavior

We gained two main insights from reviewing existing models on internet use behavior. First, early studies attempted to explain

the preconditions that could lead to internet use behavior, mainly in terms of an individual's psychosocial characteristics. However, recent studies have expanded the understanding of the interactions to include personal characteristics and environmental contexts. Therefore, when constructing a new model, it is necessary to cover all 3 basic aspects of internet usage behavior: the individual's psychosocial values and environmental contexts as well as the interaction between these two components.

Second, early studies looked at internet use behavior as a temporary problem and attempted to identify the cause or symptom of the problem by considering a simple causal relationship. However, recent studies have proposed a cyclic nature to the relationship between variables, one which creates persistent reinforcement and leads to the repetitive use of the internet. Therefore, it is necessary to examine the process that explains the types of internet utility that lead to stable and continuous problematic internet use. In addition, the model should link internet use back to the factors that exist within the context of daily life.

Based on these insights, this study proposes a hypothetical model that integrates existing theoretical approaches related to problematic internet use behavior from a developmental perspective, termed the CVCRM. The first research question of this study was: "Can we construct an integrated process model to understand problematic internet use behavior holistically?" The second research question is: "Can we identify factors and processes that interact with problematic internet use behavior in the CVCRM using children's counseling data?"

Methods

Counseling Data Collection

We conducted a thematic analysis using the counseling data provided by the National Information Society Agency in the Republic of Korea. The data comprised reports on counseling sessions from January 2012 to May 2014 with children who experienced internet-related problems. Each case consists of one initial interview and at least one follow-up counseling session, ranging from 1 to 5 sessions. During the first interview, counselors measured the severity of internet-related problems and examined the basic environmental and individual conditions of the client. The questions in the initial interview pertained to the client's home and school environments, time of the first internet use and motivation, feelings before and after internet use, how family and school respond to internet use, consequences of internet use, and the level of internet addiction. The optional follow-up counseling sessions after the initial interview were not strictly structured, and the counselors identified the clients' core problems and attempted interventions. During the entire counseling process, the counselors recorded the client's comments, as well as details about the client, his or her family members, and his or her family environment. All counseling records were archived as digital documents. We reviewed 312 cases that met the following 2 conditions: (1) case data included an initial interview report and had ≥ 1 follow-up session records and (2) clients aged between 7 and 18 years.

This range is defined as the Korean school age and comprises entry into elementary school to graduation from high school.

Thematic Analysis

Thematic analysis [37] is a qualitative research method that enables us to discover and analyze patterns or themes in data. This methodology consists of 2 approaches: top-down theoretical approach and bottom-up inductive approach. The purpose of our study was to construct a new model by integrating existing theories and to verify the model using empirical data. Therefore, we performed a thematic analysis that incorporated both theoretical and inductive approaches. Using both top-down and bottom-up approaches iteratively allows researchers to reflect on both theory and data from various perspectives. As a result, one can gain a richer understanding when using such an iterative approach compared to using just a top-down or bottom-up approach. The detailed analysis process was as follows. First, we formulated the initial model based on the integration of previous theoretical approaches. Second, we verified our model through a thematic analysis with iteration between our model and empirical data. We used counseling data from children for this bottom-up process. Our research team read 312 cases of counseling records to identify the overall problem situation (Step 1: familiarization with the data). Then, we repeatedly read all the counseling records. Each sentence in a record was read to identify meaningful statements that indicate children's psychosocial values, environmental contexts, internet utility, and internet use behavior (Step 2: generation of the initial code). We repeated this process 9 times until the identified themes were saturated (Step 3: searching for and reviewing themes). Finally, all researchers reached a consensus on defining themes (Step 4: defining and naming themes). We performed a thematic analysis at the latent level to understand and theorize the underlying structures and processes of problematic internet use behavior. To establish credibility in the analysis, we used the researcher triangulation approach [38]. For each of the coding processes, 3-7 master's and doctoral student researchers participated as coders, and 2 professors supervised the coding process and results. The Gwet's AC1 interrater reliability coefficient was calculated in the ninth iteration for each of the following main themes: Children's Psychosocial Value (10 factors, mean 0.887), Environmental Context (13 factors, mean 0.827), and Internet Utility (6 factors, mean 0.912). In case of disagreement that arose after the coding process, all the coders discussed the case to reach a final agreement.

Results

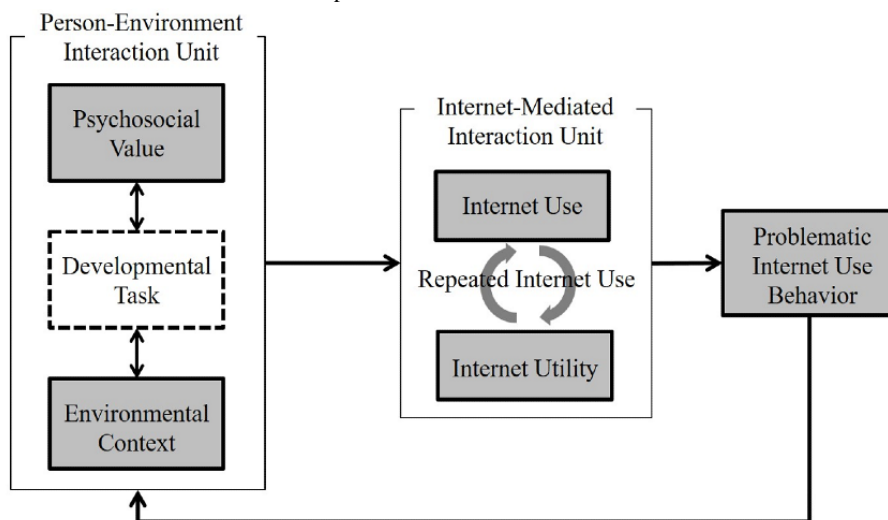

CVCRM

We formulated the CVCRM of problematic internet use behavior based on the insights drawn from previous theoretical approaches. First, we tried to cover 3 basic aspects in our model: children's psychosocial values, environmental contexts, and internet utility. Second, we incorporated repeated behavioral tendencies between internet utility and internet use in our model. Third, our model addressed the cyclic reinforcement process linkage between problematic internet use behavior and the person-environment interaction unit, which are deeply interconnected within children's daily life.

Figure 1 shows the CVCRM. The “Person-Environment Interaction Unit” is an organism in which the children’s psychosocial values, developmental tasks, and environmental contexts interact. The specific conditions formed by the interaction of these elements can increase the probability of internet use. Internet use and internet utility are grouped into the “Internet-Mediated Interaction Unit.” They circulate and form a repeated internet use state. Repeated internet use leads

to specific problematic internet use behavior, which can give feedback to the “Person-Environment Interaction Unit” to change its state. Through this process, internet use is induced and reinforced. The states of “Person-Environment Interaction Unit” and “Internet-Mediated Interaction Unit” are not static and may vary from person to person and from time to time. We defined and described each part comprising the CVCRM as follows.

Figure 1. The Cyclic Value-Context Reinforcement Model of problematic internet use behavior.

Psychosocial Value

Psychosocial value is the intrinsic value of the child that is being met through internet use. As a result of our data analysis, 3 subthemes of psychosocial value appeared: individual, relational,

and social. Psychosocial value represents relatively stable personal preferences as compared to “motivation or gratification” used in previous models. The themes and categories of the thematic analysis results are summarized in Table 1.

Table 1. Psychosocial value categories of problematic internet use behavior.

Subtheme and category	Category description	Example quotes
Individual		
To relieve stressful events	Use the internet to alleviate or eliminate psychological stress such as tension, depression, loneliness, or anxiety.	“[Using the internet] relieves my stress.” “[When using the internet,] I’m not lonely anymore.”
To express oneself	Evaluate the value of the internet as a means of expressing what one likes, one’s emotions, and one’s ideal self-image.	“[On the internet] I can express my opinions easily.”
To experience a sense of accomplishment	Attach the value of the internet as a means of experiencing fulfillment, reward, and achievement.	“I feel a sense of accomplishment when I win.” “I enjoy raising my ranking in a game.”
To spend one’s surplus time	Do not have any alternative activities other than surfing the internet and, thus, consider the internet as a convenient way to spend time.	“I get bored [when I come home], but there’s nothing else I can do [to spend my time].” “I play internet games when my parents don’t mind my time.”
To express disobedience	Evaluate the value of the internet as a means of ignoring or actively resisting an authority’s instructions.	“I played internet games more since their [parents’] actions hurt my pride.” “I used the internet more heavily since my parents’ regulation on internet use caused more stress.”
To escape from reality	Use the internet as a place to escape from real problems that cannot be fundamentally solved.	“I feel a sense of freedom since I can escape from school.” “Using the internet makes me forget about the severe conflict between my parents.”
Relational/social		
To develop a sense of closeness	Evaluate the value of the internet as a means of interacting with particular subjects and maintaining familiarity.	“Internet enables me to keep in touch with my close friends who moved to other cities.” “My friend and I speak the same language because of the games that both of us play.”
To participate in common activities in the peer group	Evaluate the value of the internet as a way to enter peer groups, follow the current trends, and collaborate with peers.	“I need the internet to hang out with my friends.” “It [the internet] makes me understand the world that my friends are in.”
To be recognized as the best	Evaluate the value of the internet as a way to obtain authority, respect, and envy within a group.	“I’m proud when my friends admire me for my gaming skills.” “[Using the internet] makes me happy since many people online recognize me when I upload a drawing of a game character.”
To experience controllability	Evaluate the value of the internet as a place where one can control one’s self, one’s group, and society.	“I want to relax, have some fun, ... and keep everything under control.”

Developmental Task

Developmental task refers to what children must achieve at each stage of development. Thus, these tasks are fundamental psychosocial issues that can affect individuals of a certain age. Further, the developmental task at a specific age can affect and change one’s environmental contexts or psychosocial values. In the model presented in [Figure 1](#), “the developmental task” is marked with a dotted box to indicate it is a latent variable. Life’s major roles are deeply interconnected with developmental tasks [39], as they refer to challenges or expectations that a culture has for individuals in different life phases [40]. The cyberspace, which is accessible via the internet, also serves as a channel for users to practice and achieve developmental tasks. For example, developing productive peer relationships is one of the important developmental tasks of school-aged children and teenagers, and it is more likely that they will have high

value for social affiliation through internet use. However, the process in which these tasks interact with environmental contexts or individual value systems is not yet exposed. Therefore, the developmental task is regarded as a latent variable in this model.

Environmental Context

Environmental context includes the surrounding situation or environmental conditions that can affect the child’s perception or behavior. In the counseling data, 3 subthemes of environmental context appeared: individual, family, and society. Some environmental contexts can change with time and can be influenced by the outcome of internet use. However, each of the children’s experiences or perceptions of the environment, whether changed or not, may have an impact on his or her problematic internet use behavior. The themes and categories of the thematic analysis results are summarized in [Table 2](#).

Table 2. Environmental context categories of problematic internet use behavior.

Subtheme and category	Category description	Example quotes
Individual		
Situations of physical illnesses that limit daily life	Daily life is restricted by physical disability or illness.	"After being diagnosed with tuberculosis, I began to visit the PC cafe frequently while recuperating at home."
Situations of psychological vulnerability	Mental illness requiring professional treatment (eg, ADHD ^a , panic disorder) or psychological instability (eg, irritability, lethargy) is observed.	"[Mother says] client has social phobia." "I'm depressed." "I'm really worried about my school grades."
Situations of insufficient satisfaction with psychosocial needs	Complaints due to unsatisfied needs (eg, self-esteem), social exchanges (eg, social belongingness), or goal achievements (eg, realization of the ideal self) are observed.	"He doesn't know how he can relieve his disappointment when his wishes cannot be granted." "She [client] said she received art lessons but was forced to quit. She wants to pursue her career in art again."
Situations of lacking lifelong goals	A lack short-term or long-term goals or life commitments is observed.	"I don't know what I should do [for the rest of my life]."
Family		
Inadequate parenting	Caregiver's undesirable parenting style, practice, or perspective, such as excessive regulation, insufficient caregiving, or physical or verbal violence, is observed.	"[Began using the internet excessively] after my mom didn't allow me go outside." "My parents don't care [about my internet usage]." "Her [client's] mother doesn't have any faith in her."
Family communication problems	Weak family bonding or communication problems between family members are observed.	"My parents don't get along. They fight over nothing." "My parents only ask me to study. I want them to hear my thoughts about what I want to do."
Instability of the caregiver	Caregiver cannot nurture the client due to physical separation (eg, long business trips, divorce, or death).	"He [client] has a father who only visits on weekends." "He [client] lives with his father after his parents got divorced when he was 6."
Internet use of other family members	Family members show problematic internet use.	"My mother is addicted to the internet." "I cannot use the internet when my sister is at home since she is addicted to the internet."
Society		
Socially imposed stigma	Peer groups, schools, and the society insulate and isolate the client (eg, bullying, internet addiction, obesity, problem behavior).	"During middle school, he [a client] severely suffered from bullying." "My family treats me as a mental patient."
Social or school maladjustment	Difficulty in social relations or social life or problematic behavior is observed.	"I'm afraid of meeting friends at school." "He [a client] used the internet a lot because of social phobia and obsession problems."
Economic constraints	Client's activity is limited due to economic constraints (includes client's perception of economic constraints).	"The client said that he felt pity about himself, and described himself as being a beggar, several times throughout the week." "I live in poverty."
Coexisting delinquent behavior	Delinquent acts (eg, runaway, truancy, drinking, smoking, sexual activity) or crimes (eg, school violence, assault, theft, robbery, or rape) are observed.	"The client bullied other students and often questioned the purpose of studying." "His [client's] teacher said she often had to search for him because he went to the PC café instead of attending school."
Unstructured daily activities	Client's daily life is unstructured (no daily structure at home after expulsion or no regular activity plan for after-school hours).	"Since quitting the job at a restaurant, I spent time playing computer games [without any future plans]."

^aADHD: attention deficit hyperactivity disorder.

Internet Use

Internet use, or more specifically "repeated internet use," refers to the state of repeated engagement in internet use activity while obtaining internet utilities.

Internet Utility

Internet utility satisfies the psychosocial value of a child, including the utility of content or relationships accessible via

the internet. Internet utility can mediate the influence of the "Person-Environment Interaction Unit" on problematic internet use behavior to induce repeated internet use. In the counseling data, 3 subthemes of internet utility appeared: individual, relational, and social. The themes and categories of the thematic analysis results are summarized in [Table 3](#).

Table 3. Internet utility categories of problematic internet use behavior.

Subtheme and category	Category description	Example quotes
Individual		
To enjoy	Derive pleasure and fun from using the internet.	“Using the internet is the only pleasure in my life.” “The internet is thrilling.”
To engage in goal-oriented learning	Establish goals to master specific skills or subjects in real life in the short or long term and gain learning effects over the internet.	“[When I’m using the internet,] I can code programs, which is both a hobby and a way of preparing for my future career.” “[On the internet,] there’re a lot of things that I can learn from.”
To surf the internet	Browse and collect fragmentary information through the internet.	“It [the internet] helps with my homework.” “I used the internet to watch a show that a singer [who the client is a fan of] starred in, listen to his songs, and communicate with other fans.”
To earn money	Acquire things that can make money or exchange money through the internet.	“I can earn a lot of money [through online gambling].” “I do online gambling because my allowances are not enough.”
To satisfy one’s sexual curiosity	Satisfy one’s sexual curiosity through the internet.	“I sometimes watch pornography online.”
Relational/social		
To be active in an online community	Communicate with new people through an online community or social networking service (including positive, neutral, and negative communication).	“It is fun to communicate with others anonymously.” “Arguing with others online is fun.”

Cyclic Reinforcing Process

Children’s psychosocial values, environmental contexts, and internet utilities interact to induce and reinforce internet use. Afterwards, problematic internet use is fed back into individual

value systems and environmental contexts, resulting in repeated and strengthened internet use. We illustrate 5 representative counseling cases in high-risk groups that vividly reveal the cyclic reinforcing process in [Table 4](#).

Table 4. Representative counseling cases that show the cyclic reinforcing process.

Case ID	Counseling content	Corresponding cyclic pattern
Case 57	"...I experienced school violence in middle school and became obsessed with games. [...] I feel like I'm out of reality and feel liberated. I also feel like I am being recognized by people. [...] The interpersonal relationship was so comfortable that I don't feel the need to make friends offline. More recognition on the internet makes it more difficult to establish relationships in the real world..."	School violence (EC ^a) > escape from reality, social recognition (PV ^b) > enjoy relationship (IU ^c) > repeated and obsessive use (PIUB ^d) > weakening of offline relationships (EC) > cycle repetition
Case 155	"...Since I'm in the third year of high school, I have to study a lot, but I keep thinking about games. Eventually, I play games in the PC room with the excuse that I am going to the reading room on weekends. [...] I'm not bored if I'm playing a game. I am anxious if I don't play games. I have to study, but I'm depressed and worried because I play a lot of games. [...] I'm worried that, like my brother, I'm going to have a serious conflict with my parents..."	College entrance exam stress (EC) > relieve stress (PV) > enjoy fun (IU) > repeated and obsessive use, feeling of depression and worry (PIUB) > expectation of conflict with parents (EC) > cycle repetition
Case 295	"...Bored at home, I started the internet. [...] I can use the internet to relieve stress and to kill time. I can meet new people in virtual space. In particular, I communicate well with people who play the same games. [...] I tried to quit the game, but I was forced to play it again because of my clan friends..."	Unstructured daily life (EC) > relieve stress and spend surplus time (PV) > to be active in online community (IU) > excessive use (PIUB) > cycle repetition
Case 324	"...When I was in the third year of elementary school, my mom took me to a PC room. The internet is fun, stress-free, and pleasant. After that, I repeatedly went to the PC room to play games. [...] I often went to PC rooms, and my mom's interference with games increased. Grandpa and grandma's nagging got worse. I go back to the PC room to avoid it..."	Internet use of mother (EC) > relieve stress (PV) > enjoy fun (IU) > repeated visits to PC room (PIUB) > conflict with family members (EC) > cycle repetition
Case 559	"...Life is boring. When I'm immersed in the internet, I can be happy and have fun in my life. [...] I spend a lot of time playing games. [...] I went to the Rescue Internet Camp last year. At first it seemed to get better, but after a while it was back..."	Lack of a lifelong goal and insufficient satisfaction of psychosocial needs (EC) > to express oneself (PV) > enjoy and feel happy (IU) > repeated use (PIUB) > intervention in Rescue Internet Camp is useless (EC) > cycle repetition

^aEC: environmental context.^bPV: psychosocial value.^cIU: internet utility.^dPIUB: problematic internet use behavior.

Funding

This project was funded from October 2015 to September 2019 to analyze counseling data from 312 children who participated in counseling sessions during January 2012 to May 2014.

Discussion

Implications

Our proposal of the CVCRM of internet use behavior and our thematic analysis of the model using children's counseling data have several implications. First, the CVCRM expanded the understanding of problematic internet use behavior by introducing the concepts of children's psychosocial values and environmental contexts. In addition, the developmental task was included as a latent variable to explain the mechanisms of the developmental process of internet use behavior. In accordance with Lin et al [34], we adopted the concept of value based on the social adaptation theory by Kahle [41] and the suggested list of values [42]. Kahle listed 9 values (ie, self-respect, security, warm relationships with others, sense of accomplishment, self-fulfillment, sense of belonging, sense of being well-respected, fun and enjoyment of life, and excitement) and regarded these values as closely related to life's major roles [42]. In addition, positive adaptation in children can be defined

by achieving age-salient developmental tasks, and these tasks reflect the expectations and standards that parents, teachers, and society set for them [43]. Therefore, we need to consider children's psychosocial values, developmental tasks, and environmental contexts in order to understand children's problematic internet use behavior. In the counseling data, we found 3 subdimensions in the environmental context (ie, individual, family, and society). The structure of these 3 hidden dimensions is similar to the bioecological model of human development [44]. Bronfenbrenner and Morris [44] explained that both risks and resources for positive adaptation and development stem from factors situated within individuals (genetic and hormonal systems, personality, and cognition) as well as in the proximal (family and school) and distal (societal, cultural, and institutional) contexts in which their life is embedded [43].

Second, we proposed an extended understanding that internet use behavior is not a short-term problem state, but rather a persistently evolving and cyclically reinforcing process. At the surface level, the purpose of repeated internet use is obtaining internet utilities in the short term. However, if we widen our viewpoint to include the person-environment interaction unit, we can understand that internet utility originated from the interaction between children's psychosocial values,

developmental tasks, and environmental context needs. These multiple dimensions are relatively long-lasting characteristics, and the dimensions cyclically reinforce each other. Therefore, our study can contribute to the exploration of the cyclical nature of the relationship between variables that produce persistent reinforcement mechanisms of the repetitive use or re-use of the internet.

Third, the CVCRM can be applied to inform preventive interventions for problematic internet use. The current interventions tend to focus on directly changing personal characteristics or symptoms. However, personal characteristics, such as personality, self-regulation, self-efficacy, and cognition, are difficult to intervene and affect. Conversely, it is relatively easy to induce behavioral change by modifying environmental contexts. For example, in one case, a girl was constantly home alone because her parents both worked full-time jobs. She felt sad when her mother told her to “Take care of the problem yourself,” in response to trying to talk to her about a problem she faced. She used the internet for entertainment when she was home alone. Her internet usage duration increased, and she did not consider reducing it. Within a symptom-centered framework, she is at high risk of developing internet addiction. Here, therapists will attempt to intervene using a cognitive-behavioral approach, in which they will improve her self-regulation and plan her internet use time. However, from the value-context perspective, it is possible to change her parents’ attitudes to meet her needs of love and belongingness or to provide her with a structured daily life by offering opportunities to engage in cultural or leisure activities. Although the individual’s internal factors, such as self-control or depression, are abstract and difficult to change with short-term intervention, environmental contexts and value-seeking activities could change through practical interventions in a relatively short period.

Limitations

There are some limitations in this study. The first pertains to the structure of the counseling data. Specifically, several factors may not have been discovered in the initial interview since the questions were semistructured. Furthermore, home-visit counseling sessions were loosely structured, so that counselors could freely talk and explore the client’s situation. The counseling record was not an exact transcript of the counseling session and was recorded as a summary based on the counselors’ comprehensive observations. Therefore, the counselors’ personal opinion may have influenced the records. Second, it is difficult to investigate cognitive factors because of the characteristics of children. Children’s self-consciousness is not yet fully developed. Without verbal statements, observations alone are not enough to identify abstract cognitive factors. Therefore, we did not include cognitive factors in the proposed model. However, cognitive factors, such as maladaptive cognitions [45] and desire thinking [46], are considered important predictors of internet use problems and may mediate the effects of values and contexts. Future research needs to explore the relationship between the factors proposed by the CVCRM and cognitive factors.

Future Research

For future studies, we propose several directions to advance research in this domain. First, it is important to validate the present model using a quantitative approach given that our approach was an empirical validation. Furthermore, it is necessary to explore the interaction between environmental contexts and psychosocial values, as proposed by this study. Therefore, while we integrated these two concepts into the concept of the “person-environment interaction unit,” the detailed interactive processes taking place inside the unit are yet to be investigated. Second, there is a need to compare the changes in how the environment is perceived, psychosocial values, and internet utilities, based on developmental periods. By expanding the present study to the entire lifecycle, which includes young adults, middle-aged adults, and the elderly, we can explore the interaction between differential developmental tasks, environmental contexts, and value systems throughout the lifespan. Third, research is needed to compare the structures of the environmental contexts and psychological values surrounding internet use across various cultures. Values are not culturally neutral. For example, community connectedness is a strong value in the Korean society. Thus, social recognition and acceptance are important values in Korea for children to master, compared to other cultures where the value of independence may be encouraged as a virtue of adolescence. Lastly, developing specific counseling techniques and how such techniques can reinforce problematic internet use behavior are important and interesting topics to pursue. An indepth development of counseling strategies based on the CVCRM and the effects of such strategies would be a great direction for future work.

Conclusions

We proposed the CVCRM of problematic internet use behavior from the developmental perspective using children’s counseling data. By performing a thematic analysis at the latent level, we could extend the current understanding of the underlying structure of internet use behavior. The core argument of our model is that children’s psychosocial values, environmental contexts, and internet utility interact to induce and reinforce problematic internet use. As a result, problematic internet use is reinforced back into the individual value system and environmental contexts, resulting in further strengthened internet use. Since the developmental task during adolescence can affect and change one’s environmental contexts or psychosocial values, it was included as a latent variable.

Human behavior is shaped by various factors, including those that underlie the environment. Once we understand the mechanisms by which children start and continue to use the internet, we can gain a deeper understanding of internet use behavior. Rather than attempting to change children’s internal traits or symptoms, it would be clinically useful to decipher and obtain the values that children seek and to create an environment that encourages them to change their behaviors on their own. From the perspective of developmental psychology, the value that children acquire by using the internet is related to a developmental task and is therefore very important in their growth process [40]. To help children derive value from the

internet without falling into problematic use, a value-context approach may be useful in helping to create an environment in which children can recognize their own values regarding the

internet and yet ultimately control and regulate their internet use behavior.

Abstract

Background: High-quality medical resources are in high demand worldwide, and the application of artificial intelligence (AI) in medical care may help alleviate the crisis related to this shortage. The development of the medical AI industry depends to a certain extent on whether industry experts have a comprehensive understanding of the public's views on medical AI. Currently, the opinions of the general public on this matter remain unclear.

Objective: The purpose of this study is to explore the public perception of AI in medical care through a content analysis of social media data, including specific topics that the public is concerned about; public attitudes toward AI in medical care and the reasons for them; and public opinion on whether AI can replace human doctors.

Methods: Through an application programming interface, we collected a data set from the Sina Weibo platform comprising more than 16 million users throughout China by crawling all public posts from January to December 2017. Based on this data set, we identified 2315 posts related to AI in medical care and classified them through content analysis.

Results: Among the 2315 identified posts, we found three types of AI topics discussed on the platform: (1) technology and application (n=987, 42.63%), (2) industry development (n=706, 30.50%), and (3) impact on society (n=622, 26.87%). Out of 956 posts where public attitudes were expressed, 59.4% (n=568), 34.4% (n=329), and 6.2% (n=59) of the posts expressed positive, neutral, and negative attitudes, respectively. The immaturity of AI technology (27/59, 46%) and a distrust of related companies (n=15, 25%) were the two main reasons for the negative attitudes. Across 200 posts that mentioned public attitudes toward replacing human doctors with AI, 47.5% (n=95) and 32.5% (n=65) of the posts expressed that AI would completely or partially replace human doctors, respectively. In comparison, 20.0% (n=40) of the posts expressed that AI would not replace human doctors.

Conclusions: Our findings indicate that people are most concerned about AI technology and applications. Generally, the majority of people held positive attitudes and believed that AI doctors would completely or partially replace human ones. Compared with previous studies on medical doctors, the general public has a more positive attitude toward medical AI. Lack of trust in AI and the absence of the humanistic care factor are essential reasons why some people still have a negative attitude toward medical AI. We suggest that practitioners may need to pay more attention to promoting the credibility of technology companies and meeting patients' emotional needs instead of focusing merely on technical issues.

artificial intelligence; public perception; social media; content analysis; medical care

Introduction

Background

High-quality medical resources are in great demand worldwide. The World Health Organization estimates that there is a global shortage of about 4.3 million doctors and nurses, a problem that poses a more serious threat in developing countries [1]. The application of artificial intelligence (AI), a field of computer science that aims to mimic human cognitive functions with computer algorithms [2,3], in medical care can reduce the burden on doctors and nurses, improve patient care, and alleviate the human resource crisis in health care [4]. In recent years, AI has made breakthroughs and has begun to be widely used in various areas of daily life, such as autonomous driving [5], weather forecasting [6], and health care practices [7].

With the increasing availability of medical data and the development of algorithms, AI has become an evolving trend in the medical field [8,9]. In medical diagnosis, AI can improve accuracy through image recognition technology and semantic analysis. In 2017, a Stanford University study revealed that AI beat human doctors in skin cancer diagnosis by attaining more than 90% diagnostic accuracy [10]. In the context of medical decision making and treatment, with the help of increasingly sophisticated algorithms and delicate instruments, AI technology can provide high-quality therapeutic options and perform specific operations. For example, the first robotic hand, developed by the research team of the American Children's National Health System, could handle soft tissue automatically [11]. In health management, researchers from the Las Vegas Department of Health have applied machine learning to Twitter data and developed an AI system that can help prevent foodborne illnesses [12]. In preventive health care, increasingly rich medical and health data provide opportunities for more accurate health monitoring and disease prevention. Recently, through a deep learning approach, researchers from DeepMind developed a model that was able to predict acute kidney injuries 48 hours in advance [13].

Although medical AI has gone through many technical advances, its usage and social influence (eg, whether AI doctors would replace human doctors) have attracted the attention of the government, media, and society. Existing research mainly focuses on revealing the attitudes and views of AI experts or medical professionals toward medical AI. Previous studies indicated that the overwhelming majority of technical experts in the field of biomedical informatics believe that AI will revolutionize many medical fields [14]. Other experts even predict that human doctors are at risk of being replaced by AI as it gets closer to general human intelligence [15]. Medical professionals, including doctors and medical students, admit that AI can outperform human doctors in some areas. However, they also considered the potential of AI to be limited and are not worried about being replaced by AI [16-18]. However, it is not known how medical AI is perceived by the general public, and few studies have empirically explored the public view on medical AI.

Compared to AI experts and medical professionals, the general public has less subject knowledge, but they are the ultimate

users of medical AI. The public's attitude toward AI in health care is crucial. Public perception and attitudes toward AI in medical care may affect the development progress of AI products (eg, collecting sufficient data from the public for machine learning) in the early stage. In contrast, public acceptance of AI products may exert an influence in the middle and late stages. Therefore, we suggest that the healthy development of the medical AI industry depends, to a certain extent, on whether practitioners in related fields comprehensively understand the public's views on AI in medical care.

The development of information science and the popularization of social media have made it possible to study the psychology and behavior of a large population based on the amount of behavioral data available from platforms such as Twitter and Facebook [19]. Compared with the questionnaire survey and experimental research, social media analysis in general has higher ecological validity and can reflect the opinions of large groups of people more objectively [20]. In recent years, researchers have started to use social media to study public awareness about certain illnesses, such as lung cancer [21] and cardiovascular disease [22]. It has also been used to explore public perceptions about health care (eg, cardiopulmonary resuscitation [23], vaccines [24]), and the application of new technologies in disease treatment (eg, virtual reality [25]).

Sina Weibo (Sina Corp), which is similar to Twitter, is one of the most popular social media platforms in China and boasts approximately 500 million daily active users from around China [26,27]. A growing body of literature has identified Sina Weibo as a useful platform for public health research, and its data have been used for studies on medical topics such as cancer misinformation [28], depression-related discourses [29], and organ donation awareness [30]. With the rapid development of medical AI, it has become an increasingly important topic of concern for the media and public. Over time, more posts and discussions about people's feelings, opinions, and concerns regarding medical AI have emerged on social media platforms, including Sina Weibo. This provides an excellent opportunity to study the general public's perception of AI in medical care based on social media posts.

Objectives

To the best of our knowledge, no study has comprehensively examined the views of the general public on AI in medical care. To address this gap, we explored the public perception of medical AI on social media through a content analysis of a large amount of data generated from the largest social media platform, Sina Weibo. Specifically, we focused on the following three questions: (1) What are the main medical AI-related topics about which the public is concerned? (2) What are the attitudes of the public toward AI in medical care? (3) Do people believe that medical AI can replace human doctors?

Methods

The data used in this study were collected from Sina Weibo through its application programming interface. First, we established a data set comprising 16 million Weibo users

throughout China, crawled these users' public posts from January 1 to December 31, 2017, and collected their public registration information (including gender, age, and geographic location). Second, we identified 4515 posts from this data set that contained at least one AI-related keyword (eg, "AI" or "artificial intelligence") and one medicine-related keyword (eg, "medicine," "treatment," or "health"). Third, we cleaned these posts further by manually inspecting and excluding 2000 invalid posts. These invalid texts were mainly caused by the keyword "AI," as it is usually used as the phonetic transcription of "爱," which means "love" in Chinese. Moreover, we also excluded invalid posts in which "AI" referred to Adobe Illustrator. Finally, we obtained 2315 posts for further analysis.

Based on these 2315 posts, we first outlined the general characteristics of public attention toward AI in medical care. Specifically, we examined the dynamic fluctuations of public attention over time and revealed the user profiles (such as gender, age, and region) of people who were concerned about medical AI through chi-square tests at the user account level. We then focused on public interest in and attitudes toward medical AI through content analysis. Referring to the coding methods used in previous research [30], we used a direct content analysis approach to code these posts, including the following: (1) topics of public concern regarding AI in medical care, (2) public attitudes toward AI in medical care and the reasons for them, and (3) public opinion on whether AI can replace human doctors. For example, for the thematic content analysis, two researchers screened the posts while one of them proposed a codebook for topic categories. A different researcher then evaluated the categories and discussed the framework with the first two researchers. Thereafter, the two researchers discussed and resolved the disparities in coding and reached a consensus on the classification of all topics. Subsequently, they coded approximately 10% ($n=236$) of posts to verify intercoder reliability. The κ score for the thematic content analysis was 0.82, which was acceptable. Finally, they independently completed the coding of the remaining posts. In this process, posts that contained more than one topic category were categorized as the more relevant of the options. The coding process of public attitudes toward AI in medical care and public opinion on whether AI can replace human doctors was consistent with the processing of the topics of public concern regarding AI. Furthermore, their intercoder reliability was also acceptable (κ scores were 0.80 for public attitudes toward AI in medical

care and 0.92 for public opinion on whether AI can replace human doctors).

Results

Public Attention Toward AI in Medical Care

To explore the characteristics of public attention toward medical AI, we first examined the dynamic fluctuation in people's discussions of AI in medical care over time. Figure 1 shows the daily counts of all posts related to medical AI from January to December 2017. Public attention toward AI in medical care demonstrated obvious event-driven characteristics. Whenever a widely reported event related to AI occurred, public attention surged accordingly. We found that there were three main categories of events that could drive public attention toward AI in medical care. The first category comprised messages about improvements and breakthroughs in AI technology, such as when AI beat human doctors at diagnosing skin cancer [31]. The second category comprised information or regulations related to AI released by the government or official institutions, such as when AI was written into a government work report and the 2017 Global Cloud Computing Conference was held. The third category comprised social entertainment events related to AI, such as AlphaGo AI defeating Ke Jie, the world's number one Go player.

In addition to the temporal characteristics, we explored users' profile characteristics to identify those who were most interested in medical AI. However, since not every user had publicly disclosed their account information, we limited our analysis to those who had. Of these 1764 accounts, 1294 (73.36%) were attributed to male users and 470 (26.42%) were female users (Table 1). Males paid more attention to AI-related medical topics than did females, even after controlling for the gender ratio of the 16 million users in the data set ($\chi^2_1=948.5$; $P<.001$). In terms of age, users under 30 years old paid less attention to AI medical topics than did users over 30 years old, and this was significantly lower than the proportion of young to old users in the data set ($\chi^2_1=491.2$; $P<.001$). Moreover, users from the regions (provinces) with above-average incomes showed more interest in medical AI than did users from regions with below-average incomes, at a level significantly higher than the proportion of such users in the data set ($\chi^2_1=90.7$; $P<.001$).

Figure 1. Number of posts about artificial intelligence in medical care from January to December 2017.**Table 1.** Overview of the general demographics of the users who were interested in medical artificial intelligence.^a

General demographics	Users in analysis, n (%)	Users of data set, n (%)
Gender		
Male	1294 (73.36)	6,267,548 (37.80)
Female	470 (26.42)	10,311,693 (62.20)
Age (years)		
≤30	231 (47.53)	6,297,207 (84.22)
>30	255 (52.47)	1,180,058 (15.78)
Region		
Above-average income	1128 (74.60)	7,858,752 (62.76)
Below-average income	384 (25.40)	4,662,573 (37.23)

^aOur statistics were limited to those users who disclosed their demographic information on the corresponding indicators publicly, so the actual number of users on different demographic indicators may be different.

Thematic Content Analysis

We employed thematic content analysis to explore the topics of public discussion on medical AI. The results showed that such contents fall into three major categories, including 10 subcategories (Table 2).

The first major category, “Technology and application” (n=987, 42.63%), focuses mainly on what AI is and which medical fields it can be applied to; people discussed technical issues (n=109, 4.71%) related to AI technology, as well as its general uses (n=210, 9.07%) and specific uses (n=668, 28.85%). With regard to the specific uses of AI, its technological application in the medical field was the most popular topic; people showed the most interest in the application of AI in diagnosis (n=436,

18.83%) and treatment (n=146, 6.31%), and some interest in prevention (n=52, 2.25%) and recovery (n=34, 1.47%).

The second major category, “Industry development” (n=706, 30.50%), is mainly concerned with the development and trends of medical AI and related industries. People were particularly concerned with the development of related companies (n=331, 14.30%) such as Baidu, Alibaba, and Tencent. They also discussed investment and market (n=186, 8.03%) and industry expectations (n=142, 6.13%), in which they estimated the financial performance and investment possibilities in such an industry. However, few mentioned policy and law (n=47, 2.03%) in their posts. Given that medical AI is new, there are limited regulations and laws related to it for people to discuss.

Table 2. Topics of public concern regarding artificial intelligence in medical care (N=2315).

Topics	Posts, n (%)	Definition	Example post
Technology and application	987 (42.63)	What is AI ^a and in which medical fields can it be applied?	N/A ^b
Technical issues	109 (4.71)	Technical discussions on AI in medical care	"Massive medical data is indispensable for AI medical treatment"
General uses	210 (9.07)	General public discussions on AI in medical care without pointing out specific medical areas	"I am looking forward to AI being applied in medicine, autonomous vehicles, and other fields so that ultimately we will all be beneficiaries of AI"
Specific uses	668 (28.85)	Medical AI applied to specific medical fields	"Vigorous development of the application of AI in treatment and rehabilitation."
Prevention	52 (2.25)	Application of AI in medical prevention	"How amazing AI is to be able to predict Alzheimer's nine years in advance."
Diagnosis	436 (18.83)	Application of AI in medical diagnosis	"Google's deep learning AI can diagnose cancer with an accuracy rate of 89%, while the accuracy rate of human diagnosis is currently 73%."
Treatment	146 (6.31)	Application of AI in medical treatment	"Intelligent doctors can list multiple treatment plans in 10 seconds"
Recovery	34 (1.47)	Application of AI in medical recovery	"Intelligent family service robots have achieved mass production and application; robots helping in the recovery and assistance of the elderly and disabled are at the prototype production stage."
Industry development	706 (30.50)	Public attention toward and views on the medical AI industry	N/A
Development of related companies	331 (14.30)	Public discussions about companies that make advancements in medical AI	"Alibaba signed contracts with the First Affiliated Hospital and began to march toward AI medical treatment."
Investment and market	186 (8.03)	Public discussions on the financial issues associated with medical AI	"Pony Ma, Tencent's boss, will invest in artificial intelligence medicine"
Industry expectations	142 (6.13)	Public prospects for the developmental trend of AI in medical care	"I think the AI medical industry has a bright future"
Policy and law	47 (2.03)	Public discussions on privacy and legal issues in AI industry development	"The development of AI can greatly shorten the training cycle of doctors, but the relevant legal and technical norms still need improvement."
Impact on society	622 (26.87)	Influence of AI in medical care on society	N/A
Impact on doctors	422 (18.23)	Public perception of medical AI's impact on human doctors	"After the development of artificial intelligence, doctors are one of the first unemployed professions. Don't let children study medicine"
Impact on hospitals	125 (5.40)	Public perception of medical AI's impact on hospitals	"Will AI and telemedicine help hospitals control medical costs?"
Influence on public life	75 (3.24)	Public perception of medical AI's impact on public life	"When AI enters the medical field, can human beings live forever?"

^aAI: artificial intelligence.^bN/A: not applicable.

The third category, "Impact on society" (n=622, 26.87%), includes the subcategories of impact on doctors (n=422, 18.23%), impact on hospitals (n=125, 5.40%), and influence on public life (n=75, 3.24%). Notably, people cared a lot about the impact on doctors, discussing both positive and negative implications, such as reduced workload and improved efficiency, as well as the need to deal with the threat of doctors being replaced. Medical AI would simultaneously impact health care modalities in hospitals and public life as well.

Public Attitudes Toward AI in Medical Care

Overview

A total of 956 posts displayed users' specific attitudes toward AI in medical care. Of these, 568 posts (59.4%) expressed positive attitudes, 329 (34.4%) conveyed neutral attitudes, and 59 (6.2%) highlighted negative attitudes. In order to understand why people hold these attitudes, we further analyzed the specific viewpoints in these posts (Table 3).

Table 3. Distributions of public attitudes toward artificial intelligence in medical care (N=956).

Attitudes	Number of posts, n (%)
Positive attitudes	568 (59.4)
Artificial intelligence's technical advantages in medical care	251 (26.3)
Optimism about industrial development	229 (24.0)
Helping human doctors	46 (4.8)
Avoiding doctor-patient conflicts	24 (2.5)
Promoting reform of medical care	11 (1.2)
New health expectations	7 (0.7)
Neutral attitudes	329 (34.4)
Information sharing, noncommittal	216 (22.6)
Hesitation	85 (8.9)
Commentary on both positive and negative aspects	28 (2.9)
Negative attitudes	59 (6.2)
Immaturity of artificial intelligence technology	27 (2.8)
Distrust of artificial intelligence companies	15 (1.6)
Fear of artificial intelligence technology	7 (0.7)
Lack of "enthusiasm" expressed by artificial intelligence	5 (0.5)
Privacy	3 (0.3)
Ethics and law	2 (0.2)

Positive Attitudes

As illustrated in Table 3, AI's technical advantages in medical care was the most mentioned reason (251/568, 44.2%) for positive attitudes, in which people identified benefits such as high diagnostic accuracy and computational efficiency. Another main reason for positive attitudes was the optimism about industrial development (n=229, 40.3%), in which people expressed confidence and expectations for medical AI's industrial development. Other reasons associated with AI making contributions to the medical field were also discussed, such as helping human doctors (n=46, 8.1%), avoiding doctor-patient conflicts (n=24, 4.2%), and promoting the reform of medical care (n=11, 1.9%). People believed that medical AI can not only improve human doctors' work quality and reduce their workload but also help avoid doctor-patient conflicts. They also believed that medical AI could maintain fairness, eliminate discrimination against patients, and would not involve under-the-table fees, thus helping reduce arguments and conflicts. In addition, people felt that medical AI would affect the development of the medical system and promote the reform of medical care, which would, in turn, boost health care efficiency and benefit more patients.

Neutral Attitudes

Posts expressing neutral attitudes conveyed noncommittal information (216/329, 65.7%). Users mainly forwarded AI-related posts or news, either summarizing the content or including ambiguous attitudes toward medical AI (eg, "AI new technology - Nature magazine reports: AI is better than doctors in early diagnosis of autism in children"). People conveyed a sense of hesitation (n=85, 25.8%) to accept medical AI,

considering that its use is not widespread and it requires time to be tested. Others provided commentary on both positive and negative aspects (n=28, 8.5%) of medical AI and did not express a preference for either view (eg, "AI may eradicate disease and poverty, but it may also destroy human beings").

Negative Attitudes

For posts displaying negative attitudes toward AI in medical care, the immaturity of AI technology (27/59, 45.8%) was the leading reason for doubt. People believe AI is far from mature and must overcome many technical difficulties, including those related to obtaining high-quality medical data, such as data fraud and obstruction of hospitals (eg, "Healthcare involves huge vested interests...huge resistance needs to be overcome"), and the difficulty of standardizing medical treatment for AI (eg, "This kind of complex inspection is difficult to standardize. And it is too difficult for AI"). Distrust of AI companies (n=15, 25.4%) also accounted for negative attitudes. Some people believed that AI-related companies would use medical AI to earn money regardless of the patients' health (eg, "AI recommends incompetent hospitals that only spend their money on advertising"). Some people mentioned a fear of AI technology (7/59, 11.9%) and the lack of "enthusiasm" expressed by AI (n=5, 8.5%), which indicated that they tended to compare AI with humans and were greatly concerned with humanistic problems. Notably, only a few people mentioned fears about the problem of privacy, ethics, and law (n=2, 3.4%) in using medical AI.

Public Attitudes Toward Replacing Human Doctors With AI

For many decades, the fear that AI will cause widespread unemployment has waxed and waned; however, some researchers believe that fears of robots and computers greatly increasing secular unemployment are unwarranted [32]. However, the relationship between AI and human workers, especially the concern that AI workers can replace human workers, has become one of the most controversial issues in the development of the AI industry. Since this is also true in the field of medical AI, we paid special attention to public attitudes toward the issue of whether AI doctors can replace human doctors.

A total of 200 posts referred to the topic of AI replacing human doctors, and 80.0% of the posts conveyed the sense that AI doctors can completely or partially replace human doctors. Of these, 95 posts (47.5%) expressed the users' belief that AI would replace all human doctors. We further identified the reasons for such attitudes. The results indicated that the most important reasons for people believing that AI will replace human doctors is that AI has technical advantages in medical care, such as high accuracy, stability, and efficiency. In addition, people expressed their hope that AI doctors would have the advantage of not having conflicts with their patients. There were 65 posts (32.5%) that expressed the users' belief that AI would partially replace human doctors. Such users believed that some medical jobs, such as pathological diagnosis, are suited to AI, while others are more suitable for human doctors. To determine which kinds of doctors were considered most likely to be replaced by AI, we further coded the posts that explicitly mentioned the doctors that users believed might be completely or partially replaced by AI. Pathologists were the most frequently mentioned ($n=17$, 43.6%), followed by radiologists ($n=8$, 20.5%) and dermatologists ($n=3$, 7.7%). In terms of medicine and surgery, physicians ($n=4$, 10.3%) were considered more likely to be replaced by AI than surgeons ($n=2$, 5.1%).

Moreover, 40 posts (20.0%) expressed the attitude that AI will not replace human doctors. The reasons for the public holding this attitude can be classified mainly in terms of technical and humanistic concerns. First, owing to the immaturity of AI technology, people believe that it cannot adequately manage medical problems. Second, people believed patients need humanistic interactions, which AI doctors could never offer. Third, considering ethics and laws, people believed that AI doctors might invade personal privacy and lack legal supervision. Finally, a very small percentage of users opposed AI doctors based on their fear of AI technology.

Discussion

Principal Results

Applying AI to medical care is believed to be a promising solution for the global shortage of medical resources. As a new field, whether the medical AI industry can develop in a healthy and smooth way depends not only on numerous technological challenges, but also on whether the public can accept and trust it. However, we still lack sufficient empirical evidence to reveal

actual public perception of medical AI. Based on social media data from Sina Weibo, this study took the lead in revealing the public perception of medical AI through content analysis. We mainly explored the general characteristics of people's attention toward medical AI, the topics of public interest in medical AI, people's attitudes toward medical AI, and their opinions on the debate regarding whether AI doctors can replace human doctors.

Overall, we found that public attention toward AI in medical care showed a noticeable event-driven trend on social media. Big social events, especially social entertainment events related to AI (eg, the world Go champion matchup between Sedol Lee and AlphaGo), generally cause a significant increase in public discussions about AI in medical care. To this end, we suggest that practitioners pay close attention to popular events related to AI and use these critical time points to promote the dissemination of knowledge related to medical AI. In addition, we revealed the profile of social media users who discussed AI in medical care; older adults, males, and people living in more affluent regions paid more attention to the issue of medical AI. These results are in accordance with previous findings that men prefer new technology products more than women [33]. As for the differences in interest across age groups, we think it may be related to the fact that older people may pay more attention to health and medical issues than younger people. Moreover, people in affluent regions may be more likely to seek information about medical AI [34] and have access to it, thus they pay more attention to it. The differential interest in medical AI between richer and relatively poorer regions in this study may support the theory of digital divide [35], and deepen the digital divide related to medical AI. How to promote the new medical technology in remote areas is also worthy of attention and future in-depth study by theorists and practitioners.

When investigating which topics interest people when discussing AI in medical care, we found that public interest mainly focused on technology and application, industry development, and societal impact. The public was most interested in AI technology and application. The specific uses of medical AI, especially in diagnosis, gained the most public attention under the category of technology and application. Our results may provide more precise guidance for the promotion and popularization of the technology and use of medical AI. In addition, the industry development and investment possibilities of medical AI (eg, development of related companies) attracted nearly one-third of public attention, among which only about 2% of posts focused on policy and law in the medical AI industry. We believe that the public's interest in industrial development is beneficial for companies that wish to rapidly promote medical AI, but the government and other regulatory authorities may need to pay attention to strengthening the formation and dissemination of relevant policies and laws in the future.

In terms of attitudes toward medical AI, our results showed that the public was optimistic, with nearly 60% of posts expressing positive attitudes. The preponderance of medical AI supporters among the general public implies that the promotion and popularization of medical AI had a relatively good public psychological basis. However, nearly 40% of public posts were neutral or opposed to AI. We found that approximately one-third of all users played the role of bystanders regarding AI in medical

care. This means that the current public attitude toward AI in medicine has considerable plasticity, and neutral people may require the most attention. Moreover, some people clearly expressed negative attitudes toward medical AI. The results showed that the immaturity of AI technology, distrust of AI companies, and fear of AI were the top three reasons for these negative attitudes. On the technical side, people questioned the ability of AI and believed that it is difficult to standardize medical care, and some even expressed a natural fear regarding the safety of AI technology. This means that it will take more time for medical AI to gain people's trust. At the organizational level, an attitude analysis revealed that people cared a lot about medical AI-related companies, and their negative attitudes could be due to their distrust of related companies (as observed with the Cambridge Analytica scandal and the #DeleteFacebook campaign). This indicates that managers from medical AI companies should not confine themselves to publicizing their technical advantages in the field of AI; rather, they should pay attention to how to actively portray a corporate image with a sense of social responsibility and trust to the public. The absence of humane care in AI was also an important reason for people's negative attitudes, which is consistent with previous studies [36]. It is noteworthy that few posts (0.5%) were concerned about issues relating to privacy, ethics, or the law in the context of medical AI. As shown in prior studies, a collectivist culture results in a lower level of privacy concerns than in an individualistic culture [37,38]. We speculate that China's collectivist culture and limited medical resources may have resulted in people from China being more interested about the benefits of AI than personal privacy.

On the controversial issue of whether AI could replace human doctors, we found that 80% of the posts indicated that AI doctors could replace human doctors completely or partially. This result was contrary to previous findings, which showed that 83% of medical students, most general practitioners, and the majority of physicians believe that AI will not replace them [16-18]. We speculate that this may be related to the psychological mechanism of self-defense of medical practitioners as stakeholders, which needs more direct evidence support from future research. It seems that the general public held a more open view about replacing doctors with AI than medical professionals, although the public is more conservative than AI experts. There is similar evidence that the general public was more enthusiastic about new medical technology than professional doctors [39]. Additionally, previous research also indicated that AI experts have made comments to the media that AI would soon replace doctors [15], and the public's attitude may be affected by these comments. However, one-fifth of the posts were against AI replacing human doctors. Their pessimism about AI's replacement of human doctors was mainly due to the immaturity of AI technology and AI's inability to express empathy and compassion. These findings correspond with those from previous studies that showed that the role of humanistic care in medical health has become increasingly prominent [40]. It is also worth noting that the public's attitudes on whether AI will replace human doctors may also affect medical enrollment and talent supply. Young people may be reluctant to go to medical school due to the fear that doctors will lose their jobs in the future. How to balance the potential conflict between the

development of medical AI and the supply of medical talent merits discussion among governments, universities, and relevant practitioners.

Limitations and Future Directions

While our study contributes to understanding the public perception of AI in medical care, there are a few limitations worth noting. First, as our study focused on users of the social media platform Sina Weibo, our sample may have been younger and more educated than the broader population. Since younger and more educated people may be more open to new technologies, we may have overestimated the public's optimistic attitude toward AI in medical care. Second, the data used in this study were specific to China; the unique cultural environment may have affected people's perception of and attitudes toward medical AI; thus, the findings may not be generalizable to other countries. In this study, we found that the public in China paid much more attention to the technology and application of medical AI than to privacy risks. Whether these conclusions can be generalized to Western countries remains to be examined in future studies. However, as the most populous country in the world, the shortage of medical resources in China is severe. It is of great practical significance to explore medical AI in China. At the same time, China has the largest number of internet users in the world and has a particular advantage in the development of AI technology. Therefore, we believe that it is an important issue to clarify the Chinese public perception of and attitude toward medical AI. Nevertheless, future research can consider exploring the public perception of medical AI in other countries. Third, our analysis based on social media data has some inevitable limitations in inferring users' apparent attitude and behavior intention. In the future, such research can be supplemented and improved with research evidence, such as a questionnaire survey.

Conclusions

Our study presents a social listening method of assessing public perception and opinions on AI in medical care through social media content analysis. Our findings indicate that social events can easily drive the public's attention to medical AI, and that older adults, males, and people living in more affluent regions were more interested in it. The general public was most interested in AI technology and application, especially its specific uses in diagnosis, but showed little interest in policy and law in the medical AI industry. The characteristics of the public attention on medical AI that we found in this study may provide practical guidance for promoting this new medical technology. Still, we need to pay close attention to the present digital divide that may deepen further. In terms of attitudes toward medical AI, the majority of people held positive attitudes and believed that AI doctors would completely or partially replace human doctors. In the aggregate, the general public attitudes toward medical AI were more open than those of medical professionals but more conservative than those of AI experts.

Although they were generally optimistic about AI in medical care, some people still had negative attitudes toward medical AI owing to the immaturity of AI technology and their distrust of AI companies. Our results revealed that distrust of companies

accounted for one-quarter of all negative attitudes toward AI. Improving the public's trust in AI companies may take more time than upgrading the technology. In addition, technical and humanistic concerns were the most important reasons for some people's pessimism about AI replacing human doctors. We suggest that in the future, practitioners should pay more attention to humanistic care and try to meet patients' emotional needs, rather than only focusing on technical issues. It is worth noting

that currently, AI in medical care is still in its early stages, and most people have not come into contact with it. Therefore, their attitudes are likely to change with the development of medical AI products. Future research should keep track of the changes and progress of public opinion toward medical AI in the long run. We hope this study can serve as a catalyst for the understanding of public perception on medical AI and expand the ongoing conversation to additional communities.

Abstract

Background: Asthma is one of the most prevalent chronic respiratory diseases. Despite increased investment in treatment, little progress has been made in the early recognition and treatment of asthma exacerbations over the last decade. Nocturnal cough monitoring may provide an opportunity to identify patients at risk for imminent exacerbations. Recently developed approaches enable smartphone-based cough monitoring. These approaches, however, have not undergone longitudinal overnight testing nor have they been specifically evaluated in the context of asthma. Also, the problem of distinguishing partner coughs from patient coughs when two or more people are sleeping in the same room using contact-free audio recordings remains unsolved.

Objective: The objective of this study was to evaluate the automatic recognition and segmentation of nocturnal asthmatic coughs and cough epochs in smartphone-based audio recordings that were collected in the field. We also aimed to distinguish partner coughs from patient coughs in contact-free audio recordings by classifying coughs based on sex.

Methods: We used a convolutional neural network model that we had developed in previous work for automated cough recognition. We further used techniques (such as ensemble learning, minibatch balancing, and thresholding) to address the imbalance in the data set. We evaluated the classifier in a classification task and a segmentation task. The cough-recognition classifier served as the basis for the cough-segmentation classifier from continuous audio recordings. We compared automated cough and cough-epoch counts to human-annotated cough and cough-epoch counts. We employed Gaussian mixture models to build a classifier for cough and cough-epoch signals based on sex.

Results: We recorded audio data from 94 adults with asthma (overall: mean 43 years; SD 16 years; female: 54/94, 57%; male 40/94, 43%). Audio data were recorded by each participant in their everyday environment using a smartphone placed next to their bed; recordings were made over a period of 28 nights. Out of 704,697 sounds, we identified 30,304 sounds as coughs. A total of 26,166 coughs occurred without a 2-second pause between coughs, yielding 8238 cough epochs. The ensemble classifier performed well with a Matthews correlation coefficient of 92% in a pure classification task and achieved comparable cough counts to that of human annotators in the segmentation of coughing. The count difference between automated and human-annotated

coughs was a mean -0.1 (95% CI $-12.11, 11.91$) coughs. The count difference between automated and human-annotated cough epochs was a mean 0.24 (95% CI $-3.67, 4.15$) cough epochs. The Gaussian mixture model cough epoch-based sex classification performed best yielding an accuracy of 83%.

Conclusions: Our study showed longitudinal nocturnal cough and cough-epoch recognition from nightly recorded smartphone-based audio from adults with asthma. The model distinguishes partner cough from patient cough in contact-free recordings by identifying cough and cough-epoch signals that correspond to the sex of the patient. This research represents a step towards enabling passive and scalable cough monitoring for adults with asthma.

Introduction

Asthma is one of the most prevalent chronic respiratory diseases [1]; it is estimated to afflict 339 million people worldwide [1]. Despite increased investment in treatment, hospital admissions and mortality rates have remained stable over the last decade [2]. This stagnation highlights the lack of scalable and easy-to-manage diagnostic tools for early recognition of exacerbations [3]. Traditional asthma self-management programs include written plans of action that cover how to recognize and respond to exacerbations [4]. These pen-and-paper approaches have shown improved health outcomes such as reduced hospital admissions, better lung function, fewer asthma symptoms, and less use of rescue medication [4-6]. The implementation of these programs, however, is low in clinical practice, with only 27% of adults with asthma receiving an asthma action plan [7]. Also, patient adherence to written action plans is poor and declines over time [8], and due to the reliance on subjective information in action plans, patients may perceive their symptoms poorly, and thus, underestimate the severity of the disease [9].

Disease control (also referred to as asthma control) is defined as the degree to which symptoms are controlled by treatment [10]. Exacerbations of asthma occur gradually over several days to weeks on a background of poor asthma control [11,12]. Although there is consensus on the importance of longitudinal and objective assessment of asthma control in the home environment, few tools enable objective measurement [3]. Current guidelines for the assessment of asthma control recommend the measurement of peak expiratory flow [13]. Changes in peak expiratory flow can occur up to 2 weeks before an exacerbation [14]. This parameter, however, is dependent on effort [3], and only 5% of adults with asthma measure peak expiratory flow regularly [15]; therefore, it has limited utility. Nocturnal cough is a physiologic parameter which has shown promise for use in the assessment of asthma. Cough is a particularly burdensome asthma symptom [16] and was shown to be associated with asthma severity [17] and a worse prognosis [18]. Cough counts per night (ie, the number of coughs produced by one individual per night) have been associated with the level of asthma control [19]. Moreover, lower levels of asthma control have been correlated with poor quality of life [20] and are a predictor for cost-of-illness [21]. Coughing may also provide valuable information to predict the effects of asthma therapy early on [22]. Thus, nocturnal cough monitoring may play an

important role in the prevention of exacerbations and in the personalization of treatment.

The monitoring of coughing by quantifying the number of coughs per unit of time has been attempted by researchers since the 1950s [23]. Although cough events may be counted manually from sound and video recordings, this process is extremely laborious. In consequence, many semi and fully automated cough monitoring systems have been in development since the 1950s. Among the more well-known systems are the Hull Automatic Cough Counter [24], the Leicester Cough Monitor [25], and LifeShirt [26]. The Hull Automatic Cough Counter is a software program written in MATLAB with the ability to differentiate cough from noncough sounds using Sony Walkman tape recordings. Leicester Cough Monitor is based on a free-field microphone necklace that records sound continuously onto a digital recorder. Recordings can then be uploaded onto a computer where an automated cough detection algorithm analyzes them. LifeShirt is an ambulatory cardiorespiratory monitoring system with a unidirectional contact microphone. Though these systems lacked scalability and cost-effectiveness, they showed feasibility with respect to automatic cough detection and counting from audio recordings.

Smartphones are now ubiquitous [27] and are equipped with sensors capable of many types of monitoring with clinically valuable accuracy [28]. Their widespread adoption in all age groups enables them to be used for measurements within different population samples [29]. In addition, they can be used to passively monitor the health status of patients without an additional task of activating a monitor. Recent advances have used only a smartphone and its built-in microphone for cough monitoring [30-32].

To develop an automatic cough monitoring system is challenging due to the rare occurrence of coughing in comparison to the occurrence of other sounds. This natural imbalance of cough and noncough sounds poses two problems. First, it demands high specificity from the cough monitoring system to avoid false alarms from other similar and more frequently occurring sounds. Second, existing classification methods tend to perform poorly on minority-class examples when the data set is highly imbalanced [33]. In addition, experts have suggested sensitivities greater than or equal to 90% as necessary for clinical use [34]. An even greater challenge is to collect sufficient data in the intended context and timeframe to allow realistic assessment of the monitoring system, particularly

with respect to respiratory conditions. Some cough monitoring systems have been developed based on data collected under lab conditions by recording voluntary coughs [35–37]. While this may be a valid approach to compare the performance of different classifiers, it may not represent the soundscape of a real-use case. No cough monitoring systems exist that have undergone longitudinal overnight testing nor do any exist that have been specifically evaluated in the context of asthma. Also, depending on the intended mode of use, new challenges arise for cough monitoring—distinguishing partner coughs from patient coughs in a room with two or more people using contact-free recordings is a difficult task. To date, there are no standardized methods, and there are no sufficiently validated cough monitors for general use that are commercially available and clinically acceptable [23].

The study was designed to mimic a real-world use case; data were collected from a smartphone placed on the bedside table in the participant's bedroom. The aim was to build a cough classifier and to evaluate its performance on unseen data. Further, we aimed to use the classifier to segment and count cough events over the course of the night. Building upon previous work [32], we adopted a convolutional neural network architecture, which performed best in comparison to that of other machine learning approaches when using voluntary cough data from different smartphone recordings. We altered the learning part of the algorithm by combining three different techniques from literature to combat the high class imbalance encountered in this real-life data set—ensemble learning [38], minibatch balancing [39], and decision thresholding [40].

Though a smartphone-based nocturnal cough monitoring service may enable passive monitoring in theory, its utility for application in practice depends on whether coughs can be correctly assigned to individuals. Prior research has shown that humans are able to determine whether the source of a cough is male or female based on sound alone [41]. In addition, sex-based differences in signal properties have been measured in cough signals [42]. Epidemiological research suggests that less than 10% of the general population identify as homosexual [43]. Assuming that most people either sleep alone or share their bedroom with a partner, for the vast majority of patients, correctly classifying cough by sex-based properties of the cough signal could allow a cough monitoring system to disregard the coughs that are not from the individual of interest. Therefore, in addition to cough detection, this work examines to what extent coughs can be correctly be classified by sex. This research represents a step towards enabling passive scalable monitoring for people with asthma.

Methods

Overview

This study involved the collection of smartphone-recorded audio and daily questionnaire data, the definition and quantification of coughs within that data (data annotation and automated cough recognition and segmentation), sex-based classification, and model performance evaluation.

Data Collection

We used data collected in a multicenter, longitudinal observational study over a 29-day period (28 nights) [41]. On the first and last day, participants underwent medical examination by health professionals at the study centers. At the start of the study, participants were equipped with a smartphone (Samsung Galaxy A3 2017, SM-A320FL) on which Clara—the study's chat-based app—was installed. This app was a study-specific enhancement of the mobile app in the open-source MobileCoach behavioral intervention platform [44,45]. At night, the app recorded audio data using the smartphone's microphone. It also delivered daily questionnaires to the patients, asking them (among other things) whether the participant slept alone.

All participant data were collected by the physician (asthma evaluation data) or the nurse (lung function evaluations) in the study centers and were transferred to an electronic format and stored online on the study server. Nightly sensor data were stored locally on the smartphone. Data were backed up to external hard drives and secure online storage once the participant had completed the study and had returned the smartphone.

The study protocol was reviewed and approved by the *Ethikkommission Ostschweiz*, which is responsible for research on humans in Eastern Switzerland (Business Management System for Ethics Committees ID: 2017–01872).

Cough Definition and Quantification

With respect to cough monitoring systems, the definition of cough depends on the modality used for monitoring [23]. In this study, we aimed to recognize coughs from sound recordings which can be done in several ways [23]. We focused on two methods: (1) counting explosive cough sounds and (2) counting cough epochs (continuous coughing sounds without a 2-second pause [23]). The latter is derived from the first metric by computing the duration between explosive cough sounds.

Data Annotation

Before annotation, silence was marked by applying a decibel filter by means of the Audacity software to the recordings. The Sound Finder filter marked sounds below –26 dB as silence with the constraint that the minimum duration of silence between sounds was 1 second. These periods marked as silence served as visual aids for the remainder of the annotation process. Human annotators listened to the smartphone recordings and labeled the periods that were not marked as silence as a cough if an explosive cough sound was identified [23,41].

We used two approaches to verify the quality of the labeling. First, we instructed human annotators to label an acoustic event if they were unsure that it was a cough. If annotators were unsure, the event was discarded and was not considered in the analysis. The remainder of acoustic events were classified as noncoughs. Second, the interrater reliability for the annotators was determined using intraclass correlation. A zero-inflated generalized mixed-effects model with a Poisson response was used [46]. Additional details of the annotation method can be found in [Multimedia Appendix 1](#).

Cough Recognition and Segmentation

Data Set Partitioning for Cough Recognition

When developing neural networks, the split into sets for training, validation, and testing of the model is favored over other approaches that involve cross-validation because of the long training phases of the models; however, this comes at the risk of overfitting the model to the specific data set and a lack of generalizability to unseen samples. To mitigate these effects, we split our data into disjunct data sets which contained a different set of participants in the training, validation, or test sets. Furthermore, the large number of cough samples and participants in comparison to former studies [7,24,25,30,31] may help mitigate the risk of overfitting.

Training, validation, and test sets were created in the following way. From participants with complete data sets, roughly 20% were drawn at random; these nocturnal audio recordings constituted the testing corpus for our evaluations. From the remaining participants, roughly 15% were drawn at random to be included in the validation set. The remaining participants then comprised the training set. Thus, data were roughly split into a ratio of 65:15:20. For model evaluation, the neural network was first trained on the training set. Hyperparameter tuning and model selection were performed on the validation set. Once the best performing parameters and model were

selected, the final training was completed on the unified training and validation set. Model results were derived from the test set. The data split proportions were motivated by the fact that larger amounts of training data improve the performance of the classifier [47].

Neural Network Architecture for Cough Recognition

This work was built upon a convolutional neural network architecture for cough recognition that we introduced in previous work [32] which recognized coughs in Mel spectrograms. Mel-scaled spectrograms are visual representations of audio signals with respect to time and frequency. Signal frequency ranges are Mel-scaled to represent the human perception of sound. In conjunction with convolutional neural network architectures, they have been reported to perform better than other time-frequency representations [48]. The detailed calculation of the Mel spectrograms used can be found in [Multimedia Appendix 1](#). We evaluated this approach against different approaches for smartphone-based cough recognition in previous work on voluntary coughs and found that it performed best [32]. Our approach produced stable results across recordings of five different devices with different hardware and service life duration. Moreover, it was designed to be lightweight and its deployment and energy-efficiency were tested on smartphones. [Figure 1](#) depicts the architecture.

Figure 1. The architecture consists of 5 convolutional layers with alternating max-pooling layers followed by a global max-pooling layer. The annotation "16@80x122" refers to a feature map with dimensions (height x width) and 16 channels. The annotation "1x7 Convolution" refers to a convolutional filter with spatial dimensions (height x width).

Network Training for Cough Recognition

Overview

A common problem in real data sets is that some classes have more samples than others. This class imbalance can have a considerable detrimental effect on convergence during the training phase and generalization of a model on the test set [40]. To counter the high imbalance in our data set, we employed 3 different techniques: ensemble learning, balanced minibatch learning, and decision thresholding. Our training approach can be summarized as follows. First, equally sized windows were extracted from the labeled acoustic cough and noncough events. From the resulting windows, we computed Mel spectrograms and employed data partitioning on the cough and noncough Mel

spectrograms. Second, we created 5 folds out of the training data. Third, from each of those folds, a separate convolutional neural network model was trained using balanced minibatch training. These models had a probability score as output that indicated the likelihood of a cough. Finally, a threshold was determined to determine the averaged predicted probability of the trained models. The trained ensemble convolutional neural network classifier including thresholding is referred to as ensemble convolutional neural network throughout this paper.

Window Extraction

To train the classifier, nonoverlapping 650 ms windows from the noncough acoustic events were extracted. The duration of the window was based upon previous work. The same

approximate duration has performed best in other cough monitoring approaches [49]. From the cough events, a single 650 ms window centered around the maximum amplitude was extracted since most cough events were shorter. Mel spectrograms were computed for these windows.

Ensemble Learning

In ensemble learning, combining individual models may help to improve generalization performance, if the individual models are dissimilar [50]. In previous work [32], we employed this approach by varying the subset of the devices from which single classifiers are trained, and thus created dissimilar classifiers. In this data set, we had a vast amount of recordings from one device model at our disposal. We, therefore, aimed to create dissimilar classifiers by training disjunct folds of the data instead. At the same time, by using disjunct folds, we reduced the training duration for a single classifier. Ensemble classifiers have also been applied successfully to other imbalanced data sets in prior work [38]. In this work, we subsampled the noncough class of the training data set into 5 participant-disjunct parts. For each of these subsamples and for the total sample of coughs in the training data, we trained a separate convolutional neural network classifier. In such a manner, we reduced the level of imbalance and still benefited from the increased prediction performance of an ensemble classifier. We limited our approach to 5 classifiers in order to limit computation, which increased linearly with the number of classifiers. To execute one of the convolutional neural network classifiers, 10.74 million floating-point operations are needed. The amount of computation may be of importance if the model is to be deployed on smartphones with limited computational resources. The output of each classifier is a probability score computed in the sigmoid neuron of the architecture.

Balanced Minibatch Training

Although the multilayer architecture of neural networks is essential, it is the back-propagation algorithm [51] that solves the optimization problem of minimizing the error between the samples and the predictions during the training phase using gradient descent. It computes the gradients of this error with respect to the neural network weights and propagates it back over the different layers defined by the architecture.

This process was done iteratively using the learning rule defined as follows:

$$\theta^{\tau+1} = \theta^{\tau} - \eta \partial E$$

where n was the number of samples, $\theta^{\tau+1}$ was the new updated weight, θ^{τ} was the current weight, η was the learning rate, E was the error, and ∂ was the differential operator. A more efficient technique for the evaluation of the learning rule is minibatch training [39] which introduces a trade-off when updating the weights. While using all training samples at once would have allowed for a precise update of the weights, it would also have taken longer and would have required excessive memory, and using a single instance to update the weights would have introduced noisy updates and would have been computationally inefficient. Minibatch training, however, splits the training data into small batches and computes weight updates

from those batches. We employed balanced minibatch training, which also balanced the amount of majority and minority class instances per batch. Finally, we trained each of the convolutional neural network classifiers using balanced minibatch training and the Adam adaptive learning rate optimization algorithm [52]. This training approach relied on a number of hyperparameters, which were tuned and selected on the validation set, learning rate, batch size, and the number of iterations. Furthermore, weight initialization was accomplished using Xavier initialization [53] and dropout which is a regularization technique to prevent overfitting [54]. A dropout rate of 50% was used.

Thresholding

Thresholding adjusts the decision threshold of a classifier. It is typically applied in the test phase and involves changing the output class probabilities [40]. Since we used balanced minibatch training, in the training phase, we implicitly assumed that cough and noncough windows were each as likely to occur as the other. To account for the class imbalance and to find the best decision threshold, we employed a grid search on probabilities in the range of [0.5, 1) and tuned it on the validation set. The single classifier is one randomly selected classifier out of the 5 classifiers that constitute the ensemble classifier. We computed the threshold-based decision rule for the ensemble classifier as follows:

$$Q_i(x|\lambda_{cough}) > t$$

where $Q_i(x|\lambda_{cough})$ is the probability score of the classifier i for the Mel spectrogram x and the class cough λ_{cough} , and t is the threshold.

Cough and Cough-Epoch Segmentation

In cough segmentation, the objective is to segment coughs from continuous audio recordings by employing a trained convolutional neural network ensemble classifier. We extracted 650 ms window with an overlap of 65 ms. To discard silent windows, each of these windows passes through a decibel filter that removes windows with sounds below -26 dB as in the annotation process. Subsequently, preprocessed into Mel spectrograms for each window were computed (as described in Multimedia Appendix 1). From these Mel spectrograms, cough probabilities were computed using the trained ensemble classifier. The continuous probabilities that were output were then transformed into segmentations by applying 3 postprocessing rules: (1) Only consecutive probabilities above the derived threshold were considered to be coughs, to reduce the number of false detections. (2) Single probabilities above the threshold were then considered, when the mean of the probability above the threshold and the following probability was above 0.9. (3) When more than eight consecutive detections occurred, they were recognized as two coughs. This was done to compensate for the limited resolution caused by the size of the overlap. These rules were derived by observation and yielded the best results on the validation set. Figure 2 illustrates the cough segmentation process. From the segmentation of cough, cough counts were computed. Cough epochs were recognized when two (or more) coughs occurred without a 2-second pause

in between. An annotated cough epoch was considered to be correctly identified when at least one of the predicted coughs of the cough epoch corresponded with the annotated cough in the cough epoch.

Figure 2. The steps for the segmentation of coughs from continuous audio recordings (from top to bottom): First, the continuous extraction of overlapping windows from continuous audio recordings; second, the discarding of silent windows by applying a dB filter; third, the computation of Mel spectrograms; fourth, the computation of the prediction probability of cough by the convolutional neural network ensemble; last, the recognition of cough by applying the postprocessing rules. CNN: convolutional neural network.

Sex Classification

Data Set Partitioning

For the data set partitioning for determining the source of each cough by sex, we used the complete data set and did not consider the partitioning used for cough recognition. The reason for this lay in the limited amount of data that fulfilled the filtering requirements for the analysis. Since the data collection study included couples or multiple people in one room, we filtered the annotated cough data based on the information collected daily regarding whether the participant slept alone or not. We then filtered the data of the corresponding nights to create a balanced data set of male and female coughs that included 19 female and 19 male participants. We conducted our analysis on both extracted cough and cough-epoch signals. In both cases, we partitioned the data set into a disjunct training set of 10 female and 9 male and a test set of 9 female and 10 male participants.

Gaussian Mixture Models

Gaussian mixture models in combination with Mel-frequency cepstral coefficients [55] are a known method for tackling several different recognition tasks in the audio domain, such as text-independent speaker recognition [56] or gender recognition

from speech [57]. For the sex classification of cough signals, we used the 650 ms windows that were labeled as coughs and the resulting cough epochs to compute the Mel-frequency cepstral coefficients. In addition, their first time-derivative estimate and the first time-derivative estimate of the zero-crossing rate computed over the signal were used as features. The idea of training Gaussian mixture models was to approximate the probability distribution of a class by a linear combination of K Gaussian distributions. The likelihood function of feature vector X given class λ can be described as follows:

$$P(X|\lambda) = \sum_{k=1}^K \omega_k P_k(X|\mu_k, \Sigma_k)$$

where $P_k(X|\mu_k, \Sigma_k)$ is the Gaussian distribution. The parameters mean μ_k , covariance Σ_k , and weights ω of the distributions are determined during the training of the features X of class λ .

Considering the equal distribution of both sexes in the partitioned data set, a feature vector x_i of a cough or cough epoch can then be evaluated as follows:

$$P(X|\lambda) = \sum_{k=1}^K \omega_k P_k(X|\mu_k, \Sigma_k)$$

Mel-frequency cepstral coefficients ($n=20$) were computed with 256 samples between successive frames and a 4096-point fast Fourier transform. Analogously, the zero-crossing rate was computed over frames of 4096 samples with 256 samples between successive frames. These features were then vertically concatenated, which resulted in a matrix where the first dimension contained 41 entries. Feature selection and specific parameters were determined by employing 5-fold cross-validation on the training set. Hyperparameters of the Gaussian mixture models were also determined by employing 5-fold cross-validation on the training set which resulted in 30 Gaussian distributions each for female and male classes. Further hyperparameters were the number of initializations ($n=3$), number of expectation-maximization iterations ($n=200$), and the use of diagonal-type covariance.

Performance Evaluation

For the evaluation of the performance of the different models, we reported several metrics such as sensitivity (true positive rate), specificity (true negative rate), accuracy, Matthews correlation coefficients, predictive positive value, negative predictive value, receiver operating characteristic curve, precision-recall curve, and Bland-Altman plot. These metrics are commonly used in machine learning and research in the context of clinical decision-support systems. For the segmentation of cough and cough epoch, we reported the number of false positives, true positives, and false negatives per night. These metrics are defined in [Multimedia Appendix 1](#).

Results

Data

Participant Data

A total of 94 participants (female: 54/94, 57%; male: 40/94, 43%) were recruited for the study. Ages of the participants ranged from 18 to 89 years with a mean of 43 (SD 16) years. Fifteen of the 94 participants were excluded from the analysis; 2 participants withdrew, 3 participants were not involved in the study procedures for more than 5 days, and 10 participants had more than 5 nights of missed audio recordings. Some of the missed audio recordings were due to technical difficulties (such as the app crashed) while some were participant-related (such as the participant's smartphone had been turned off).

Data Set Partitioning

Cough Recognition

Of the 79 participants whose data were included for analysis, 15 participants were initially drawn at random to be included in the test set. From the remaining 64 participants, 12 additional participants were drawn at random and included in the validation set. Data from the remaining 52 participants comprised the training set.

Window Extraction

Of a total of 704,697 acoustic events, 30,304 were clearly classified as coughing and 0.11% (767/704,697) were discarded. A total of 2,547,187 noncough and 30,304 cough Mel spectrograms were computed yielding a 0.015 class ratio.

Thresholds

Thresholds of 0.98 and 0.95 yielded best results in terms of Matthews correlation coefficient for the single and ensemble convolutional neural networks of 84% and 91% on the validation set, respectively.

Annotator Intraclass Correlation

Two of the annotators together accounted for 90.23% of all nights. These two annotators had an intraclass correlation of 95.79% (mean absolute error: 0.44 coughs per night). We calculated the intraclass correlation based on 65 nights. The intraclass correlation was interpreted as excellent.

Evaluation Cough Recognition Classifier Performance

We evaluated the classifiers on the testing set, which consisted of 5489 cough and 541,972 noncough events. The test set represented the soundscape encountered in the bedrooms of 15 participants over the course of 28 nights. As shown in [Table 1](#), the performance of the ensemble classifier was better than that of the single classifier. The difference was especially notable for true negative rate, negative predictive value, Matthews correlation coefficient values, and the area under the curve of the precision-recall curve. Both classifiers showed better performance for true positive rate compared to that for true negative rate which indicated a superior capability to recognize cough whenever a cough sound was presented compared to the capability to recognize noncough sounds. As a consequence, the false positive rate was higher than the false negative rate ([Figure 3](#)).

Table 1. Results of the convolutional neural network classifier for cough recognition.

Model type	True positive rate, %	True negative rate, %	Accuracy, %	Matthews correlation coefficient, %	Positive predictive value, %	Negative predictive value, %
Single	99.9	87.5	99.7	87.2	99.9	87.1
Ensemble	99.9	91.5	99.8	92.0	99.9	92.6

The dashed line represents the curve for a random classifier showing the proportion of cough-class instances to the total amount of instances. AUC: area under the curve; CNN: convolutional neural network.

Evaluation Cough and Cough-Epoch Segmentation

The test set included 15 participants and 421 nights; human annotators counted as few as zero and as many as 368 coughs in one night. The mean count difference between automated and annotator coughs was -0.1 (95% CI $-12.11, 11.91$) coughs per night (Figure 4). Further, our classifier produced a mean of 1.76 false positives per night and 1.66 false negatives per night. In total, 241 nights were identified with a count difference of

0 coughs (Figure 5) and 5 nights had count differences greater than 20 coughs. Human annotators counted as few as zero and as many as 101 cough epochs in one night. The mean count difference between automated and observer cough epochs was 0.24 (95% CI $-3.67, 4.15$) epochs per night (Figure 6). Our classifier produced a mean of 0.33 false positives per night and 0.57 false negatives per night. In total, 312 nights were identified with a count difference of 0 cough epochs (Figure 7) and 6 nights had count differences greater than 6 cough epochs.

Figure 5. Histogram of the differences between automated and annotator cough counts per night.**Figure 6.** Bland-Altman plot of the automated and annotator cough-epoch counts per night.

Figure 7. Histogram of the differences between automated and annotator cough-epoch counts per night.

Evaluation of Sex Classifier Performance

Using the data set that included 19 female and 19 male participants which had been selected for a balanced set of male and female coughs, both extracted cough and cough-epoch signals were analyzed. The partitioning resulted in 1532 female and 1527 male coughs for training and 500 female and 498 male coughs for testing. In the case of cough epochs, this partitioning led to 366 female and 351 male cough epochs for training, and 194 male and 134 female cough epochs for testing.

As shown in Table 2 and Figure 8, the performance of the classifier that was based on cough-epoch signals outperformed

the classifier based on cough signals. The difference was especially notable on true positive rate, accuracy, Matthews correlation coefficient, positive predictive values, negative predictive values, and the area under the curve of the receiver operating characteristic curve. Both classifiers showed better performance for true positive rate than for that of true negative rate, which indicated a superior capability to recognize female cough or cough-epoch signals whenever a female cough or cough-epoch signal presented itself, in comparison to the corresponding capability to recognize a male cough or cough-epoch signal.

Table 2. Gaussian mixture model results of sex recognition for coughs and cough epochs.

Model for	True positive rate, %	True negative rate, %	Accuracy, %	Matthews correlation coefficient, %	Positive predictive value, %	Negative predictive value, %
Cough	81.0	71.8	74.8	49.6	57.8	88.8
Cough epochs	95.0	74.9	83.2	69.1	72.8	95.5

Figure 8. Receiver operating characteristic curves with corresponding area-under-the-curve values for cough and cough epoch–based sex assignment. The dashed line represents the curve for a random classifier. AUC: area under the curve; ROC: receiver operating characteristic.

Discussion

Principal Findings

To the best knowledge of the authors, the data set in this paper is the largest, real-life cough data set with published recognition and segmentation results, not only for adults with asthma but across all respiratory conditions. Given the data set of continuous overnight recordings of 79 adults with asthma in different soundscapes (excluding dropouts), our results demonstrate that cough recognition from smartphone-based audio recordings is feasible. The ensemble classifier performed well with values greater than 90% across different metrics for the pure classification task and achieved comparable cough counts to that of human annotators in the segmentation of coughing from continuous overnight audio recordings. In specific cases (for example, the 6 nights with a difference in cough counts of 20 and above), a need for further development was demonstrated. We listened to the original recording of these cases and believe these failures were caused by strong background noise, peculiar chuckle and laughter sounds, and a specific type of music, among others. These sounds, however, strongly suggest that the participant was not asleep.

We also provided a first step towards distinguishing partner cough from patient cough by determining the source of cough signals classifying those that corresponded to sex of the patient as patient coughs. This can be applied to cough recordings from the bedrooms of opposite-sex couples, even when both are coughing. Our results further indicate that cough epoch–based sex classification has greater potential than that of cough-based sex classification. This may be explained by the fact that cough epochs are longer and may contain more periodic information, rather than the limited amount of periodic information contained in the short bursts of the explosive cough sound. Speech signals of a typical adult male contain a fundamental frequency from 85 to 180 Hz and those of a typical adult female from 165 to 255 Hz [58]. This discrepancy gives rise to sex classification

from speech with greater than 90% of accuracy [59]. Finally, we also investigated the automatic segmentation of cough epochs from continuous audio recordings which yielded results that were comparable to those of annotated cough epochs. These results and the fact that 86% of the coughs in our study originated from cough epochs provided a foundation for cough epoch–based sex classification. Our classifier determined the source of cough epochs based on sex with 83% of accuracy.

Comparison With Prior Work

Cough-monitoring systems that are capable of detecting reflex coughs in audio recordings have been proposed in previous work [24,25,30,60], and some of them have achieved sensitivity (true positive rate) and specificity (true negative rate) values greater than 90% [25,30,60]; however, these data sets contain coughs that have been recorded in various conditions and that have been applied in different contexts which makes a comparison with our work difficult. To our knowledge, no models or systems have been trained and evaluated on such an extensive asthmatic cough database; our data set contained 30,304 coughs. None of these systems underwent longitudinal evaluation (for more than one night). For instance, the Leicester Cough Monitor system was one of the few systems that was evaluated over a longer period of time; 6-hour and 24-hour cross-sectional recordings of patients with chronic cough [25]. Only a few approaches proposed modes of use that were comparable to our mode of use where the microphone was not attached to the patient [24,31,60]. Among those, only one involved a smartphone, where 1-hour recordings were collected for each participant in a laboratory setting [31,61]. None of these approaches addressed the problem of distinguishing the participant's cough from the coughs of other people in contact-free recordings.

Limitations

There were several limitations in our study regarding the generalization of our results. First, we only used data collected

by one specific model of smartphone. It has previously been demonstrated [32] that noisy or low-quality recordings from a different device can have a detrimental effect on the performance of the classifiers. Second, the data set may limit the generalizability of our sex-classification results. For the analysis, we included data from different male and female participants, who slept alone but were recorded in different rooms, in contrast to a real scenario of a couple, where both are sleeping and coughing in the same room. Due to the amount and length of the recordings, the annotation process was extremely laborious. As a consequence, the majority of the recordings were only annotated by one annotator. This gives rise to the possibility that certain coughs were missed or wrongly annotated.

Conclusions

Our study proposed a combined approach to combat the detrimental effect of learning from highly imbalanced data sets by combining techniques such as ensemble learning, balanced minibatch training, and decision thresholding. We showed that automated methods can recognize nocturnal coughs and cough epochs in smartphone-based audio recordings. The model addressed distinguishing subject coughs from those of a bed partner in contact-free recordings by classifying cough and cough-epoch signals to the corresponding sex of the participant. This research enables smartphone-based cough monitoring of individuals and of couples of different sexes in their bedrooms. It represents a step towards passive, scalable cough monitoring for people with asthma, and thus contributes to the development of a scalable diagnostic tool for early recognition of exacerbations.

Acknowledgments

MB, MAP, PT, FB, CS-S, FR, and TK contributed to the study design. FR and CS-S were responsible for the study execution. PT and FB provided the technological support of the study execution. FB developed the study app and embedded the content created by PT and TK. The data annotation process was designed by PT and FB, and evaluated by PT. Data preprocessing, analysis, and machine learning were conducted by FB. Writing and editing of the manuscript was done by FB. Critical review and revision of the manuscript were done by DK, MB, MAP, TK, PT, CS-S, FR, and EF. FR was the principal investigator of the clinical study. This study was funded by CSS Insurance, Switzerland. The CSS insurance supported the recruitment of participants but had no role in study design, app design, data management plans, or in reviewing and approving the manuscript for publication. DK's participation in this research was funded by Dartmouth College and by the US National Institute of Drug Abuse through the Center for Technology and Behavioral Health at Dartmouth College. Abstract

Background: As a critical driving power to promote health care, the health care–related artificial intelligence (AI) literature is growing rapidly.

Objective: The purpose of this analysis is to provide a dynamic and longitudinal bibliometric analysis of health care–related AI publications.

Methods: The Web of Science (Clarivate PLC) was searched to retrieve all existing and highly cited AI-related health care research papers published in English up to December 2019. Based on bibliometric indicators, a search strategy was developed to screen the title for eligibility, using the abstract and full text where needed. The growth rate of publications, characteristics of research activities, publication patterns, and research hotspot tendencies were computed using the HistCite software.

Results: The search identified 5235 hits, of which 1473 publications were included in the analyses. Publication output increased an average of 17.02% per year since 1995, but the growth rate of research papers significantly increased to 45.15% from 2014 to 2019. The major health problems studied in AI research are cancer, depression, Alzheimer disease, heart failure, and diabetes. Artificial neural networks, support vector machines, and convolutional neural networks have the highest impact on health care. Nucleosides, convolutional neural networks, and tumor markers have remained research hotspots through 2019.

Conclusions: This analysis provides a comprehensive overview of the AI-related research conducted in the field of health care, which helps researchers, policy makers, and practitioners better understand the development of health care–related AI research and possible practice implications. Future AI research should be dedicated to filling in the gaps between AI health care research and clinical applications.

KEYWORDS

health care; artificial intelligence; bibliometric analysis; telehealth; neural networks; machine learning

Introduction

From its birth in the 1950s to present, artificial intelligence (AI) and its application in modern health care have boomed with the advancement of science and technology [1-3]. As a critical driving power that promotes the coming and development of industry 4.0, AI has become an indispensable component of the

advancement and innovation of health care and medical diagnosis. Medical AI technologies provide algorithms and programs that analyze symbolic models of diseases and their relationships to patient signs and symptoms [4-6].

In the field of health care, the implementation of AI technologies fosters the prediction, diagnosis, and treatment of diseases, which benefits both patients and health care providers [7]. The

promise of improving diagnostic accuracy is one of AI's most exciting health care applications. AI can effectively assist health care providers in diagnosing symptoms at a faster rate than most medical professionals [8]. AI can mimic the predictive power of human doctors to improve the accuracy of diagnosis by horizontally and vertically assessing the electronic health records of patients in a short period of time [9]. A meta-analysis reported that the diagnostic sensitivity of AI was higher than that of dermoscopy (91% vs 88%) [10]. Additionally, AI can help patients keep track of complex symptoms, improve patients' quality of life, and increase medication adherence [11]. For example, a randomized clinical trial study indicated that an AI platform successfully increased medication adherence in stroke patients on anticoagulation therapy by 50% [12].

The widespread application of AI in health care advances the processing of related research. The body of relevant literature grows rapidly. As a result, health care-related AI studies are thriving in recent health care literature. Although health care-related AI research has gained popularity, only a few bibliometric analyses focus on AI applications in specific types of health problems, such as depression [13]. A bibliometric analysis of general health care-related AI studies can depict a map that helps researchers better understand the development of health care-related AI research and the direction of patterns and trends in the future. Keeping abreast of the fast-growing body of health care-related AI studies helps practitioners and policy makers to seize the opportunities of applying AI interventions to promote the well-being of patients and their caregivers.

Bibliometrics is a measurable informatic method that analyzes the emerging trends and the knowledge structure within a certain field to obtain quantifiable, reproducible, and objective data [11]. Bibliometric analysis provides researchers and related stakeholders the opportunity to gain an informative understanding of the field of study and promotes interdisciplinary collaboration [14]. This study aims to provide a holistic view of health care-related AI research and the directions of future work to benefit patients and health care providers. Through an extensive and global review of literature on AI in health care, the purpose of this analysis is to examine the AI research focused on promoting health care. This analysis is an indispensable resource for researchers to have as an overview of the AI field in health care, which will help them to develop health care-related AI studies. This analysis is also an essential resource for someone who is less familiar with this field but is interested in AI applications in health care.

Methods

Search Strategy

Based on bibliometric indicators, we developed a search strategy in an iterative manner, starting from search terms used in the literature already known to us. This bibliometric analysis provided critical insights into the current state of health care-related AI research up to September 2019. The Web of Science (WoS) (Clarivate PLC) Core Collection was used to

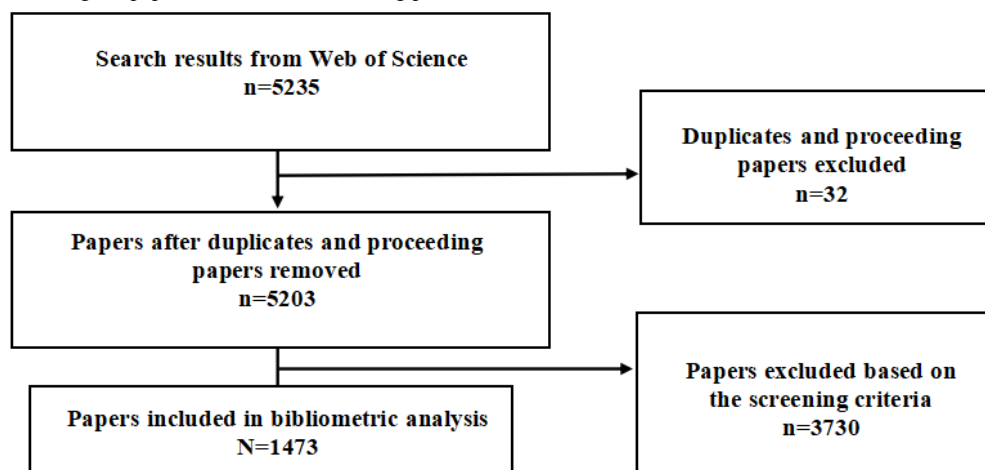

search all existing and highly cited AI publications. We opted for using the Science Citation Index (SCI) and the Social Science Citation (SSCI) databases in Web of Science, and then we conducted the temporal and spatial analysis, analysis of word co-occurrence, coauthorship analysis, and cocountry analysis.

Search keywords related to (1) AI technologies and (2) health care and medicine were identified from a preliminary literature review and consultation with a librarian. We entered the retrieval search string by combining keywords with Boolean operators: TI=((artificial intelligence) OR TI=("data learning") OR TI=("machine learning") OR TI=("expert systems") OR TI=("fuzzy logic") OR TI=("computer vision") OR TI=("automatic programming") OR TI=("speech understanding") OR TI=("autonomous robots") OR TI=("intelligent tutoring") OR TI=("intelligent agents") OR TI=("neural network") OR TI=("voice recognition") OR TI=("text mining") OR TI=("electronic health record")) AND (TS=(health) OR TS=(healthcare) OR TS=(medicine) OR TS=(mental health) OR TS=(behavior health)), Indexes=SCI-EXPANDED, SSCI Timespan=All years. The final search was conducted on September 09, 2019, in the WoS. A total of 5235 papers that were registered between January 1995 and September 2019 in the SCI Expanded and the SSCI Index databases from the Web of Science.

Screening Strategy

In this analysis, all journal papers about AI in health care were included for screening. The papers for analysis were restricted to those that (1) were written in the English language, (2) focused on promoting health or health care, and (3) involved AI technologies. As AI technology is a leading-edge and rapid update research area, papers published in peer-reviewed journals, conference proceedings, and early access articles were included. Book chapters and books were excluded from this bibliometric analysis.

The coauthors received training of bibliometric analysis screening by watching the video of Müller's study screening guide [15]. The screening procedure was conducted based on the screening guide [15]. Two coauthors (YG and ZH) conducted a pilot screening with the same set of 50 papers. During the pilot screening process, papers from the preliminary searches were categorized into include, exclude, or unsure. Papers marked as unsure were screened by 3 of the authors (YG, ZH, and FY) and discussed until consensus was reached in team meetings. The practical inclusion and exclusion criteria were determined. After that, 2 coauthors (ZH and YG) each received a unique set of papers for title and abstract screening. Different from a systematic review, a bibliometric analysis only requires screening of the abstract and full text when it is necessary. First, 32 inapplicable and duplicate papers were removed. According to the screening criteria, 3730 papers were excluded either because they did not focus on promoting health care or did not involve AI technologies. Finally, 1473 papers were included for bibliometric analysis (Figure 1).

Figure 1. Flowchart detailing the paper collection and screening process.

Bibliometric Analysis

Bibliometrics is the quantitative study of literature and a measurable method used to identify the developmental trends within a certain field to obtain quantifiable, reproducible, and objective data. In this analysis, we computed the growth rate of publications, characteristics of research activities (topics and keywords), publication patterns (countries and journals), and research hotspot tendencies (citation bursts and timeline map).

Growth Rate of Publications

The growth rate of publications over time was computed by raising the rate of the number of publications in 2019 over the number of publications in 1995 to the power of 1/24, as shown below. The publication trends of the number of publications each year were also reported.

Growth rate = $\left(\frac{\text{number of publications in the last year}}{\text{number of publications in the first year}} \right)^{\frac{1}{\text{last year} - \text{first year}}} - 1 \times 100$

Publication Patterns

Citation trends of the top 10 countries, top 10 journals, and top 10 research domains were analyzed for the publication patterns. Frequencies and percentages of publications in each journal and each country were computed based on the publication years. The countries were identified by the affiliations of the listed authors. This information was provided by WoS. The rank of research impact of each country and each journal was provided based on the citation rates.

Characteristics of Research Activities

The characteristics of research activities were analyzed according to the topics and the keywords of publications. Top

topics, including health problems, AI technology, function, and population, were identified and described by frequency, percentage, and citation rate of keywords listed by the authors. The centrality of a keyword was a combination of statistic equations that measure the representativeness of selected words for the text content according to betweenness, closeness, degree, eigenvector, PageRank (Google LLC), eccentricity, coreness, clustering coefficient, and term frequency scores [16]. The centralities of keywords were computed using HistCite. .

Research Hotspot Tendencies

Citation bursts and a timeline map were developed using the HistCite software. The cluster view was generated based on publications between 1995 and 2019, and each cluster was labeled by the keywords used by the paper. The time slice was set as 1 year and the threshold interpolation citations, cocitations, and cocitation coefficient were set as 4, 1, and 20, respectively. A minimum tree calculation formula was adopted to tailor the network.

Results

Growth Rate of Publications

Figure 2 plots the annual trends of publications about AI in health care. From 1995 to 2019, the average growth rate of scientific research papers on health care-related AI research was 17.02%. The growth rate from 1995 to 2010 was 6.33%, the growth rate from 2011 to 2014 was 23.02%, and the growth rate from 2015 to 2019 was 42.67%. The number of publications increased steeply between 2014 and 2019, accounting for 70.67% (1041/1473) of all included papers.

Figure 2. The distribution of the bibliographic records per year.

Publication Patterns

Overall, 95.59% (1408/1473) of the included papers were published from 10 countries, shown in Table 1. About 45.42% (669/1473) of the included studies were from the United States. China was the next leading country (183/1473, 12.42%), followed by England (113/1473, 7.67%). The papers were published in 715 different journals. As demonstrated in Table 2, *PLOS One* published the most papers (57/1473, 3.87%),

followed by *Artificial Intelligence in Medicine* (24/1473, 1.63%), and *Expert Systems with Applications* (1.63%, 24/1473). WoS subject categories were employed to indicate the research domains of included publications, as seen in Table 3. The research domains of computer science (252/1473, 17.11%), engineering (192/1473, 13.03%), and medical informatics (169/1473, 11.47%) are the top research domains of health care–related AI research.

Table 1. The distribution of the bibliographic records by top 10 (by quantity) countries.

Countries	Ranking based on total output	Output ^a , n (%)	Ranking based on citations	Citations ^b , n (%)
United States	1	669 (47.79)	1	10,794 (51.11)

Characteristics of Research Activities

Keywords are the core word extractions provided by researchers in the studies. Table 4 shows information about the frequency and centrality of keywords. The top 5 health problems are cancer, depression, Alzheimer disease, heart failure, and diabetes. The top 5 AI technologies are machine learning, artificial neural networks, deep learning neural networks, electronic health records, and support vector machines. The top 5 functions are case classification, diagnosis, prediction, risk estimate, and chronic condition management. The top 5

populations focused on in health care–related AI studies are children, adults, women, men, and elderly persons.

HistCite intelligently classified the research topic into 12 clusters, labeled from 0 to 11 in Figure 3. The modularity (Q) was 0.423, which was higher than 0.3, indicating that the cluster results were significant. Cluster 0 is the largest cluster (coronary artery disease) and cluster 11 is the smallest one (diabetes mellitus). Each cluster was generated based on the number of keywords under one research domain, not the frequency of keywords.

Table 4. The top keywords of artificial intelligence health care publications.

Category	Frequency (as identified by title, keywords, or manuscript)	Centrality
Health problem		
Cancer ^a	273	0.13
Depression	16	0.02
Alzheimer disease	7	0.00
Heart failure	5	0.00
Diabetes	3	0.00
Technology		
Machine learning	288	0.09
Artificial neural network	270	0.13
Deep learning neural network	95	0.01
Electronic health record	87	0.06
Support vector machine	62	0.03
Function		
Case classification	269	0.11
Diagnosis	165	0.14
Prediction	149	0.06
Risk estimate	116	0.10
Chronic condition management	71	0.02
Population		
Children	25	0.01
Adult	15	0.00
Women	11	0.00
Men	9	0.00
Elderly persons	7	0.00

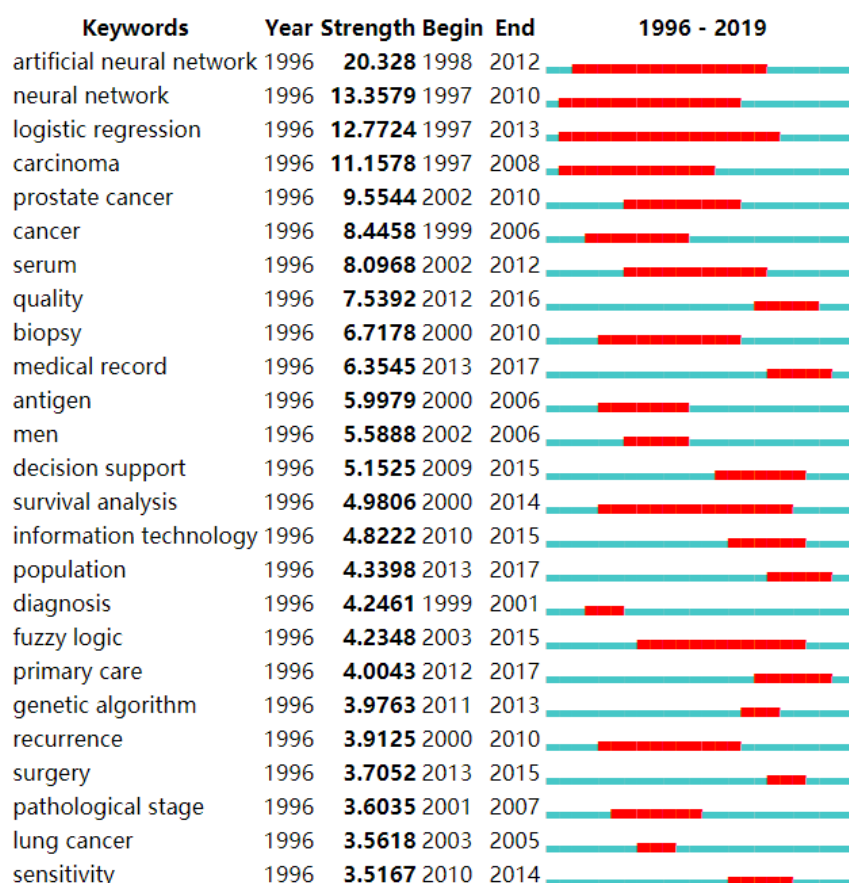

^aBreast: n=124; carcinoma: n=46; prostate: n=45; lung: n=44; other: n=14.

Figure 3. Cluster analysis of artificial intelligence health care publications.

Research Hotspot Tendencies

We presented the major milestones in the development of AI in health care by analyzing the list of keywords that had strong citation bursts between 1996 and 2019, as seen in [Figure 4](#). The first milestone keywords in the studies were neural network, logistic regression, and carcinoma. The next milestone was the artificial neural network (highly cited in 1998-2002). The most recent milestone was survival analysis, highly cited until 2014.

We also generated a timeline visualization to depict clusters along a horizontal axis, seen in [Multimedia Appendix 1](#). The clusters we analyzed in [Figure 3](#) were vertically listed in descending order of their sizes on the right of [Multimedia Appendix 1](#). Each cluster was analyzed on each horizontal timeline from left to right, with the year shown on top of the view. The colored curves represent cocitation links added in the year of the corresponding color. Large-sized nodes are of particular interest because they are either highly cited, have citation bursts, or both.

Figure 4. Top 15 keywords with the strongest citation bursts.

Discussion

By using bibliometric data, this study analyzed the health care–related AI research through examining the growth rate of publications, characteristics of research activities, publication patterns, and research hotspot tendencies.

Growth Rate of Publications

Since the first publication in 1995, health care–related AI research had a slow increase in the following 17 years. However, since 2012, the field has started to move forward at a fast pace. In the past 5 years, the growth rate of publication reached 45.1%, which is more than 4 times the publication growth rate from 1995 to 2014. The recent rapid growth is due to multiple reasons. The technological breakthroughs of AI in this time period contributed to the explosive growth of AI adoption in health care–related AI research [17]. From 2015 to 2018, the appearance of autonomous robots, voice recognition, neural networks, and machine learning provided unprecedented opportunities for the prediction, diagnosis, and treatment or management of diseases [18,19]. According to the exponential growth pattern of health care–related AI research, the publications in health care–related AI will continue to grow in the future. Applying the growth rate of the past 5 years to the next 5 years, we can estimate that the publication volume in health care–related AI research will double about every two years.

Publication Patterns

The field of AI health care has attracted people from all around the world, but the high-income countries are the main force in health care–related AI research. The United States itself contributed about half of the research in the field of health care–related AI research. Compared with the rapid advancement of health care–related AI research, this research field in non-high-income countries is still meager. This observation of the small outputs in middle-income and low-income countries causes concern because many low-income countries have limited health care resources, but their public health issues are nonetheless increasing dramatically due to rapid globalization and urbanization [20]. Some developed countries have launched federal AI health care policies incorporating guidance on the development and regulation of AI in health care, such as the UK Code of Conduct for Data-Driven Health and Care Technology [21]. Consequently, about 85% of the research outputs were generated in developed countries, but 80% of the world population lives in developing countries. Multiple barriers, including funding, prioritization, research capacity, infrastructure, and language contribute to these disproportionate results [22]. From a global perspective, AI technologies are promising in terms of promoting health outcomes in low-income countries with limited health care resources.

Based on the output and citation counts, health care–related AI research is generally favored by large-scale journals related to health care. However, the sizes of the research effect are

field-specific. The improvement and sophistication of the fields of computer science and engineering have paved the way for the development of AI. It is worth noting that the field of oncology received the second most citations. These results are consistent with the findings of the top keywords of included papers, implying that published AI papers on cancer care accumulated a high number of citations.

Characteristics of Research Activities

AI is redefining and disrupting the way health care is being carried out across diverse levels, based on the results of the characteristics of AI publications. According to the top keywords in the identified categories, the top domains of disease in AI research are cancer, coronary artery disease, chronic kidney disease, prostate cancer, and diabetes mellitus. The diseases of the leading causes of death received the major attention of AI research. By 2030, chronic diseases will contribute 80% of the human deaths globally and result in severe global burden of disease [23-25]. Specifically, the cancer mortality rate has steadily risen by 6% during the past 10 years [26]. Therefore, researchers direct their hopes and efforts on early detection and condition management by using advanced technology [27,28]. AI is making its way into cancer treatment from diagnostic classification to tumor behavior prediction [29,30]. Furthermore, cardiovascular diseases are also highly related to behaviors, especially among older adults [31,32]. AI can exert a proactive role in predicting risk factors for cardiovascular diseases related to older adults' behaviors in order to remarkably reduce the hospitalization rate, readmission rate, cost of care, and even mortality rate [33-35].

Extensive functions of AI have assisted modern health care by providing smart medical data analysis and developing accurate and efficient prediction for treatment [36]. Machine learning is the most commonly used AI technique in health care. Artificial neural networks are the next biggest research area related to health care. There are promising applications of these AI technologies to the development of interventions for other diseases in future research, such as mental health interventions, health education, and chronic disease management.

AI research is witnessing widespread adoption in the prediction, detection, diagnosis, classification, treatment, and survival prediction of diseases [30,37]. The most common application of AI technologies is reflected in the domains of medical classification and quality of care. AI is investing significantly in improving the quality of care in the health care system [38]. The potential of AI in reviewing medical images and analyzing large-scale data has led to significant improvement in the quality of care [39]. Additionally, AI-based risk prediction models can investigate the complex relationships between clinical data and disease treatment [40].

Regarding the research populations, researchers seem more interested in child populations. Due to the development of cognitive aids to support diagnosis, treatment, care coordination, surveillance and prevention, and health maintenance, improvement of AI in clinical pediatric health care is remarkable [41]. However, cancer and various chronic diseases are the main focus of the current health care-related AI publications. Considering that elderly populations are the primary sufferers

of chronic diseases, future studies may shift their angle to further explore AI implications on health in older adult populations.

Research Hotspot Tendencies

In the last three decades, the times and lengths of citation bursts of each health care-related AI research topic have varied. Certain keywords were extraordinary consistent for a long period of time, while some keywords only briefly surged in the field of AI health care. The period of 1997 to 2014 contained a concentrated outbreak of multiple health care-related AI study bursts (Figure 4). AI technology research involved more health care fields and produced more diverse keywords in recent years. It is possible that the more diverse keywords of health care-related AI research diluted the citation bursts.

According to the citation rates, artificial neural networks, support vector machines, and convolutional neural networks have the highest impact on health care. These techniques have been widely adopted by oncology research to predict disease and survival rates [42]. Historically, logistic analysis has been a widely used research method of health care-related AI. However, survival analysis has had a recent citation burst in this field.

The studies in these clusters focus on testing AI techniques and translating these techniques into practical settings [37,43]. The next step of health care-related AI research may transform from lab-based research to the development of clinically validated and safe regulated systems. The current health care-related AI research faces the challenges of deploying lab-based AI intervention into clinical practice [44]. These challenges include ethical issues brought up by AI application [45] and the quality and quantity of medical data and cases [46], which will decide the diagnosis and treatment ability of AI.

Health care-related AI research experienced several paradigm shifts during the past decades and continues to shift. As shown in the timeline overview (Multimedia Appendix 1), the sustainability of health care-related AI research clusters is influenced by the increasing availability of health care data and the rapid progression of AI techniques. The research of cancer, convolutional neural networks, and nucleosides sustained a hotspot over the past twenty years, whereas some clusters were relatively short-lived, such as chronic kidney disease, prostate cancer, and diabetes mellitus. Particularly, nucleosides, convolutional neural networks, and tumor markers have remained research hotspots through 2019. These research domains exert strong impacts on the field and these analysis results suggest that their influence will likely continue in the next few years.

Limitations

Limitations of our work need to be acknowledged. First, although we are confident that a single database—WoS—is a large enough database to offer a wide variety of publications vital for our analyses, future studies will apply other databases, such as Scopus, to explore more potential papers. Second, the search keywords (eg, mental health, behavioral health, and health care) related to health care were quite general, which may not be able to identify AI-related studies in all aspects of health care. For example, AI-related studies of HIV might have

been omitted. Third, some keywords, although they were ranked as top keywords, were uninformative by themselves (eg, risk, model, and system) and could not be analyzed. Fourth, we did not include gray literature (eg, books), and we did not include papers published in languages other than English. Therefore, we may have missed relevant studies conducted in different forms, languages, and countries. Future studies can broaden the search scope to explore more relevant research to enrich the literature.

Conclusions

We aimed to provide a bird's-eye view of the entirety of the health care-related AI research. This analysis provides a comprehensive overview of the AI-related research conducted in the field of health care. With multiple searching and screening rounds, 21 finalized search terms, and a 25-year timespan from 1995 to 2019, we are confident that we have identified inclusive health care-related AI studies.

This analysis also depicted research trends of AI-related health research: (1) the growth rate of health care-related AI publications has grown rapidly in the past decade and the rate showed a trend of continuous growth; (2) high-income countries are the main force of health care-related AI research; (3) most AI research was focused on chronic diseases, particularly on cancer; (4) machine learning and neural networks are the most commonly used AI techniques in classification, diagnosis, and prediction; and (5) the research domains of nucleosides, convolutional neural networks, and tumor markers are currently research hotspots of health care-related AI research. AI research on health care is accelerating rapidly, with potential applications being demonstrated across various domains of medicine. However, there are currently limited examples of such techniques being successfully deployed into clinical practice. Future AI research should be dedicated to filling the gap between health care-related AI research and clinical applications.

Abstract

Background: The global shortage of mental health workers has prompted the utilization of technological advancements, such as chatbots, to meet the needs of people with mental health conditions. Chatbots are systems that are able to converse and interact with human users using spoken, written, and visual language. While numerous studies have assessed the effectiveness and safety of using chatbots in mental health, no reviews have pooled the results of those studies.

Objective: This study aimed to assess the effectiveness and safety of using chatbots to improve mental health through summarizing and pooling the results of previous studies.

Methods: A systematic review was carried out to achieve this objective. The search sources were 7 bibliographic databases (eg, MEDLINE, EMBASE, PsycINFO), the search engine “Google Scholar,” and backward and forward reference list checking of the included studies and relevant reviews. Two reviewers independently selected the studies, extracted data from the included studies, and assessed the risk of bias. Data extracted from studies were synthesized using narrative and statistical methods, as appropriate.

Results: Of 1048 citations retrieved, we identified 12 studies examining the effect of using chatbots on 8 outcomes. Weak evidence demonstrated that chatbots were effective in improving depression, distress, stress, and acrophobia. In contrast, according to similar evidence, there was no statistically significant effect of using chatbots on subjective psychological wellbeing. Results were conflicting regarding the effect of chatbots on the severity of anxiety and positive and negative affect. Only two studies assessed the safety of chatbots and concluded that they are safe in mental health, as no adverse events or harms were reported.

Conclusions: Chatbots have the potential to improve mental health. However, the evidence in this review was not sufficient to definitely conclude this due to lack of evidence that their effect is clinically important, a lack of studies assessing each outcome, high risk of bias in those studies, and conflicting results for some outcomes. Further studies are required to draw solid conclusions about the effectiveness and safety of chatbots.

Introduction

Background

Mental illness is a growing public health concern worldwide [1]. One in 4 adults and 1 in 10 children are likely to be affected by mental health problems annually [2]. Mental illness has a significant impact on the lives of millions of people and a profound impact on the community and economy. Mental disorders impair quality of life and are considered one of the most common causes of disability [3]. Mental disorders are predicted to cost \$16 trillion globally between 2011 and 2030 due to lost labor and capital output [4].

There is a shortage of mental health human resources, poor funding, and mental health illiteracy globally [5,6]. This lack of resources is especially evident in low-income and middle-income countries where there are 0.1 psychiatrists per 1,000,000 people [7], compared to 90 psychiatrists per 1,000,000 people in high-income countries [8]. According to the World Health Organization, mental health services reach 15% and 45% of those in need in developing and developed countries, respectively [9]. This could be a major factor contributing to the increase in suicidal behavior in recent decades [10].

The demand for better mental health services has increased, and meeting these demands has become increasingly difficult and costly due to a lack of resources [4]. Therefore, new solutions are needed to compensate for the deficiency of resources and promote patient self-care [4]. Distance can impede the reach of traditional mental health services to populations in remote areas in both high-income and low-income countries. Technology-based treatment, such as mobile apps, can overcome most of these barriers and engage hard-to-reach populations [11]. A World Health Organization survey of 15,000 apps revealed that 29% focus on mental health diagnosis or support [10].

One technology that offers a partial solution to the lack of capacity within the global mental health workforce is mobile apps. They have the potential to improve the quality and accessibility of mental health [12]. Chatbots are one of the main mobile apps used for mental health [13]. Chatbots, also known as conversational agents, conversational bots, and chatterbots, are computer programs able to converse and interact with human users [5,14]. Chatbots use spoken, written, and visual languages [5,14]. The use of chatbots has grown tremendously over the last decade and has become pervasive in fields such as mental health [13]. It is expected that chatbots will make a positive contribution to addressing the shortfall of mental health care [15]. Chatbots can facilitate interactions with those who are reluctant to seek mental health advice due to stigmatization [5] and allow more conversational flexibility [16].

Research Problem and Aim

Adoption of new technology, especially those heavily related to artificial intelligence and machine learning, relies on first ascertaining the levels of safety and effectiveness [17]. There has been a steady rise in the number of studies assessing the effectiveness and safety of using chatbots for mental health [5]. There is a need to critically evaluate and statistically combine

findings to inform policy and practice. Previously conducted reviews [5,18,19] did not assess the effectiveness and safety of chatbots in mental health. Accordingly, the current systematic review aimed to assess the effectiveness and safety of using chatbots in mental health through summarizing and pooling the results of previous studies. The review question is “what is the effectiveness and safety of using chatbots for improving mental health?”

Methods

Overview

A systematic review of the literature was conducted to accomplish the objective. This review is reported in line with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses statement ([Multimedia Appendix 1](#)) [20]. The protocol for this systematic review is registered at PROSPERO (number CRD42019141219).

Search Strategy

Search Sources

The following bibliographic databases were searched in this review: MEDLINE, EMBASE, PsycINFO, IEEE Xplore, ACM Digital Library, Scopus, and Cochrane Central Register of Controlled Trials. The search engine “Google Scholar” was also searched. As Google Scholar retrieved a large number of studies ordered by their relevance to the search topic, we screened the first 100 hits (10 pages). The search started on the June 8, 2019 and finished on June 11, 2019. We carried out backward reference list checking, where reference lists of the included studies and reviews were screened for further studies of relevance to the review. In addition, we conducted forward reference list checking, where we used the “cited by” function available in Google Scholar to identify studies that cited the included studies.

Search Terms

Search terms in this review were related to population (eg, mental disorder, mood disorder, and anxiety disorder) and intervention (eg, conversational agent, chatbot, chatterbot, and virtual agent). The search terms were derived from previous reviews and informatics experts interested in mental health issues [13]. Further, search terms related to mental disorders were derived from the Medical Subject Headings index in MEDLINE. The search strings utilized for searching each bibliographic database are shown in [Multimedia Appendix 2](#).

Study Eligibility Criteria

The population of interest was individuals who use chatbots for their mental health, but not physicians or caregivers who use chatbots for their patients. Eligible interventions were chatbots operating as standalone software or via a web browser. Chatbots that were integrated into robotics, serious games, SMS, or telephone systems were excluded. The current review also excluded chatbots that relied on human-operator generated dialogue. There were no restrictions regarding the type of dialogue initiative (ie use, system, mixed) and input and output modality (ie spoken, visual, written). There were no limitations related to the comparator (eg, information, waiting list, usual

care). This review focused on any outcome related to effectiveness (eg, severity or frequency of any mental disorders and psychological wellbeing) or safety (eg, adverse events, deaths, admissions to psychiatric settings) of chatbots. Regarding the study design, we included only randomized controlled trials (RCTs) and quasiexperiments. The review included peer-reviewed articles, dissertations, conference proceedings, and reports. The review excluded reviews, conference abstracts, proposals, and editorials. Only studies written in English were included in the review. There were no restrictions regarding study setting, year of publication, and country of publication.

Study Selection

Two steps were followed for selecting studies. First, the titles and abstracts of all retrieved studies were screened independently by two reviewers (AA, MA). Second, the full texts of studies included from the first step were read independently by the same reviewers. Any disagreements between the reviewers were resolved by discussion or by consulting a third reviewer (MH). Cohen κ [21] was calculated to assess interrater agreement between reviewers, which was 0.85 and 0.89 in the first and second step of the selection process, respectively, indicating a very good level of agreement [22].

Data Extraction

Before extracting data, we developed a data extraction form and piloted it using three included studies to conduct a systematic and precise extraction of data (Multimedia Appendix 3). Two reviewers (AA, MA) independently extracted data from the included studies, and disagreements were resolved by discussion or by consulting the third reviewer (MH). Interrater agreement between the reviewers was very good (Cohen $\kappa=0.84$) [22].

Assessment of Risk of Bias

Two Cochrane tools were used to assess the risk of bias in the included studies. Risk of bias in RCTs was assessed using the Risk of Bias 2 (RoB 2) tool [23], and risk of bias in quasi-experiments was examined using the Risk Of Bias In Non-randomized Studies – of Interventions (ROBINS-I) tool [24]. The results of the risk of bias are presented as a graph showing the reviewers' judgments about each "risk of bias" domain. Further, they are presented as a figure showing the reviewers' judgments about each "risk of bias" domain for each included study. Two reviewers (AA, AR) independently assessed the risk of bias, and disagreements were resolved by discussion or by consulting the third reviewer (MH). Interrater agreement between the reviewers was good (Cohen $\kappa=0.75$) [22].

Data Synthesis

Data extracted from studies were synthesized using narrative and statistical methods. The statistical approach was used when there was more than one RCT for a certain outcome and the study reported enough data for the analysis. Where statistical findings were not available, a narrative approach was used to

synthesize the data. Findings of studies were grouped and synthesized according to the measured outcome.

Statistical analysis was carried out using Review Manager (RevMan 5.3). As all extracted data were continuous, the effect of each trial and the overall effect were measured using either the mean difference (MD) or the standardized mean difference (SMD). To be more precise, when the outcome was measured using the same method between studies, the MD was utilized. The SMD was used when, between studies, the outcome was assessed using different measurement tools. A random-effects model was used for combining results because there was clinical heterogeneity between studies in terms of population (eg, clinical versus nonclinical samples), intervention (eg, rule-based versus artificial intelligence chatbots), and comparator (eg, treatment as usual versus information).

When there was a statistically significant difference between groups, we assessed how this difference was clinically important. A minimal clinically important difference refers to the smallest change in a measured outcome that a patient would deem as worthy and significant and which mandates a change in a patient's treatment [25]. Boundaries of a minimal clinically important difference for each outcome were calculated as ± 0.5 times the SD of the control arms of the studies at baseline.

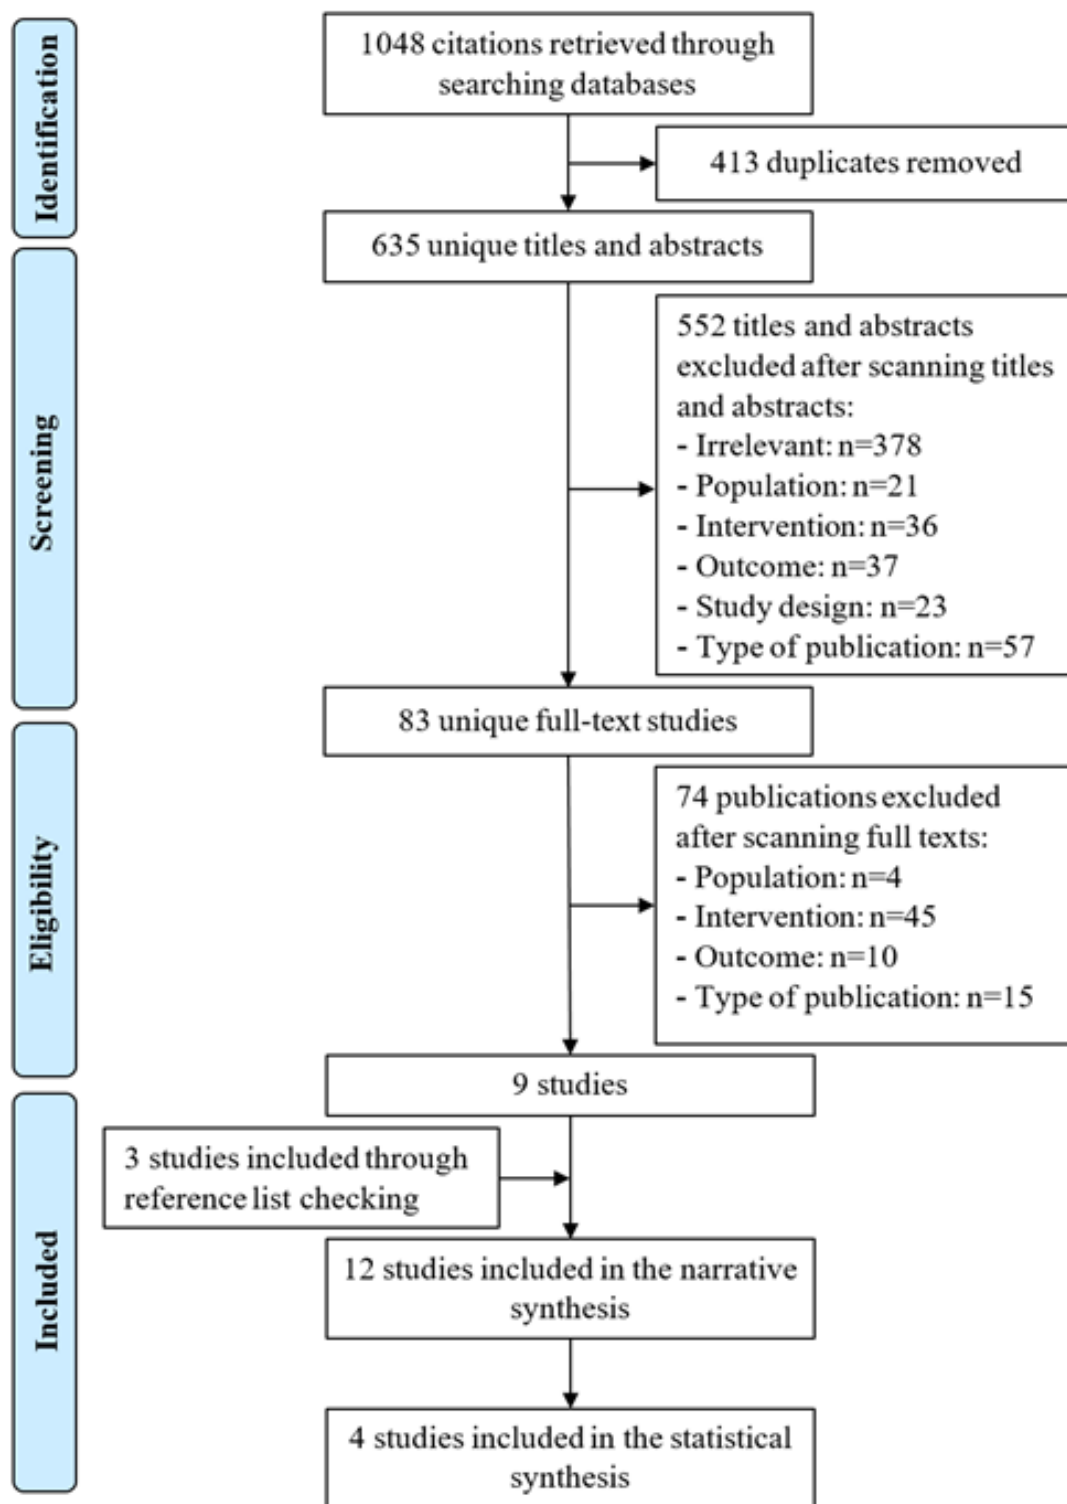

Clinical heterogeneity of the meta-analyzed trials was assessed by checking their participants, interventions, comparators, and measured outcomes. Statistical heterogeneity was assessed by calculating the statistical significance of heterogeneity (chi-square P value) and I^2 . A chi-square P value $>.05$ indicates that the studies are homogenous [26]. I^2 was used to quantify the heterogeneity of studies, where I^2 of 0%-40%, 30%-60%, 50%-90%, and 75%-100% represents unimportant, moderate, substantial, and considerable heterogeneity, respectively [26].

When the evidence was synthesized statistically, the overall quality of that evidence was assessed using the Grading of Recommendations Assessment, Development and Evaluation [17]. Two reviewers (AA & AR) assessed the quality of the evidence, and disagreements were resolved by discussion or by consulting the third reviewer (MH). There was considerable interrater agreement between the reviewers (Cohen $\kappa=0.86$) [22].

Results

Search Results

The search retrieved 1048 citations (Figure 1). After removing 413 duplicates, 635 unique titles and abstracts remained. By screening those titles and abstracts, 552 citations were excluded. Of the remaining 83 studies, 9 studies were included after reading the full text. Two additional studies were identified from forward reference list checking, and one study was identified by backward reference list checking. Overall, 12 studies were included in the narrative synthesis, but only 4 of those studies were meta-analyzed.

Figure 1. Flow chart of the study selection process.

Description of Included Studies

As shown in [Table 1](#), half of the studies (6/12) were RCTs, while the other half were quasiexperimental. Two-thirds of studies (8/12) were journal articles. Studies were conducted in more than 11 countries. Studies were published between 2015 and 2018. The majority of studies was published in 2018 (7/12). The sample size was <100 in 6 studies (6/12, 50%), and sample sizes ranged from 10 to 454 participants, with a median of 71.5

participants. The age of participants was reported in 10 studies; the mean age of participants in those studies was 31.3 years. The sex of participants was reported in 9 studies; the mean percentage of male participants in those studies was 35%. Half of the studies (6/12) recruited nonclinical samples. Participants were recruited from either community (6/12), educational (4/12), or clinical (3/12) settings. The characteristics of each included study are shown in [Multimedia Appendix 4](#).

^rNumbers do not add up as two studies assessed outcomes at 2 different points of time.

The included studies investigated the effect of 11 different chatbots. In most studies (10/12) chatbots were used for delivering therapy (Table 1). Chatbots were implemented using standalone software (6/12, 50%) and in web-based platforms (6/12, 50%). Chatbot responses were based on predefined rules or decision trees (rule-based) in two-thirds of studies (8/12). Chatbots in the remaining one-third of studies (4/12) utilized machine learning and natural language processing (artificial intelligence) to understand users' replies and generate responses. Chatbots led and controlled the conversation in 75% (9/12) of the studies. Users could interact with the chatbots using only written language via keyboards and mouse (9/12), only spoken language via microphones (2/12), or a combination of written and spoken languages (1/12). Chatbots used the following modalities to interact with users: only written language via text

on the screen (6/12); a combination of written, spoken (via speakers), and visual languages (via embodiment) (3/12); a combination of spoken and visual languages (2/12); and a combination of written and visual languages (1/12). In half of the studies, chatbots contained virtual representations (eg, avatar). Chatbots in 58% of the studies targeted depression (7/12). Multimedia Appendix 5 shows the characteristics of the intervention in each study.

There was no comparator in the 4 one-arm quasiexperiments; these quasiexperimental studies assessed outcomes before and after the intervention (Table 1). In 4 additional studies, an intervention was not provided to the control group. In 3 additional studies, chatbots were compared with providing information or education. In the remaining study, the comparison

was between high users (more engaged app users) and low users (less engaged app users). The most common outcome assessed by the included studies was severity of depression (6/12). The Patient Health Questionnaire (PHQ-9) was the most used outcome measure in the included studies (4/12). The follow-up periods were 2 weeks (6/12), 4 weeks (6/12), 6 weeks (1/12), and 12 weeks (1/12). Characteristics of the comparators and measured outcomes in each included study are presented in [Multimedia Appendix 6](#).

Risk of Bias in the Included Studies

Most of the RCTs (5/6) used an appropriate random allocation sequence, concealed that allocation sequence, and had comparable groups. These studies were rated as having a low risk of bias in the randomization process ([Figure 2](#)). Although participants, carers, and people delivering the interventions were aware of the assigned intervention during the trial in most studies (this may be normal due to the nature of the intervention), there were no deviations from the intended intervention because of the experimental context in all studies. Given the lack of deviation and using an appropriate analysis to estimate the effect of assignment to the intervention, a risk of bias due to deviations from the intended interventions was considered low for all studies ([Figure 2](#)). The domain of missing outcome data was judged as having a low risk of bias in 4 studies while it was rated as having a high risk of bias in the remaining 2 studies due to a high attrition rate, lack of analysis methods used to correct for bias, and presence of differences between intervention groups in the proportions of missing outcome data.

Although the methods of measuring the outcomes were appropriate and they were comparable between intervention groups (in terms of tools, thresholds, and timing), the risk of bias in the measurement of the outcome was high in 5 studies ([Figure 2](#)). This is attributed to the fact that assessors of the outcome were aware of the intervention received by study participants and this knowledge could affect the outcome assessment in those 5 studies. Five studies were judged to raise some concerns in the selection of the reported result ([Figure 2](#)). This judgment was due to a discrepancy between studies and their protocols in planned outcome measurements and analyses, unavailability of their protocols, or insufficient details in their protocols regarding outcome measurements and analyses. The overall risk of bias was rated as high for all studies because 5

studies were assessed as high risk in at least one domain, while the remaining study had some concerns in two domains. [Multimedia Appendix 7](#) shows the reviewers' judgments about each "risk of bias" domain for each included RCT.

There was moderate risk of bias due to confounding in all quasiexperimental studies ([Figure 3](#)). This judgment was based on a potential for confounding of the effect of intervention in all studies, and it was not clear whether authors in all studies used an appropriate analysis method to control for all confounding domains. The selection of participants was not based on participant characteristics observed after the start of the intervention in 5 studies, and the start of follow-up and start of intervention coincided for most participants in all studies. Accordingly, the "risk of bias due to selection of participant" domain was judged as low in the 5 studies ([Figure 3](#)). Although all studies clearly defined the intervention groups at the start of the intervention, it was not clear whether classification of intervention status could be affected by knowledge of the outcome in 3 studies. Therefore, the risk of bias in the classification of the interventions was rated as high in those 3 studies. Further, the risk of bias in this domain was judged as serious in one study, as the classification of the intervention status could be affected by knowledge of the outcome in that study.

Given that there were no deviations from the intended intervention beyond what would be expected in usual practice in all studies, the risk of bias from the deviations from the intended interventions was considered low in all studies ([Figure 3](#)). The risk of bias due to missing outcome data was judged as low in 3 studies while it was rated as moderate in the remaining 3 studies due to availability of less than 95% of the participants' data. The risk of bias in the measurement of the outcomes was serious in all studies ([Figure 3](#)); assessors of the outcome were aware of the intervention received by study participants, and this could affect the assessment of outcomes. In 5 studies, there was moderate risk of bias in the selection of the reported results ([Figure 3](#)); this is because there were insufficient details about the analyses used in the study. While the overall risk of bias was rated as critical in 1 study, it was judged as moderate and serious in 3 and 2 studies, respectively. [Multimedia Appendix 8](#) shows the reviewers' judgments about each "risk of bias" domain for each included quasiexperiment.

Figure 2. Risk of bias graph for randomized controlled trials, showing the review authors' judgments about each risk of bias item.**Figure 3.** Risk of bias graph for quasiexperiments, showing the review authors' judgments about each risk of bias item.

Results of Studies

Depression

Half of the included studies (6/12) examined the effect of using chatbots on the severity of depression [27-32]. Of these 6 studies, 4 studies were RCTs [27-30], and the remaining 2 studies were pretest-posttest quasiexperiments [31,32]. Four

studies were conducted in the United States [28-30,32], and each of the 2 remaining studies was conducted in multiple countries [27,31]. The severity of depression was measured using PHQ-9 [28,29,31,32], Beck Depression Inventory II [27], and Hospital Anxiety and Depression Scale [30].

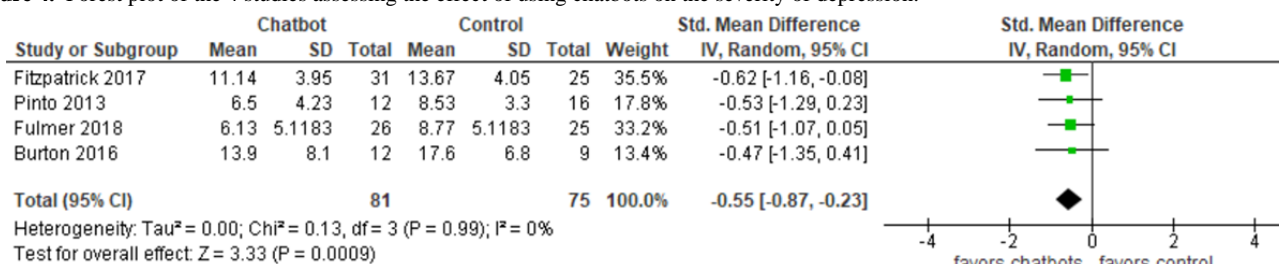

We meta-analyzed the results of only 4 RCTs. However, the results of the 2 quasiexperiments were synthesized narratively

because such a study design has a greater risk of bias than RCTs, and some data required for the meta-analysis was missing from 1 of the 2 studies. The meta-analysis showed a statistically significant difference ($P<.001$) favoring chatbots over treatment as usual or information on the severity of depression (SMD -0.55 , 95% CI -0.87 to -0.23 ; Figure 4). However, this difference was not clinically important, as the total effect (-0.55) was within the boundaries of a minimal clinically important difference (-4.7 to 4.7); the boundaries of a minimal clinically important difference for this outcome was calculated as ± 0.5 times the median SD of the control arms of the studies at baseline. The heterogeneity of the evidence was not a concern

($P=.99$; $I^2=0\%$). The quality of the evidence was low because it was downgraded by 2 levels for a high risk of bias (Multimedia Appendix 9).

Of the 2 quasiexperiments that measured depression, 1 study concluded that the severity of depression decreased significantly postintervention in the high user ($P<.001$) and low user ($P=.01$) groups [31]. Further, the improvement in depression was significantly higher in the high user group than in the low user group ($P=.03$). The second study found a statistically significant decrease in the severity of depression after the intervention (mean 9.78) compared to before the intervention (mean 13.03) [32].

Figure 4. Forest plot of the 4 studies assessing the effect of using chatbots on the severity of depression.

Anxiety

Of the 12 studies, 3 studies assessed the influence of using chatbots on the severity of anxiety [28,29,32]. All studies were conducted in the United States. The severity of anxiety was measured using the Generalized Anxiety Disorder scale [28,29] and Overall Anxiety Severity and Impairment Scale [32]. While 2 studies were RCTs [28,29], the third study was a pretest-posttest quasiexperiment [32]. In contrast to the 2 RCTs, the quasiexperiment was a one-arm trial [32]. For this reason, only the findings of the 2 RCTs were meta-analyzed.

As shown in Figure 5, no statistically significant difference ($P=.55$) in the severity of anxiety was found between those allocated to receive the chatbot intervention compared to those receiving information only (MD -1.38 , 95% CI -5.5 to 2.74). There was substantial heterogeneity ($P=.02$; $I^2=80\%$). The quality of the evidence was very low because it was downgraded by 3 levels due to a high risk of bias and heterogeneity (Multimedia Appendix 9). The third study concluded that there was a statistically significant decrease in anxiety level among participants after using chatbots (mean 10.45 versus 7.89) [32].

Figure 5. Forest plot of the 2 studies assessing the effect of using chatbots on the severity of anxiety.

Positive and Negative Affect

The effect of using chatbots on positive and negative affect, which is an indicator of depression and anxiety, was examined in 2 studies [28,29]. Both studies were RCTs conducted in the United States [28,29]. The outcome in the 3 studies was measured using the Positive and Negative Affect Schedule. Meta-analysis could not be executed as only 1 study reported enough data for the analysis [28].

The first study found no statistically significant difference between chatbot use and information on positive affect ($P=.71$) and negative affect ($P=.91$) [28]. In contrast, Fulmer et al [29] found a statistically significant difference favoring chatbot use over information on positive and negative affect at the 2-week follow-up ($P=.03$).

Subjective Psychological Wellbeing

The effect of using chatbots on subjective psychological wellbeing was examined by 3 studies [33-35]. Those studies were conducted in Sweden, Turkey, and Japan, respectively [33-35]. Of the 3 studies, 2 studies were quasiexperiments [34,35], and the remaining study was an RCT [33]. The Flourishing Scale was used to measure subjective psychological wellbeing in 2 studies [33,34], whereas the WHO-5 Well-Being Index was used by the third study [35]. Given that the high risk associated with quasiexperiments and availability of only one RCT, the results of the 3 studies were synthesized narratively.

In the first study [33], the intention-to-treat analysis showed that subjective psychological wellbeing was not statistically different ($P=.97$) after treatment between the chatbot (mean

45.14) and waiting list (mean 45.07) groups. Further, when analyzing data from only the participants who adhered to the intervention, there was no statistically significant difference ($P=.72$) between the chatbot and waiting list groups on subjective psychological wellbeing after treatment (mean 45.07 versus 45.85) [33]. The second study demonstrated a slight improvement in subjective psychological wellbeing after using chatbots, but this improvement was not statistically significant ($P=.06$) [34]. Similarly, the third study found no statistically significant difference ($P=.32$) between the chatbot and control groups on subjective psychological wellbeing after treatment [35].

Psychological Distress

The influence of using chatbots on psychological distress was examined by 2 studies, conducted in Japan and Australia [35,36]. Distress was measured using the Kessler Psychological Distress Scale. While 1 study was a one-group quasiexperiment [36], the other study was a two-group quasiexperiment [35]. Therefore, a narrative approach was used to analyze their results.

According to Suganuma et al [35], there was a statistically significant difference ($P=.005$) favoring chatbot use (mean 21.65) over no intervention (mean 23.97) on distress levels after treatment. Further, there was a statistically significant improvement in distress level among the chatbot group after treatment (mean 21.65) compared with before treatment (mean 23.58). Likewise, the other study found a statistically significant decrease ($P<.001$) in distress from a pre-intervention score of 33.27 to a post-intervention score of 28.90 [36].

Stress

Stress was an outcome in 2 studies [33,37]. The first was an RCT conducted in Sweden [33], and the second was a quasiexperimental study conducted in China [37]. The Perceived Stress Scale was utilized to measure stress in both studies. A meta-analysis was not carried out for this outcome as 1 study [37] did not report data required for the analysis.

Ly and colleagues [33] found a statistically significant difference favoring chatbots over the waiting list on stress when they analyzed data from all participants ($P=.03$) and from those who only adhered to the intervention ($P=.01$). Huang et al [37] concluded that stress status improved over time when using a chatbot.

Acrophobia

The effect of using chatbots on acrophobia (ie, fear of height) was examined by 1 RCT conducted in the United Kingdom [38]. The outcome was measured using two tools: Heights Interpretation Questionnaire and Acrophobia Questionnaire. Compared with participants who received usual care, the chatbot significantly decreased the severity of acrophobia as measured by both tools at 2-week and 4-week follow-ups ($P<.001$) [38].

Safety

Safety of chatbots was assessed in 2 RCTs [30,38]. While 1 study was conducted in the United States [30], the other study was conducted in the United Kingdom [38]. The former study concluded that the chatbot was safe because users did not report any harm, distress, adverse events, or worsening of depressive

symptoms resulting from using the chatbot during the study [30]. Similarly, Freeman et al [38] concluded that the chatbot was safe because no serious adverse events (eg, suicide attempts, death, serious violent incidents) or discomfort caused by the chatbot were reported.

Discussion

Principal Findings

This study systematically reviewed the evidence regarding the effectiveness and safety of using chatbots to improve mental health. We identified 12 studies examining the effect of using chatbots on 8 outcomes. For the first outcome (depression), low-quality evidence from 4 RCTs showed a statistically significant difference favoring chatbots over treatment as usual or information on the severity of depression, but this difference was not clinically important. Two quasiexperiments concluded that the level of depression decreased after using chatbots. As evidence from the 2 studies was synthesized narratively, we could not identify whether this decrease in depression was clinically important. Findings in the 2 studies may be affected by serious bias in the measurement of outcomes. Given that no reviews assessed the effectiveness of chatbots in mental health, the results were compared with other reviews regarding similar interventions (ie, internet-based psychotherapeutic interventions). The overall effect on depression in this review (-0.55) was comparable to other reviews. Specifically, while the overall effect of internet-based and computerized psychological interventions of depression without therapist support was 0.25 (95% CI 0.14-0.35) in a meta-analysis conducted by Andersson and Cuijpers [39], another meta-analysis showed that the total effect of internet-based psychotherapeutic interventions of depression was 0.32 [40].

With regards to anxiety, very low-quality evidence from 2 RCTs showed no statistically significant difference between chatbots and information on the severity of anxiety. In contrast, one quasiexperiment concluded that anxiety levels considerably decreased after using chatbots. These contradictory findings may be attributed to 2 reasons. First, pretest-posttest quasiexperiments are not as reliable as RCTs for finding the effect of an intervention due to low internal validity resulting from selection bias [35,41]. Second, in contrast to the 2 RCTs, the chatbot in the quasiexperiment [32] contained a virtual representation (ie, embodiment), which enables chatbots to communicate with users verbally and nonverbally (through body movements and facial expressions). It is purported that embodiment makes conversations with chatbots more empathetic and facilitates effective rapport with users [19,42,43]. Results of the meta-analyses in this review and another review related to smartphone mental health interventions were contradictory. A meta-analysis of 9 RCTs showed a considerable reduction in the anxiety level after using smartphone mental health interventions compared to no intervention (SMD 0.325, 95% CI 0.17-0.48) [44]. These conflicting results may result from either differences in interventions (chatbots versus different mobile interventions) in both reviews or the number of meta-analyzed studies (2 versus 9).

Findings regarding the effect of chatbots on positive and negative affect were conflicting. While one study concluded that chatbots improved the positive and negative affect at the 2-week follow-up [29], another study did not find any significant influence of chatbots at the 2-week follow-up [28]. Although the 2 studies were very homogenous in terms of study design, sample characteristics, comparator characteristics, and outcome measures, they were different in the type of chatbots and data analysis, and these differences may have led to contradictory findings. Specifically, the chatbot in the first study [29] was more advanced than the one in the second study [28]; it depended on artificial intelligence and machine learning to generate responses to users, and this makes it more humanlike and lets users feel more socially connected [5]. With regards to the second difference, while the first study assessed the effect of the chatbot on positive and negative affect together [29], the other study examined the effect of the chatbot on positive affect and negative affect separately [28].

A narrative synthesis of 3 studies showed no statistically significant difference between chatbots and control group on subjective psychological wellbeing. The justification for the nonsignificant difference is the use of a nonclinical sample in the 3 studies. In other words, as participants already had good psychological wellbeing, the effect of using chatbots may be less likely to be significant.

According to the 2 studies synthesized in a narrative approach, chatbots significantly decreased the levels of distress. Both studies had a high risk of bias; therefore, this finding should be interpreted with caution. Studies in a similar context reported findings comparable to our findings. To be more precise, an RCT concluded that online chat counselling significantly improved psychological distress over time [45].

In this review, chatbots significantly decreased stress levels over time. Unfortunately, we cannot draw a definitive conclusion regarding the effect of chatbots due to the high risk of bias in the evidence.

Chatbots were effective in decreasing the severity of acrophobia according to one RCT. The effect size of chatbots on acrophobia in this RCT [38] was substantially higher than the total effect size of therapist-assisted exposure treatment on phobias reported by a meta-analysis (2.0 versus 1.1) [46]. This indicates that chatbots may be equivalent to, if not better, exposure treatment delivered by a therapist in treating phobias.

Of the 2 RCTs measuring the safety of chatbots, both concluded that chatbots are safe for use in mental health, as no adverse events or harm were reported when chatbots were used to treat users with depression and acrophobia. However, this evidence is not sufficient to conclude that chatbots are safe, given the high risk of bias in the 2 studies.

Strengths and Limitations

Strengths

This study is the first review of the literature that assessed the effectiveness and safety of chatbots in mental health. The findings are of importance for users, providers, policymakers, and researchers. This review was developed, executed, and

reported according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses statement [20]. Accordingly, this enabled us to produce a high-quality review.

In this review, the most popular databases in health and information technology were used to run the most sensitive search possible. The review minimized the risk of publication bias as much as possible through searching Google Scholar and conducting backward and forward reference list checking to identify grey literature. The search was not restricted to a certain type of chatbots, comparators, outcomes, year of publication, nor country of publication, and this makes the review more comprehensive.

To reduce selection bias, two reviewers independently selected studies, extracted data, and assessed the risk of bias in the included studies and quality of the evidence. Agreement between reviewers was very good, except for the assessment of the risk of bias (which was good). When possible, findings of the included studies were meta-analyzed; thereby, we were able to increase the power of the studies and improve the estimates of the likely size of effect of chatbots on a variety of mental health outcomes.

Limitations

The intervention of interest in this review was restricted to chatbots that work within standalone software or via a web browser (but not robotics, serious games, SMS, nor telephones). Further, we excluded studies that contained chatbots controlled by human operators. Accordingly, this review cannot comment on the effectiveness of chatbots that involve human-generated content or those that use alternative modes of delivery. It was necessary to apply those restrictions because these features are not part of ordinary chatbots. For this reason, 3 previous reviews about chatbots applied these restrictions [5,13,19].

Owing to practical constraints, the search was restricted to English studies. Therefore, it is likely that we missed some non-English studies. The overall risk of bias was high in most of the included studies. The quality of evidence in the meta-analyses ranged from very low to low. Accordingly, the high risk of bias and low quality of evidence may reduce the validity of the findings and their generalizability.

Ideally, the difference between pre-intervention and post-intervention data for each group should be used in a meta-analysis [47]. However, we used only post-intervention data in each group for the meta-analysis because studies did not report enough data (eg, change in SD or SE of the mean between the pre-intervention and post-intervention for each group). In this review, it was possible to meta-analyze pre-intervention and post-intervention data from one-group trials (ie, did not include comparison groups). However, such analysis was not carried out in this review as such trials are very vulnerable to several threats of internal validity, such as maturation threat, instrumentation threat, regression threat, and history threat [41,48].

Practical and Research Implications

Practical Implications

Although this review found that chatbots may improve depression, distress, stress, and acrophobia, definitive conclusions regarding those results could not be drawn due to the high risk of bias in the included studies, low quality of evidence, lack of studies assessing each outcome, small sample size in the included studies, and contradictions in results of some included studies. For this reason, results should be viewed with caution by users, health care providers, caregivers, policymakers, and chatbot developers.

Given the weak and conflicting evidence found in this review, users should not use chatbots as a replacement for mental health professionals. Instead, health professionals should consider offering chatbots as an adjunct to already available interventions to encourage individuals to seek medical advice where appropriate and as a signpost to available support and treatment.

Most chatbots in this review were implemented in developed countries. People in developing countries may be more in need of chatbots than those in developed countries given that developing countries have a greater shortage of mental health professionals than developed countries (0.1 per 1,000,000 people vs 9 per 100,000 people) [7,8]. System developers should consider implementing more chatbots in developing countries.

Two-thirds of the chatbots in this review used predefined rules and decision trees to generate their responses, while the remaining chatbots used artificial intelligence. In contrast to rule-based chatbots, artificial intelligence chatbots can generate responses to complicated queries and enable users to control the conversation [13]. Artificial intelligence chatbots can exhibit more empathetic behaviors and humanlike filler language than rule-based chatbots [19]. This may make artificial intelligence chatbots more effective in building rapport with users, thereby improving their mental health [42]. It could be argued that artificial intelligence chatbots are more prone to errors than rule-based chatbots, but these errors can be minimized and diminished by extensive training and greater use [49]. Accordingly, we recommend developers concentrate efforts around artificial intelligence chatbots to improve the effectiveness.

Research Implications

This review showed that there is a lack of evidence assessing the effectiveness and safety of chatbots. Accordingly, we encourage researchers to conduct more studies in this area. Further, they should undertake more studies in developing countries and recruit large, clinical samples given the lack of such evidence, as found in the current review.

The overall risk of bias was high in most included studies mainly due to issues in the measurement of the outcomes, selection of the reported result, and confounding. Future studies should follow recommended guidelines or tools (eg, RoB 2 and ROBINS-I) when conducting and reporting their studies in order to avoid such biases.

Due to poor reporting practices, we were unable to include many studies in the meta-analysis. As well as encouraging more

high-level studies (ie, RCTs), there is a need for authors to be more consistent in their reporting of trial outcomes. For example, in our review, many studies failed to report basic descriptive statistics such as mean, SD, and sample size. Ensuring studies adhere to accepted guidelines for reporting RCTs (eg, CONSORT-EHEALTH [50]) would be of considerable benefit to the field.

In the current review, the comparators in all two-group trials were either no intervention or education. For those outcomes that hold promise (eg, depression, distress, and acrophobia), we encourage researchers to compare chatbots with other active interventions such as asynchronous electronic interventions or other types of chatbots (eg, rule-based chatbots versus artificial intelligence chatbots or embodied chatbots versus non-embodied chatbots).

According to a scoping review conducted by Abd-alrazaq et al [13], chatbots are used for many mental disorders, such as autism, post-traumatic stress disorder, substance use disorders, schizophrenia, and dementia. The current review did not find any study assessing the effectiveness or safety of chatbots used for these disorders. This highlights a pressing need to examine the effectiveness and safety of chatbots targeting patients with autism, post-traumatic stress disorder, substance use disorders, schizophrenia, and dementia.

As this review focused on the effectiveness and safety of chatbots, we excluded many studies that assessed the usability and acceptance of chatbots in mental health. Given that usability and acceptance of technology are considered important factors for their successful implementation, the evidence regarding those outcomes should be summarized through systematic reviews.

The current review identified heterogeneity in the tools used to measure the same outcomes and in the research design. For instance, severity of depression was measured using PHQ-9, Beck Depression Inventory II, or Hospital Anxiety and Depression Scale. Further, while some studies assessed outcomes before and after interventions, other studies examined them only after interventions. The field would benefit from future studies using a common set of outcome measures to ease comparison and interpretation of results between studies. Only one study assessed the long-term effectiveness and safety of chatbots, where participants were followed for 12 weeks. The effectiveness and safety outcomes of chatbots may be different when considering long-term, relative to short-term, findings; it is essential to assess long-term outcomes.

Conclusion

Although the included studies showed that chatbots may be safe and improve depression, distress, stress, and acrophobia, definitive conclusions regarding the effectiveness and safety of chatbots could not be drawn in this review for several reasons. First, the statistically significant difference between chatbots and other interventions on the severity of depression was not clinically important. Second, the risk of bias was high in most included studies, and the quality of the meta-analyzed evidence ranged from very low to low. Third, the evidence for each outcome came from only a few studies that also had small

sample sizes. Fourth, studies showed conflicting results for some outcomes (ie, anxiety and positive and negative affect). Researchers should avoid shortcomings in the study designs reported in this review. Health care providers should consider offering chatbots as an adjunct to already available interventions.

Abstract

Background: Acceptance and commitment therapy (ACT) is a pragmatic approach to help individuals decrease avoidable pain.

Objective: This study aims to evaluate the effects of ACT delivered via an automated mobile messaging robot on postoperative opioid use and patient-reported outcomes (PROs) in patients with orthopedic trauma who underwent operative intervention for their injuries.

Methods: Adult patients presenting to a level 1 trauma center who underwent operative fixation of a traumatic upper or lower extremity fracture and who used mobile phone text messaging were eligible for the study. Patients were randomized in a 1:1 ratio to either the intervention group, who received twice-daily mobile phone messages communicating an ACT-based intervention for the first 2 weeks after surgery, or the control group, who received no messages. Baseline PROs were completed. Two weeks after the operative intervention, follow-up was performed in the form of an opioid medication pill count and postoperative administration of PROs. The mean number of opioid tablets used by patients was calculated and compared between groups. The mean PRO scores were also compared between the groups.

Results: A total of 82 subjects were enrolled in the study. Of the 82 participants, 76 (38 ACT and 38 controls) completed the study. No differences between groups in demographic factors were identified. The intervention group used an average of 26.1 (SD 21.4) opioid tablets, whereas the control group used 41.1 (SD 22.0) tablets, resulting in 36.5% ([41.1-26.1]/41.1) less tablets used by subjects receiving the mobile phone-based ACT intervention ($P=.004$). The intervention group subjects reported a lower postoperative Patient-Reported Outcome Measure Information System Pain Intensity score (mean 45.9, SD 7.2) than control group subjects (mean 49.7, SD 8.8; $P=.04$).

Conclusions: In this study, the delivery of an ACT-based intervention via an automated mobile messaging robot in the acute postoperative period decreased opioid use in selected patients with orthopedic trauma. Participants receiving the ACT-based intervention also reported lower pain intensity after 2 weeks, although this may not represent a clinically important difference.

Introduction

Opioid Medication Issues

Public health concerns regarding opioid medications persist, and health care systems are currently seeking solutions to the ongoing epidemic [1]. In 2017, the rate of drug overdose deaths involving opioids in the United States increased by 12%, totaling 47,600 cases, and prescription opioid medications accounted for over 17,000 of these [2]. Even small amounts of additional daily opioid utilization (10 morphine milliequivalents [MME]) by patients can lead to an increased risk of long-term misuse [3]. In addition, every week of continued opioid utilization represents an increased risk of eventual misuse by patients [3]. Previous studies have found that orthopedic trauma patients use a decreasing amount of opioid medication in the first 2 postoperative weeks, with 6-15 days being the optimal opioid use period [4,5]. In line with these findings, previous studies have used a 2-week postoperative period to assess opioid medication consumption in surgical patients [4].

Patient-Reported Outcomes

Patient-reported outcomes (PROs) allow patients to quantify aspects of their orthopedic condition in a standardized fashion [6,7]. These are important tools for determining the efficacy of health care treatments and assessment of clinical research and can be used in determining compensation for health care services provided [6-8]. The National Institutes of Health developed the Patient-Reported Outcome Measure Information System (PROMIS) tools to advance PROs by creating question banks that could be used for many major health issues [9]. The

PROMIS Pain Intensity 1A Short form, PROMIS Pain Intensity 3A Short form, PROMIS Pain Interference 8A Short form, and PROMIS Emotional Distress-Anxiety 8A Short form all employ a fixed low number of questions that are highly reliable when compared with their respective domain's full item bank, making them excellent tools for both patients and clinicians [9,10].

Acceptance and Commitment Therapy

Acceptance and commitment therapy (ACT) is a cognitive contextual behavioral therapy that employs a pragmatic approach to help individuals decrease pain and live according to self-identified personal values [11,12]. The goal of ACT is to augment an individual's psychological flexibility, thus improving their life according to 6 core cognitive processes: acceptance, defusion, contact with the present moment, self-as-context, values, and committed action (Table 1) [11]. Employing these cognitive processes to increase psychological flexibility allows people to choose their actions based on what they value most, resulting in decreased avoidance behaviors and negative cognitive associations [11]. ACT has proven to be effective across multiple studies and patient populations in the treatment of pain [13]. Several studies report a high value for ACT in the management of chronic pain when compared with standard pharmacological treatment alone [13-16]. Moreover, earlier cessation of pain and opioid utilization in at-risk orthopedic surgery patients receiving office-based ACT interventions has also been reported [17]. However, traditional ACT interventions require a clinic-based, interdisciplinary team approach, which is not always feasible for both patients and health care systems [17,18].

Table 1. Acceptance and commitment therapy core principles with associated messages.

Core principle	Example mobile phone message
Values: know what matters most	Stop for a moment and remember the 3 values you identified earlier today. Remind yourself how important these values are in your life. As your day comes to an end, remember that YOU are in control of the thoughts that exist in your mind. We encourage you to spend time thinking about your 3 core values identified earlier today.
Acceptance: setting expectation that pain is a part of surgery	Feelings of pain and feelings about your experience of pain are normal after surgery. Acknowledge and accept these feelings as part of the recovery process. Remember how you feel now is temporary and your healing process will continue. Call to mind pleasant feelings or thoughts that you experienced today.
Present moment awareness: mindfulness and awareness for our thoughts in the present moment	Awareness of the present moment and your breathing may change with pain-related emotions or thoughts. Remember you can always count on your breathing to bring you back to the present moment and help you move through your current experience of pain.
Self-as-context: awareness of what is being observed and noticed by ourselves	We cannot change that a feeling or thought may arise, but we can choose how we respond to our feelings and thoughts. Remember that dwelling on pain, discouraging feelings, and thoughts after surgery are NOT consistent with your life goals and values. Observe things that try to move you away from your values and only act on things that are compatible with who you want to be and what matters to you.
Committed action: doing what it takes to live according to our values	Healing after surgery requires you to act. We previously discussed your life goals, meaning, and purpose. Take action today and move closer toward what you want in life. Recognize that pain may be present but make the choice that it will not impede your progress toward what you really want in life. Be present in the moment and ensure your actions remain true to what you want most. All actions you make no matter how small, are an important steppingstone on your road to recovery.
Defusion: watch your thinking and interact with thoughts in a way consistent with your values	If you ever feel pain after surgery know that the feeling is real but what it actually represents is not what you might think. Our mind is capable of making us feel pain, even though there is no damage going on in our body. Pause, become more aware in the moment and chose a skillful response that will help you move toward your overall goals and values.

Mobile Phone Messaging Communication

Evolving communication methods, such as automated mobile phone messaging [4,19-21], for health care purposes are increasingly important, as patients prefer these communication methods for delivering and receiving medical information [22]. Software-driven, automated mobile phone messaging robots (also called chatbots or conversational agents) are low-cost tools that can deliver predefined text-based information and receive incoming responses with high reliability when patients either prefer it or it is necessary to communicate at distance [19,23]. This technology demonstrates high efficacy as part of the treatment of conditions ranging from hypertension to substance abuse [24-26], and it has also proved effective in increasing perioperative communication after hip and knee arthroplasty [27] and collecting pain and opioid medication data from patients following orthopedic trauma and hand procedures [4,19]. In addition, automated mobile phone messaging robots have been validated in the collection of PROs in patients undergoing orthopedic hand [20] and hip preservation procedures [23]. Although mobile phone messaging robots (*Chat bots*) provide the benefit of communicating with patients at distance with no need for human intervention, they do introduce delivery of health care that lacks human interaction with unknown effects [28].

Health care teams caring for patients with traumatic orthopedic injuries have traditionally used opioid medication in the postoperative setting, and these patients are at risk for prolonged opioid utilization in the postoperative period. We theorized that the combination of ACT delivered via automated mobile phone messaging may help to decrease pain and opioid utilization in the acute postoperative setting. The aim of this prospective randomized controlled trial was to evaluate the effectiveness of

ACT delivered via an automated mobile messaging robot on (1) decreasing early postoperative opioid utilization and (2) pain-related PROs in the first 2 weeks following surgery for acute traumatic orthopedic injuries.

Methods

Study Approval

This randomized controlled trial was registered with ClinicalTrials.gov (NCT03991546) and reporting is consistent with the Consolidated Standards of Reporting Trials guidelines (Multimedia Appendix 1) [29]. The study was performed at a single center university hospital in Iowa City, Iowa, United States. Ethical approval of this study was provided by the University of Iowa institutional review board, and the study was determined to be Health Insurance Portability and Accountability Act compliant.

Recruitment and Randomization

Adults presenting to a university hospital level 1 trauma center indicated for operative fixation of a traumatic upper or lower fracture were considered for the study (Table 2). The exclusion criteria are listed in Textbox 1. Eligible patients were approached before surgery by a research assistant in a private room. Individuals not excluded by screening questions and interested in participating underwent the informed consent process (Textbox 1). During consent, all subjects were informed of the outcomes of interests, different study arms, and that no changes would be made to their care in terms of postoperative medication, regardless of study participation.

Participants were randomized to either the control or intervention group using a standard web-based random number generator with a range set from 1 to 10 and a 1:1 ratio by a

research assistant. Owing to the nature of this study, subjects and the enrolling research assistant were not blinded to the participant's study group following randomization.

At the time of consent, subjects were required to complete paper forms comprising a basic demographics questionnaire and baseline PROs consisting of the PROMIS Pain Intensity 1A Short form, PROMIS Pain Intensity 3A Short form, PROMIS

Pain Interference 8A Short form, and PROMIS Emotional Distress-Anxiety 8A Short form ([Multimedia Appendix 2](#)). Following completion of all PROs, participants were randomized to their study group. Subjects who received an odd number from the 1 to 10 range set on the random number generator were placed in the intervention group, whereas subjects given an even number were placed in the control group.

Table 2. Injury by final study group (N=76).

Injury	Acceptance and commitment therapy group participants, n	Control group participants, n

^aPolytrauma was defined as a patient with a fracture to more than one upper or lower extremity.

Textbox 1. Exclusion criteria.

Screening questions
<ul style="list-style-type: none"> No personal mobile phone with text messaging capabilities Poor familiarity reading or sending mobile messages
Patient factors
<ul style="list-style-type: none"> Open fracture Infection at the fracture site Prior fracture temporization with an external fixator Revision surgery for nonunion or hardware failure Bilateral upper extremity injuries impeding their ability to use a mobile phone Fractures of the distal hand or distal foot only Admission to an intensive care unit Current cancer diagnosis or dementia Inpatient for more than 7 days of the 2-week study period Discharged without an opioid pain medication prescription Initial plan for operative fixation changed to treatment with joint arthroplasty

Study Interventions

The intervention group received twice-daily, text-based mobile messages communicating an ACT-based intervention for the first 2 weeks following surgery ([Multimedia Appendix 3](#)). Control group subjects did not receive the ACT intervention or any other form of mobile message communication. The mobile messaging ACT protocol consisted of twice per day mobile messages, morning and evening, starting on postoperative day (POD) 1 and ending on POD 14. These mobile phone messages provided participants with an ACT-based intervention that was developed in collaboration with a pain psychologist (VK) specializing in ACT for chronic pain. These messages used all the principles presented in [Table 1](#) with the objective of helping recipients understand and develop better coping skills in relation to their postoperative pain. An example message from day 1 is as follows:

Maintaining focus on what you value most in life is sometimes difficult after surgery. Do not let the momentary discomforts due to surgery take away from what you want most in life. Pick 3 things that matter most to you in life. Remind yourself of these 3 things you value most during your recovery process.

Outside of the mobile messaging intervention, both groups received the same standard postoperative care, health care team communications, and instructions for completing the study follow-up.

A chart review was performed to collect demographic information such as subject age, comorbid conditions, and preoperative outpatient opioid medication prescriptions for treatment of their current traumatic orthopedic injury. All subjects, regardless of group, were seen by a research team member after surgery to review which of their discharge medications was the medication of interest for the study and to confirm that the intervention group subjects received their first mobile phone ACT message. Participants in both groups were

instructed to have their opioid medication bottle available at follow-up to confirm their opioid tablet consumption. Owing to the changes in health care teams, staff preferences, and allergies, the opioid pain medications administered at discharge were not standardized between study groups. Following discharge on POD 14, subjects were contacted by phone or seen in the clinic by the research team for follow-up. At this time, the subjects' opioid pain medication consumption was assessed, and they completed a second set of PROs.

Outcome Measures

The primary outcome of this study was the amount of opioid pain medication consumed by subjects, and the secondary outcomes analyzed were net changes from baseline PRO scores at the 2-week follow-up.

The method that participants employed to report their opioid medication consumption and how PROs were captured during follow-up were recorded ([Table 3](#)). Subjects using their pill bottle to confirm the remaining number of opioid pain medication tablets from their discharge prescription on POD 14 were denoted as reporting a pill count. Cases where subjects or their care facility kept a log of tablet consumption were classified as reporting a daily log. Subjects reporting the number of tablets they used without the use of a log or pill count were designated as providing an estimate. The percentage of opioid pain medication used, total MME, and percentage of available MME consumed were calculated. The mean number of opioid pain medication tablets and MME used by the subjects were compared between groups. The raw scores for PROs were converted to corresponding *t*-scores using the appropriate PROMIS scoring manual [30]. The changes in PROs from baseline to POD 14 were also calculated by subtracting POD 14 scores from baseline scores, as higher *t*-scores signify a poorer outcome; thus, lower scores on POD 14 indicate an improvement from baseline PROs. The mean PRO scores and changes were compared between the groups.

Statistical Analysis

Participant characteristics were described using mean (SD) or median (minimum to maximum) for continuous variables and frequencies (percentages) for categorical variables. Visual review of histograms and the results of the Shapiro-Wilk test of continuous variables revealed that only age and BMI were not normally distributed. Between-group differences were evaluated using *t* tests or Wilcoxon rank-sum tests (age and BMI) for continuous variables and chi-square or exact tests for categorical variables, as appropriate.

To evaluate whether the intervention versus control group had a lower opioid use on average, we determined the number of tablets and MME taken in each group and compared means using *t* tests. Using a previous study of opioid medication usage in orthopedic trauma patients [4], the sample size estimated to observe a 30% decrease in opioid utilization among 2 groups required a total of 74 subjects to achieve 80% power at an alpha of .05. The percent decrease is calculated using the formula . A separate power analysis was calculated for the PRO portion of the study, and it was determined that a total of 36 subjects would provide 80% power to detect a 10-point difference (1 standard deviation) in *t*-scores for the PROMIS instruments at an alpha level of .05. Statistical analyses were performed using SAS software version 9.4 (SAS Institute, Inc).

Results

Study Participants

A total of 125 individuals were approached regarding the study over the 5-month enrollment period between February 2019

and June 2019. Of the 125 individuals, 2 patients were excluded at this time, as they were non-English-speaking, and an additional 24 patients were excluded because they did not use mobile phone messaging or did not have a personal mobile phone. This resulted in a total of 99 eligible people who were presented the study, 17 of whom declined participation (Figure 1). Overall, 82 subjects were enrolled, and 6 dropped from the study after providing consent because of various issues: one patient lost to follow-up, one patient withdrew at follow-up, one patient had incomplete follow-up, one patient's operative plan changed to arthroplasty, and 2 subjects remained inpatient for over 7 days of the study period (Figure 1). This resulted in a final population of 76 subjects (38 per study group). The enrollment period concluded once a powered sample for the primary aim was obtained. A breakdown of the subjects enrolled, reasons for excluding subjects, and subjects removed from the study after consent are presented in Figure 1. Participant demographics for the intervention and control groups are presented in Table 3. The analyses of all collected demographic factors showed no differences between the intervention and control groups in all factors such as subject age ($P=.42$), current psychiatric diagnosis (including depression, anxiety, bipolar type 1, obsessive-compulsive disorder, posttraumatic stress disorder, panic disorder, and attention-deficit disorder; $P=.14$), or substance abuse history ($P=.10$; Table 3). Furthermore, no differences between groups were found for injury type, disposition following discharge, method for reporting opioid medication consumption, preoperative opioid medication prescriptions, or preoperative PROs (Table 3).

Figure 1. Consolidated Standards of Reporting Trials flowchart detailing the selection of eligible patients for study enrollment and their status through study completion. ACT: acceptance and commitment therapy.

Opioid Pain Medication Use

No differences between groups were observed in the amount of opioid medication tablets or MME prescribed at discharge (tablets for the ACT group: mean 58.8, SD 27.3 vs tablets for the control group: mean 61.6, SD 22.0). A further breakdown of the medications prescribed to subjects within the study period is presented in Table 4. The mean opioid tablet use for subjects

in the ACT-based intervention group was 26.1 (SD 21.4) tablets, whereas the control group used a mean of 41.1 (SD 22.0) tablets, resulting in 36.5% less tablets used by subjects receiving the ACT-based intervention ($P=.004$; Table 5). Similarly, subjects in the intervention group consumed a mean of 199.9 (SD 163.2) MME, on average, whereas the control group subjects consumed a mean of 307.0 (SD 166.0) MME, indicating 34.9% less MME used by subjects in the intervention group ($P=.006$; Table 5).

Table 4. Frequency of outpatient opioid pain medications prescribed by enrolled study group (N=82).

Medication	Morphine milliequivalents per tablet	Frequency	
		Acceptance and commitment therapy	Control
Hydrocodone-acetaminophen 5-325 mg	5	1	2
Hydrocodone-acetaminophen 10-325 mg	10	2	0

Patient-Reported Outcomes

PROMIS instrument *t*-score values for both ACT and control group subjects are presented in Table 6. At 2-week follow-up, the intervention group subjects reported lower postoperative PROMIS Pain Intensity 3A (mean 45.9, SD 7.2) and Pain

Interference 8A (mean 56.6, SD 9.4) scores compared with the control group's postoperative Pain Intensity 3A (mean 49.7, SD 8.8; *P*=.04) and Pain Interference 8A scores (mean 60.6, SD 8.2; *P*=.05; Table 6). No differences were observed between groups at 2-week follow-up in the PROMIS Pain Intensity 1A or PROMIS Emotional Distress-Anxiety 8A forms (Table 6).

Table 6. Mean Patient-Reported Outcome Measures Information System score and change within the 2-week study period by study group.

Discussion

Principal Findings

This randomized trial delivered an ACT-based intervention via an automated mobile messaging robot to postoperative orthopedic patients. The subjects who received the ACT-based mobile phone intervention used a lower number of opioid tablets and consumed less MME in the first 2 weeks after their injury. We also found that the intervention group reported less pain intensity and pain interference at the 2-week follow-up. These data demonstrate that ACT-based automated mobile messaging protocols may be effective in reducing the amount of opioid medication used and may positively affect postoperative PROs in patients undergoing operative fixation of their acute fractures.

Effects on Opioid Use

Improved mood symptoms, less pain interference, and faster cessation of opioid pain medication are some of the recognized benefits of using ACT in clinic-based, interdisciplinary approaches to pain management after surgery [17,18]. Previous investigations have used automated mobile phone messaging robots to deliver PROs [20,23], improve communication with patients [27,31], deliver postoperative orthopedic care [32], and inquire about pain and opioid utilization [4,19,33]. In this study, we used ACT and a mobile phone messaging robot to assess whether these tools in combination could decrease opioid utilization and improve individuals' perception of their early recovery from injury. Prior work has demonstrated a quicker time to opioid cessation and a decrease in postoperative opioid utilization (14% less in the ACT group) when used in office ACT-based treatments [17,18]. Subjects receiving the ACT

intervention via automated mobile phone messages reported over 36% less opioid tablets and more than 34% less MME consumed than corresponding control subjects who did not receive ACT. Our findings suggest that software-based communication using ACT through a mobile phone has the potential to have a large impact on the utilization of postoperative pain medication by patients in the first weeks after surgery for fractures. Further study is required to determine if these effects are long lasting and to determine which injuries and patients receive the greatest benefit. In addition, future investigations and trials should consider the effect of software delivery of ACT and other behavioral therapies on different cohorts of patients.

Effects on PROs

PROs, such as PROMIS, allow patients to quantify aspects of their orthopedic condition in a standardized fashion [6,7]. These are important tools for determining the efficacy of health care treatments and assessment of clinical research and can be used in determining compensation for health care services provided [6-8]. The National Institutes of Health developed the PROMIS tools to advance PROs by creating question banks that could be used for many major health issues [9]. We found that despite less utilization of opioids, subjects in the ACT-based intervention group reported less pain intensity and pain interference at 2 weeks. This most likely does not represent a clinically important difference based on the SD methodology used in prior works with PROMIS tools (Table 6), but it at least suggests that the intervention group did not experience greater pain [34]. There were no other differences between study groups in the other domains at the 2-week follow-up. Previous studies have reported that patients who consume more opioid medication report higher pain at both short- and long-term time points, which is reflected in our findings for both PROMIS pain intensity 3A and the employed pain interference measure [35,36]. Future research efforts may benefit from employing alternative PRO measures to identify the effects of ACT-based interventions, including assessment of psychologic flexibility. Future research may also consider possible modifications of our study protocol to include a longer intervention period and more than one follow-up data point. Future work may also

consider designing an ACT-based tool that is more focused on demonstrating an effect on PROs.

Limitations

Several limitations were present in this study. First, we were limited to a single level 1 trauma center, which may affect the reproducibility of our results across other health care settings. Next, the exclusion criteria for this study were extensive, and thus, the results may not be generalizable to the entire scope of orthopedic trauma patients. We attempted to include a diverse set of injuries and yet excluded patients with a high likelihood of confounding problems from open fractures or prolonged initial hospitalization. Future studies assessing the effects of ACT-based interventions similar to ours should aim for less restrictive exclusion criteria to apply this intervention to a larger, more diverse population. The research assistants were not blinded to the patients' study group. In addition, patients understood the outcomes of interest in this study, which could be susceptible to reporting bias. In addition, participants were not blinded to their treatment group. The lack of blinding could potentially introduce response or reporting bias, making this a potential area of improvement for studies seeking to follow the present methodology. This could be accomplished through the implementation of a control messaging protocol. Moreover, a retrospective chart review was used to obtain several patient factors, including comorbid conditions and dispensing of preoperative outpatient opioid medication prescriptions. The collection of information in this manner relies on accurate charting and transfer of documents from outside institutions, which may have been incomplete.

Conclusions

In this study, delivering an ACT-based intervention via an automated mobile messaging robot in the acute postoperative period decreased opioid utilization in orthopedic trauma patients in the first 2 weeks after their injury. Subjects in the ACT-based intervention group also reported lower pain intensity and pain interference after 2 weeks, although this likely did not represent a clinically important difference. Future studies may apply this intervention in other patient populations to assess its efficacy on a larger scale and may include assessment of pain and opioid use in a longer time frame after injury.

Acknowledgments

This study was possible thanks to a generous grant from the Orthopaedic Trauma Association.

Abstract

Background: Inadequate fruit and vegetable consumption causes a considerable disease burden and premature mortality. Despite public health promotion of a healthy diet, the average consumption is still below recommended levels. Fruit and vegetable consumption influences human skin color, increasing red/yellow/orange pigment in the skin. Given that this color is deemed attractive and healthy-looking, the appearance benefit may motivate to eat more fruit and vegetables. Such appearance motivation could be particularly useful in young individuals who currently eat the least fruit and vegetables.

Objective: Our objectives were to assess how widely the impact of diet on skin color is known within the UK and to compare the strength of motivation to eat fruit and vegetables based on health and appearance benefits among different demographic groups.

Methods: Four groups of UK residents (N=200 per group) were recruited through the Prolific online platform. Groups comprised younger (aged 18-24) and older adults (aged 40-60) of low and high self-reported socioeconomic status (1-5 and 6-10 on a 10-point rating scale). Facial images simulating the skin color associated with low and high fruit and vegetable diets were shown to participants. Questionnaires were used to assess (1) background knowledge of the health and skin color effects of dietary fruit and vegetables, (2) the specific motivational impact of the skin color illustration, and (3) the relative importance of motivation to consume fruit and vegetables arising from health and skin color appearance benefits.

Results: We found that 61% (n=487) of all participants were unaware of the dietary-skin color association. We also found that 57% (n=457) of participants found the simple demonstration of the dietary impact on skin color positively motivating to eat more fruit and vegetables. The visual demonstration was equally motivating for participants of high and low self-reported socioeconomic status ($P=.63$) and different ethnic backgrounds (White N=453, Black N=182, Asian N=87, $P=.22$). Health benefits from a diet high in fruit and vegetables were regarded as more motivating than skin color appearance benefits. The appearance-changing benefits of a high fruit and vegetable diet (compared to the health benefits) were relatively more important for the younger participants (Mann-Whitney $U=96,263$, $P<.001$) and for women (N=489) than for men (N=310, $U=83,763$, $P=.01$).

Conclusions: These findings indicate that the promotion of the skin color effects of diets high in fruit and vegetables could provide additional motivation for a healthier diet. Our study indicates the broad appeal of appearance benefits from dietary fruit and vegetable (across ethnicity and socioeconomic status) and particularly amongst young adults where an inadequate diet is most prevalent.

Introduction

Background

Inadequate fruit and vegetable consumption is estimated to lead to between 5.6 to 7.8 million premature deaths per year worldwide [1], chiefly through incidences of cardiovascular disease including coronary heart disease and stroke [1-3], diabetes and its complications [4,5] and several cancers [1,2,6]. Globally inadequate intake of fruit and vegetables is also responsible for the loss of up to 103 million years of healthy life due to disability [7]. The negative ramifications of these lifestyle-attributable diseases are widely felt. In addition to the consequences for personal wellbeing, poor population health contributes to an overburdening of healthcare systems and fiscal strain due to lost productivity [8].

Only 29% of adults in the UK [9] report eating the recommended 5 portions of fruit and vegetables per day. Fewer men (26%) than women (32%) meet the 5 a day guideline. Young people aged 16-24 were also less likely than other adults aged 45-60 to get their 5 a day (average 3.3 portions per day compared to 3.8). Figures are worse for children, with only 18% of children aged 5-15 eating 5 portions per day. The National Diet and Nutrition Survey showed that the proportion of adults (~30%) consuming the 5 a day recommendation has changed little over the last decade [10]. Residential area deprivation and lower socioeconomic status independently predict decreased fruit and vegetable consumption [11,12].

Health promotion efforts to increase fruit and vegetable consumption vary from individual approaches such as personal (or parental) advice and counseling to public health campaigns. Although much has been achieved in terms of understanding what psychological techniques may work or not to facilitate healthy eating [13], given the current state of inadequate consumption of fruit and vegetables, we are still in need of novel and innovative methods in addition to existing ones to encourage healthy eating.

Skin Color Effects

Fruit and vegetable consumption influences human skin color, increasing the presence of red/yellow carotenoid pigments in the skin [14-18]. Indeed, this skin color is a reliable biomarker of fruit and vegetable and carotenoid intake [19-22]. When asked to choose the skin color that looks healthiest in photographs of themselves or others, participants consistently choose a skin color that represents a higher fruit and vegetable consumption [14,23-25]. Likewise, when asked to choose the most attractive facial photograph, participants choose the one with increased carotenoid skin coloration over baseline coloration [26] and even over increased suntan coloration [27,28]. Some reports point to a limitation of the effect of carotenoid skin color. Appleton et al [29] found that carotenoid color did not affect attractiveness when pose and expression were unconstrained, and Tan et al [24] found that while a subtle level of carotenoid color increased attractiveness a large amount was deemed unattractive in a Malaysian Chinese population.

In terms of using the effect of fruit and vegetable consumption on skin color to motivate increased fruit and vegetable

consumption, limited trials have been conducted. Whitehead et al [30] found that those shown a personalized demonstration of the potential skin color improvements arising from increased fruit and vegetable consumption reported an increase in fruit and vegetable consumption at a 10-week follow-up.

The present study aimed to assess the extent to which the effects of fruit and vegetable consumption on skin color are known within the UK. After extensive media coverage, we expected that the effect of fruit and vegetable consumption on skin color would be known by a proportion of the population, but the demographics of those familiar with the effect are unclear.

Secondly, we aimed to assess the extent to which UK residents are motivated to eat fruit and vegetables by a simple demonstration of the effects of fruit and vegetable consumption on skin color. Given the previous studies, we expected that a majority of individuals would express positive motivation following the online demonstration.

Specific subsections of society may be more receptive to appearance-based incentives than others. Within the US, Hayes and Ross [31] found younger participants to be more concerned about their appearance than older participants. Women were also more concerned about their appearance than men [31]. Across all demographic groups, the appearance was a powerful motivation for healthy eating [31]. By analyzing questionnaire data from 236 college-age women, Chung et al [32] found appearance (particularly weight maintenance) to be an essential factor in women's decisions to eat fruit and vegetables. It was, therefore, predicted that younger and female participants would show the greatest motivation to increase fruit and vegetable consumption following the online demonstration of appearance changes related to diet. While it is clear that low socioeconomic status is predictive of reduced fruit and vegetable consumption [11,12], it is unclear whether socioeconomic status relates to the dietary motivation from skin color change.

Methods

Participant Enrollment

Ethical approval was obtained from the University of St Andrews School of Psychology Ethics Committee (PS13092). The study was completed with 802 participants recruited via Prolific, an online UK-based recruitment platform for surveys and behavioral experiments [33].

The Prolific company supplies sociodemographic information for their panelists. Prolific asks recruits to answer the following question: "Think of a ladder (image of a ladder with 10 rungs) as representing where people stand in society. At the top of the ladder are the people who are best off—those who have the most money, most education, and the best jobs. At the bottom are the people who are worst off—who have the least money, least education and the worst jobs or no job. The higher up you are on this ladder, the closer you are to people at the very top, and the lower you are, the closer you are to the bottom. Where would you put yourself on the ladder? Choose the number (1-10) whose position best represents where you would be on this ladder."

Participants were recruited in four waves: (1) 202 18-26 year-olds who rated themselves as belonging to the lower half of self-perceived socioeconomic status (rating of 1-5 on the 10-point visual analog ladder scale), (2) 199 18-26 year-olds who rated themselves as belonging to the upper half of self-perceived socioeconomic status (6-10 rating on the 10 point scale), (3) 200 40-60 year-olds who rated themselves as belonging to the lower half of self-perceived socioeconomic status, and (4) 201 40-60 year-olds who rated themselves as belonging to the upper half of self-perceived socioeconomic status.

Participants were paid £0.6 for taking part (at an average rate of £9 per hour, 80% above stipulated minimum rate), with the questionnaire taking approximately 4 minutes to complete.

Image Transforms

Participants were shown before and after images of a male face (Figure 1). The left-hand image was a composite image made by combining 13 images of men who had consented to their

image being published. This image was then graphically changed to represent the skin color changes that occur following the consumption of 5 portions of fruit and vegetables for 6 weeks. Image transformation to simulate the effect of increasing dietary fruit and vegetables followed methods outlined previously [14,23,24,27]. This single image pair was used to make the demonstration as simple as possible.

The color change in the presented image pair was measured by selecting a large patch of the image of facial skin between the eyes and neck and analyzing the average color values of the pixels within the image patch. The right-hand image in Figure 1 was darker, redder, and yellower than the left image. The color difference between right and left images in CIE Lab color space was $L^*a^*b^* = -1.5, 2.0, 4.1$. The displayed color difference is equivalent to the skin color change ($L^*a^*b^* = -1.8, 1.2, 3.8$) after 4 weeks of a 500 mL/day dietary smoothie supplement of 6 extra daily portions of fruit and vegetables [15]. The color difference we use is one-quarter of the difference used in other studies [27,34].

Figure 1. The image shown to participants before answering questions about the skin color benefits of fruit and vegetable consumption.

Procedure

Participants were first shown an image (Figure 1) showing the effect of fruit and vegetable consumption on skin color benefits. Participants were then given a questionnaire asking demographics (gender, age, ethnicity) and how many portions of fruit and vegetables they eat per day (0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11 or more). They were also asked whether they were aware that diet affected skin color appearance and health. “Before seeing this display, were you aware that eating fruit and vegetables (a) can impart a golden glow to your skin color? (b) may help reduce the risk of the two main killer diseases in the UK—heart disease and some cancers?”. Answer options were: no, somewhat, yes (rescored as 0, 1, 2).

One question assessed the motivational effect of the display: “Has seeing the effect of diet on skin color in this exhibit made you want to eat less or more fruit and vegetables?”. Answer

options were: a lot less, a little less, no change, a little more, a lot more.

Two further questions assessed the relative motivation of participants: “How much would the following make you want to eat more fruit and vegetables: (a) getting a skin color that looks healthy and attractive (within 20 days), (b) reducing your chance of heart disease and some forms of cancer?”. Answer options were: none at all, a little, a moderate amount, a lot, a great deal.

Analysis

Non-parametric statistics were used for ordinal data (awareness and motivation), and fruit and vegetable consumption as skew departed from normality. Mann-Whitney U tests were used to compare 2 groups, Kruskal-Wallis, to compare more than 2 groups and Wilcoxon Signed Rank test T to explore choice across a single group. Three of the 802 (<1%) participants reported consuming 11 or more portions of fruit and vegetables

per day. Therefore, consumption data was approximated as an interval scale ranging from 0 to 11.

Missing Data

For each variable, the analysis was restricted to participants with data either through their registration with Prolific (younger 18-26 vs older 40-60 age bracket, socioeconomic status) or through our questionnaire (age at the time of testing, gender, ethnicity). Data were missing for 36 participants (5%) for age at the time of testing, 20 (3%) for ethnicity, and 12 (1%) for socioeconomic status. Descriptions of the study population in terms of gender, age, and ethnicity are based on answers to our questionnaire. No attempt was made to compensate for missing data.

Results

Participant Demographics

Gender

Participants included 489 females (61%) and 311 males (39%). Two individuals reported their gender as “Other.”

Age

In our questionnaire, 381 of the 401 younger participants (in the age bracket 18-26) reported age at the time of testing age (mean 21.57, SD 2.09, range 18-30 years). Of the 401 older participants in the 40-60 age bracket, 385 reported age at the time of testing (mean 48.7, SD 5.83, range 38-61 years).

Socioeconomic Status

We observed 790 participants (1% missing data) who had Prolific categories of self-perceived socioeconomic status scale ranging from 1 (the lowest) to 10 (the highest), mean rating=5.32 (SD 1.67). The frequency of self-report rating was 12 (1%), 32 (4%), 72 (9%), 123 (20%), 157 (24%), 190 (19%), 148 (6%), 47 (1%), 4 (1%), and 5 (1%) across the 10 status levels (a distribution with acceptable skew -0.27 and kurtosis=0.17).

Ethnicity

We observed that 782 participants (2% missing data) chose an image that best represented their ethnic background from four images representing Black (African), White (Caucasian), East Asian, and West Asian (Indian/Pakistani). Of these, 182 participants (23%) identified themselves as having African ethnicity, 87 participants (11%) as Asian, 454 participants (57%) as Caucasian, 23 participants (3%) as West Asian, 36 participants (5%) as having more than one ethnicity, and 18 participants (2%) reported an ethnicity not shown by our questionnaire stimuli.

Fruit and Vegetable Consumption

The mean level of fruit and vegetable consumption across the entire sample was mean 3.38 (SD 1.76) (skew 0.40 and

kurtosis=0.10) portions per day. Young adults reported eating less than older adults (3.13, SD 1.72 vs 3.63, SD 1.76 portions per day; younger adults mean rank=363.9, N=399; older adults mean rank=436.9, N=401; Mann-Whitney U=94,601, $P<.001$, $r=.161$). Low socioeconomic status participants reported eating less than those of high socioeconomic status (3.15, SD 1.70 vs 3.62, SD 1.78 portions per day; low status mean rank=363.45, N=395; high status mean rank=425.71, N=393; U=89,884, $P<.001$, $r=.139$). Men reported eating less than women (3.11, SD 1.60 vs 3.55, SD 1.83 portions per day; men mean rank=367.25, N=310; women mean rank=419.99, N=488; U=85,638, $P<.001$, $r=.114$). Consumption of fruit and vegetables did not differ across three ethnic groups, Black, White, and Asian (N=721, Kruskal-Wallis Test=1.884, $df=2$, $P=.39$).

Awareness of Appearance Benefits

We had 487 participants (61%) report they were unaware of the association between diet and skin color; 219 (27%) were somewhat aware, and 95 (12%) were aware. In contrast, 66 (8%) participants were unaware of the health risks (eg, cancer, heart disease) associated with a diet low in fruit and vegetables. Younger participants were more aware of the fruit and vegetable effect on skin color than older participants (younger adults mean rank=417.67, N=400; older adults mean rank=384.37, N=401; U=73,531, $P=.02$, $r=-.081$). Participants who reported low socioeconomic status were equally aware of the effect as participants reporting high socioeconomic status (low socioeconomic status mean rank=397.13, N=396; high socioeconomic status mean rank=392.86, N=393; U=76,972, $P=.76$, $r=-.01$). Women were more aware of the fruit and vegetable effect on skin color than men (women mean rank=416.67, N=489, men mean rank=373.71, N=310; U=83,946, $P=.003$, $r=.104$). Awareness of the fruit and vegetable effect on skin color differed across three ethnic groups, Black, White, and Asian (N=722, Kruskal-Wallis Test=7.915, $df=2$, $P=.02$). White participants showed the least awareness (Black mean rank=382.71, Asian mean rank=392.55, White mean rank=347.02).

Motivation Change from Seeing an Effect on Skin Color

We observed 457 participants (57%) reporting that the simple demonstration of the dietary impact on skin color positively motivated them to eat more fruit and vegetables.

Age

Comparing younger (18-26 years old) and older participants (40-60 years old) showed that the younger group was more likely to endorse the view that the appearance demonstration motivated diet change than the older group (Figure 2, younger participants mean rank=435.79, N=400; older participants mean rank=366.30, N=401; U=66,284, $P<.001$, $r=-.164$).

Figure 2. Effect of age on appearance motivation. Change in motivation to eat fruit and vegetables as a result of seeing the demonstration images for two age groups. Younger adults were more positively motivated than older participants.

Gender

Participant gender had no significant effect on the motivation for diet change from the demonstration of the effects of fruit and vegetables on skin color (women mean rank=408.37, $N=489$, men mean rank=386.80, $N=310$; $U=79,886$, $P=.16$, $r=.05$). The appearance demonstration was thus equally motivating to women and men.

Socioeconomic Status

Comparing low (self-reporting levels 1-5) and high socioeconomic status (self-reporting levels 6-10) participants showed that the two groups were equally likely to endorse the view that the appearance demonstration was motivating to change diet (mean rank low=396.12, $N=396$; mean rank high=393.88, $N=393$; $U=77,372$, $P=.88$, $r=-.005$). Hence, the appearance motivation was equal across socioeconomic status.

Ethnicity

The distribution of answers (to the question of whether the demonstration of skin color change motivated dietary change) across three ethnic groups, Black, White and Asian, was not significantly different ($N=721$, Kruskal-Wallis Test=2.999,

$df=2$, $P=.22$). Comparing the median score of participants answering this question to a median of zero, the score expected by random choice, each ethnic group showed a significant bias to answer the question affirmatively (Black participants: One-Sample Wilcoxon Signed Rank test $T=5,899.5$, $N=182$, asymptotic two-tailed significance $P<.001$; Asian participants: $T=1,573.5$, $N=87$, $P<.001$; White participants: $T=31,311$, $N=452$, $P<.001$). Hence Black, White and Asian groups found the color demonstration motivating (Figure 1).

Appearance vs Health Motivation for Dietary Fruit and Vegetables

The vast majority ($n=720$, 90%) of participants answered that skin color appearance would motivate them to eat more fruit and vegetables. By contrast, virtually all participants ($n=792$, 99%) were motivated to a greater or lesser extent by the health benefits of fruit and vegetables in reducing the chance of heart disease and cancer (Figure 3). The response categories were recoded as a score (0-4) to compare the relative importance of health and appearance motivation. The mean numerical score for health motivation was 3.27, while the mean score for appearance was 2.30 (Wilcoxon Signed-Rank test $T=118,103$; $N=801$, $P<.001$, $r=.618$).

Figure 3. Relative motivation of health and appearance for the consumption of fruit and vegetables.

Gender

An appearance/health contrast score was computed for each participant (the 0-4 score of the importance of appearance minus the 0-4 score of the importance of health for consuming fruit and vegetables) to compare health and appearance motivation. Comparing contrast scores for women and men showed that the relative importance of appearance to health in motivating diet change was higher for women (mean rank=416.29, N=489) than men (mean rank=374.3, N=310; U=83,763, $P=.01$, $r=.09$).

Age

Younger adults (mean rank=442.96, N=400) found the appearance benefits more motivating relative to the health benefits (mean rank=359.15, N=401, U=63,416, $P<.001$, $r=.19$).

Socioeconomic Status

There was no effect of socioeconomic status on the relative motivation of health and appearance (mean rank high=392.52, N=393; mean rank low=397.46, N=396; U=78,839, $P=.75$, $r=-.011$).

Knowledge of the Effect of Fruit and Vegetables on Skin Color

The importance of appearance relative to health in motivating diet change was higher for those participants who already knew that diet alters skin color (mean rank=445.79, N=314) than for those not aware of the effect (mean rank=372.12, N=487, U=90,522, $P<.001$, $r=.161$).

Discussion

Principal Findings

The primary findings of the study were (a) the limited percentage of people (40%) with knowledge of the dietary-skin color association and (b) that many people (57%) found the simple demonstration of the dietary impact on skin color positively motivating to eat more fruit and vegetables, while very few (1%) reported the demonstration was demotivating. The combination of these two findings points to the benefits

that can be accrued through publicizing and demonstrating the dietary effect on skin color. Media coverage in the UK has been extensive (reaching millions of TV viewers), but there is still a substantial proportion of the population that reports not knowing the dietary effects. Of the 801 participants, 487 (61%) were unaware of the effects of fruit and vegetable consumption on skin color. Of these, 248 (51%) stated they were motivated to eat more fruit and vegetables as a result of seeing the demonstration. Hence increasing public awareness of the dietary effects on the skin could provide additional motivation for a healthy diet for 31% of the sample population (% of those unaware multiplied by % of those motivated). Extrapolating this to the UK adult population of approximately 50 million, this amounts to 16.5 million people.

Age and Socioeconomic Status

Low socioeconomic status and young adult age are established independent categories predicting low fruit and vegetable consumption [10,11]. In the current study, it was again evident that the younger adults and those reporting low socioeconomic status were reporting lower fruit and vegetable consumption. It is noteworthy that the motivational effects of appearance were most prominent in younger adults. By contrast, we were unable to detect any influence of socioeconomic status on appearance motivation. Hence, it is reasonable to expect that promotion of appearance benefit would not widen health inequalities, and drawing attention to the color benefits of a healthy diet would have an impact on a younger population independent of socioeconomic status, thereby increasing the chance of their life-long adoption of an improved diet.

Gender

We expected women to be more motivated by appearance benefits than men. Comparing reactions to the visual demonstration, we found no significant impact of gender. For both men and women in the present study, motivation for a diet high in fruit and vegetables was more significant for the benefits to health than the motivation for an improved skin color appearance. Nonetheless, motivation from benefits to appearance relative to benefits to health was higher in women than in men.

Fruit and Vegetable Consumption

The average consumption of fruit and vegetables reported by the entire sample here was 3 portions per day (significantly less than the 5 a day recommended by the British National Healthcare System). Hence publicity of the appearance benefits of a proper diet rich in fruit and vegetables could augment motivation for a healthy diet. It is relevant here that the majority of our participants (57%) reported that the appearance benefits were positively motivating. Indeed, appearance has proved valuable in encouraging other aspects of healthy behavior (eg, sun protection) [35].

Ethnicity Effects

The participants in this study reported a variety of ethnic backgrounds (23% Black, 11% Asian, and 57% White). The effect of carotenoids is likely to be less apparent for individuals with darkly pigmented skin. Nonetheless, carotenoid effects on skin color are apparent across different ethnicities. Coetzee & Perrett [36] found that carotenoid supplementation produced an increase in skin yellowness in sun-protected skin regions of African participants. Likewise, a diet rich in fruit and vegetables increases skin yellowness in Asian participants [15,24] as it does in White participants [14,16,26].

While the skin color effects of diet are detectable in a range of ethnic groups, different cultures may vary in their perception of whether the skin color change is desirable. Black South African participants were found to perceive increased skin yellowness positively [23]. However, a recent report indicates that Asian participants from Malaysia find only a slight increase in carotenoid skin color more attractive than the skin color baseline [24]. A further report concludes that mainland Chinese participants do not find increased yellow skin pigmentation attractive [37]. Nonetheless, whatever the influence of culture on color preferences, the current study found that Asian, Black,

and White participants from the UK were equally impressed by the impact of diet on skin color.

Limitations

We detected several factors associated with attitudes to the appearance benefit arising from a diet high in fruit and vegetables. Socioeconomic status did not influence appearance motivation. Our measures of socioeconomic status and dietary intake were self-reported, and portions of fruit and vegetables were not defined (eg, as 80 g). More objective measures and greater sampling of those with low and high socioeconomic status individuals are needed to be confident in null effects. We have not assessed residential area deprivation [11] or sense of personal relative deprivation [38], both predictors of diet and self-reported health.

We illustrated the dietary effect with a single Caucasian male face. The demonstration may be more effective if displayed with the same gender, age, and ethnicity as the participant or better still with an image of the participant [30]. The demonstration was made early in the survey, which may have led to participants increasing their reported fruit and vegetable consumption. The dietary effect on skin color is not unique since other aspects of lifestyle (eg, fitness and reduced body fat) have similar impacts on skin color appearance [39].

We measured the effects of appearance on self-reported motivation to consume more fruit and vegetables. We acknowledge that motivation is necessary but not sufficient for actual dietary change [40]. The impact of appearance on real dietary change is likely to be smaller than the impact on motivation to change. Translating motivation into an actual increase in fruit and vegetable consumption remains an issue that is affected by a person's perception that they can control their behavior [14,40,41]. Nonetheless, any change in motivation to consume more fruit and vegetables is an essential step in the right direction of a healthy lifestyle.

Abstract

Background: Blockchain offers a promising new distributed technology to address the challenges of data standardization, system interoperability, security, privacy, and accessibility of medical records.

Objective: The purpose of this review is to assess the research on the use of blockchain technology for patient care and the associated challenges and to provide a research agenda for future research.

Methods: This review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analysis guidelines. We queried the Cumulative Index of Nursing and Allied Health Literature (CINAHL), PubMed, Excerpta Medica dataBASE (EMBASE), and Web of Science databases for peer-reviewed research articles published up to December 2019 that examined the implementation of blockchain technology in health care settings. We identified 800 articles from which we selected 70 empirical research articles for a detailed review.

Results: Blockchain-based patient care applications include medical information systems, personal health records, mobile health and telemedicine, data preservation systems and social networks, health information exchanges and remote monitoring systems, and medical research systems. These blockchain-based health care applications may improve patient engagement and empowerment, improve health care provider access to information, and enhance the use of health care information for medical research.

Conclusions: Blockchain health information technology (HIT) provides benefits such as ensuring data privacy and security of health data, facilitating interoperability of heterogeneous HIT systems, and improving the quality of health care outcomes. However, barriers to using blockchain technology to build HIT include security and privacy vulnerabilities, user resistance, high computing power requirements and implementation costs, inefficient consensus algorithms, and challenges of integrating blockchain with existing HIT. With 51% of the research focused on medical information systems such as electronic health record and electronic medical record, and 53% of the research focused on data security and privacy issues, this review shows that HIT research is primarily focused on the use of blockchain technologies to address the current challenges HIT faces. Although Blockchain presents significant potential for disrupting health care, most ideas are in their infancy.

KEYWORDS

blockchain; health information technology; systematic review; security; privacy; interoperability; health outcomes

Introduction

Background

There is a growing need to integrate health care information across a range of uses and stakeholders and to secure such data from unauthorized breaches, while making it easier for patients to access patient data. Blockchain is a distributed technology that has the potential to address data standardization challenges, system interoperability, and accessibility of medical records to support a more secure, patient-centric approach to health care information systems.

Blockchain is a secure and immutable transaction ledger [1,2], which is distributed in a decentralized manner across all computing devices that are part of the blockchain infrastructure [3]. Blockchain's decentralized design facilitates peer-to-peer-based network transactions between users without the need for a trusted third party. Although more commonly used in decentralized financial applications such as cryptocurrencies and initial coin offerings (ICOs), blockchain's advanced features (eg, consensus mechanisms, digital signatures, and hash chains) promise to address the unique challenges health information systems commonly face, such as poor security, privacy, efficiency, and interoperability.

Blockchains can be classified into 2 types: permissionless and permissioned blockchains [4]. The permissionless blockchain is open to the public, allows anyone to join the blockchain without approval, and usually provides an economic incentive for participating in the blockchain. Most known cryptocurrency blockchains are public, such as Bitcoin and Litecoin. A permissioned blockchain incorporates access control mechanisms to restrict user access. Permissioned blockchains are further classified as private or consortium blockchains based on their governance structure. A private blockchain is managed by a single organization and is usually used in enterprise solutions. The consortium blockchain is semiprivate, has a controlled user group, and works across different organizations. Compared with the public blockchain, permissioned blockchains are restrictive, and a central authority grants access to the blockchain. Therefore, permissioned blockchains lose some of the advantages of decentralization, but are more effective in securely sharing and managing real-time data among participating health care stakeholders. Emblem and the Synaptic Health Alliance are examples of health care blockchain consortia that allow selected health care stakeholders, including patients, advocacy groups, life sciences companies, payers, authorities, and care centers, to form nodes on the networks and manage health data securely, without a central authority.

Researchers are recognizing blockchain's potential as a disruptive technology in health care and have begun to conduct research on how to leverage blockchain. We seek to understand what progress has been made in blockchain health care research and which problems researchers are addressing and encountering in use case implementations. We answer these questions by conducting a literature review and synthesizing the empirical blockchain health care research. The format of this systematic review adhered to the literature review standards of the review

methodology, Preferred Reporting Items for Systematic Reviews and Meta-Analyses (Multimedia Appendix 1) [5].

This analysis shows that health care researchers are focusing on interoperability and platform issues and are exploring opportunities to use blockchain to enhance privacy and security and improve data integrity and transparency. We also identify the different types of blockchain health information technology (HIT) and discuss their implications for patient engagement and empowerment, provider access to personal health information (PHI), and medical or clinical research. We discuss the barriers and challenges of using and implementing blockchain HIT and propose new research directions.

The rest of the paper is organized as follows. First, in the *Methods* section, we describe the search process and selection criteria. In the *Results* section, we summarize our findings by highlighting the HIT challenges that blockchain addresses, the different types of blockchain-based HIT, how blockchain HIT research has evolved over time, and barriers and challenges to implementation. In the *Discussion* section, we suggest potential areas of research. In the *Conclusion* section, we end our review by summarizing and highlighting the implications of our key findings.

Objective

The purpose of this review is to evaluate the current literature on the application of blockchain technology in health care with a focus on patient care, to assess the current state of research, the associated challenges, and potential areas for future research. In accordance with our objectives, the research questions are as follows:

1. What current HIT challenges does blockchain address?
2. What are the predominant applications for patient care in blockchain HIT research?
3. How has blockchain HIT research evolved over time?
4. What health care activities are impacted by current blockchain HIT research?
5. What are the challenges associated with blockchain-based HIT implementations?

Methods

Study Identification and Selection

Eligible papers were published in academic peer-reviewed journals and conference proceedings in English.

We searched bibliographic databases such as Web of Science, PubMed, Cumulative Index of Nursing and Allied Health Literature (CINAHL), and Excerpta Medica dataBASE (EMBASE). As PubMed, CINAHL, and EMBASE focus mostly on medical content, we used the search term "blockchain" to query these databases to execute a broad search so as not to miss important results. As the Web of Science provides content related to a broader range of topics, we used the search terms "blockchain" AND "health" OR "blockchain" and "medical" to query this database. We searched for all papers published up to December 12, 2019. The searches identified 800 potential articles: Web of Science, 298; PubMed, 184; CINAHL, 129; and EMBASE, 189. To validate our results, we conducted an

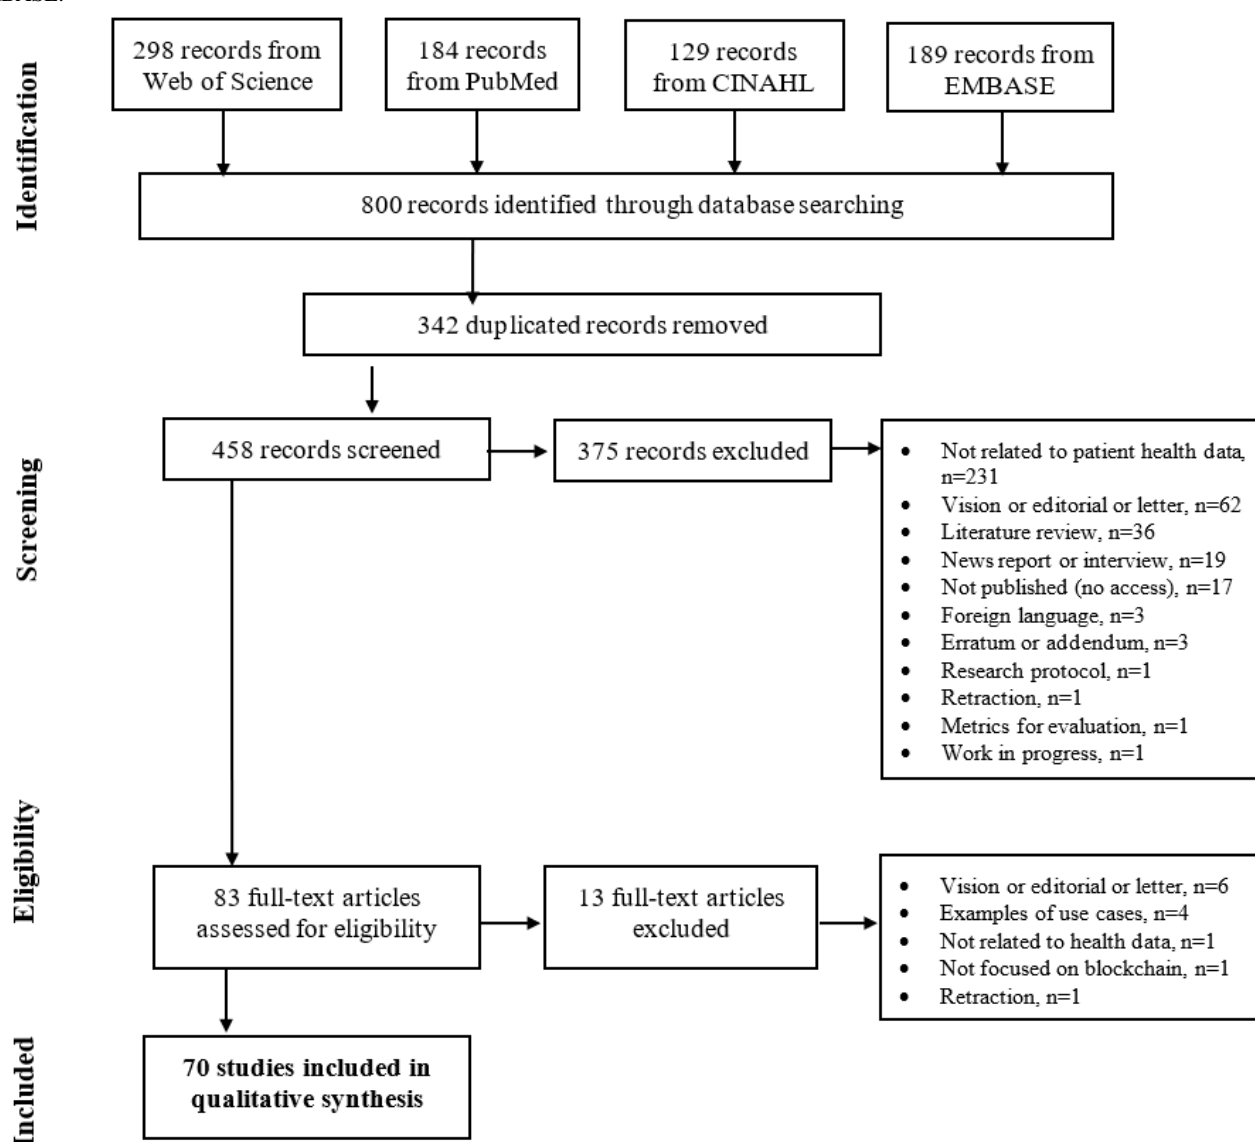

alternative search using the search terms “blockchain” AND (health OR medic OR biomedic OR clinic). The alternative search terms came from prior research [6]. This alternative search identified only 652 potential articles and no new results, compared with the 800 potential articles initially identified: Web of Science, 264; PubMed, 146; CINAHL, 9; and EMBASE, 151.

Data Extraction and Analysis of Types of Blockchain Health Care Applications and Benefits

Two reviewers used Rayyan, a web app for systematic reviews, to independently review all titles and abstracts. A total of 342 duplicates were identified and removed, resulting in 458 papers being selected for full review. The reviewers disagreed on 29

papers, resulting in an inter-rater reliability of 93.7% (429/458). All disagreements were resolved during a consensus meeting. After this assessment, 83 out of the 458 studies remained for analysis. Most of the excluded papers (n=231) were not related to patients' health data. For example, some studies focused on the application of blockchain in supply chains or cryptocurrency. We labeled 62 excluded papers pertaining to speculations about future blockchain technology projects for the health industry as visionary/editorial/commentary papers. Focusing primarily on peer-reviewed publications, we also excluded news reports, literature reviews, working papers, and research protocols. After screening for full-text eligibility, we identified 70 studies for the final review. Figure 1 presents our study identification and selection process.

Figure 1. Study identification and selection process. CINAHL: Cumulative Index of Nursing and Allied Health Literature; EMBASE: Excerpta Medica dataBASE.

We evaluated each paper to determine the following: (1) the types of blockchain-based HIT applications that researchers focused on including electronic health records (EHRs), personal health records (PHR), health information exchange (HIE), and telemedicine; (2) benefits of using blockchain for HIT; (3) health care activities that would benefit from their use, including

patient engagement and empowerment, medical/clinical research, and provider access and use; and (4) the barriers and challenges associated with the implementation and maintenance of blockchain-based HIT.

The next stage of analysis was to further characterize the studies based on 4 categories that represent the issues that blockchain

technology addressed in each paper: security, privacy, interoperability, and health care outcomes. These categories were determined a priori based on prior research that identified these as major challenges experienced during HIT implementation and use [7-9]. As the analysis proceeded, additional subcategories emerged. We also merged data access, security, and privacy into a single category. At each stage of the review, the reviewers resolved all disagreements by discussion and reached a consensus. Further details can be found in [Multimedia Appendix 2](#).

In the next section, we report on the results of this analysis.

Results

How Blockchain Addresses HIT's Challenges

In this section, we examine the current HIT challenges that blockchain addresses.

Health care data have special properties. The content must be true and complete, and the data must be traceable and resistant to alteration, forgery, or deletion. Due to legal requirements to preserve patient privacy and secure protected health information, health care data must also be safe and anonymous when stored. Health care data contain sensitive personal information, and thus, prevention mechanisms must be established to prevent unauthorized staff from obtaining and extracting information. To facilitate medical or clinical research, health care data must be made accessible while hiding the identity of the patients to whom it belongs. In addition, the data should be encrypted so that once the data are stolen, they cannot be understood without decryption.

HIT faces challenges with respect to ensuring data security, privacy, and integrity. Sharing health care data is challenging because patient data are often stored in disparate systems and achieving interoperability presents challenges such as connecting heterogeneous systems securely, restricting access by unauthorized parties, and maintaining data integrity. Poor health care data quality adversely affects the quality of health care outcomes.

Prior research shows that blockchain can help to overcome the aforementioned challenges. We categorize this research into 3 groups to represent the main HIT challenges that blockchain can address: data security and privacy, interoperability, and health care quality outcomes ([Table 1](#)).

Most of the research reviewed focused on blockchain's use to strengthen HIT security or patients' privacy during health data exchange or access; 53% (37/70) papers focused on addressing patients' lack of control over the privacy and security of their data [10-46], and 40% (28/70) papers addressed blockchain's ability to prevent data tampering [10,12,21,25,33,34,37,38,40-44,46-60]. Data breaches were addressed in 37% (26/70) papers [15,18,19,22,24,29,31,32,34,36-38,43,44,54,56-66], 9% (6/70) papers mentioned malicious attacks (eg, impersonation) that blockchain could potentially resolve [17,34,44,56,60,67], and 4% (3/70) papers focused on how

blockchain can preserve patients' anonymity while third parties accessed their health and medical records for activities such as medical research [41,42,68].

The research studies also investigated how blockchain addresses HIT interoperability issues. Interoperability is the ability of different information systems, devices, and applications (*systems*) to access, exchange, integrate, and cooperatively use data in a coordinated manner, within and across organizational, regional, and national boundaries, to provide timely and seamless portability of information [69]. Given that HIT infrastructure might vary by hospital, department, and other structural divisions, HIT incompatibility may arise when data transfer is attempted across these systems, as in the case of HIE; 9% (6/70) papers evaluated blockchain's use for resolving the poor incompatibility of existing HIT [21,22,26,27,30,55], and 4% (3/70) papers focused on how blockchain can address the poor integration of large volumes of data from different sources [26,37,61]. One challenge to interoperability is the waiting time for data to be updated, affecting the temporal facet of interoperability and real-time access. The lack of real-time access in interoperable systems was discussed in 6% (4/70) papers [13,40,70,71]. The inconsistency of data structures across heterogeneous systems makes it difficult to ensure data integrity when data transfer is attempted across interoperable systems; 23% (16/70) papers indicated that blockchain could enhance data integrity across interoperable systems [16-18,33,35-37,40,41,44,49,64,66,72-74]. Furthermore, data transparency (which refers to the accessibility to data despite its location, data credibility, and data accuracy) across interoperable systems was discussed in 14% (10/70) papers [14,33,40,47,52,59,70,72,75,76].

The third category covers HIT's alignment with the health organizations' goals to achieve specific health care outcomes such as health care quality and system satisfaction; 10% (7/70) papers focused on addressing the inefficiency of current health systems, such as lengthy processing times and the inability to simultaneously process large data volumes [16,24,28,37,55,67,77]. With regard to the quality of patient care, quite often, missing or incorrect health data lead to repetitive lab tests or diagnostic errors, which can be detrimental to patients' health; 9% (6/70) papers discussed how blockchain can reduce misdiagnosis and overtreatment [27,32,35,40,78,79]. Data dredging may occur in clinical trials where researchers may alter or omit data to achieve a statistically significant result in their experiments; 4% (3/70) papers addressed data dredging [32,52,70]. Another issue is the lack of trust between stakeholders (patients, providers, and researchers) because of stakeholders' capability to modify and edit health data, which may lead to errors. A total of 4% (3/70) papers examined how blockchain could facilitate the immutability and traceability of health records updates [32,61,80]. The high cost of maintenance of the current health systems was mentioned in 3% (2/70) papers [37,73]. Blockchain technology could potentially reduce maintenance costs by increasing the efficiency and speed of health care data management.

Table 1. Health information technology challenges that blockchain addresses.

Challenge	Frequency (N=70), n
Data access, security, and privacy	
Patient lack of control over data	37
Data tampering	28
Data breaches	26
Other malicious attacks (eg, impersonation)	6
Nonanonymous access to records	3
Interoperability	
Lack of data integrity	16
Lack of data transparency	10
Poor compatibility with existing electronic health structures	6
Lack of real-time access to results	4
Poor integration of large volumes of data	3
Health care outcomes	
Low efficiency	7
Misdiagnosis/overtreatment	6
Data dredging	3
Lack of trust between stakeholders	4
High cost of maintenance and data management	2

In the next section, we discuss how blockchain addresses the current challenges surrounding data security and privacy, interoperability, and health care outcomes across a broad spectrum of health care applications and activities.

Blockchain HIT Applications and Health Care Activities Impacted

Table 2 illustrates the different types of blockchain HITs that researchers focused on. Blockchain HIT research focuses predominantly on improving medical information management systems (MIMS) such as EHRs, electronic medical records (EMRs), and PHRs.

Table 2. Blockchain health information technology applications.

Blockchain health information technology	Frequency (N=70), n
Medical information management system	36
Personal health records	7
Clinical trial or health research platform	6
Health information exchange	6
Remote patient monitoring	5
Mobile health	3
Medical image sharing platform	2
Telemedicine platform	2
Predictive or classification modelling	2
Pervasive social network	1
Data preservation systems	1

We analyzed the blockchain HIT research by the year of first mention (Figure 2). In 2016-2017, researchers worked on providing comprehensive and secure real-time access to patient data in HIT applications such as EHR, EMR, PHR, mobile health (mHealth), remote patient monitoring (RPM), pervasive

social networks (PSNs), and clinical trial systems. Research during this period focused on increasing data security and privacy and leveraging blockchain's unique properties of decentralization, immutability, anonymization, and transaction synchronization to provide a single view of patient data. In

2018, blockchain HIT research expanded to include improving health information management, exchange, and synchronization across decentralized nodes in telemedicine, medical image sharing, data preservation systems (DPSs), and HIE. In 2019, blockchain HIT research expanded to leveraging blockchain's decentralization properties to eliminate a single point of control

while carrying out predictive analytics and classification modeling across multiple institutions.

Blockchain HIT improves patient engagement and empowerment, research quality and processes, and provider's information access and use (Figure 3). We describe how blockchain can improve each of these areas in further detail in the next section.

Figure 2. Blockchain health information technology research evolution over time by date of first mention.

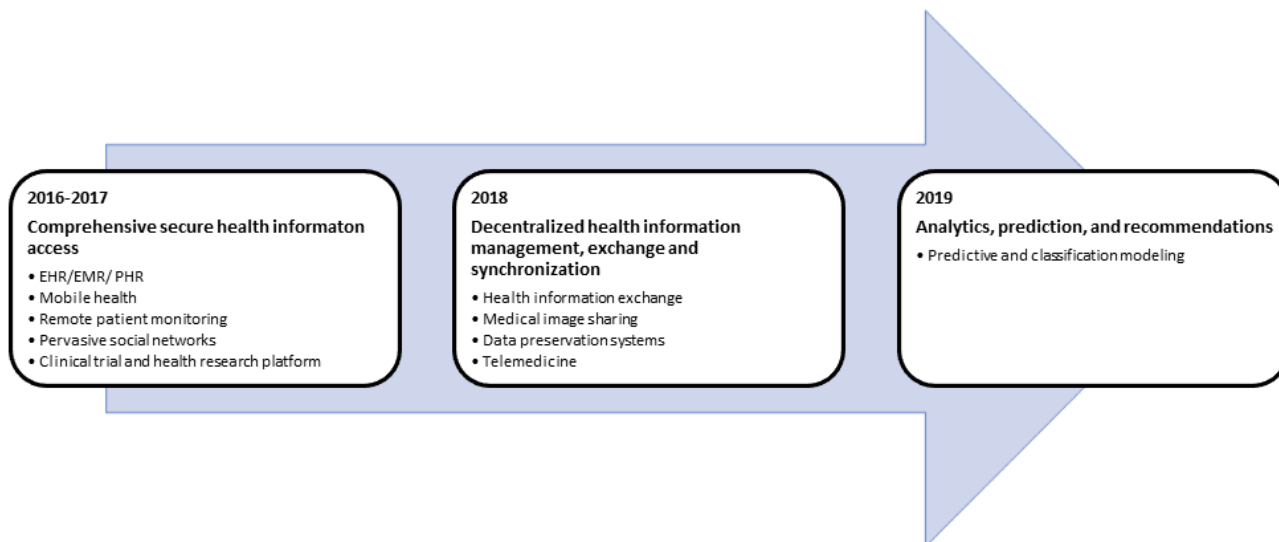

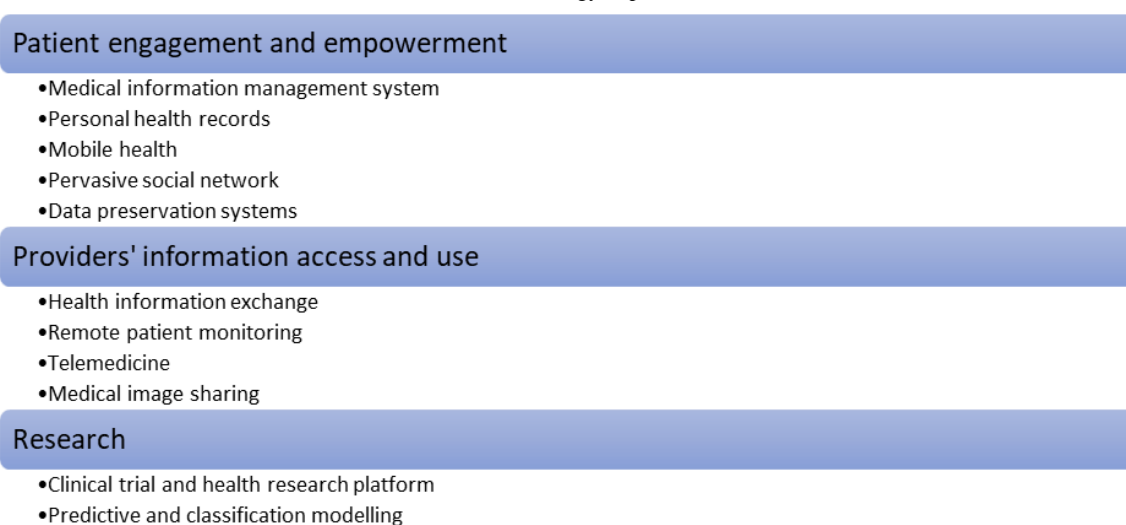

Figure 3. Health care activities that blockchain health information technology impacts.

Patient Engagement and Empowerment

We define patient engagement as the act of patient and provider working together to improve the patient's health [81]. Patient engagement may result in patient empowerment. Patient empowerment refers to a process through which patients gain greater control over decisions and actions that affect their health [82]. Patient engagement and empowerment promote shared decision making about the patient's care by both the providers and the patient and patient-centered care that is highly responsive to individual patients' preferences, needs, and values [83].

Patient engagement and empowerment may benefit from 6 types of blockchain HIT: MIMS, PHRs, mHealth, telemedicine, PSNs, and DPSs.

Medical Information Management Systems

MIMS refer to EHRs and EMRs, which store and manage patients' health information. The EHR is a computerized and standardized information model with information relevant to the health and wellness of an individual, enabling integration among multiple health care providers [30]. The EMR differs from the EHR as it focuses on the internal medical domain of health organizations and is not integrated between health care providers. Blockchain's use for EHRs, EMRs, and other record systems in which records are originated and controlled by

providers was discussed in 51% (36/70) papers [11,14-21,27,29,30,33,35-37,40,42-44,46,49,53,55,59,60,63,67,68,72-74,76-78,84]. Using blockchain to integrate various health record systems (EHR, EMR, PHR, etc), mHealth, and telemedicine platforms can contribute to patient empowerment and patient engagement by providing a synchronized view of patient information to patients and health care providers, to support patient decision making and control.

It is challenging to keep track of all data and ensure its immutability in the context of complex medical cases that require multiple diverse activities, patients' visits, and providers' treatments [17]. Blockchain-based MIMS facilitate the creation of immutable records with traceable transactions that cannot be changed over time. Blockchain can provide patients and providers with more secure and private access to the data and allow them to better collaborate in complex medical situations.

Blockchain technology facilitates smart contracts, which is a computer protocol intended to digitally facilitate, verify, or enforce the negotiation or performance of a contract between two parties without a third party's involvement. Smart contracts can facilitate formalized contracts to streamline patient consent for treatment, patient authorization for access to and release of PHI, and the authentication and verification of those seeking access to patient data. Patient privacy is also enhanced as blockchain can allow patients to authorize access to their records while remaining anonymous, for example, for research purposes. Patients can also publish medical information to the blockchain anonymously, which is also useful for sharing information with third parties and for research purposes. Blockchain's properties, including its cryptographic techniques and immutability and autonomy, enhance user authentication and verification, access control, and HIT security and privacy [18].

In the health care sector, the resilience of health records systems in medical information systems is crucial, given the increasing number of data breaches in health care [85]. Blockchain's distributed design is more resistant to malicious attacks, as there is no single point of control or failure. Overall, such increased security and privacy may motivate patients to engage in full disclosure of their condition and contribute to patient empowerment by facilitating better provider feedback, counseling, and patient decision making.

PHRs

PHR refer to the representation of information regarding an individual's health, including wellness, development, and welfare, which the patient owns and can share with third parties [30]. PHR is oriented to the patient but can be integrated with the EHR. Blockchain's use for PHR was discussed in 10% (7/70) papers [13,23,25,26,30,64,78]. PHR's main challenges include poor interoperability with other systems, large data volumes, outdated data, duplication, lack of standardization, and fragmentation. Due to its distributed design, a permissioned blockchain is well positioned to address these challenges by providing a distributed ledger where transactions can be recorded by multiple, authenticated parties. Due to its decentralized design, blockchain-based PHR can provide patients with a unified view of their scattered health records by interconnecting scattered patient data across several health care

organizations. Furthermore, as the PHR is updated with the patient's medical conditions and services received, health providers can become aware of changes in their patients' conditions and alter and modify treatment plans, even though updates may occur elsewhere. These features can improve the communication effectiveness between a provider and a patient, providing the patient with the information needed to take charge of their health care decision making. In terms of patient engagement and empowerment, blockchain-based PHR can provide patients with control over their health data and facilitate providers' real-time updates of patient data.

mHealth and Telemedicine

mHealth, telemedicine platforms, DPSs, and PSNs can also contribute to patient engagement and empowerment. A total of 4% (3/70) papers focusing on mHealth indicated that blockchain's distributed design can prevent data tampering and provide a single point of control [22,31,51]. Data tampering may occur during a malicious attack and lead to a loss of data reliability within the mHealth application [51]. Tamperproof systems are critical in scenarios where treatment is automatically administered to patients without human intervention, based on the data the mHealth application collected. Tamperproof systems are also essential to ensure that medical decision making is based on accurate information to prevent harm to patients. Blockchain enables tamper-resistant systems by maintaining a constantly growing list of transactional records divided into blocks and uses consensus algorithms to allow multiple parties to agree on a common state. Due to its distributed design, blockchain is well suited to mHealth applications as it allows for frequent updates.

A total of 3% (2/70) papers [48,71] mentioned blockchain-based tele-dermatology and other telecare platforms. Blockchain enhances telemedicine platforms by (1) anonymizing patients' information and access; (2) decentralizing control and allowing patients to manage their data and consultations independently; (3) providing a secure global EHR to share and exchange data for research, teaching, or clinical work; (4) limiting health care fraud by using smart contracts to automate invoice processing; (5) eliminating mediators and reducing administrative costs; and (6) fundraising through ICOs (eg, DocCoin, PointNurse, and Medical Chain). In the case of DermaNet, the tele-dermatology platform, blockchain shortens the virtual distance between patients and providers by efficiently sharing information about changes in dermatological disease, improving quality of care, and allowing actors to trust each other [44]. Building trust between health care providers and patients supports patient engagement and empowerment.

DPSs and PSNs

DPSs notarize *data to provide legal evidence for medical disputes and medical negligence* [58]; 1% (1/70) of papers addressed how blockchain can enhance DPSs [58].

Current DPSs may be unreliable as persons can tamper with the data, reducing the accuracy of patient information. If a third-party notarized company is contracted to provide preservation services, personal information may be leaked, and it is difficult to guarantee the reliability and availability of DPSs [66].

Blockchain provides an immutable, distributed transaction ledger that reduces the abovementioned challenges associated with DPSs. Blockchain-based DPSs provide a reliable and secure data storage solution that prevents data tampering and allows transactions to be synchronized. Decentralization makes the DPS more secure, as attackers are not able to attack all nodes simultaneously. Information security and data integrity are strengthened as blockchain's synchronization and consensus algorithms ensure that all copies of the data are the same at every node. The DPS is capable of storing patient data anonymously, thus preserving patient privacy in the event of tampering or breach.

A total of 1% (1/70) of papers focused on the creation of a secure system for PSN-based health care systems [54]. PSN-based health care systems enable users to share health data that medical sensors collect, for disease monitoring and control and remote medical care. Due to its distributed design, blockchain reinforces the synchronization of transactions and operations in such systems, increasing health information's security, reliability, and accuracy. These features contribute to patients' confidence in the security and privacy of their data and promote health care engagement and empowerment.

Health Care Provider's Health Information Access and Use

HIEs, RPM Systems, and Medical Image Sharing Platforms

Blockchain-based HITs such as HIE, RPM systems that leverage Internet of Things (IoT) technologies, and medical image sharing systems provide benefits to health care providers by improving health information access and use.

HIE refers to the process of electronic transfer of patient health information and medical data among health care providers and institutions so as to provide health care providers with better information for diagnosis and patient treatment. The potential benefits of HIE include decreasing rates of patient readmission, avoiding medication errors, improving diagnoses, and decreasing duplicate testing [20]. However, HIE systems suffer from challenges such as threats to patient privacy, information security threats and vulnerabilities, poor integration of disparate data sources, and dependency on centralized data storage [16]. Furthermore, most HIE are designed for health care providers, and patients cannot access their data in the HIE when they visit hospitals outside their home systems; 9% (6/70) papers discussed how blockchain could improve HIE systems to facilitate the sharing of health records between providers, patients, and hospitals [16,32,39,50,57,79]. These papers suggest that blockchain's features of decentralized transaction validation, data provenance insurance, data sharing, and data integration may resolve HIE's challenges. For example, as blockchain technology utilizes distributed databases to store all transactions, it is possible to design a permissioned blockchain system to connect multiple EHR databases from different clinical sites to perform information exchange [20]. The private chain allows only authorized users to join the system, and smart contracts regulate all transactions. These blockchain-enabled smart contracts ensure data provenance and immutability, decentralization, restricted access to and anonymity of patients' records, and other benefits.

RPM enables health care providers to use sensor data to monitor patients outside of the clinical setting [12,41,62,66,75]; 7% (5/70) papers explored the use of blockchain in RPM systems. As the RPM realm expands, concerns about efficient and secure transmission of medical data arise as data come from different sensors, are a lucrative target for hackers, and must conform to health care data security and privacy regulations. Furthermore, patient treatment events initiated by IoT must be securely logged to show the patient's treatment and a record of who permitted it, to protect the integrity of the patient's care and maintain an accurate timeline of events.

These papers proposed the design of blockchain-based IoT technology to build a network architecture to better manage data from remote sensors to address these challenges. For example, smart contracts could support real-time patient monitoring and medical interventions by sending notifications to patients and medical practitioners while maintaining a secure record of who initiated these activities [77]. Blockchain-based IoT systems could also allow patients to maintain anonymity, create a permanent digital trace of patients' health records, and prevent a single point of control or failure through a highly decentralized system structure. These features would allow providers to securely access their patients' data and better control their patients' conditions.

A total of 3% (2/70) of papers focused on the development of blockchain-based cross-domain medical image sharing platforms [24,65]. In the past, digital images between providers were predominantly shared through a physical copy (eg, a CD) [24]. To address issues associated with digital image transfer, the Radiological Society of North America developed the Image Sharing Network that allows digital image transfer through a third-party clearinghouse. This raised new concerns regarding data storage centralization and intermediaries' involvement in the medical image exchange process [24]. Blockchain solves these concerns by decentralizing the entire system by removing the need for a central intermediary, creating immutable records that ease communication between providers, and eliminating third-party access to protected health information. This approach satisfies many criteria of an interoperable health system and is generalizable to other contexts [56].

Health Care Research

Clinical Trial Management and Health Care Research

When conducting medical research, data records are usually widely accessible, but the patients to whom they refer are anonymous [84]. Blockchain improves health care research practices and supports patient data anonymization during the research process through sophisticated cryptographic techniques. A total of 9% (6/70) of papers focused on creating blockchain-based systems capable of improving clinical trial management and enhancing patients' trust in health care research, impacting activities such as collecting, storing, and tracking patients' informed consent; improving data integrity; and sharing clinical data between providers [10,16,52,61,70,80]. This is particularly relevant to clinical investigator-related deficiencies, as the US Food and Drug Administration reports that about 10% of clinical trials suffer from consent collection issues such as unapproved forms and outdated consent

documents [10]. In BlockTrial [52], consent algorithms in the blockchain system can enable clinical research stakeholders to share and update patient consent forms and retrieve relevant data. In addition, the system can empower patients to become more active and fully informed research partners [52]. Blockchain can also ensure data accuracy in clinical trials without confirmation by a third-party contract research agency, thus reducing the cost of clinical trials [63].

In the health care analytics domain, blockchain was used in privacy-preserving predictive modeling [47] and a cloud-based health resource-sharing model used for breast tumor diagnosis [79]. In the case of blockchain-based privacy-preserving modeling, the removal of the *server* role eliminated a single point of control [47]. This single point of control poses various security risks, as multiple institutions that want to create a generalizable model on health or genomic data would have to rely on a single party.

Blockchain HIT Implementation Challenges

As shown in Table 3, despite blockchain's multiple advantages for health care use, studies indicated various downsides. These limitations point to open areas for research; 16% (11/70) papers revealed that blockchain technologies have the capability of enhancing security and privacy, yet have security and privacy vulnerabilities and weak access control mechanisms [23,24,32-34,41,57,58,70,75,79]. For example, blockchain-based structural health monitoring systems do not have mechanisms to guarantee the security of the data placed on the blockchain, although it is expected that the blockchain would enhance the security of the overall system [75]. Furthermore, research has shown that although it is almost impossible to alter and modify blockchain records in an EMR system, it is possible to tamper with and hack smart contracts [40].

Researchers have discussed high computing power and implementation costs in 16% (11/70) papers [12,23,25,29,47,48,52,57,61,76,79]. Prior research shows that blockchain-based EHRs consume significant computational power and take a large amount of time to execute tasks [29]. Blockchain-based clinical trial platforms that utilize Ethereum blockchain technology are also costly [52].

Researchers raised concerns about lengthy response and transaction processing times in 7% (5/70) papers [12,32,36,41,57]. For example, blockchain RPM systems rely on sensor-based data that must be accumulated, acted upon, and added to the blockchain, potentially introducing delays [41].

The potential resistance to blockchain adoption by patients and providers was raised in 7% (5/70) papers [11,24,32,48,70]. Public perceptions of blockchain technology might stand in the way of the successful implementation of blockchain-based EHRs because of blockchain's nascency and association with the negative use of blockchain-based technology such as cryptocurrencies within black markets [11].

Although researchers have indicated that blockchain-based electronic health (eHealth) structures may resolve the incompatibility of existing eHealth structures [21,22,26,27,30,55], new blockchain health systems may be incompatible with health care legacy systems [13,48,52,61,76]. Therefore, more research is needed to investigate approaches to address the interoperability between legacy and blockchain systems.

A total of 6% (4/70) of papers pointed out issues associated with blockchain's consensus algorithms [33,36,51,75]. For example, in small networks with a limited number of peers, the Practical Byzantine Fault Tolerance algorithm, which is designed to prevent catastrophic system failures due to malicious nodes, can be disabled if more than a third of the peers are offline at the same time. Therefore, it is important to increase the number of peers to prevent malicious peers from occupying the entire system.

Linking participants to their digital identity is a predominant concern [10,13,25]. Guaranteeing the blockchain informant's identity and authenticity is not foolproof, whether the informant is a patient, physician, or a sensor connected to a patient. Although blockchain technology helps prevent data block fraud, it is challenging to ensure that only authentic informants can access the health records and to prevent attacks on the blockchain [55]. Although blockchain demonstrates the potential to preserve the privacy of patients, further testing for security, privacy, and user authentication is needed.

Another constraint is data storage limitations, as discussed in 4% (3/70) studies [23,25,60]. Stakeholders are constrained by the amount of data that they can store in the blockchain. Furthermore, legislation such as Article 17 Right to Erasure, in Europe's General Data Protection Regulation (GDPR), gives citizens the right to request the modification and deletion of personal data, which is difficult, given the permanency of data recorded on the blockchain [19].

Table 3. Blockchain health information technology barriers and challenges.

Barrier or challenge	Frequency (N=70), n
No guarantee of security or privacy	11
Computing power and implementation costs	11
Users' resistance to a new technology	5
Long response time	5
Integration of existing electronic health structures into blockchain	5
Issues (eg, lack of efficiency) associated with consensus algorithms	4
Linking participants to their digital identity	3
Data storage limitation	3
Not mentioned	44

Discussion

Principal Findings

We presented the current state of research on blockchain technologies in patient care. We identified 3 main categories of research: data privacy and security, interoperability, and health care outcomes. We highlighted the health care applications that leverage blockchain technology. These health care applications include MIMS (EHR and EMR), PHRs, mHealth and telemedicine, DPSs and social networks, HIEs, remote monitoring systems, and medical research systems. These applications may improve patient engagement and empowerment, improve health care providers' access to information, and enhance health care information use for medical research. However, several challenges and implementation barriers exist, such as security and privacy vulnerabilities, user resistance, high computational power and implementation costs, inefficient consensus algorithms, and challenges integrating blockchain with existing HIT. Despite blockchain's disruptive potential, it is important that blockchain's limitations are further examined and understood and available alternatives considered before embarking upon any large-scale blockchain implementation.

Future Directions

Following are some of the challenges that have received the least attention in the literature. Therefore, researchers should focus on investigating the following research questions.

1. How can blockchain's interoperability and compatibility with existing HIT infrastructures be improved?
2. How can blockchain's storage limitations be addressed?
3. How can blockchain adoption be promoted?
4. What blockchain HIT research should be pursued to disrupt health care?

Improving Blockchain's Interoperability and Compatibility With Existing HIT Infrastructure

Organizations need to understand how to connect their HIT blockchain to compatible blockchains, noncompatible blockchains, or nonblockchain platforms. Research should focus on ascertaining effective integration governance models and new interoperability and data standards and exploring

performance optimization approaches. Researchers should also explore the feasibility of integration approaches for health care systems, such as cross-authentication (for compatible blockchains), oracles (which transfer external data to the blockchain for on-chain use), or application programming interfaces (for incompatible blockchains). The feasibility of translators that use open standards such as Health Level 7 and Fast Healthcare Interoperability Resources and *open* EHR or an equivalent ontology to connect proprietary systems to blockchain HIT is an open area of research [13]. Blockchain silos that different stakeholders create present complexity and interoperability challenges that should be investigated. An understanding of the legal and regulatory implications of blockchain interoperability is needed, as security and privacy concerns are pertinent issues.

Addressing Blockchain Storage Limitations

HIT researchers are becoming aware of the technical limitations regarding data storage on the blockchain, and researchers are beginning to explore alternative approaches to conform with the GDPR. Recommendations include recording metadata such as addresses, hash values, and time stamps on the blockchain while storing PHI off-chain elsewhere, such as in the cloud or on hospital servers [23]. However, splitting data storage may degrade system performance. Future research should determine feasible ways to optimize the cost, performance, and efficiency of implementations that split data storage on and off the blockchain.

Promoting Adoption of Blockchain

The public's negative perception of blockchain applications, such as cryptocurrencies, contributes to user resistance [11]. Lessons learned from the financial technology domain show that users are motivated to adopt cryptocurrencies when these applications are aligned with users' value systems [86]. To support this perspective, nascent HIT research shows that patients hold a favorable attitude toward the implementation of blockchain-based HIE mechanisms for privacy protection, coordination, and information exchange purposes [32]. User resistance may also arise because stakeholders do not understand blockchain technology. Researchers can explore how industry consortia of influential health care players working together to educate stakeholders and illustrate proof of concept may increase network effects and spur adoption. Further research could also

explore what incentivizes stakeholders to work together to adopt blockchain and to find common solutions. The role of the blockchain HIT startup ecosystem in stimulating user adoption is also a relevant area of research. Researchers can also explore how to lift adoption barriers presented by legal and regulatory constraints caused by legislation such as the Health Insurance Portability and Accountability Act of 1996 (HIPAA) and the GDPR, which did not contemplate the unique ways in which blockchain technology handles data privacy and security. Considerations of what should be stored on and off chains are important for HIPAA and GDPR compliance and adoption.

Pursuing Research Opportunities for Disruption of Health Care

HIT researchers are currently focused on improving health care applications, but there is room for researchers to explore blockchain HIT's disruptive potential. Most HIT research has focused on the use of smart contracts in HIT applications. It is worth noting that smart contracts are the building blocks of decentralized autonomous organizations (DAOs) and decentralized applications and services (D-APPs). DAOs and D-APPs have the potential to facilitate novel DAOs to disrupt patient care in areas such as organ and blood donations, electronic prescriptions, laboratories, and other diagnostic services.

Limitations

This review did not focus on the use of blockchain in the health industry outside of patient care, such as in the health insurance marketplace, pharmaceutical industry supply chain, or the health care provider credentialing process where blockchain is being proposed to reinvent these industries. The COVID-19 pandemic has exposed many high-value use cases where blockchain-enabled technology could address evolving societal needs and support accelerated responses to disruptions, such as supply chain management to connect health care organizations to trusted sources for necessary medical supplies, tracking and monitoring drugs' origin and journey from pharmacy to patient administration, and verifying credentials of clinicians and health care professionals volunteering at hospitals to alleviate workforce demands. A further review could explore blockchain research in these areas as part of the pandemic response.

Comparison With Prior Work

Prior reviews included conceptual papers, industry reports, and empirical research and primarily focused on identifying use cases and associated challenges [1-3,6,87-89]. To ascertain the

current state of research, this review only focused on empirical research on the use of blockchain for patient care. Prior reviews included studies up to 2018 [1-3,6,87-89]. In this review, 58 of the 70 included empirical research studies were published in 2018 and 2019. We further distinguish this review by describing how blockchain HIT research focused on patient care evolved over time, from 2016 to 2019.

We build upon a systematic review of the blockchain HIT literature up to 2018 conducted by Agbo et al [6], which differs in its focus, inclusion criteria, results, and research agenda. Specifically, Agbo et al [6] identified 4 blockchain applications used for patient care: EMRs (which we expanded to include EHRs and PHRs); research; RPM; and health analytics, which we further broke down into predictive analytics and classification modeling. This review updates the blockchain HIT applications reported in the study by Agbo et al [6] by identifying 5 additional discrete categories of blockchain HIT research focused on patient care: HIEs, medical image sharing, mHealth and telemedicine, PSNs, and DPSs. Agbo et al [6] identified 5 challenges when implementing blockchain HIT applications: interoperability, security and privacy, scalability, speed, and patient engagement. Challenges found in our review but not included in the study by Agbo et al [6] included computing power and implementation costs, user resistance during implementation, consensus algorithm inefficiencies, difficulties in linking patients to their digital identity, and data storage limitations. To validate our search terms, we performed an alternative search of the literature using the search terms provided by Agbo et al [6]. However, the search terms we developed provided more relevant results for our purposes than the search terms by Agbo et al [6].

Conclusions

We have presented the current state of research on the use of blockchain technologies with a focus on patient care. Although blockchain presents significant potential for disrupting health care, most ideas are in their infancy. With 51% of the research focused on medical information systems such as EHR and EMR and 53% of the research focused on data security and privacy issues, this review shows that HIT research is primarily focused on the use of blockchain technologies to address the current challenges HIT faces. Future research can focus on how blockchain can disrupt patient care and help overcome the challenges in health care delivery post-COVID-19 by creating new decentralized organizations, applications, and services.

Abstract

Background: Lebanon currently hosts around one million Syrian refugees. There has been an increasing interest in integrating eHealth and mHealth technologies into the provision of primary health care to refugees and Lebanese citizens.

Objective: We aimed to gain a deeper understanding of the potential for technology integration in primary health care provision in the context of the protracted Syrian refugee crisis in Lebanon.

Methods: A total of 17 face-to-face semistructured interviews were conducted with key informants (n=8) and health care providers (n=9) involved in the provision of health care to the Syrian refugee population in Lebanon. Interviews were audio recorded and directly translated and transcribed from Arabic to English. Thematic analysis was conducted.

Results: Study participants indicated that varying resources, primarily time and the availability of technologies at primary health care centers, were the main challenges for integrating technologies for the provision of health care services for refugees. This challenge is compounded by refugees being viewed by participants as a mobile population thus making primary health care centers less willing to invest in refugee health technologies. Lastly, participant views regarding the health and technology literacies of refugees varied and that was considered to be a challenge that needs to be addressed for the successful integration of refugee health technologies.

Conclusions: Our findings indicate that in the context of integrating technology into the provision of health care for refugees in a low or middle income country such as Lebanon, some barriers for technology integration related to the availability of resources are similar to those found elsewhere. However, we identified participant views of refugees' health and technology literacies to be a challenge specific to the context of this refugee crisis. These challenges need to be addressed when considering refugee health technologies. This could be done by increasing the visibility of refugee capabilities and configuring refugee health technologies so that they may create spaces in which refugees are empowered within the health care system and can work toward debunking the views discovered in this study.

KEYWORDS

Syrian refugees; Lebanon; health technologies; eHealth; mHealth; primary health care

Introduction

Lebanon currently hosts around one million Syrian refugees [1]. This influx of refugees has resulted in a 30% increase in the country's total population size, placing a burden on the Lebanese health care system [2]. However, despite political and social turmoil and a shortage in international financing and support in addressing the refugee crisis, the Lebanese health care system has proven to be resilient through coordinating efforts of various stakeholders (international and local) and maintaining a diverse health system while strengthening infrastructure and health and human resources [3]. As a result, refugee health care provision has been integrated into the Lebanese health care system with primary health care centers (PHCs) as the first point of entry into the health care system [3].

Technology that facilitates the transmission of health-related information (eHealth) [4] has been considered by the World Health Organization to be an effective tool that improves equity and quality of health care provision while reducing costs [5]. As such, it is argued that eHealth is an enabler of achieving universal health coverage, which is part of the agenda of meeting Sustainable Development Goal 3 to “ensure healthy lives and promote well-being for all at all ages” [5]. More specific to the context of refugees, eHealth has been found to aid in the monitoring and evaluation of refugee health statuses during times of protracted crises [6].

The increasing ubiquity of technologies among refugee communities has created a space in which refugee communities may engage with aid services through technologies [7]. Interviews with over 100 Syrian refugees in Lebanon found that most interviewees have access to a cell phone, of which 40% had smartphones [8]. A study with Syrian refugees in Lebanon [9] identified that refugees in informal tented settlements in rural Lebanon have access to at least one smartphone per household and access the internet through a Wi-Fi network set up in the settlement. Furthermore, Talhouk et al [9], through a series of focus groups, found that Syrian refugees in rural Lebanon are highly motivated to use smartphones as a means of communicating with health care providers and accessing health services provided by PHCs.

Several projects in Lebanon have begun integrating eHealth and mHealth, a category of eHealth technologies that use mobile phones for health services [10], to strengthen PHCs and improve the delivery of health care services to Syrian and Palestinian refugees as well as to Lebanese citizens. One initiative aimed to improve quality of care delivered by providing health care providers with electronic learning materials allowing for peer-to-peer exchanges through online forums [11,12]. An mHealth app for refugees was also piloted with clinicians in PHCs in Lebanon as a means of improving the provision of services to refugees suffering from chronic diseases and was shown to improve a number of quality of care indicators [13]. It is important to note that the mHealth tool used patient's cell

phone number as an identifier in order to ensure that clinicians can access patient medical records if patients change locations [13].

Saleh et al [14] conducted a randomized controlled trial (RCT) with PHCs in rural Lebanon and in Palestinian refugee camps in which short message service (SMS) messages communicating medical information, importance of compliance, and appointment reminders were sent to participants in the intervention group and were shown to significantly improve blood pressure control and hemoglobin A_{1C} levels used for the diagnosis and monitoring of diabetes. However, this RCT also indicated that SMS had no significant impact on patients' use of primary health care services [14]. Also in collaboration with PHCs in rural Lebanon and Palestinian refugee camps, a netbook application was piloted as an eHealth tool to support community health workers in screening community members for diabetes and hypertension and subsequently referring them to primary health care clinics [4]. The study highlighted the ability of eHealth community-based interventions to identify new cases of diabetes and hypertension and refer them to the appropriate health services [4].

Low levels of agency in the Syrian refugee population in Lebanon and their low level of access and use of antenatal care services has also been the subject of mHealth interventions. Talhouk et al [15] piloted community health radio shows through mobile calls that delivered health information and responded to refugees' reproductive health questions. These interactions around reproductive health led to an increase in refugee agency and trust within patient-provider relationships [15]. A quantitative study conducted with primary health care providers across 22 PHCs in Lebanon showed high health care provider readiness to adopt eHealth and encouraged the Lebanese Ministry of Public Health (MoPH) and policy makers to enhance and scale up eHealth initiatives within the primary health care system [18]. Additionally, based on their success in piloting eHealth and mHealth technologies in PHCs run by the MoPH and the United Nations Relief and Works Agency for Palestine Refugees in the Near East [4,14], the authors called for the scaling up of mHealth and eHealth interventions to the wider PHC network in Lebanon (ie, PHCs funded and managed by other health care organizations).

While research has been conducted on eHealth systems for refugees in Lebanon, no study provides a qualitative perspective that engages with multiple stakeholders on the potential of implementing eHealth for Syrian refugees in Lebanon with the aim of meeting SDG3. Indeed, the existing studies to date do not explore the added considerations needed to integrate eHealth technologies into primary health care services specifically for refugees. We present a qualitative study to gain a deeper understanding of the potential for technology integration in the provision of primary health care in the context of the protracted Syrian refugee crisis in Lebanon. We use reproductive and maternal health care as an entry point as this research is part of a wider project on technologies for refugee women's health.

The findings from interviews with participants highlighted factors that need to be considered when implementing eHealth projects, such as (1) varying resources available at PHCs, (2) mobility of refugee populations, and (3) varying views of refugee technology and health literacies. In our discussion, we provide practical and theoretical implications for integrating eHealth technologies for refugee health care that include countering views regarding refugee health and technology literacies.

Methods

Data Collection

We recruited key informants and health care providers involved in the provision of reproductive and maternal health services to refugees. Participants spanned the humanitarian health response system both vertically (from policy makers to clinical staff) and horizontally (participants from multiple organizations). Key informants were identified from meeting minutes published on the United Nations High Commissioner for Refugees Regional Refugee Response Interagency portal for Lebanon

[1]. Potential participants were approached via email, and a convenience sample was drawn based on responses (response rate: 80%). Three PHCs catering to large numbers of Syrian refugees were purposively selected. The PHCs were situated in the West Bekaa region of Lebanon, and the centers varied in terms of management and affiliation with the MoPH primary health care network. Participants consisted of a convenience sample of health care providers available at the PHCs on the days of the research visit (response rate: 100%). Recruitment was completed once data saturation was met.

A total of 17 face-to-face semistructured interviews lasting around an hour each were conducted with key informants ($n=8$) and health care providers ($n=9$) involved in the provision of health care to the refugee population (Table 1).

Data were collected between January and March 2015. Ethical approval was obtained from the institutional review board of the American University of Beirut and Newcastle University's ethics committee. All interviews were conducted in Arabic by local coauthors with a background in health system management and policy at the workplace of interviewees.

Table 1. Description of study participants detailing the gender and role of participants within the humanitarian health system. Participant code presented is used in the reporting of results.

Participants	Number	Gender	Participant code
Key informant			
Public sector employees	2	Male (1), female (1)	Key informant 1,2
Health center directors	2	Male (2)	Key informant 3,4
Academics	2	Male (1), female (1)	Key informant 5,6
Nongovernmental employees	2	Female (2)	Key informant 7,8
Health care provider			
Nurses	5	Male (2), female (3)	Nurse 1-5
Medical doctors	2	Male (2)	Doctor 1,2
Social workers	2	Female (2)	Social worker 1,2

Key Informant Interviews

Key informant interviews were conducted with PHC directors, nongovernmental organization employees, public sector employees, and academics working on eHealth within the Lebanese health care system. It is important to note that both PHC directors were also physicians. We probed on the current technologies being used, participant views on technology use, possible future use of technology, and willingness of their organizations to support the use of technology. This involved ascertaining equipment availability and organizational technological literacy. Interviewees were then asked to brainstorm about possible technologies that may be useful and the feasibility of these technologies within their current context.

Health Care Provider Interviews

Nurses, doctors, and social workers constituted this subset of study participants. In these interviews, questions focused on the day-to-day processes and challenges of health service provision to Syrian refugees and the interactions between health care providers and Syrian refugees. Interactions explored included

those within the PHC, those within the community, and those conducted through technology. We also explored the ways in which health care providers are currently using technology, both formally and informally, and their comfort and willingness to use different forms of technology for refugee health care provision.

Data Analysis

Simultaneous translation, from Arabic to English, and transcription of the audio-recorded interviews was undertaken. Thematic analysis was conducted using NVivo 10 (QSR International) by two of the coauthors [16]. Codes were then grouped into themes and validated by a third coauthor. Data collection was concluded once data saturation was met and no new themes were emerging from the (data) interviews.

Results

Findings

Our analysis identified differences in levels of resources available across PHCs to be a key factor that needs to be

considered when integrating and scaling a health technology within the primary health care system. Additionally, the mobility of refugee communities was found to be a disincentive consideration for the integration of technologies specifically for refugee reproductive health. Lastly participants recounted experiences of engaging with refugees in which they identified varying views regarding refugee technology and health literacies. Such views are key considerations that should be accounted for when designing technologies that specifically connect refugees to the health care system.

Varying Resources Available at Primary Health Care Centers

A key consideration that needs to be accounted for when considering integrating and scaling up technologies within the refugee health care response system is the shortage in human resources as reported by key informant 2.

...they [center staff] might tell you we want to invest in more staff than in smartphones because we have a shortage in staff. [Key informant 2]

In only one out of the three health centers visited by the research team did participants not identify shortages in staff and equipment as issues. Staff shortage was compounded by the increase in patient load due to the influx of Syrian refugees, resulting in nurses having to take work home with them.

[Since the refugee crisis began] in a short time my working hours increased [by] 6 hours, which then doubled and tripled. [Nurse 3]

High patient load led to time constraints that discouraged the use of available health information systems (HISs).

We do not always have the time [to use the HIS]. We do a hundred things at the same time. [Nurse 2]

Limited equipment available was also indicated to be a barrier to the use of existing technologies in PHCs.

We both are using one laptop...when she is working on the laptop, I cannot work on it... I have to enter 400 files and I'm 6 days behind... The time she [my colleague] spends on the laptop is time lost from my work. [Nurse 3]

The main issue is [we need] to have more computers. All the work is being assigned to me [because there is one laptop] and I have to take the work home sometimes when this is not necessary. [Nurse 1]

Interviews conducted at the PHC, which had an advanced HIS and was well resourced, revealed that shortage of resources was not a barrier for the integration of technology. The varying resources available at the different PHCs were attributed to the diversity of stakeholders involved in the health care provision of refugee reproductive health services. While some of the PHCs were part of the MoPH's primary health care network, others were not.

The current process is that we are working with MoPH but not all primary health care centers are within the network. Not all PHCs are supported by the MoPH. [Key informant 2]

This resulted in varying levels of support regarding the health center management and funding received as well as the use of varying eHealth systems. Interviewees reported that while several health centers were in the process of transitioning at the time of data collection to the use of a new HIS designed and supplied by the MoPH, other health centers were not as they have their own systems. In fact, the MoPH was reported to be incentivizing PHCs to adopt health information technologies by adding them to their accreditation standards and making HIS integration a key compliance criterion for MoPH contracting.

[Implementation of] the information system is a main criterion of the [MoPH] contract with PHCs. The centers can use their own system or the MoPH's. [Key informant 2]

However, both the contracts and accreditation are not extended to PHCs outside the MoPH primary health care network. The MoPH is also encouraging the use of HIS by providing training for health care providers on the system that they have developed. An interviewee indicated that continuous training is needed due to the high staff turnover at the PHCs.

Training sessions are continuously held centrally with follow-ups at PHCs [Key informant 2]

Academics working on an eHealth project in Lebanon stated that they were collaborating with health centers managed by one stakeholder to overcome the variations in human and technological resources available among multiple stakeholders.

Mobility of Refugee Populations as a Disincentive to Investing in Refugee Health Technologies

The use of technology specifically for refugee populations was discouraged by participants when they considered refugees' unstable political and physical environments.

We are facing a difficulty in this [using mobile technology] actually. They might have a phone but are afraid of giving [their number]. For [security] reasons they don't give you the real number. [Doctor 2]

Now regarding maintaining it [the technology], it might be low because they may go from one place to another or go back to Syria or change the location of the tents. You know things are happening, like a fire in a tent or the flooding of a tent. Forces of nature are impacting them a lot so they are [moving] quickly. [Social worker 1]

Pilot eHealth interventions have excluded Syrian refugees due to their mobility.

Because they are a mobile population. For ethical reasons if a community health worker encounters Syrian refugees, they will be screened [for chronic diseases] but not included in our database. [Key informant 6]

A PHC director attributed his hesitance in investing in using a technological system to improve the provision of health care for refugees to the high mobility of the community and their unstable presence in Lebanon.

So let us say we make something advanced and then they leave; everything we have done would be lost.
[Key informant 3]

Varying Views of Refugee Technology and Health Literacies

Participants recounted experiences of engaging with refugees that resulted in varying views regarding refugee technology and health literacies. Participants highlighted that the low level of education among refugees limits their ability to use technologies as well as actively engage with the health care system. This notion was disputed by two participants who indicated that refugee women they are encountering are highly educated and highly concerned with their health and that incentivization may support refugees in engaging with health technologies.

Experiences of Technology Literacy of Refugees

All participants except two questioned the ability of Syrian refugees, who were reported to be of lower technology literacies and not capable of engaging through digital technologies with service providers.

You don't want to forget that they are of low educational status with all my respect for them. They [Syrians] have educated people but the pregnant women and the refugees...are of a low educational status... They would not know how to [create a voice] record as there is a lot of ignorance. [Nurse 5]

A participant, a social worker who visits refugee settlements, contradicted this view and stated that technological interventions would be feasible given the high education among a large proportion of female refugees.

There are very few ignorant women. Did you know that most of the women in camps have finished their college education? [Social worker 1]

Experiences of Health Literacy of Refugees

Although participants reported that many Syrian refugees attended health centers to address their health concerns, they indicated that there was a lack of motivation among the refugee community to engage with ways that facilitated access and provision of health care. Participants used Syrian refugees' lack of maintenance of medical papers and documentation as an analogy to refugees' inability to maintain technologies. When brainstorming the feasibility of using a technology that embeds audio recording hardware into a health education book/health journal, several participants stated:

They don't maintain a paper, I don't think they would maintain a file. [Nurse 4]

They barely maintain their ID; they bring it torn. Even the vaccination record they bring it ripped apart.
[Key informant 1]

Another participant indicated that refugees are health literate however incentives are needed to support them in adopting and participating in any technology that connects them to health care providers.

You should tell them...if you take care of it [the technology], you will be compensated somehow in the end. [Key informant 7]

Discussion

Principal Findings

Our findings indicate that in the context of integrating technology into the provision of health care for refugees in a low or middle income country such as Lebanon, some barriers for technology adoption are common with those found elsewhere [17]. However, certain factors that hinder the use of technology were found to be specific to the provision of refugee health care. Such distinctions have not been made in previous studies assessing the eHealth readiness of Lebanese primary health care centers [18] nor in the literature on the use of technologies to improve refugee health [4,13,14].

The multitude of stakeholders involved within the underresourced health care system poses a huge barrier for the consistent use of technology across the primary health care system. Additionally, participants indicated time constraints to be a major factor that contributes to the perception of technology as a burden within health centers. Such barriers are consistent with literature on technology integration into health care systems [19] and with studies conducted in Lebanon where mHealth technologies situated in PHCs were found to be redundant given the presence of parallel technological systems already in use in the PHCs [13]. Additionally, previous eHealth and mHealth [4,13,14] studies in Lebanon have been primarily conducted with one organization managing multiple PHCs thus providing limited insight on the barriers of scaling up such technologies to the wider primary health care system. Within such contexts, Khalifehsoltani et al [19] recommends practical implications that constitute a top-down policy approach as a means of overcoming barriers to the integration of health technologies introduced by the fragmentation and underresourcefulness of the health care system. For successful eHealth integration in low and middle income countries, policies should be put in place that strengthen the government's capacity to plan, manage, regulate, and enforce eHealth policies in a way that incentivizes or mandates third party actors to adopt eHealth technologies [19]. Furthermore, a top-down approach to eHealth integration would allow for the exploration of interoperability of programs within health care systems that include a multiplicity of stakeholders [17,19]. Yassin et al [10] have indicated the Lebanese MoPH has begun introducing policies to encourage the uptake of eHealth and mHealth technologies in PHCs in a manner that would aid in overcoming the systematic challenges identified in our study.

Moreover, our findings provide theoretical contributions through highlighting that when it comes to integrating technologies for the provision of health care for refugees specifically, new factors are at play which require further consideration. Participants justified the unfeasibility of using technology within refugee health care based on their view of refugees as a mobile community that is of low health and technology literacy. Such notions were disputed by other participants who viewed refugees to be of high literacy and in need of support to engage in health

technologies. Such factors have not been previously reported within literature on integrating eHealth.

In light of such evidence, practical implications include raising awareness among health care providers and PHC management that existing research indicates that Syrian refugees in Lebanon have high technological and health literacies [8,9,20] and creating spaces in which refugees may practice and demonstrate their technological and health literacies. Interactions between health care providers and refugees mediated through technological interventions themselves may create spaces in which refugees are empowered within the health care system and can work toward debunking the negative views surfaced in our study. Virtual nurse agents were explored by Bickmore et al [21] as a means of empowering low health literacy hospital patients, while medical information visualization has been used to better inform patients of their medical conditions and consequently facilitate their communication with health care providers and inform decision making processes [22]. Such technologies aim at empowering patients by providing them with information regarding their health issues. Other technologies aim to empower patients in the health care system by facilitating their offline communications with health care providers. Jacobs et al [23] and Mirkovic [24] highlighted the potential for health technologies to allow cancer patients to prioritize the issues they would like to discuss during their face-to-face engagements with health care providers, while Colley et al [25] introduced a dual-sided tablet to be used during clinical consultation where one side of the tablet provides constructive information to the patient regarding what the doctor is inputting.

Technological designs may allow us to reconfigure the current modalities of communication to allow refugees to take on a more proactive role within their health care rather than being just recipients of a service [26]. Indeed, technology may be situated within refugee communities where they could initiate the use of the technology themselves, in order to communicate with health care providers and/or other parts of the humanitarian system. Such an approach would overcome the barriers of refugee mobility by giving refugees the possibility of initiating contact with the health care system regardless of where they are. Moreover, such a reconfiguration may play a role in changing the views of health care providers toward refugees by creating more open communication mediums where refugees

can demonstrate their technological literacy and health agency [15]. Previous work with Syrian refugees has shown that such configurations mediated through refugee-led community radio shows provide health care providers with a deeper understanding of the refugee community and enable refugees to vocalize their health concerns [15].

Strengths and Limitations

This study provides an understanding of the barriers to integrating refugee health technologies in underresourced health systems such as Lebanon. The study was conducted in the West Bekaa region where a large number of refugees live; however, it may not represent the realities of other geographies in this context. Further research is thus needed in order to ascertain the generalizability of the results. Additionally, future studies and eHealth endeavors in similar contexts should actively engage with technology designers and developers who are stakeholders playing key roles in the configuration and deployment of health technologies.

The diversity of participants in this study reflects the different stakeholders and actors who engage in the provision of primary health care for refugees in Lebanon. The selection of a range of different stakeholders and actors ensures that the varying perspectives are reflected and information can be triangulated for reliability and validity. Our findings highlight factors that need to be further investigated before the implementation of eHealth for refugees.

Conclusions

The introduction of technologies into health care systems in underresourced countries for the provision of health services to refugee communities is likely to face barriers similar to those we identified in this study, particularly in contexts with fragmented and underresourced health systems. Our study provides theoretical contributions by highlighting barriers specific to how refugees are perceived by health care providers and actors within the health care system. While there is evidence that may disqualify such views, the technological literacy and health motivation of refugees should be made more visible to health care providers and other actors within the system. Technologies that empower refugees when accessing health care and those that challenge the current modalities in which refugees communicate with health care providers could play a role in debunking such perceptions in the future.

Abstract

Background: China is currently piloting a “Sharing Nurse” program that aims to increase the accessibility of nursing services to at-home patients by enabling patients to order nursing services using mobile apps or online platforms.

Objective: This study aims to assess nurses' perceptions of the Sharing Nurse program, including their acceptance, concerns, needs, and willingness to take part in the program.

Methods: A total of 694 nurses participated in the questionnaire survey. The survey collected their sociodemographic and work-related information and their perceptions of the Sharing Nurse program using a self-developed questionnaire.

Results: The 694 respondents agreed that the Sharing Nurse program could provide patients with better access to nursing care (n=483, 69.6%). Their main concerns about the program were unclear liability division when medical disputes occur (n=637, 90.3%) and potential personal safety issues (n=604, 87%). They reported that insurance (n=611, 88%), permits from their affiliated hospital (n=562, 81.0%), clear instructions concerning rights and duties (n=580, 83.6%), real time positioning while delivering the service (n=567, 81.7%), and one-key alarm equipment (n=590, 85.0%) were necessary for better implementation of the program. More than half of the respondents (n=416, 60%) had an optimistic attitude toward the development of the Sharing Nurse program in China. However, only 19.4% (n=135) of the respondents expressed their willingness to be a “shared nurse.” Further analyses found that nurses with a master's degree or above ($\chi^2_3=28.835$, $P<.001$) or from tertiary hospitals ($\chi^2_3=18.669$, $P<.001$) were more likely to be aware of the Sharing Nurse program and that male nurses were more willing to be shared nurses ($Z=-2.275$, $P=.02$).

Conclusions: The Chinese Sharing Nurse program is still in its infancy and many refinements are needed before it can be implemented nationwide. Generally, Chinese nurses are positive about the Sharing Nurse program and are willing to participate if the program is thoroughly regulated and supervised.

KEYWORDS

sharing nurse; home visiting; internet plus nursing program; perception; China

Introduction

Home visiting is a strategy to deliver various nursing or medical services to families or individuals within their home

environment for an extended period of time [1,2]. Nurse home visits are employed in a number of settings, from managing acute or chronic illnesses to aiding the overall health and well-being of the patient. Home visits are also used to ease

adults into outpatient settings from inpatient settings. Home visits play an important role in enhancing health and independency, as well as providing high quality end-of-life care to older adults [3,4].

Home visiting nurses, in the provision of their services, have the opportunity to tailor the services to meet a family's unique needs more effectively [5,6]. Home visiting programs also allow qualified professionals to build a rapport with families, which may not be possible during other types of interventions [7,8]. Home visiting has also been shown to lead to many positive health outcomes. These include improved daily functioning among adults who are disabled, which may reduce Medicaid medical costs [9]; increase quality of life and increased number of days free of asthma symptoms for patients with asthma [10]; reduce child abuse and neglect; and improve child development and parenting outcomes [11-14].

Home visiting has been widely practiced in the United Kingdom, the United States, and many other developed countries. In the United Kingdom, home visiting programs have been expanded since 2005, delivering services to 16,000 disadvantaged new parents each year [15]. In the United States, about US \$1.5 billion had been proposed by President Barack Obama's 2014 Budget to maintain and expand evidence-based voluntary home visiting services [16]. In Germany, since 2012, the federal and local governments have spent €102 million (US \$115 million) each year to expand home visiting programs [17].

Nurse home visiting services in China are generally provided by community health care nurses, which began in the late 1990s [18]. Community health care involves a wide range of services such as disease prevention, rehabilitation, health education, and family planning guidance [19]. However, it is seen that community health care nurses remain at community health centers or stations, waiting passively for patients to arrive [18], instead of going into homes to provide health care, even though home visiting is one of their responsibilities. As a result, the traditional community health care service cannot meet the rising needs of at-home-services propelled by the large and continuous increase in the ageing population [20]. In response to this situation, the online nursing service platform (or "Sharing Nurse" platform)—where patients can request registered nurses to visit them at home and provide nursing services—emerged in China.

The Sharing Nurse platform originated as early as 2016 in the Shandong Province and has since spread to other provinces as well as first-tier cities such as Beijing, Shanghai, Guangzhou, and Shenzhen [21]. However, it did not receive official recognition until 2019. On February 12, 2019, the National Health Commission announced that they were launching a pilot Sharing Nurse program as part of the "Internet Plus" initiative for nursing care in six provinces and metropolitan cities (ie, Beijing, Tianjin, Shanghai, Jiangsu, Zhejiang, and Guangdong), as well as some capital cities and regions across the country [22].

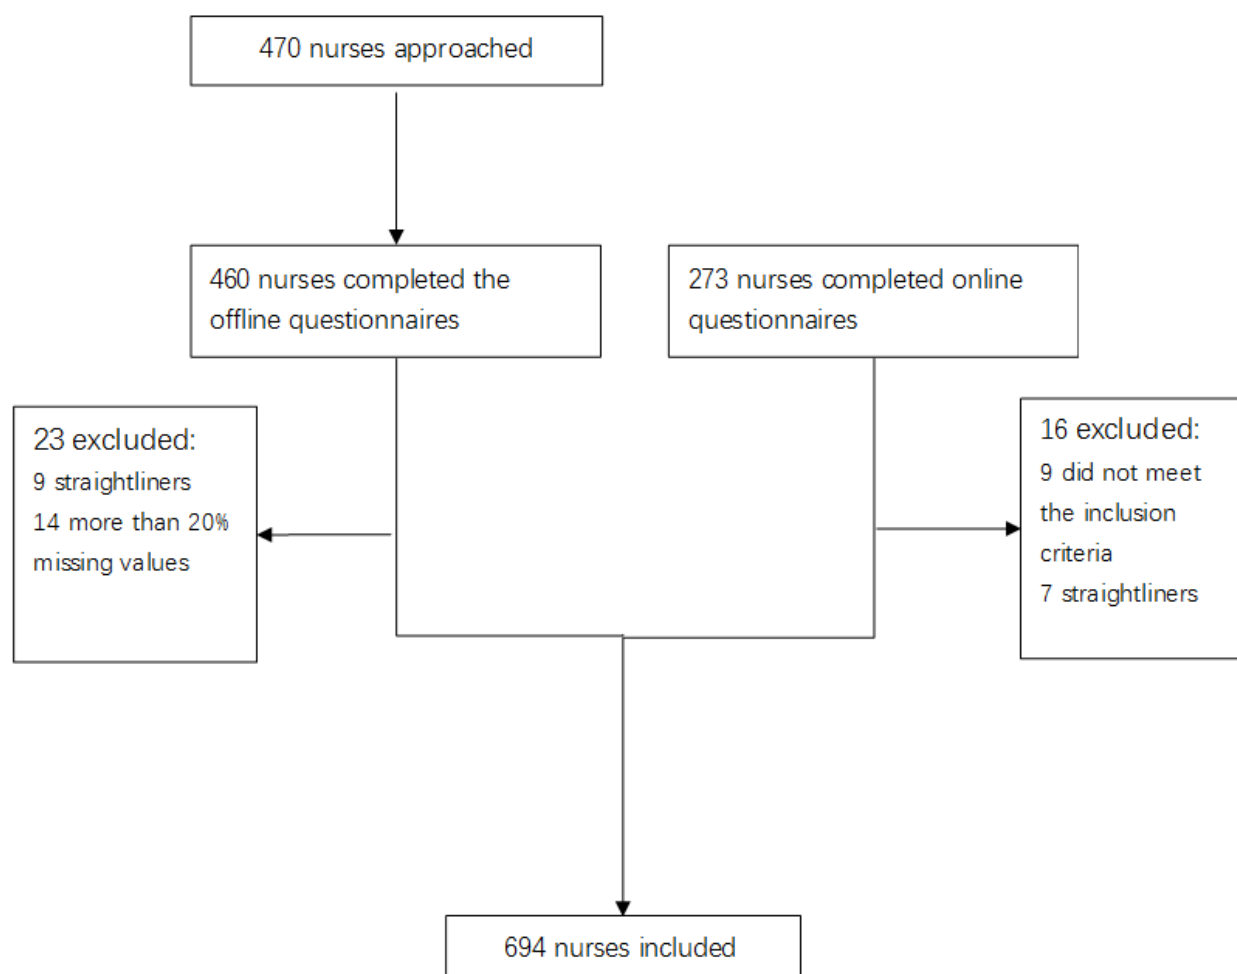

The Sharing Nurse Program refers to the use of internet technology (ie, mobile apps, online websites, or other internet-based platforms) to facilitate home visiting nursing service delivery. To our knowledge, there are currently more than 20 Sharing Nurse apps in China. These apps or websites collect and verify the information of registered nurses who want to be part of the program ("shared nurses"). Clients register on the apps or websites to make an online appointment to reserve or order medical services, choose nurses to deliver services based on their preferences, and decide when and where the services are expected to be delivered. The appointed nurse then arrives at the scheduled time with the required medication and equipment to provide the ordered services [23]. After the service is completed, clients can evaluate the nurse's service and provide feedback on the platform. Currently, services provided by shared nurses include intramuscular injection, intravenous injection, collecting blood samples, and special care like newborn examinations or urethral catheterization, among others [24]. Unlike the home visiting nurses in many developed countries who are employed by agencies specializing in home visiting services, the Chinese shared nurses, in addition to delivering home visiting services through the sharing nurses platforms, are registered nurses affiliated with approved medical institutions (hospitals, community health care centers, and private clinics), and routinely serve in the medical institutions in which they are employed.

The Sharing Nurse program enables clients to actively use health care services without going to the community care centers or stations. As a new health care delivery mode, the program's quality and effectiveness is heavily dependent on both nurses and clients. Nurses' perceptions, such as acceptance of the program, as well as concerns, needs, and perceived benefits of being a shared nurse can greatly influence their willingness and motivation to participate in the program and to provide high-quality care. Eventually the success of the program also depends on how the government addresses the nurses' concerns and needs. However, research regarding nurses' perceptions (ie, acceptance, concerns, needs, and perceived benefits) of the Sharing Nurse program is still scarce. To address this gap, we conducted a questionnaire survey to assess nurses' perceptions of the program, as well as their willingness to be a shared nurse.

Methods

Design and Participants

A cross-sectional survey was conducted, both online and offline, in Jinan, China, from March to May 2019. A convenience sampling method was used to recruit registered nurses from two tertiary hospitals, one secondary hospital, seven community health centers, and four private hospitals in the capital city of Shandong Province, where the Sharing Nurse platform originated. The eligibility criterion for the nurses' participation in this study was more than 1 year of bedside nursing experience. A final sample of 694 nurses completed the questionnaires. The method of inducing participants is illustrated in the flow chart (Figure 1).

Figure 1. Flow diagram of the participants recruitment and questionnaires screening.

Measurements

Sociodemographic Information

The sociodemographic items were age, gender, professional title (nurse, senior nurse, nurse-in-charge, associate director, or director of nurses), years of work experience, educational background, and level of the affiliated hospital (tertiary hospital, secondary hospital, community hospital, or private hospital).

Nurses' Perceptions of the Sharing Nurse Program

We developed a questionnaire to assess nurses' perceptions of the Sharing Nurse program following these steps. First, we created an initial version of the questionnaire by developing items based on existing literature and interviews with a panel of 20 clinical nurses. Second, an expert panel comprising of two health care researchers, a senior nurse, and a community nurse refined these items. Third, five nurses took a pretest of the questionnaire and modifications were made according to their feedback to obtain the final version of the questionnaire.

The final version of the questionnaire contained five questions concerning nurses' familiarity with the Sharing Nurse program, whether they have ever been a shared nurse before, and reasons why they do not try to become a "shared nurse"; seven questions about their concerns about the program, rated on a 5-point Likert scale (1="strongly unconcerned" to 5="strongly concerned"); seven questions about the possible needs of shared nurses, rated on a 5-point Likert scale (1="strongly disagree" to 5="strongly agree"); four questions about the perceived benefits of the program, rated on a 5-point Likert scale (1="strongly disagree" to 5="strongly agree"), and one question about their willingness to be a shared nurse (response options including "willing to," "not willing to until regulations are refined," and "not willing to even though regulations refined").

Data Collection

First, hospitals of different levels were selected to enable us to explore possible variations in nurses' perceptions of the program across all hospital levels. At each chosen hospital, researchers distributed the questionnaires to nurses on site. To reach out to more nurses, such as those who were not on duty, we also

distributed electronic questionnaires (e-questionnaires) in the WeChat work group of the hospitals by using an online questionnaire platform Wenjuanxing. In the e-questionnaire, we added an extra question: “Have you ever attempted this questionnaire before?” at the end of the questionnaire to filter duplicate respondents. The willingness to participate, and thus provide informed consent, was determined at the receipt of the completed questionnaire. This study was approved by the Ethical Committees of Shandong University School of Nursing (Reference Numbers: 2019-R-009).

Data Analysis

Descriptive statistics were used to describe the respondents' sociodemographic and work-related information, as well as their responses to the questions regarding their perceptions of the Sharing Nurse program. A comparison analysis was conducted to test whether the perception differed by age, gender, educational background, and hospital levels using a chi-square test, Kruskal-Wallis tests, or the Mann-Whitney U test. For all tests, the significance level was set at $P \leq .05$. Data analysis was performed using SPSS 22.0 software (IBM Corp).

Results

Demographic and Work-Related Characteristics of the Participants

Of the 694 participants, 672 were female and 22 were male. The age of the participants ranged from 20 to 55 (mean 30.5,

SD 6.8) years. The participants had been practicing clinical nursing for an average of 8.5 (SD 7.1) years. The highest percentage of the total 694 nurses ($n=313$, 45.1%) were from tertiary hospitals, 207 (29.9%) were from secondary hospitals, 81 (11.7%) were from community health care centers, and 114 (16.4%) were from private hospitals. Regarding their educational background, 210 (30.2%) held an associate's degree, 449 (64.7%) held a bachelor's degree, and 13 (1.9%) held a masters' degree or above. Concerning the distribution of nurses according to their different titles, 260 (37.5%) were nurses (junior title for the nursing profession), 275 (39.6%) were senior nurses, 143 (20.6%) were nurses-in-charge, and 7 (1.0%) were either associate directors or directors of nurses.

Perceptions of the Sharing Nurse Program

Close to half of the participants (300/694, 43.2%) were not aware of the Sharing Nurse program. Considering the nurses who knew about the program, only 6 had actually delivered services through a “Sharing Nurse” app. According to their answers, the factors that kept nurses from being a shared nurse included concern about personal safety (128/688, 18.6%), unclear regulations (126/688, 18.4%), lack of time (289/688, 42%), and dearth of energy (275/688, 40%). The concerns of the nurses are presented in [Table 1](#).

Table 1. Concerns about home visiting as a shared nurse (N=694).

Concerns	Strongly unconcerned, n (%)	Partially unconcerned, n (%)	Neither concerned nor unconcerned, n (%)	Partially concerned, n (%)	Strongly concerned, n (%)	Missing, n (%)
Personal safety	16 (2.3)	9 (1.3)	57 (8.2)	82 (11.8)	522 (75.2)	8 (1.2)
Information security	26 (3.7)	38 (5.5)	97 (14)	143 (20.6)	383 (55.2)	7 (1)
Service quality supervision	18 (2.6)	25 (3.6)	120 (17.3)	164 (23.6)	357 (51.4)	10 (1.4)
Public recognition about shared nurse	33 (4.8)	35 (5.0)	128 (18.4)	145 (20.9)	345 (49.7)	8 (1.2)
Division of liability in medical disputes	11 (1.6)	8 (1.2)	41 (5.9)	59 (8.5)	568 (81.8)	7 (1.0)
Medical waste management	56 (8.1)	63 (9.1)	147 (21.2)	120 (17.3)	301 (43.4)	7 (1.0)
Service quality at home	18 (2.6)	25 (3.6)	120 (17.3)	164 (23.6)	357 (51.4)	10 (1.4)

Regarding the services that the participants think a shared nurse can deliver at home, the top three choices were blood collection for laboratory tests (489/694, 70.6%), intramuscular injection (473/694, 68.1%), and health education (508/694, 73.3%). The majority of the participants thought that at least 5 years of experience in bedside practice and the title of senior nurse were necessary qualifications to be a shared nurse.

Participants stated that they would consider being a shared nurse if they could obtain customized insurance (611/694, 88%), program training (488/694, 70.3%), clear statements on shared nurses' rights and duties (580/694, 83.6%), real time position tracking services while delivering service (567/694, 81.7%), and alarm equipment (590/694, 85.0%). A few nurses also regarded video recording of the service procedure as essential. [Table 2](#) presents the full details of these answers.

Table 2. Needs to meet to consider to be a shared nurse of participants (N=694).

Needs	Strongly disagree, n (%)	Partially disagree, n (%)	Neither agree nor disagree, n (%)	Partially agree, n (%)	Strongly agree, n (%)	Missing, n (%)
Permits from the hospital	12 (1.7)	9 (1.3)	50 (7.2)	49 (7.1)	562 (81.0)	12 (1.7)
Insurance	12 (1.7)	4 (0.6)	22 (3.2)	34 (4.9)	611 (88.0)	11 (1.6)
Video recording of the service procedure	30 (4.3)	30 (4.3)	90 (13.0)	104 (15.0)	427 (61.5)	13 (1.9)
Clear statements about shared nurses' rights and duties	9 (1.3)	6 (0.9)	28 (4.0)	58 (8.4)	580 (83.6)	13 (1.9)
Real time position tracking while delivering service	14 (2.0)	8 (1.2)	37 (5.3)	57 (8.2)	567 (81.7)	11 (1.6)
Alarm equipment	10 (1.4)	3 (0.4)	26 (3.7)	54 (7.8)	590 (85.0)	11 (1.6)
Program training	11 (1.6)	12 (1.7)	69 (9.9)	101 (14.6)	488 (70.3)	13 (1.9)

More than half of the 694 participating nurses regarded the program as beneficial in terms of increasing public access to nursing care (n=483, 69.6%), extra income for nurses (n=402, 57.9%), preventing nurse turnover (n=371, 53.3%), and saving

on health care costs (n=375, 54.0%). More than half (n=416, 60.0%) of the participants were optimistic about the program and were willing to be a shared nurse if there were clear and thorough regulations and supervision (Table 3).

Table 3. Perceived benefits toward sharing nurse program in China of participants (n=694).

Benefits	Strongly disagree, n (%)	Partially disagree, n (%)	Neither agree nor disagree, n (%)	Partially agree, n (%)	Strongly agree, n (%)	Missing, n (%)
More access to nursing care	40 (5.8)	29 (4.2)	129 (18.6)	140 (20.2)	343 (49.4)	13 (1.9)
Extra source of income for nurse	58 (8.4)	45 (6.5)	175 (25.2)	145 (20.9)	257 (37.0)	14 (2.0)
Preventing nurse turnover	82 (11.8)	66 (9.5)	160 (23.1)	119 (17.1)	252 (36.2)	15 (2.2)
Saving health costs for patients	66 (9.5)	57 (8.2)	182 (26.2)	129 (18.6)	246 (35.4)	14 (2.0)

Variations in Perceptions of the Sharing Nurse Program

It was seen that older nurses ($\chi^2_3=32.926$, $P<.001$), nurses with higher levels of education ($\chi^2_3=28.835$, $P<.001$), and nurses

from tertiary hospitals were more likely to be aware of the program. Male nurses were more willing to be shared nurses than female nurses ($Z=-2.275$, $P=.02$; see Tables 4 and 5).

Table 4. Nurses who were aware of the sharing nurse platform.

Groups	Participants, n/N (%)	Chi-square (<i>df</i>)	<i>P</i> value	Post hoc
Age (years)		32.926 (3)	<.001	C>B, B>A
A <25	47/120 (39.2)

Discussion

To the best of our knowledge, this is the first study conducted to assess nurses' perceptions of the Sharing Nurse program in China. Nurses were specifically targeted because they are the executive body of the Sharing Nurse program; therefore, their perceptions and insights are of vital importance to policy makers and for the effective implementation of the program.

We found that almost half (300/694, 43.2%) of the participants did not know about the ongoing Sharing Nurse program. This may be because the survey was conducted less than 1 month after the program was officially piloted, and therefore, there was limited time for the nurses to learn about it. It may also be because the official announcement had not been disseminated widely and efficiently, or the employer hospitals or community health care centers had not made attempts to take part in the program.

Home visiting should be a part of community-based family support services [1]. In fact, the health care system in China emphasizes the central role of community health care nurses in primary care and home visiting services [25,26]. However, the results showed that nurses from the community health centers were less likely to be aware of the Sharing Nurse program. Cogdill [27] found that nurses with a master's degree were more perceptive to information needs more frequently than their colleagues. The low rate of community health care nurses who

were aware of the Sharing Nurse program indicates, on the one hand, that community nurses, most of whom hold a diploma or associate's degree, lack information. On the other hand, this also reflects a flaw in policy promotion among community health care centers, which should be the frontier of the Sharing Nurse program implementation.

The main reasons for the respondents not willing to be a shared nurse were work stresses, as 40% (275/688) of nurses reported they did not have time or energy after work. This is consistent with previous study findings in England and Australia, where nurses have reported that administrative work not related to the practical task of delivering home visits was a significant barrier to home visiting work [28]. In the study city, shared nurses affiliated to approved medical institutions have to sacrifice their own time to deliver home visiting services through Sharing Nurse platforms, which adds more stress to their already high level of workload [29]. China also faces a shortage of nurses, and the growth in the number of health care professionals does not meet the increasing demand [30]. The Sharing Nurse program is expected to reduce this imbalance in a more efficient way. Therefore, the number of nurses should be expanded to attract more individuals to the nursing profession and better motivate nurses to engage in the program.

Safety issues are also a major concern about the program that the respondents shared. Studies in other countries have found that clients who received home visiting services without prior knowledge were inclined to report concerns about their safety

because they did not seek help but had been identified by others as potential beneficiaries of home visiting programs [31,32]. This can result in clients feeling vulnerable and powerless when they allow service providers into their homes [33]. Although we did not find any literature on clients' safety concerns related to the Sharing Nurse program, we found that more than two-thirds of nurses were concerned about their personal safety. Thus, the safety of visiting homes is a concern not only for the clients but also for the nurses. Hence, to better implement the Sharing Nurse program, efforts should be made to ensure the nurses' personal safety. There are many suggested measures to enhance home visiting safety. For example, the Sharing Nurse platforms verify the accuracy of information the clients upload, such as location, service requirements, and identity. The government may carry out strict inspections of the platforms. Necessary protective equipment such as real time positioning and alarm equipment could be provided to the shared nurses while delivering the home visiting service.

Liability division, when medical disputes occur while delivering a home visiting service through a Sharing Nurse platform, was found to be another major concern for the participating nurses. This concern relates to problems such as defining and dealing with medical disputes related to the services at home and whether accidents that happen to nurses when they are on the way to or back from the clients' home are workplace accidents or not. This demonstrates that there is a need for clear regulations and practical guidelines. This is supported by the finding that over 80% (580/694) of the respondents agreed that "clear statements about shared nurses' rights and duties" is necessary to the consideration of being a shared nurse. Previous findings also showed that the absence of related policies and practical guidelines was one of the major organizational barriers for Korean nurses to implement home visiting services [34].

Our study found that insurance is regarded by nurses to be essential to improve the program. Home visiting nurses face unique and complex risks in their workplaces as well as uncertainties on their way to and from clients' homes. These nurses need insurance support including traffic accident insurance and personal accident insurance. Previous studies have also pointed out that a lack of professional indemnity insurance is an obstacle both for the employment of nurses and for the fulfilling of their professional role [35]. Additionally, during a labor shortage, employment-based benefits such as insurance can be used to help recruit and retain nurses [36]. Therefore, we recommend the formulation of customized insurance options for shared nurses by policy makers and relevant agencies.

Well-planned and effective preservice and ongoing training contributes to home visitor readiness and prepares them for the demands of the job [37]. According to our participants, program

training is also needed. We, therefore, suggest tailoring nursing education and training to include aspects of home visiting for the benefit of prospective home visiting nurses.

Additionally, more than half of the respondents agreed that the program could be beneficial in saving on health care costs for patients, providing extra income for nurses, and preventing nurse turnover. Considering patients' possible health care savings, the result is consistent with previous findings that home visiting could save costs such as parking fees, travel time, and time off work associated with travelling to a clinic [38]. It also cancels out the waiting time in hospital lines [24]. Shared nurses on the sharing nurse apps generally earn ¥100-300 (US \$14-42) per visit for their services, which is more than what they could earn for their daily work [39]. Evidence [40,41] has shown that higher wages are associated with less turnover. The extra income, more flexibility, and the opportunities that the Sharing Nurse program offers make it more attractive to join the program.

The limitations of this study cannot be ignored. First, the participants in this study all came from one city in Shandong Province, which is not an official piloting area of the Sharing Nurse program. Nevertheless, Jinan is one of the earliest cities where the platform originated. Second, the convenience sampling method limits the generalizability of our findings. However, the sample of this study was purposefully selected to cover various levels of health care that are typical to China to explore differing perceptions among clinical nurses from different settings. Third, we only explored the perceptions of the Sharing Nurse program from nurses' perspective, not from clients' perspective. Future studies focusing on clients' perceptions and the actual effectiveness of the program are warranted.

China's Sharing Nurse program is a new way to facilitate home visiting services. However, in the early stage of the program, the awareness of the nurse program was low. The major concerns of the program include unclear liability division when medical disputes occur and potential personal safety issues. The participating nurses identified several needs that must be met for them to become a shared nurse, including insurance, permits from their employers, clear instructions concerning rights and duties, real time positioning while delivering the service, and one-key alarm equipment. Although the participating nurses noted many barriers of becoming a shared nurse, most of them held an optimistic view of the program and expressed their willingness to be part of it once regulations and practical guidelines are refined. The findings contribute to promoting knowledge about China's Sharing Nurse program and, hopefully, provide implications for further refinement and regulations of the program.

Acknowledgments

We would like to thank all the participants of the survey and the nurses who participated in the questionnaire refinement. We extend our gratitude to the Supporting Grant for Candidates for "Qilu Outstanding Scholars" (2018WLJH46) from the Shandong University and Zhenhui Wang for providing critical information about Sharing Nurse program.

Conflicts of Interest

None declared.

Abstract

Background: Gift giving, which has been a heavily debated topic in health care for many years, is considered as a way of expressing gratitude and to be beneficial for the physician-patient relationship within a reasonable range. However, not much work has been done to examine the influence of gift giving on physicians' service quality, especially in the online health care environment.

Objective: This study addressed the consequences of gift giving by mining and analyzing the dynamic physician-patient interaction processes in an online health community. Specifically, gift types (affective or instrumental) based on the motivations and physician-patient tie strength were carefully considered to account for differences in physicians' service quality.

Methods: The dynamic interaction processes (involving 3154 gifts) between 267 physicians and 14,187 patients from a well-known online health community in China (haodf.com) were analyzed to obtain empirical results.

Results: Our results reveal that patient gift giving inspires physicians to improve their service quality as measured by physicians' more detailed responses and improved bedside manner, and the degree of influence varied according to the strength of the physician-patient tie. Moreover, affective gifts and instrumental gifts had different effects in improving physicians' service quality online.

Conclusions: This study is among the first to explore gift giving in online health communities providing both important theoretical and practical contributions. All of our results suggest that gift giving online is of great significance to promoting effective physician-patient communication and is conducive to the relief of physician-patient conflicts.

KEYWORDS

online health community; gift giving; affective/instrumental gifts; service quality; bedside manner; physicians; physician-patient relationship

Introduction

Background

Online health communities have recently emerged as an important channel for seeking medical information and physicians' help [1], improving the physician-patient relationship [2], and raising the level of public health [3]. The Pew Research Center reported that 59% of American adults had

searched for health information online [4]. An increasing number of scholars have been paying specific attention to patient [5,6] or physician [7-9] behaviors in online health communities. However, little is known about how patient behaviors influence physician behaviors.

Patient behaviors online can be mainly divided into purchase and review behaviors. The former has already been investigated in a large number of studies. With respect to review behaviors,

positive behaviors were shown to account for almost 99% of all reviews (calculated based on data collected on Haodf.com [10]), which might be due to the unequal relationships between patients and physicians. Among the various ways of expressing gratitude, gift giving is popular among patients, although this behavior has been widely questioned by the public [11]. One cause of these debates is that the possible impact of gift giving on the service quality of physicians remains unclear. Both academia and industries have raised the question as to whether patients buy gifts for physicians in fear of receiving poor treatment rather than as a gesture of expressing gratitude [12]. To address these questions, we have been exploring patients' motivations of gift giving as well as the impact of gift giving on physician behavior (ie, service quality).

Within a reasonable range, gift giving has benefits for emotional expression and relationship building in interpersonal communication [13] and can be considered to be a benefit for the physician-patient relationship. From the patient perspective, on the one hand, gifts can be used to express gratitude. On the other hand, gift giving helps to reassure patients that physicians will be more likely to fulfill their responsibilities after receiving gifts. From the physician perspective, on the one hand, gifts from patients make them feel respected and recognized for their efforts. On the other hand, gifts may inspire them to improve service quality.

Despite recognition of the many advantages of gift giving for both patients and physicians, these effects should also be empirically examined. To the best of our knowledge, only one study has investigated the relationships between gift giving and physicians' service delivery to date [14]. However, the influence according to gift types distinguished by motivations has not been given full consideration. Moreover, the influences of gift giving on physicians may demonstrate time effects, which have also not been analyzed. In the previous study, service quality was measured by the physicians' response speed to patients' question. Response speed, as a dimension of service quality, will ultimately influence patients' perceived service quality. However, we believe that the quality of the reply content to the question may be more important and highly valued by patients.

To extend existing studies, we systematically analyzed the motivations and effects of gift giving in online health care. First, gifts were classified into affective gifts and instrumental gifts based on different motives [15]. All gifts that physicians received were judged and categorized based on the complete interaction process (including gift giving) between physicians and patients. The different effects of affective and instrumental gifts on physicians' service quality were further examined. Second, the degree of intimacy of the physician-patient relationship (ie, the tie strength) may influence the effects of gift exchange [16] and was also considered in our study. Third, the time effects of gift giving were comprehensively analyzed to obtain conclusions that can offer more practical guidance to patients. Fourth, the level of detail and emotional support of physicians' replies were used to measure service quality. Therefore, the specific research questions in this study were as follows: (1) Does gift giving influence physicians' service quality in online health communities? (2) Are the effects of different types of gifts (affective and instrumental gifts) on

physicians' service quality consistent? (3) How does the physician-patient tie strength moderate the relationships between gift giving and service quality? and (4) Does gift giving show time effects on service quality?

To address these questions, we adopted a quantitative approach and examined the effect of gift giving for the whole interaction process on physicians' service quality by analyzing longitudinal data gathered from a popular online health community in China, Haodf.com [10].

Gift Theory

Gift exchange plays a vital role in social interactions [17]. Gift theory, which involves the norm of reciprocity and explains why gift givers frequently receive return gifts, provides a suitable theoretical basis for this study.

The principle of reciprocity, which is considered as a benefit for individuals participating in social exchange, is often defined as a set of socially accepted trading rules in which one party provides resources to the other and obliges the other to return the favor [18]. The reciprocity principle is the internal cause of continuous communication between people since people will always repay each other owing to the nature of mutual indebtedness within the principle [19]. Moreover, referring to the partition manner of gifts in sociology, we divide gifts into affective and instrumental gifts based on different motives. Affective and instrumental gifts are defined as having "emotional expression" and "utilitarian purpose," respectively. However, both affective and instrumental elements, with different proportions, rarely exist in the process of gift exchange simultaneously. Hence, the gift type in our study was defined as the major element in a given exchange.

Professional Identity

Professional identity is defined as how one perceives the goals, social values, and other factors of their profession, and how this is communicated to others [20]. Relevant literature has paid more attention to the professional identity of physicians, nurses, and teachers; there are diverse definitions of professional identity in different fields [21,22], although this identity is of relevance for each worker. Only when one recognizes the occupation they are engaged in can they become more devoted to the work, exert their full potential, and realize their value in the course of the work. Studies concerning professional identity have revealed that high professional identity can be viewed as a unique way of shaping a good professional image, whereas the absence of such identity may drive one to leave the field [23]. Furthermore, professional identity can be enhanced through recognition and encouragement from others [24].

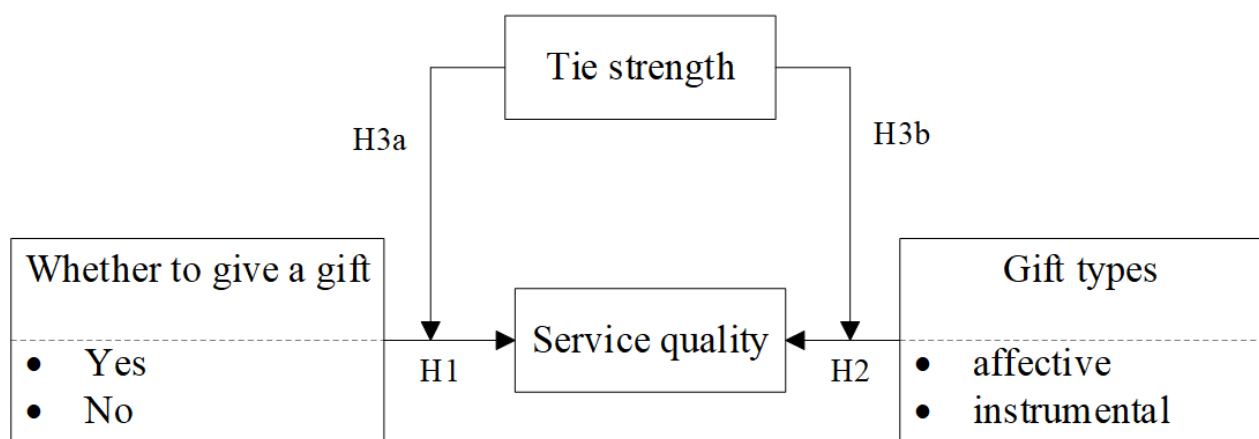

Tie Strength Theory

Following prior studies, tie strength is defined as the level of intimacy and interaction between individuals. Granovetter [25] conducted a comprehensive study to define and classify tie strength, which was categorized according to weak and strong ties defined by "unfamiliar interpersonal relations" and "familiar interpersonal relations," respectively. Thus, strong ties reflect closer relationships and more frequent interactions compared to weak ties [26]. Therefore, in the context of online health

communities, tie strength can be considered to consist of two dimensions, intimacy and interaction, which are measured by the cumulative number of gifts and interaction times, respectively. Strong ties can provide material and reliable support, whereas weak ties, along with multiple information, cannot [27]. Hence, the strength of ties determines the quality of the information available and the likelihood that individuals will achieve their goals [28].

We therefore framed our study based on these perspectives to examine how tie strength influences the effect of giving gifts in online health communities. The judgment on gift types and the subsequent attitude about gift giving will both be influenced by the relationships between receivers and givers [29].

Figure 1. Conceptual model.

Gift theory states that receivers will have the moral norm and obligation of returning the favor because of the reciprocity norm [30]. Online virtual gifts provide physicians with economic and honorary utility. Therefore, physicians always face the obligation and motivation to reciprocate patients after receiving a gift. Considering the online health care environment, we believe that physicians may improve their service quality to patients after receiving a gift, leading to the following hypothesis (H1): gifts help improve physicians' service quality in online health communities.

Previous studies based on the offline environment found that gift exchange offers a way to connect socially [31]. However, gifts provided at different times and different communication stages may have different effects. Even if we consider that all gifts are beneficial to the improvement of physicians' service quality, gifts with different purposes may have different effects. Kirchler and Palan [32] tested the value of unconditional nonmonetary gifts as a way to improve health worker performance in a low-income country health setting, and found that unconditional nonmonetary gifts enhanced performance by 20% over 6 weeks compared to conditional nonmonetary gifts.

Affective gifts are used to express the givers' appreciation, regardless of the possibility of return, whereas instrumental gifts are often given for a utilitarian purpose. Compared with instrumental gifts, affective gifts can provide not only economic benefits and improvement of online reputation [33] but also encouragement and recognition from patients, which can in turn enhance the professional identity of physicians and then inspire

Specifically, gift giving is more likely to be accepted when the two sides are in a close relationship such as family, romantic partnership, friendship, and even geographical proximity. However, the receivers can easily suspect the motives of the gift, which will then be refused when the receivers and givers are strangers. Hence, we surmise that tie strength will not only moderate the impact of gift giving on physicians' service quality but will also influence the physicians' judgment of gift types.

Research Model and Hypotheses

Figure 1 shows the proposed research model based on the above theoretical background. To understand the relationships among several constructs, we proposed and tested several hypotheses.

them to improve their service quality. Based on these perspectives, we developed our second hypothesis (H2) as follows: compared with instrumental gifts, affective gifts will be more effective in improving physicians' service quality.

Tie strength affects the quality of the information available and the likelihood that individuals will achieve their goals; a strong tie helps to obtain a gift that is more expensive and valuable [27]. When a patient and a physician know each other well, affectivity and compulsoriness will play major roles in their interaction process [26]. In such a situation, physicians always serve patients conscientiously. Therefore, a strong tie may weaken the effect of gift giving on physicians' service quality, leading us to establish the following hypothesis (H3a): tie strength negatively moderates the relationships between patients' gift giving and physicians' service quality.

The lower the degree of intimacy between givers and receivers, the more likely people regard gifts with utilitarian features [29]. Therefore, tie strength may affect the receiver's judgment on the motivations of gifts. Specifically, strong ties between physicians and patients decrease the feelings of physicians on the differences between affective and instrumental characteristics. A strong tie between a physician and patient will mitigate the effects of gift types on the physician's behavior. Based on these perspectives, we developed the following hypothesis (H3b): tie strength mitigates the difference of the effect of gift type on physicians' service quality.

Methods

Research Context

To test the research hypotheses, we collected data from one of the most popular online health communities, Haodf.com [10], which was established in 2006 in China. More than 490,000 physicians from 7500 hospitals are currently working on the site. Haodf.com creates a homepage for each physician (see Figure 2; all screenshots of web pages were translated to English

for clarity). For each physician, the entire interaction process with all patients is archived on the site. The interaction process includes the communicator (physician or patient), time, and content (physician-patient dialog or patient gift giving) for each interaction. An example of the interaction process is shown in Figure 3. Data collection was facilitated since most of the physician-patient interaction processes on Haodf.com are public, except for a few processes that are encrypted for privacy protection.

Figure 2. Physician's homepage.

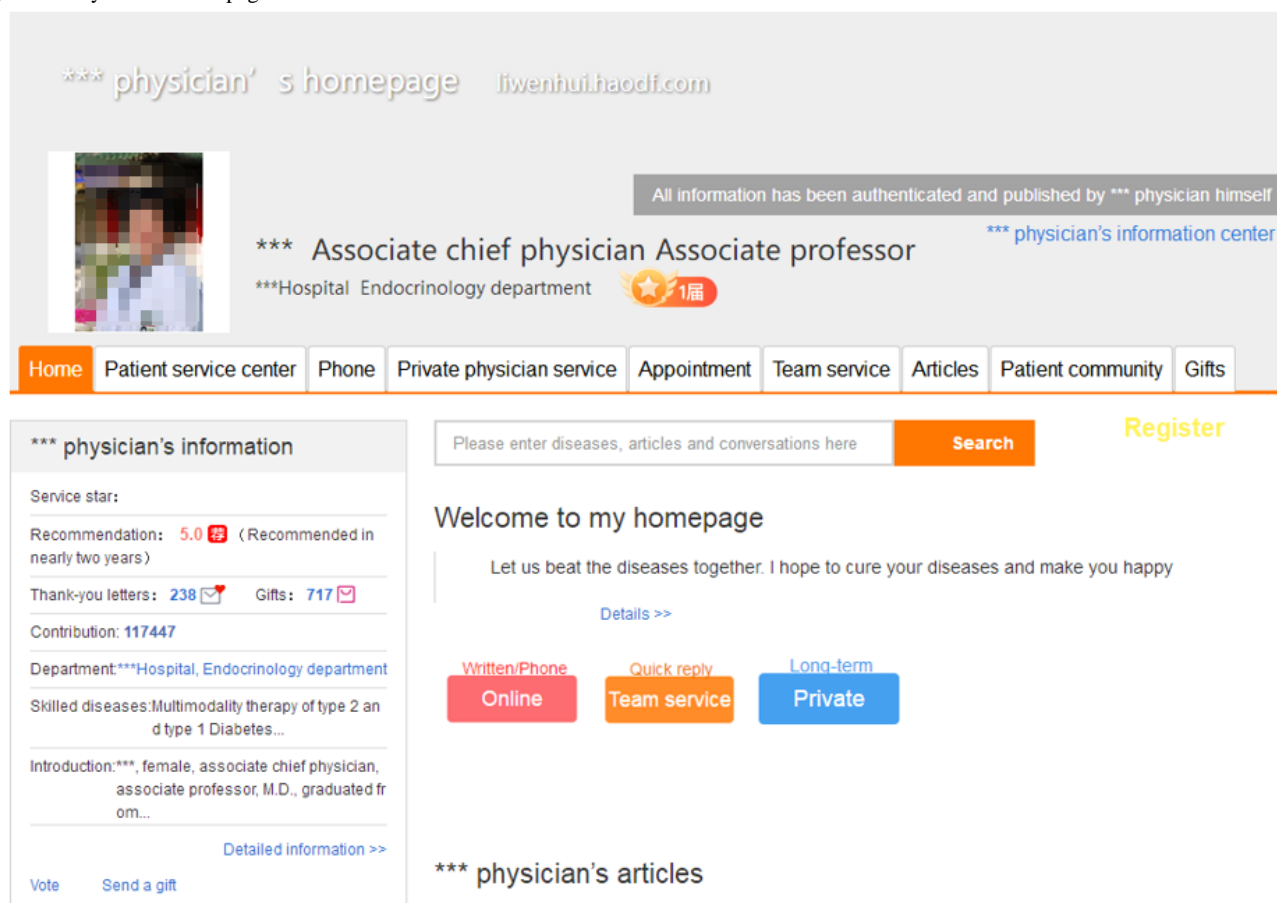

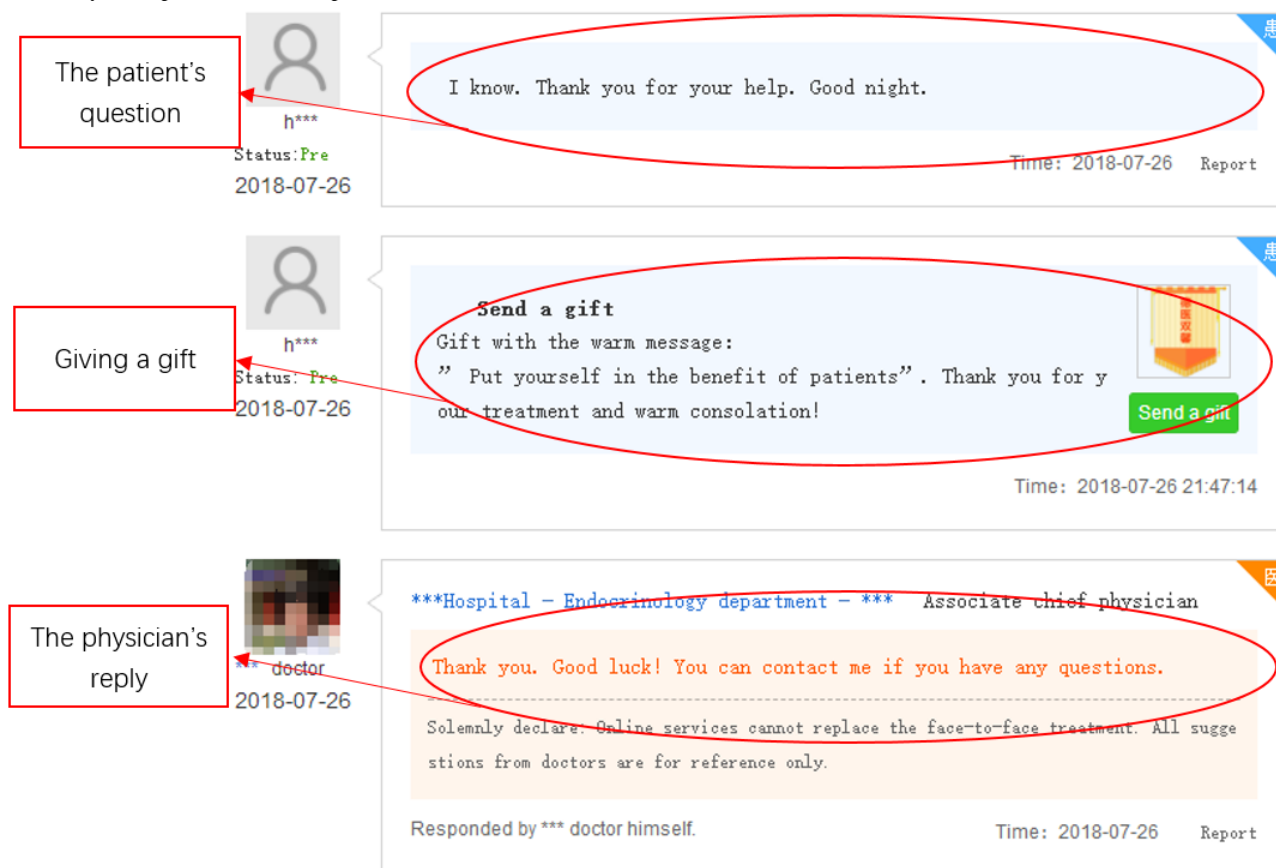

Figure 3. Physician-patient interaction process.

Sample and Data Collection

To reduce the influence of disease types, we only included physicians who treat patients with diabetes as our sample. We developed a crawler to automatically download information, including physicians' information and each physician-patient interaction content, on Haodf.com. We collected the data on March 25, 2018, and the entire process was conducted for 1 week. After downloading, cleaning up, and matching information processes, 217,458 interactions (X_1) between 14,187 patients and 267 physicians were included in our model.

The data cleaning and processing (see Figure 4) were broken down into the following steps: (1) cleaning missing data, in which the records for patients' purchase behaviors (see example in Figure 5) and physicians' replies by voice messages (see example in Figure 6) were deleted, resulting in 212,303 records (X_2) retained; (2) records integration (X_3) from each physician-patient interaction process per day to ensure communication continuity; and (3) gift giving judgment, in which each record in X_3 was divided into two records based on the first gift giving behavior, namely prior to and after gift giving. Finally, 28,546 records (X_4) were included in our model.

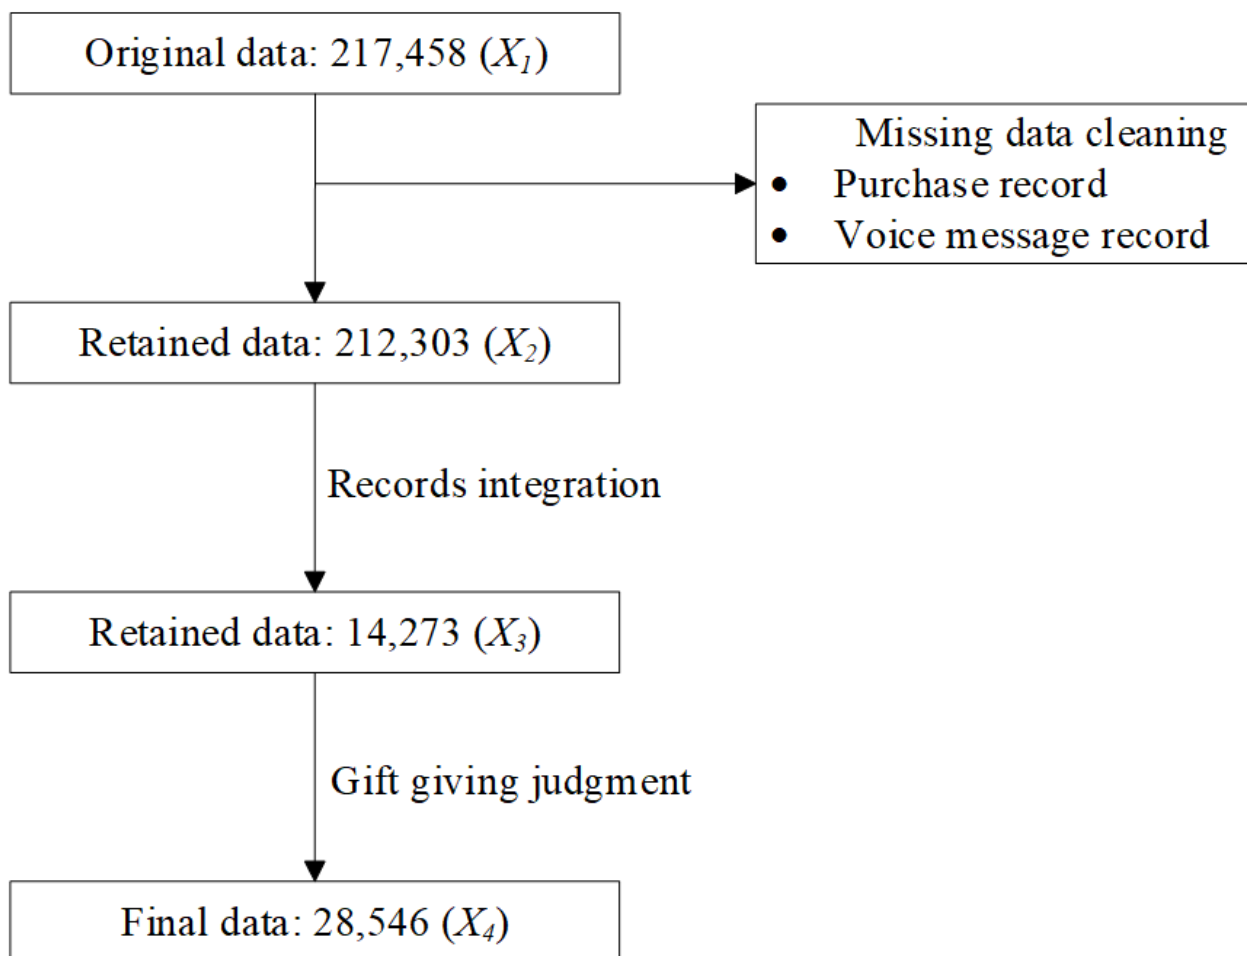

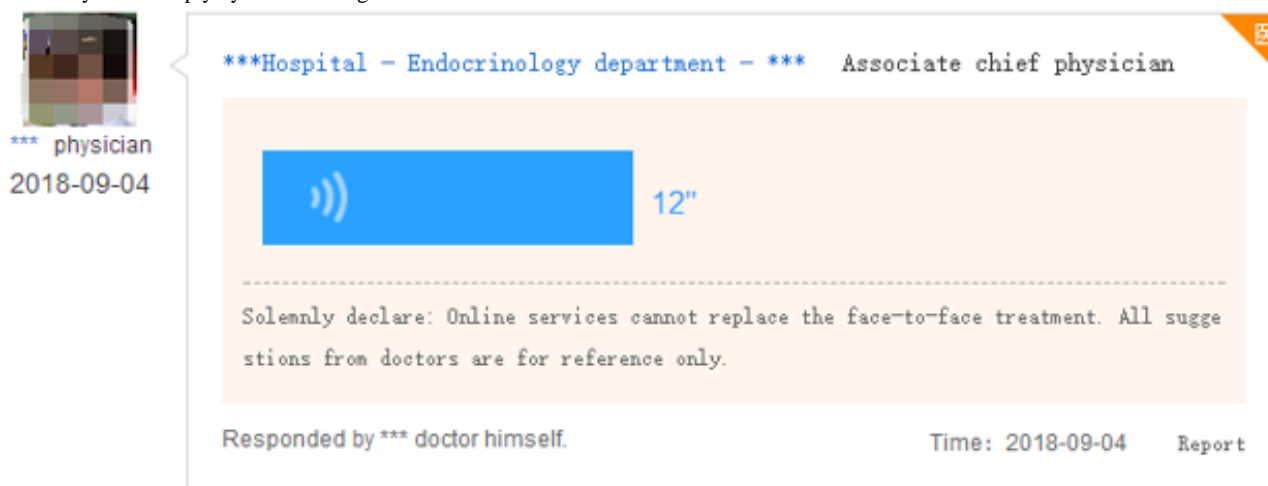

Figure 4. Data cleaning and processing.**Figure 5.** Patient's purchase process.

Figure 6. Physician's reply by voice message.

Judgment of Gift Types and Tie Strength

Judgment of gift types and tie strength was based on text mining.

Manual Coding for Gift Types

Gift types were judged according to whether gift giving occurred in conjunction with patients' questions. An instrumental gift is one that is purposefully given to physicians (eg, with the goal of obtaining better service). Therefore, gifts that are given close to a patient's questions were considered to be instrumental gifts (see Figure 7 for an example); otherwise, the gift was considered to be affective (see Figure 8 for an example). With respect to

the judgment of whether the dialog involved a question, two assistants with a research background in medical informatics were trained to recognize patients' questions based on the keywords shown in Multimedia Appendix 1. One hundred whole interaction processes, including 300 dialogs between patients and physicians, were chosen at random and assigned to be judged. The two assistants coded the contents of the 300 dialogs independently, and consistent judgment was obtained for 296 (98.7%) dialogs. After analyzing the remaining ambiguous dialogs, consistent judgments were reached. Finally, one assistant was assigned to code the remaining contents.

Figure 7. Instrumental gift example.

Figure 8. Affective gift example.

Measurement of Tie Strength

Tie strength was measured based on the cumulative quantity of gifts and conversations. A conversation includes a question and a reply. Therefore, the tie strength will increase as the number of physician replies increases. We standardized the cumulative quantity of gifts and conversations, respectively, and tie strength was calculated according to the following formula: standardized number of gifts + standardized number of physician replies.

Variables and Empirical Models

The empirical variables included in our model are shown in Table 1. As the dependent variable, we used the ratio of average

word count for a physician to respond to the patient in dialog i as a measure of service quality. More words contain more information. Specifically, a long reply may cover solutions for the question from all aspects and offer a detailed explanation of each aspect. In addition, a long reply may reflect the physician's patience and serious attitude to their patients. We also considered that a long question may lead to a long reply. Therefore, we also controlled for the word count from the patient's question. The formula is as follows: word count ratio _{i} = $\ln(\text{average word count for physician dialog } i) / \ln(\text{average word count for patient in dialog } i)$.

Table 1. Variables description.

Variable	Explanation
<i>Ratio_WordCount_{ij}</i> (Dependent variable)	The ratio of average word counts for physician <i>j</i> to that of the patient in dialog <i>i</i>
Independent variables	
<i>GiftGiving_{ij}</i>	Dummy variable in which “1” represents that a gift has been sent and “0” represents no gift
<i>GiftType_{ij}</i>	Dummy variable in which “1” represents an instrumental gift and “0” represents an affective gift
<i>TieStrength_{ij}</i>	Summation of standardized interaction times and the standardized cumulative number of gifts
Control variables	
<i>Phone_j</i>	Dummy variable in which “1” represents that the physician provides phone consultation and “0” represents no phone consultation
<i>Written_j</i>	Dummy variable in which “1” represents that the physician provides written consultation and “0” represents no written consultation
<i>Outpatient_j</i>	Dummy variable in which “1” represents that the physician provides outpatient service appointments and “0” represents no appointment provision
<i>PhonePrice_j</i>	Service price for phone consultation service set by the physician
<i>WrittenPrice_j</i>	Service price for written consultation service set by the physician
<i>Thank-you Letter_j</i>	Number of thank-you letters that physician <i>j</i> received
<i>No. Gifts_j</i>	Number of gifts that physician <i>j</i> received
<i>Contribution_j</i>	Calculated by site to measure the effort of physician <i>j</i>
<i>No. Patients_j</i>	Number of patients that physician <i>j</i> consulted
<i>Recommendation_j</i>	Total number of votes for each physician from patients
<i>Title_j</i>	Dummy variable in which “1” represents that physician <i>j</i> is a chief physician and “0” otherwise
<i>City_j</i>	Economics of the city where the hospital is located to measure patients’ consumption capacity. Expressed as a dummy variable in which “1” represents that the physician works in a first-tier city and “0” otherwise
<i>Level_j</i>	Evaluated by the government reflecting the hospital’s ability, equipment, and technology. Expressed as a dummy variable in which “1” represents that the physician works in a “III A” level hospital and “0” otherwise

Three independent variables were included in our study: (1) whether physician *j* received gifts in dialog *i* (gift giving), (2) gift type (affective or instrumental), and (3) tie strength.

To control for heterogeneity among physicians, we collected physicians’ information online. Haodf.com provides three primary services for physicians to choose whether to provide, including written consultation, phone consultation, and an outpatient service appointment (details can be found in [33]). Three dummy variables were used to measure the three services. If a physician provided a written or phone consultation, the service price was also included in the model. The physician’s professional title (chief, associate chief, or attending physician) evaluated by the health sector was also included. The detailed explanations for other control variables are provided in Table 1.

Our analyses were conducted in two steps. In the first step, multiple linear regression was used to explore the impacts of patients’ gift giving (whether to give a gift) on physicians’ service quality. In the second step, based on the situation in which gift giving occurred, the impacts of gift types and tie strength on physicians’ service quality were examined.

Therefore, only dialogs including gift giving were included in this step. Our empirical models for each step are as follows:

$$\text{Step 1: Word count ratio} = \alpha_{ij} + \alpha_1 \times \text{GiftGiving}_{ij} + \alpha_2 \times \text{Control}_j + \epsilon_j$$

$$\text{Step 2: Word count ratio} = \alpha'_{ij} + \alpha'_1 \times \text{GiftGiving}_{ij} + \alpha'_2 \times \text{Control}_j + \epsilon'_j$$

$$\text{Word count ratio} = \alpha''_{ij} + \alpha''_1 \text{GiftGiving}_{ij} + \alpha''_2 \times \text{TieStrength}_{ij} + \alpha''_3 \times \text{GiftGiving}_{ij} \times \text{TieStrength}_{ij} + \alpha''_4 \times \text{Control}_j + \epsilon''_j$$

$$\text{Word count ratio} = \alpha'''_{ij} + \alpha'''_1 \text{GiftType}_{ij} + \alpha'''_2 \times \text{TieStrength}_{ij} + \alpha'''_3 \times \text{GiftType}_{ij} \times \text{TieStrength}_{ij} + \alpha'''_4 \times \text{Control}_j + \epsilon'''_j$$

where *i* denotes a dialog and *j* denotes a physician; α is the coefficient to be estimated. Control_j represents the control variables for physician *j*, and ϵ_j is the standard error.

Results

Descriptive Statistics and Correlations

The descriptive statistics and correlations for the key variables are presented in [Multimedia Appendix 2](#). Independent variables were significantly related to the dependent variable. The correlation matrix showed no serious multicollinearity, which assured obtaining reliable results.

Empirical Results

The multiple linear regression method was applied to examine the effect of patients' gift giving on physicians' service quality, and the empirical results are shown as Model 1 (adjusted $R^2=0.018$, $F_{\text{change}}=19.774$, $P<.001$) and Model 2 (adjusted $R^2=0.027$, $F_{\text{change}}=27.171$, $P<.001$). We found that the decision to give gifts positively influenced physicians' service quality, thereby supporting hypothesis H1 ([Table 2](#)).

We then investigated the impacts of gift types and tie strength on physicians' service quality. The results are shown in Model 3 (adjusted $R^2=0.031$, $F_{\text{change}}=19.737$, $P<.001$). Compared with instrumental gifts, affective gifts had a stronger influence on physicians' service quality, thereby supporting hypothesis H2 ([Table 2](#)).

In Model 4 (adjusted $R^2=0.017$, $F_{\text{change}}=11.184$, $P<.001$), we examined the moderating effect of tie strength on the relationship between gift giving and physicians' service quality. We found that the relationship between patients' gift giving and physicians' service quality was smaller when they had a strong tie ([Table 2](#)). In Model 5 (adjusted $R^2=0.035$, $F_{\text{change}}=19.071$, $P<.001$), a positive moderating effect of tie strength on the relationship between gift types and physicians' service quality was identified ([Table 2](#)). The relationship between gift types and physicians' service quality was smaller when there was a strong tie between the physician and patient, thereby supporting hypotheses H3a and H3b.

Table 2. Regression results on associations of gift giving and physical service quality.

Robustness Check

The dependent variable in our study was physicians' service quality, which was measured by the ratio of the average word count for a physician in the patient in dialog i . Specifically, we divided the logarithm of the average word count for a physician

by the logarithm of the average word count for the patient to calculate physicians' service quality. Robustness was calculated by dividing the average word count for a physician by that of the patient (see Table 3). These values were consistent with the main results of the model in Table 2, which assured the good robustness of the results.

Table 3. Robustness check.

Posthoc Analysis

We further tested the impacts of gift giving on physicians' bedside manner, which is also important for patients and a dimension of service quality. Text mining was used to analyze physicians' replies and to judge their attitude. TextMind, a psychoanalytic software system developed by the Chinese Academy of Sciences for language analysis (especially for Chinese), was used for this analysis. This software has been widely used to analyze various characteristics of the text content in previous studies (eg [34]). By using TextMind, we conducted a sentimental analysis for physicians' text content. The specific process is shown in [Multimedia Appendix 3](#).

The average number of the physician positive sentiment words in each dialog was used to measure the physician's bedside manner. As shown in [Table 4](#), we found a positive impact of gift giving on physicians' bedside manner; however, the impact was smaller when the tie strength was strong (Model 2). In addition, compared with instrumental gifts, affective gifts had a greater impact on physicians' bedside manner (Model 3), but the gap was reduced when the tie strength was stronger (Model 5). These results are consistent with our main results, indicating that gift giving works effectively with respect to both the physicians' reply and bedside manner.

Table 4. Empirical model results for physician bedside manner.

Variables	Step 1, β (SE)				Step 2, β (SE)

Discussion

Principal Findings

The aim of this study was to determine the main motivations and effects of online virtual gift giving on physicians' service quality in online health communities using text mining and econometric methods. Specifically, we evaluated the impact of whether to give gifts and gift types systematically. Moreover, tie strength was carefully considered in the model as it may influence the effects of gift giving. Further, both the physicians' reply and bedside manner were used to measure service quality. The empirical results support all of our hypotheses.

Gift giving can enhance physicians' service quality, which was proven in our model and is consistent with prior studies [14]. As an important tool in social interactions [17], gift exchange is beneficial for individuals to participate in social contact. A reciprocity norm exists among people and is scrupulously obeyed; that is, people always repay each other for the mutual indebtedness within the reciprocity principle [19]. For example, in return for gifts from employers, workers will be more productive [35]. Therefore, we believe that physicians will improve their service quality when they have received gifts from patients under the reciprocity principle. In addition, gifts provide psychological gratification to the physician, as gifts from patients make them feel respected and recognized for their effort, and thus inspire them to improve their service quality.

Gifts with different motivations had different effects on influencing physicians' behaviors. We extended existing studies on gift types (eg, [15]) by investigating the consequences for giving different types of gifts, and found that although gift giving can inspire physicians to improve their quality overall, affective gifts play a more prominent role in enhancing quality compared with instrumental gifts. Our results are consistent with a previous study [32] that examined the impact of unconditional nonmonetary gifts on health worker performance in a low-income country in which unconditional nonmonetary gifts improved the performance of workers by 20% in 6 weeks compared with conditional nonmonetary gifts. Affective gifts are unconditional nonmonetary gifts, and instrumental gifts are similar to conditional nonmonetary gifts.

With respect to the moderating effects of tie strength between physicians and patients, we found that the more familiar a physician is with their patient, the role of whether to send gifts and gift type on physician service quality is decreased. Strong ties improve people's trust and obligation. Although weak ties play an important role in information transmission, a strong tie helps to obtain something more expensive and valuable [27]. Specifically, a strong tie between a physician and their patient will mitigate the effects of whether to send gifts and gift types on the physician's behavior. Our results suggest that a strong tie helps patients obtain high-quality medical services from physicians in an online health environment.

Based on the systematic empirical analyses on the motivation and effects of gift giving in an online health community, we have revealed the nature and mechanism of online gift giving. The value of the gift ranges from 5 to 200 RMB (approximately

US \$1 to \$30), which is too small to be judged as "a red envelope" (cash wrapped in an envelope). Furthermore, an online virtual gift can improve the efficiency of physician-patient communication and contribute to the establishment of a good physician-patient relationship.

Theoretical Implications

This study contributes to theory from four aspects. First, to the best of our knowledge, this study is among the first to explore the motivations and consequences of gift giving in online health communities. Although previous studies have questioned the value of gift giving in the health sector (mainly in hospital settings) and even treat gift giving as a reason to explain the current tense physician-patient relationship and moral reduction in the medical field [36,37], the specific factors that influence gift giving in an online health environment have been unknown. In contrast to the study of Zhao et al [14], both the details of reply and bedside manner of physicians were included as potential consequences of gift giving in our study. Therefore, we empirically confirmed the role of gift giving in an online health environment.

Second, this study contributes to gift theory and tie strength theory by empirically examining the different effects of gift giving on receiver behaviors in different giver-receiver relationships, which were measured by tie strength. By using unique interaction data between physicians and patients in an online forum, this study revealed significant moderating effects of tie strength on the relationships between gift giving and physicians' behaviors. Our results suggest that environmental factors need to be carefully considered to make an accurate judgment on the effects of gift giving.

Third, to the best of our knowledge, this study is among the first to empirically explore the different effects of gift types, especially in health care. Based on the characteristics of both affective and instrumental gifts, we first coded each gift by analyzing the whole interaction process between physicians and patients and then examined their respective effects. These results contribute to the current literature on gift giving by demonstrating that these two types of gifts have different impacts on the improvement of physicians' service quality.

Fourth, this study contributes to prior studies by using a large sample with a real operation date and analysis under strict criteria. Compared with survey data, our data were collected from the open transaction platform and are therefore more practical. Moreover, text mining was used to conduct sentiment analysis of the whole interaction content between physicians and patients. Text mining can help to obtain more comprehensive and accurate information with respect to an individual's emotion.

Practical Implications

The practice of gift giving has been questioned since it was first launched on online health communities, even though patients are not obligated to buy physicians gifts. Therefore, exploring the motivations and impacts of gift giving in medical services in online health communities is important because it can provide guidance on how to improve communication efficiency. All of our results suggest that giving online virtual gifts is of

considerable significance to promoting effective physician-patient communication and is conducive to the relief of physician-patient conflicts. This study offers several important practical implications for both online health community users and administrators.

For patients, a gift can be provided to physicians when the patient desires better service, as we found that digital gifts may lead to a satisfactory reply during the interaction between patients and physicians. Moreover, patients should be aware that the gift will be more powerful when their relationship with the physician is more alienated. In addition, it is better to give an affective gift in the early stage of the interaction, as these types of gifts have a more powerful influence when the patient and the physician are strangers.

For administrators of online health communities, a more useful mechanism should be established to encourage patients to give digital gifts to the physician when necessary, such as construction of a more convenient interface. In addition, reminders can be set for patients to send a gift to physicians at the right time. Moreover, the site should not immoderately encourage patients to give gifts to physicians. The original

objective of the gift-giving function is to provide a channel for patients to express their appreciation to physicians. Excessive gift giving will obstruct the development of good relations between physicians and patients. Therefore, we suggest that the administrators of online health communities set a suitable mechanism to moderate guidance for gift giving.

Limitations and Future Research

The limitations of this study can offer potential directions for future research. First, we did not obtain information on patients such as age, gender, and occupation, as patient information is rarely disclosed on the online health communities in China for privacy protection. Future research can attempt to obtain more thorough data or to eliminate the influences of patient characteristics using more complex techniques or methods. Second, as the number of physician replies by voice messages in the physician-patient interact process was very small, we deleted these from our analysis. However, voice messages may also include relevant information and may be more important than text messages as voice can convey emotion. Future studies should therefore attempt to obtain more data on voice content and useful related information.

Abstract

Background: Academics in all disciplines increasingly use social media to share their publications on the internet, reaching out to different audiences. In the last few years, specific indicators of social media impact have been developed (eg, Altmetrics), to complement traditional bibliometric indicators (eg, citation count and h-index). In health research, it is unclear whether social media impact also translates into research impact.

Objective: The primary aim of this study was to systematically review the literature on the impact of using social media on the dissemination of health research. The secondary aim was to assess the correlation between Altmetrics and traditional citation-based metrics.

Methods: We conducted a systematic review to identify studies that evaluated the use of social media to disseminate research published in health-related journals. We specifically looked at studies that described experimental or correlational studies linking the use of social media with outcomes related to bibliometrics. We searched the Medical Literature Analysis and Retrieval System Online (MEDLINE), Excerpta Medica dataBASE (EMBASE), and Cumulative Index to Nursing and Allied Health Literature (CINAHL) databases using a predefined search strategy (International Prospective Register of Systematic Reviews: CRD42017057709). We conducted independent and duplicate study selection and data extraction. Given the heterogeneity of the included studies, we summarized the findings through a narrative synthesis.

Results: Of a total of 18,624 retrieved citations, we included 51 studies: 7 (14%) *impact studies* (answering the primary aim) and 44 (86%) *correlational studies* (answering the secondary aim). Impact studies reported mixed results with several limitations, including the use of interventions of inappropriately low intensity and short duration. The majority of correlational studies suggested a positive association between traditional bibliometrics and social media metrics (eg, number of mentions) in health research.

Conclusions: We have identified suggestive yet inconclusive evidence on the impact of using social media to increase the number of citations in health research. Further studies with better design are needed to assess the causal link between social media impact and bibliometrics.

social media; research; bibliometrics; Altmetrics; journal impact factor; translational medical research

Introduction

Social Media and Its Impact in Health Research

Individual researchers and academic institutions use social media to disseminate their research findings to a broad audience that includes the public and health care practitioners. According to Carr and Hayes [1], social media can be broadly defined as “internet-based, disentrained, and persistent channels of mass personal communication facilitating perceptions of interactions among users, deriving value primarily from user-generated content”. For example, social media can be used by clinicians who would benefit from the findings in dealing with patients. A recent scoping review of the literature on social media use in health research revealed that social media are increasingly used to recruit patients, collect data, and establish and maintain user engagement, especially in the name of research dissemination [2]. At the same time, in the era of the internet and web 2.0 technologies that allow content generation and sharing [3], social media have been increasingly used as a source for measuring the impact of research, as they contribute to knowledge generation, dissemination, and translation [4]. Indeed, social media are increasingly required to measure their research performance and demonstrate the value of their research to governments and funding organizations [5]. Researchers in the domain of health and medical sciences have been particularly concerned about demonstrating the impact of their work as it usually bears implications for public health [6]. Hence, measuring the impact of health research is essential for influencing policy-making processes, improving health systems, and health-related socioeconomic impact [6]. According to the research impact framework (RIF) for health research [4], the domain of research-related impact is generally and traditionally evaluated according to conventional and traditional bibliometric approaches, which generally include the number of citations, the impact factor (IF), or the h-index [7]. Some academic institutions in the United States, Canada, and Europe started including social media impact as an evaluation criterion in their tenure and promotion policies [8]. According to the systematic review by Cruz Rivera et al [6] on the impact of health care research, researchers should consider indicators such as “the number of reads for published articles; article download rate and number of journal webpage visits; and citations rates in non-journal media such as newspapers and mass and social media (ie, Twitter and blogs)”.

Researchers can now discuss their papers and share their publications on various social networking sites [9] or with the *general public* interested in their topic. Using typology of social media by Constantinides and Fountain [10], health researchers can use 5 types of dissemination platforms: (1) blogs or web-based journals; (2) social networking sites, such as Facebook or Twitter, or professionally oriented platforms such as LinkedIn, ResearchGate, and Academia, which have recently emerged as social networking sites for academics [11]; (3) content communities; (4) forums or bulletin boards; and (5) content aggregators, such as Diigo, CiteULike, Delicious, Evernote, or through reference management software such as EndNote, Mendeley, RefWorks, Papers, and Zotero. These software companies have developed proprietary communities

of users who share citations. In this way, an article can reach new and widespread audiences, broader than those of the limited subscribers of academic journals whose content is generally protected by paywalls. Some publishers have also embraced the movement of social media dissemination by including options for authors to semiautomatically share their output on academic content aggregators that include dashboards to measure the reach and impact of social media posts, based on the link or digital object identifier (DOI) associated with each article. Examples include free platforms such as the nonprofit-owned ImpactStory; or the profit-oriented Kudos, independent from publishing houses; or Publons, owned and managed by Clarivate Analytics; and PlumX [12], owned by Elsevier.

Social Media Impact Measures

How is social media impact defined and measured? In the late 1990s, researchers started studying the phenomenon of internet-based dissemination of knowledge and information, forging the terms of *webometrics* or *cybermetrics* [13]. In 2010, a group of researchers defined a new set of metrics, Altmetrics (which stands for *alternative metrics*) that include web-based metrics (eg, number of link shares, likes, tweets, and views) and qualitative data that are complementary to traditional, citation-based metrics [14]. The so-called Altmetrics attention score (AAS) includes various indices of performance of a paper, such as the number of views; the number of discussions on social media (tweets, Facebook posts, and Wikipedia pages); recommendations (eg, Faculty of 1000); saved articles on popular social bookmarking services such as Mendeley or CiteULike; and the number of citations obtained from Google Scholar, CrossRef, PubMed Central, and Scopus [15]. Despite some intrinsic limitations—as the AAS can be inflated by self-citations, automatic retweeting, or sharing on various social media platforms [7]—Altmetrics is considered the current standard for measuring the impact of research on the internet and beyond [14–16].

Similar to the number of citations, the number of social media mentions of an article is a function of time since its publication. In 2011, Eysenbach published, in this journal, a seminal paper entitled, *Can tweets predict citation metrics on social media* [17]. The author proposed a set of measures for social media impact that would account for the dimension of *time*. The paper introduced the concepts of *Tweetations*, *Twimimpactfactor*, and *Twindex*. Tweetations were defined as “citations in a tweet,” that is, tweets mentioning the exact journal article URL (hence excluding links to DOI, PubMed entries, or other links). The twimimpact factor was defined as the “cumulative number of tweetations within n days after publication” (eg, tw7 means the total number of tweetations after 7 days) [17]. The Twindex (or tweetation index) was defined as a “metric ranging from 0 to 100 indicating the relative standing of an article compared to other articles.” It is based on a percentile, rank-ordering of an article by tweetations, relative to other articles published in the same journal, which were published around the same time [17]. The author recommended that papers investigating the relationship between citations and social media mentions should adjust for time since the publication of an article (or specify a timeframe when these metrics were obtained), journal type,

seasonal variations, and other possible confounders that might explain a nonlinear distribution of social media mentions.

Social Media and Bibliometrics

How is social media dissemination related to citations? Social media dissemination is generally associated with the higher reach of an article. Some research, sponsored by Academia.edu, showed that by sharing an article on this specific academic, social networking site, a researcher could receive up to 69% more citations over 5 years [18]. In Eysenbach's (2011) paper, the author found a positive correlation between social media and subsequent citations and social media [17]. However, to what extent is there a causal link between the use of social media and subsequent citations? In other words, what is the impact of social media on citations and bibliometric indicators? To the best of our knowledge, to date, there is only one experimental study, using a randomized controlled trial (RCT) design, that has clearly shown a causal relationship between subsequent citations and the dissemination of articles through a proprietary web-based distribution platform (TrendMD) [19]. Although TrendMD does not meet the definition of social media as intended in this paper [1], as it is not based on user-generated content, but on content that is pushed by an algorithm of sponsored recommendations, the study provides a useful benchmark. The authors found significant effects on citations and Mendeley saves for the intervention group (TrendMD) compared with the control (no diffusion on TrendMD) after 6 and 12 months [19]. In addition, the intervention had positive effects on citations at both 6 and 12 months for articles in the area of health and medical sciences [19].

However, evidence from systematic reviews on this matter seems to be scarce. A basic search for systematic reviews on Altmetrics on Google Scholar, on April 2, 2019 (in titles of articles) yielded only 24 results, 3 of which were reviews: 1 systematic review mapping the evidence for marketing research [20] and 2 literature reviews on Altmetrics used for generic scholarly research output [21,22]. In terms of health research, the review evidence is also limited. To the best of our knowledge, there is only one ongoing systematic review—whose protocol is registered in the International Prospective Register of Systematic Reviews (PROSPERO) [23]—that is aimed at evaluating the use of social media to disseminate research findings among health care professionals. A similar research conducted on April 2, 2019, on PubMed, yielded 18 hits, 2 of which were systematic reviews: the first focused on medical research output and reported significant associations between Altmetrics and traditional citations, without linking measures of impact [24]; the second is a systematic review of reviews and meta-analyses and focused on the evaluation of methodological quality in the domain of skin psoriasis [25]. The latter reported that a journal's IF could predict the number of tweets, whereas the years of publication and number of Mendeley readers predicted the number of citations on Google Scholar. Nevertheless, the authors concluded there does not seem to be a connection between scientific quality, social media, activity, and article usage [25].

Therefore, the primary aim of this study was to systematically review the literature on the impact of using social media on the

dissemination of health research. The secondary aim was to assess the correlation between Altmetrics and traditional citation-based metrics.

Methods

Protocol and Eligibility Criteria

We developed a priori protocol for this systematic review and registered it in the PROSPERO database (CRD42017057709) [23]. This review focuses on health research, which includes biomedical, epidemiological, clinical, public health, and health systems research [26]. The inclusion criteria were as follows:

- *Population*: The unit of analysis of this review is studies (ie, study reports) published in health-related journals, including primary and secondary research, and editorials.
- *Interventions/exposures*: For both aims, we included studies that evaluated the use of social media to disseminate health research, which reported the outcomes described below. In the protocol, we included examples of social media and web 2.0 applications, defined as “a group of internet-based applications that build on the ideological and technological foundations of web 2.0, and that allow the creation and exchange of user generated content” [27]. Web 2.0 applications included interactive websites, blogging platforms, social networking, and social sharing sites, as described in the *Introduction* section.
- *Comparator*: The comparator for the primary aim (assessing the impact) was not using social media.
- *Outcome measures*: To be included, studies had to report measures of research dissemination such as traditional bibliometrics, Altmetrics, or webometrics indicators. Traditional bibliometric indicators were defined as quantitative data and statistics to publications such as journal articles and their accompanying citation counts. Altmetrics were defined as web-sourced metrics and qualitative data that are complementary to traditional, citation-based bibliometrics [15]. Webometrics were defined as the study of the quantitative aspects of the construction and use of information resources, structures, and technologies on the web, by drawing on bibliometric and infometric approaches [13]. Studies were included if they measured Altmetrics about webometrics and traditional bibliometrics, without any restrictions to any specific types of metrics.
- *Study design*: Experimental studies (eg, RCTs and nonrandomized studies or cohort studies), case series, and case studies.
- *Publication type*: We included original research papers, including scientific meeting abstracts or research letters, if they contained sufficient information to fill the extraction forms.

Search Strategy

We searched the following electronic databases on July 12, 2017: Medical Literature Analysis and Retrieval System Online (MEDLINE; access via Ovid), Excerpta Medica dataBASE (EMBASE; access via Ovid), and Cumulative Index to Nursing and Allied Health Literature (CINAHL; access via EBSCO). We updated the searches on August 22, 2019. We developed a

search strategy with the help of a health information specialist with experience in systematic reviews. The search strategy encompassed 2 main concepts: *social media* (based on the search strategy of a related systematic review by one of the authors [28]) and impact on dissemination (including *bibliometrics*, *Altmetric* and *academic impact*). The search strategy used both keywords and medical subject heading terms. The search strategies used are provided in [Multimedia Appendix 1](#).

We did not use language restrictions. We did restrict the search timeframe by using the start date of January 2005, the year of the introduction of the *web 2.0* concept [3]. We also reviewed the reference lists of relevant papers and searched our files for both published and unpublished studies.

Selection Process

Before starting the selection process, we conducted calibration exercises to train the reviewers and clarify the eligibility criteria. In all, 3 reviewers (EWA, MC, and ASR) and 2 research assistants screened the titles and abstracts of identified references in duplicate and independently for potential eligibility.

We obtained the full texts for all references judged as potentially eligible by at least one reviewer through our local library. For articles not found through the library, we searched on Google, Google Scholar, ResearchGate, or Academia.edu to locate self-archived copies. We contacted corresponding authors via ResearchGate or emailed them to obtain a copy of the articles. Then, the same 3 reviewers screened the full texts in duplicate and independently for eligibility, using a standardized pilot-tested full-text screening form. Once acceptable interrater reliability was achieved, the reviewers completed the selection tasks independently. All disagreements were resolved by discussion and with the help of a third reviewer (MB), who double-checked all decisions and confirmed the reasons for exclusion.

We assessed the interrater reliability for titles and abstract screening using Gwet AC1 index, as it is less prone to bias when there is a large disproportion in binary categories (ie, excluded vs included articles) that are not judged as relevant [29,30]. We assessed the interrater reliability for full-text screening using the kappa statistic.

Data Abstraction Process

The review teams abstracted data from eligible studies in duplicate and an independent manner, using a standardized and pilot-tested data abstraction form with detailed instructions. Disagreements were resolved through discussions and with the help of a third reviewer (MB and EAA). Any inconsistencies in the abstraction tables were discussed within the research team (MB, EAA, RER, EWA, MC, and ASR) until consensus was reached. The abstracted data items included:

1. general information about the report, such as the first author's name, year of publication, type of study (eg, experimental, cross-sectional, cohort, or qualitative), health area, journal, population/unit of analysis, sources of data, and period of investigation;

2. metrics reported, such as type of social media used and type of metrics (eg, social media metrics, such as Altmetric attention score; bibliometrics, such as citations; and webometrics, such as page views and number of downloads);
3. results, as reported by the study authors; and
4. funding and reported conflicts of interest.

For experimental studies, we collected additional specific information about the intervention (eg, sample size, frequency and reach of the intervention, duration and frequency of the intervention, and profile owner) and control conditions, where applicable. We also extracted the information about effects (eg, *F* tests and *t* tests) and *P* values, as reported by the authors. We used a web-based effect size calculator [31] to estimate effect sizes if they were not included in the original publication. One author (MB) checked all abstraction tables for consistency.

When correlations between social media metrics and citations were reported, following Eysenbach recommendations [17], we also extracted details about whether the paper: (1) reported social media metrics adjusted for time (eg, Twimpact factor) or provided a rationale for selecting a timeframe to assess the relationship, (2) included social media metrics that adjust for some kind of confounders (eg, using Twindex metric or stratifying by article type and/or topic), (3) the type of correlation test used (eg, using Spearman rho and/or Pearson *r*), and (4) explored the correlation using scatterplots or employed tests for nonlinear relationships (eg, log-linear and/or nonparametric tests).

Data Synthesis

Given the heterogeneity of the included studies in terms of characteristics of the population, health area, study design, and reported outcomes (including *P* values and correlation coefficients), we summarized the findings through a narrative synthesis. In the summary tables included in this review, we reported *P* values and correlation coefficients and measures of effect sizes, as explicitly mentioned by the authors of the selected studies. We followed *Journal of Medical Internet Research's* convention for reporting *P* values (3 digits) and correlation coefficients (2 digits). We included the text of the original source in quotation marks. For studies reporting correlations between social media and citation metrics, we defined the methodological quality of the paper using 4 indicators, using Eysenbach (2011) paper as a benchmark [17]: (1) appropriately adjusting for time, (2) appropriately adjusting for confounders, (3) appropriately exploring correlations, and (4) appropriately reporting nonlinear correlations tests and statistics. Appropriately adjusting for time means that the article accounted for the variability in the metric by time or specified a time when the social media metric was obtained about the time of data analysis. Appropriately adjusting for confounders means that the social media metric was adjusted for confounders, such as journal type, article type, and for the journal and the season, for example by using the Twindex metric, which is a percentile ranking relative to other articles published in the same journal and the same period. Appropriately exploring correlations involves the authors checking for correlations between social media metrics and bibliometrics by inspecting

scatterplots. Appropriate reporting of tests for nonlinear correlations, such as Spearman rho correlations, log-linear tests of relationships, or other statistics, was based on ranking for non-normal distributions in the citations and social media mentions. We used the following scoring convention: (1) accounting for the time when selecting the data timeframe or acknowledging the role of time since publication (+) and adjusting the social media metric for time (++); (2) appropriately adjusting for confounders such as article type, topic, and/or subject (+) and seasonality or time factors using Twindex or similar metrics that account for the relative ranking of the article to the journal and season (++); (3) appropriately exploring correlations by including scatterplots (+); and (4) appropriately reporting nonlinear correlation tests and statistics (+) as well as log-linear relationship tests (++).

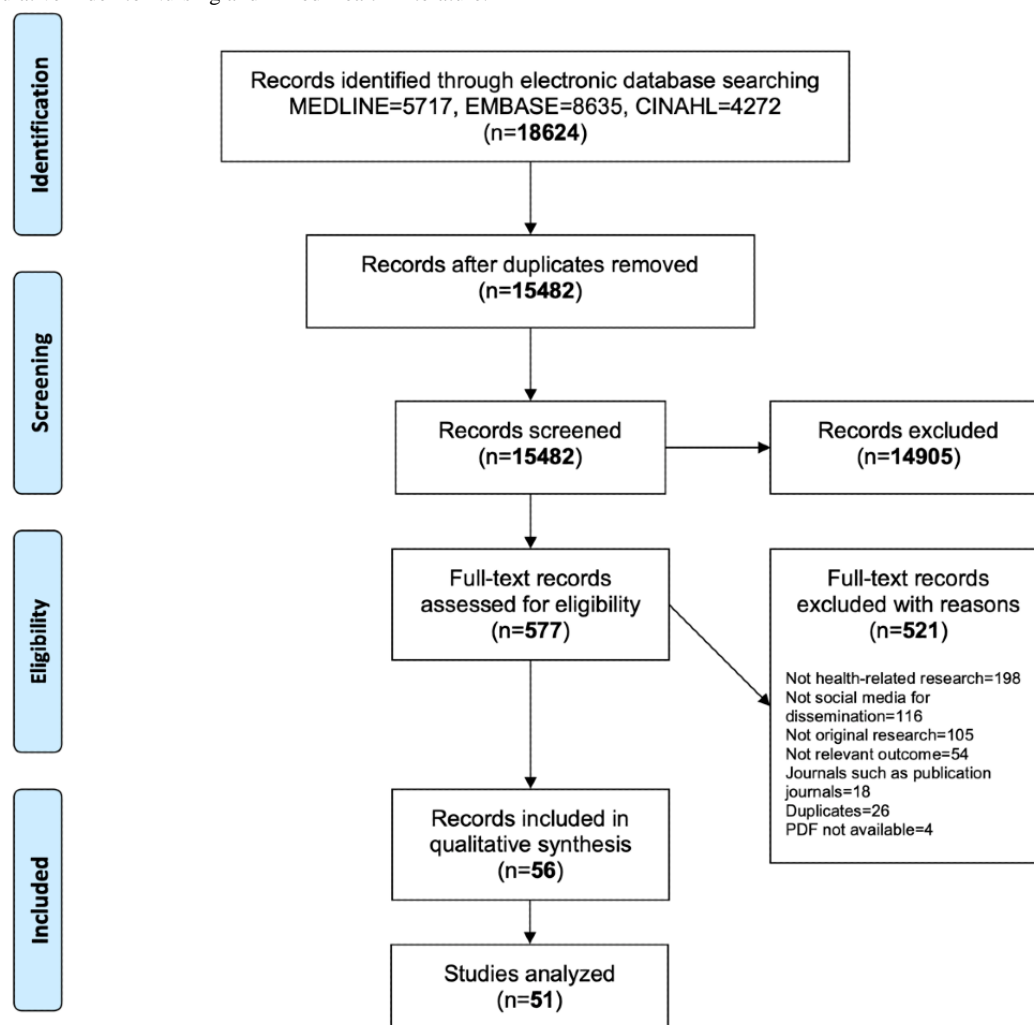

Results

Study Selection

Figure 1 shows the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram. Searches in the selected electronic databases yielded 13,576 records in July 2017 and 5048 in August 2019, totaling 18,624. Of these, 577 were selected for full-text screening, following a duplicate

and independent selection process. The level of agreement at the title and abstract screening phase was high (mean Gwet AC1 0.96, SD 0.03). Similarly, we excluded 521 of 577 full-text records, achieving a substantial interrater agreement (mean Kappa 0.69, SD 0.22; mean Gwet AC1 0.77, SD 0.04). We excluded these 521 articles for the following reasons (a list of excluded records is provided in [Multimedia Appendix 2](#)): 198 did not discuss health-related research; 116 discussed social media application use, but not for disseminating research; 105 were not original research articles (ie, editorials, commentaries, conceptual papers, literature reviews, praising the use of social media for research dissemination); 54 did not report relevant study outcomes (ie, focusing either on Altmetrics, social media, or citation metrics separately); and 18 were records discussing the use of social media to increase the impact of a journal. Other reasons for exclusion were as follows: 26 were duplicates and 4 were citations of conference abstracts. After consensus-seeking discussions, we judged 56 records as eligible for inclusion in this systematic review, representing 51 unique studies, as 5 studies presented the same data in different publications (an abstract followed by a publication in a journal). The studies were by Amath [32,33], Hayon [34], Knight [35,36], Nolte [37,38], and O'Connor [39,40]. A total of 5 articles included only a conference abstract but were deemed to provide sufficient data for inclusion [41-45].

Figure 1. PRISMA flow diagram. MEDLINE=Medical Literature Analysis and Retrieval System Online, EMBASE=Excerpta Medica dataBASE, CINAHL=Cumulative Index to Nursing and Allied Health Literature.

Characteristics of the Included Studies

A total of 7 of 51 studies (14%) were categorized as *impact studies* [46-52], as they presented some interventions that tested the use of social media to disseminate research articles. The main characteristics of impact studies are summarized in Table 1. In all, 86% (44/51) studies were categorized as *correlational studies* [16,17,25,32,34,36,38,39,41-45,53-83], as they described the associations between traditional bibliometrics and Altmetrics. Correlational studies were classified according to

the number of quality indicators as follows: *very good quality*, with 4/4 indicators (7/44, 16% studies; Table 2); *good quality*, with 3/4 indicators (8/44, 18% studies; Table 3); *fair quality*, with 2/4 indicators (10/44, 23% studies; Table 4); *poor quality*, with 1/4 indicators (12/44, 27% studies; Table 5); and *very poor quality*, with 0/4 indicators (7/44, 16% studies; Table 6). Detailed information of all 51 studies is included in Multimedia Appendix 3. In the next paragraphs, the results are presented separately, following the primary and secondary aims of this study.

Table 1. Characteristics of studies assessing the impact of social media interventions (n=7).

References	Health research area	Unit and period of analysis	Type of study	Social media interventions	Metrics reported	Results
Allen, 2013 [48]	Clinical pain sciences	16 original research articles from <i>PLOS ONE</i> (2006-2011)	Quasi-experimental (before-after)	Blog posts shared on Facebook, Twitter, LinkedIn, and ResearchBlogging.org	Citations (Scopus); HTML views and PDF downloads	Significant increase in HTML and PDF views; no significant effect on citations approximately 1 year after publication
Cawcutt 2019 [50]	Women's health	8 original research articles published in 8 journals (2018)	Quasi-experimental (before-after)	Tweets shared during a Physician's Weekly tweet chat event (#PWChat)	Article downloads; AAS ^a	Increased AAS; increased downloads (statistical significance not reported)
Fox, 2015 [46]	Cardiology	243 articles, 121 intervention and 122 control, available from <i>Circulation</i> journal (2013-2014)	Experimental (RCT ^b)	Twitter and Facebook posts through the official circulation of social media accounts	HTML views and PDF downloads	No significant difference in 30 days' HTML views (and downloads)
Fox, 2016 [47]	Cardiology	152 articles, 74 intervention and 78 control, available from <i>Circulation</i> journal (2015)	Experimental (RCT)	Twitter and Facebook posts through the official circulation of social media accounts	HTML views and PDF downloads	No statistically significant difference in 6-day or 30-day page views (and downloads)
Hoang, 2015 [52]	Radiology	2 research articles appearing on the <i>American Journal of Neuroradiology</i> and the <i>American Journal of Roentgenology</i> (2013-2014)	Quasi-experimental (retrospective cohort)	Blog posts on Radiopaedia.org; podcast shared on Twitter and Facebook	HTML views and PDF downloads	Increased page views during the intervention; no increased activity beyond the podcast
Thoma, 2018 [51]	Emergency medicine	29 articles selected for intervention and control from the <i>Canadian Journal of Emergency Medicine</i> (2016)	Experimental (RCT)	Podcast or infographic or standard social media promotion through Twitter and Facebook	HTML views	Using podcasts and infographics was associated with increased Altmetric scores and abstract views but not full-text article views; they did not significantly increase full-text readership
Tonia, 2016 [49]	Public health	130 articles, 65 intervention and 65 control, from the <i>International Journal of Public Health</i>	Experimental (RCT)	<i>International Journal of Public Health</i> blog, Twitter, and Facebook accounts dissemination	Article abstract, PDF views, and downloads; citations; AAS	Number of downloads and the number of citations significantly correlated for all papers, with the correlation being stronger in the intervention group

^aAAS: Altmetrics attention score.^bRCT: randomized controlled trial.

Is There Evidence of the Impact of Social Media?

In this section we elaborated on the findings related to the different areas of research, study type, social media intervention characteristics, metrics assessed, and reported results, as summarized in Table 1.

Areas of Health Research

Impact studies have reported the use of social media interventions to promote original research articles published in academic journals in the subject areas of clinical pain sciences (ie, *PLOS ONE*) [48], cardiology (ie, *Circulation*) [46,47], radiology [52], emergency health [51] public health (ie,

International Journal of Public Health) [49], and women's health (various journals) [50].

Study Types

We identified 4 randomized controlled experiments, further referred to as RCTs [46,47,49,51], and 3 quasi-experimental trials [48,50,52].

Social Media Intervention Characteristics

Articles in the intervention conditions were shared on Twitter or Facebook social media profiles of the targeted journals using automated or manually made posts leveraging the organic (ie, unpaid) reach of each social networking site. One study used

advertising to increase the views of Facebook posts (ie, *boosted* content) to increase reach, which is the number of viewers of the post [47]. Intervention duration ranged from 12 [49], 18 [48], 34 [47], to 52 weeks [46]. The intensity varied considerably: only once the content was blogged [48], 1 post every 2 weeks and 12 weeks [49], 1 or 2 posts per week [46], or several posts per day [47]. Three studies used blogs to diffuse the studies further [48,49,52]. Thoma et al [51] tested the use of a podcast and infographics as complementary information in addition to Facebook and Twitter content sharing. The interventions varied in nature of the message posted, the profile of the social media owner(s), the duration of the posting, its intensity, and whether an incentive or paid promotion was used. For example, in one of the quasi-experimental trials [48], the authors advertised the posts related to 16 original research articles about clinical pain sciences, published on *PLOS ONE*, through a systematic intervention targeting Facebook, Twitter, LinkedIn, and ResearchBlogging.org. The authors used a systematic protocol (ie, timing the frequency of release of the messages) to direct social media users to read a web-based version of the original research article.

Metrics Assessed

These studies investigated the effect of social media interventions on subsequent access to web-based journal content and article downloads. Two studies (1 experimental [49] and 1 quasi-experimental [48]) reported the effect on the number of citations.

Reported Results

Although the quasi-experimental trials reported an increase in HTML and PDF views during the intervention [48,50,52], the RCTs reported no significant changes in the same metrics [46,47,49,51]. There were no significant effects on the number of citations in both the quasi-experiment [48] and the RCT [49].

What Is the Association Between Altmetrics and Bibliometrics in Health Research?

In this section we present the results related to the correlational studies identified.

Areas of Health Research

The 44 correlational studies evaluated the relationship between Altmetrics and bibliometrics in a variety of health research fields and disciplines, covering generic medical or biomedical research disciplines [16,57,60-62,66,70,78,81-83], or more specific disease-related research fields, such as multiple sclerosis [43], neurological research [73], Parkinson disease [53], psoriasis [25], and sepsis [44,67]. Some articles covered clinical or dental medicine [64,65,75] and different kinds of surgery [59,68,77]; others focused on specialized branches of medicine, such as urology [34,38,39,58], radiology [76], and coloproctology [69].

Study Types

Almost all correlational studies were quantitative cross-sectional studies (43/44, 97%) examining the relationship between bibliometrics and various social media metrics or monitored citation trends over time [52,83]. The association between social

media use and citations was also discussed in a qualitative study [53].

Metrics Assessed

Correlational studies encompassed a wide variety of Altmetrics and bibliometrics. Some correlational studies have investigated the association between Altmetrics scores and citations in Web of Science, Scopus, or Google Scholar [36,39,53,61,62,66,70,74,76,81-83]. One study investigated the correlation between ImpactStory indices and Scopus citations [60]. Other studies focused on the usage metrics of specific social media platforms, such as Twitter [17,42,56,74], blogs, web-based posts [52,58], ResearchGate, or Mendeley [57]. A total of 4 studies reported data on the association between the Altmetric of articles and the IF of journals in which they were published [38,59,60,83]; 3 studies investigated the relationship between sharing articles on academic social media platforms, such as ResearchGate and reference management software Mendeley [44,57,75].

Methodological Quality

As shown in the last 4 columns of Tables 2 to 6, the methodological quality of the papers varied according to the type of article and amount of detail included in the publication. The 5 conference abstracts included in the list of correlational studies [41-45] did not provide sufficient information to meet most of the methodological quality indicators. Only 3 of these [41,42,44] provided different correlation results according to the type of disease area, topic, or article type; hence, they were deemed to have adjusted for confounders. Of the remaining 39 studies with full-text, 16 adjusted the social media metric for time (16/39, 41%); 22 studies adjusted for confounders such as article type or topic (22/39, 56%), but none included the seasonality and timeframe of the article publication. Some 21 studies included scatterplots to explore the type of correlation (21/39, 54%), and 18 studies reported the use of Spearman rho or other nonparametric tests when comparing social media citation counts (18/39, 46%). However, only 2 studies [74,81] reported analyses for tests based on ranking similar to log-linear correlations included in a study by Eysenbach [17]. The method used in a study by Quintana and Doan [74], but described in the paper by Thelwall et al [81], “compares a given publication against the publications that appeared immediately before and after it. A successful test occurs when the number of Twitter mentions and citations for a given publication are both higher (or both lower) than the average of Twitter mentions and citations of the two adjacent articles” [81].

A total of 6 of 39 studies (15%) [16,36,61,64,71,72] met the minimum standard in all 4 criteria mentioned above, but none followed exemplar paper by Eysenbach [17] when reporting correlations between social media metrics and citations. In all, 7 studies scored at least three criteria (7/39, 18%). Of these studies, 4 scored criteria 2-3-4 [40,66,76,78], 2 studies scored 1-2-4 [62,82], and 1 study 1-2-3 [67]. The remaining 18 studies scored less than 2 of any quality criteria (18/39, 46%).

Reported Results

Twitter was the most popular social media platform discussed in correlational studies (21 of 44 studies)

[16,17,32,34,38,42,45,53,55,56,59,62,63,68,69,72,74,76,78-80], followed by Mendeley (15 studies) [25,45,55,57,60,63,71,72,75-79,82,83]. In reference to the association between Altmetric scores and bibliometrics, the results were mixed. No significant correlations were reported in 12 of 44 studies (27%) [25,41,42,44,45,55,64-66,71,77,83]; *weak* or *moderate* correlations were reported by authors in 13 of 44 studies (30%) [16,17,39,43,53,61-63,67,72-74,76]. *Strong* positive associations were reported by the authors of half (22) of the correlational studies. In particular, strong associations were found between Mendeley readership (reads and downloads) and subsequent citations [25,45,57,60,75,77-79,82]. This is also consistent with the findings reported in one of the impact studies [49], which found significant correlations between the number of downloads of a paper and the subsequent number of citations ($r=0.52$; $P<.001$), which were larger in the intervention group ($r=0.67$; $P<.001$). Only 2 studies reported no significant associations between traditional and social media metrics [66] and between Altmetric score and journal IF, ResearchGate reads, and the number of article downloads [83].

When focusing only on the 7 high quality studies (ie, those meeting all methodological quality criteria 1-4) [16,17,36,61,64,71,72], 5 studies reported correlation coefficients of moderate size [16,17,36,61,72] and 2 studies, from the same discipline (orthodontics), reported no significant correlations [64,71].

Discussion

Is There Evidence of the Impact of Social Media?

The primary aim of this review was to evaluate the effect of social media on the dissemination of health research output. Of the 51 identified studies, only 7 were experimental studies aimed at establishing a causal link between social media use and subsequent citations. The identified impact studies provide suggestive yet inconclusive evidence on the effect of using social media to increase the number of citations, thus contributing to the dissemination of health research according to traditional bibliometric indicators. This result is consistent with findings reported in a systematic review, which was aimed at describing the interactions between bibliometric factors and social media activity on the impact of reviews in the field of psoriasis [25]. The findings suggest that although Google Scholar citations were predicted by the number of readers on Mendeley and year of publication (ie, 2015 and 2016), the number of tweets and the IF of a journal were not. Moreover, a journal's IF was the sole significant predictor of the number of tweets [25]. Careful considerations should be made, as the limited number of studies we identified does not allow us to generate strong conclusions or recommendations.

In our review, we identified four impact studies [46,47,49,51], which used randomized controlled experiments. However, unlike in the TrendMD dissemination study [19], these RCTs did not show consistent effects of the social media dissemination strategies on citations over time. This finding might be due to several limitations. First, the experiments used *social media interventions*, which had very different intensities (eg, once vs several posts per day) and duration (ie, 12-52 weeks). This fact

does not allow us to determine whether the effect was due to a *dose-response* or to mere exposure to the intervention. Consequently, the long-term effects of social media interventions are still unclear as the only long-term study (52 weeks) [46] reported no difference in median 30-day page views between the intervention and control conditions. However, a larger, longitudinal RCT on TrendMD distribution showed higher citation counts in health and medical science articles after 6 and 12 months than in a control group [19]. Second, the reported social media impact outcomes differed in terms of content and type of social media channel used, frequency and intensity of social media use, type of exposure, and unit of analysis. It is important to note that careful consideration should be made when comparing social media interventions across the spectrum of platforms and types of social networking sites. A journal's or author's Facebook page or Twitter handle that originally has 100,000 followers would very likely increase the reach of an article shared, compared with a page that has only 1000 followers. This finding could have implications on the effect of increased citations in journals that already have a high IF compared with journals that have a low IF (as the accounts of the former would have a higher number of followers). In other words, the *social media interventions* were too heterogeneous to compare among each another and to perform meta-analyses.

Future impact studies should maintain a rigorous study design; consistently report social media outcomes using standard Altmetric scores; provide better and more detailed explanations about the specific timeframes, exposure, frequency, and intensity of interventions for comparability. In other words, future studies should answer research questions such as to what extent does the frequency of social media posting influence short-term indicators (eg, number of PDF downloads) and long-term indicators (eg, Altmetric score and citations)? To what extent does posting on Mendeley and Twitter, as opposed to Twitter, have an impact on the Altmetric score and citations?

This information could help researchers specialized in systematic reviews to develop accurate evidence, including meta-analyses; the information could also be helpful for researchers aimed at testing different social media intervention strategies or at comparing similar methodologies in different domains or disciplines. Other factors that can explain the lack of findings are in the topics of the information shared on social media. Some very specific health disciplines have limited readership, as they require specific knowledge to understand the content that is shared.

What Is the Association Between Altmetrics and Bibliometrics in Health Research?

Another finding of this review is that most of the available evidence focuses on describing correlations between traditional and social media metrics in health research. The included 44 correlational studies provide further support that, in general, the higher the AAS, the higher the subsequent citations will be. However, the studies reported wide variability in the magnitude of correlation coefficients and provided a variety of interpretations for the strength of these correlations, which warns some caution. Most reports did not provide in-depth evaluations

of the correlations, including, for example, confidence intervals of the correlation coefficients; an analysis of the distribution of citation counts and social media metrics, which tend to violate the assumptions of normality; and the use of visual representations such as scatterplots, as recommended by some researchers [84,85]. We identified only 6 correlational studies [16,36,61,64,71,72] meeting the minimum methodological quality criteria (1-4) described in the methodology, in addition to the seminal paper by Eysenbach, 2011 [17]. Most notably and quite surprisingly, none of the identified 44 studies followed the recommendations and metrics suggested by Eysenbach. No paper included the Twindex or the Twimetric factor or correctly adjusted the social media metrics for the time since publication or seasonality in publication and for the skewed distribution of the metric, for example, by dichotomizing result or testing for log-linear correlations.

Twitter and Mendeley seem to be the indicators that contribute the most to the Altmetric score. Mendeley and ResearchGate were positively associated with subsequent citations [25,45,77,79]. Although Twitter can be used to disseminate research output among a broader, general public, the use of Mendeley and ResearchGate seems to be restricted to specific target audience of researchers or media professionals. Unsurprisingly, the more an article is shared on ResearchGate or Mendeley, the more it will be cited. This finding might indicate that researchers use reference management software (Mendeley) to organize their libraries for research purposes and then share their research on a specialized social networking site (ResearchGate). This software allows users to discover new *related research* because the platform itself suggests new evidence based on the users' previous reads and mentions. Although this does not imply that research has been disseminated among the wider public, ResearchGate and Mendeley appear fundamental for the research community.

Our findings are consistent with some existing review evidence investigating the domain of medical research output [24], as well as other multidisciplinary research fields [21,22], or marketing [20]. Another review that focused on orthopedic research journals [86] reported that web-based mentions were weakly yet positively related to various bibliometric indices, such as the number of citations, journal IF, Eigenfactors, and h-index values for the first and last authors. In addition, a systematic review of reviews published in scientific journals related to skin psoriasis [25] found an association between Altmetrics and bibliometric indicators. The association between traditional bibliometrics (eg, number of citations) and social media metrics (eg, number of mentions) could be an indicator of a positive effect of using social media on research dissemination. However, not all correlational articles identified showed strong positive correlations. The association could be confounded by several factors, such as the value of the research paper or the popularity of the topic, as we have previously discussed. In other words, a high-value research paper could lead to both high exposure on social media and a high number of citations, depending on the intrinsic subject. An article discussing skin psoriasis, or another more common disease, might attract the attention of the wider general public, compared with coloproctology and neuro-interventional surgery, which

attract audiences of specialized health care professionals. Moreover, researchers can discover articles to cite from other *traditional* sources, such as electronic databases and libraries. Once an article is published and cited, other researchers might want to share the discovery on their social networking sites. Hence, using social media to diffuse health research may generate a virtuous circle that can be beneficial for both individual researchers and journals, as this will result in an increased IF. We need more evidence of good quality experimental, *impact studies* rather than correlational studies to establish a causal link between social media use and impact on citations. We also need better reporting of correlational studies; following the suggestions included in the seminal paper by Eysenbach [17], researchers should strive to provide more insight (and data) on the actual distribution of bibliometrics and social media metrics analyzed so that more meaningful interpretations of the relationship between these variables could be drawn.

Recommendations

Scientific impact is a multidimensional concept that cannot be adequately measured by a single indicator [87]. As the AAS suggests, social media impact is even more multidimensional, as it is linked to various web-based tools that a particular researcher can use. This researcher is also embedded in a unit within an institution [88]; the researcher's work is then published in a journal, which has a specific and independent impact (IF, citations, and Altmetrics). The evaluation of the researcher's scientific impact on social media should then take into account various dimensions and indicators and be aligned with more qualitative evaluation on other domains of the RIF [4], which includes policy, service, and societal impacts.

In conclusion, is social media dissemination worth the effort? On the basis of the findings of this review, we recommend researchers in health sciences to continue using social media to disseminate their research, as there is some data suggesting its long-term impact on citations following dissemination on the internet using paid services (eg, TrendMD study) [19]. Researchers should use popular social networking platforms, such as Twitter or Facebook, first to engage with the general public and the media, to design more citizen-oriented research and democratize their findings. Researchers should also use popular social networking sites to interact with peers and discuss their research as well as disseminate their findings. Researchers should also diffuse their work on specialized social networking sites for academics, such as Mendeley, ResearchGate, and Academia. The content shared on these networks is very likely to be cited, as researchers who are on Mendeley may use it as a reference management software. Mendeley and ResearchGate databases may be used in combination with traditional electronic databases for literature reviews and similar activities. Storing copies of articles on these platforms could increase the chances of a paper being cited in the future.

Although more rigorous longitudinal research needs to establish whether social media activity can be linked to increased citations, it is important to consider social media as useful tools to reach a wider public, not just specialized audiences. Researchers should put effort into translating knowledge for

different target audiences, bearing in mind the users of each social media channel. The AAS can be a useful instrument that allows researchers and institutions to evaluate social media impact by distinguishing among the attention generated by specialized applications (Mendeley and ResearchGate) or by the wider public and traditional media (Facebook, Twitter, and blogs).

Strengths and Limitations

This review sheds light on the use of social media to disseminate health research output. The main strength of this review is the use of standard methods of a systematic review, including a comprehensive search strategy, a duplicate approach to study selection and data abstraction, and detailed data abstraction. The main limitation is that we were not able to conduct a meta-analysis because of the substantial variability in the included studies. For example, the impact studies varied in terms of the interventions evaluated (eg, type of social media used, the message posted, and its duration and intensity) and the outcomes assessed.

Conclusions

Our findings have implications for research in the field of health-related metrics. There is a need for more and better

designed experimental studies testing the use of social media to increase the dissemination of health research. These studies should be of a randomized design, evaluate the appropriate use of social media, and assess a variety of outcomes (both all Altmetrics dimensions and traditional bibliometrics) over a meaningfully long period. For example, experimental trials could test different strategies to diffuse research articles on social media, by comparing paid (or *boosted*) content with nonpaid, *organic* posts. Other trials could include the diffusion of research article links on numerous social networking sites versus a limited number of sites. Once there is evidence of the effectiveness of using social media (as opposed to not using them), different approaches should be investigated.

Our findings also have implications for the practice of using social media for research dissemination. Researchers should not use social media for the sole purpose of increasing their research productivity (ie, number of publications), as there is currently no evidence to support such an effect. They can use it for other purposes, such as disseminating their findings to social media users. When using social media, they have to be attentive to details such as the content of the message, its frequency, and the use of incentives or paid promotions, as this could affect the reach of the posts.

Acknowledgments

The authors would like to acknowledge Ms Aida Farha from AUB libraries for her help in developing the search strategy and Ms Layal Hneiny, who performed the electronic database search updates. The authors would also like to thank Mr Fadel Al Turki, Dr Sanaa Baddour, Ms Maya Hammoud, and Ms Matilda Sang for their help in reviewing the abstracts.

Authors' Contributions

EAA, RER, MB, LIM, and SB conceived and designed the review, and EAA, RER, and MB coordinated it. EAA, RER, MB, and LIM were involved in developing the search strategy, and MC, EWA, ASR, and MB extracted the data. Data analyses were undertaken by EAA, RER, and MB, whereas data interpretation was done by EAA, RER, and MB. RER, EAA, and MB drafted the review. All authors reviewed and approved the final version of the manuscript.

Abstract

Background: Data standards for race and ethnicity have significant implications for health equity research.

Objective: We aim to describe a challenge encountered when working with a multiple-race and ethnicity assessment in the Eastern Caribbean Health Outcomes Research Network (ECHORN), a research collaborative of Barbados, Puerto Rico, Trinidad and Tobago, and the US Virgin Islands.

Methods: We examined the data standards guiding harmonization of race and ethnicity data for multiracial and multiethnic populations, using the Office of Management and Budget (OMB) Statistical Policy Directive No. 15.

Results: Of 1211 participants in the ECHORN cohort study, 901 (74.40%) selected 1 racial category. Of those that selected 1 category, 13.0% (117/901) selected Caribbean; 6.4% (58/901), Puerto Rican or Boricua; and 13.5% (122/901), the mixed or multiracial category. A total of 17.84% (216/1211) of participants selected 2 or more categories, with 15.19% (184/1211) selecting 2 categories and 2.64% (32/1211) selecting 3 or more categories. With aggregation of ECHORN data into OMB categories, 27.91% (338/1211) of the participants can be placed in the “more than one race” category.

Conclusions: This analysis exposes the fundamental informatics challenges that current race and ethnicity data standards present to meaningful collection, organization, and dissemination of granular data about subgroup populations in diverse and marginalized communities. Current standards should reflect the science of measuring race and ethnicity and the need for multidisciplinary teams to improve evolving standards throughout the data life cycle.

Introduction

The cutting edge of precision medicine, such as the integration of contextual data about the social determinants of health with

individual health data and the leveraging of data from across different studies, is seen as a mechanism to innovate and solve health problems for all populations [1,2]. These solutions can only be realized by grounding them in the concept of health

equity [3,4]. According to the Robert Wood Johnson Foundation [5],

Health equity means that everyone has a fair and just opportunity to be healthier. This requires removing obstacles to health such as poverty, discrimination, and their consequences, including powerlessness and lack of access to good jobs with fair pay, quality education and housing, safe environments, and health care.

To attain health equity, the research community must identify where health disparities exist but may inadvertently exacerbate health disparities by failing to identify invisible or at-risk populations. Without this information, we may reinforce inequities rather than identify policies, laws, systems, environments, and practices that can improve opportunities for health in these communities [6-9].

There is a significant body of literature about the collection of and proposed definitions for more granular data for race, ethnicity, and other demographic data in the health sciences that would better identify at-risk populations. In some areas, more granular data collection is used to be more inclusive of the ways that individuals self-identify and to examine how racism and discrimination affect health in these populations [10-13]. However, the research community has not sufficiently considered how to meaningfully organize granular data about subgroup populations in diverse communities so that these data can be used across multiple studies to address the challenges in these communities [5,14]. In this paper, we used our experience with a cohort study in the eastern Caribbean to illustrate the need for an updated and comprehensive data standard to enable future data integration and sharing of data sources for diverse multiracial populations.

Methods

The Eastern Caribbean Health Outcomes Research Network (ECHORN) cohort study follows community-dwelling adults older than 40 years residing in Barbados, Trinidad, Tobago, and the United States' territories of the US Virgin Islands and Puerto Rico [15]. Baseline participants were enrolled between 2013 and 2016 and completed a questionnaire to capture self-reported sociodemographics and health-related information. In the questionnaire, participants had the option to self-identify race and ethnicity by selecting any of the items listed: mixed or multiracial, white, black or African, Caribbean, Asian, East Indian, Hispanic or Latino, Puerto Rican or Boricua, other, or prefer not to answer. This list was developed with stakeholder input to reflect the current scientific literature on the measurement of race and ethnicity in epidemiologic and health outcomes research. Excluding the choice of "other", there were 256 potential answers.

The National Institutes of Health (NIH) requires investigators to collect and report race and ethnicity based on Office of Management and Budget (OMB) Statistical Policy Directive No. 15 data standards, developed in 1977 and updated in 2007 [16]. The standards include 7 race and ethnicity categories, with instructions to use 2 questions. The first question collects

ethnicity information (Hispanic/Latino or not Hispanic/Latino), and the second provides the option to select more than one of the 5 racial categories (American Indian or Alaska Native, Asian, black or African American, Native Hawaiian or other Pacific Islander, or white). Data reported are required to include (1) the number of respondents in each ethnic category, (2) the number of respondents who selected only 1 of 5 racial categories, (3) the number of respondents who selected multiple racial categories, and (4) the number of respondents in each racial category who identified as Hispanic or Latino. Reporting detailed distributions of multiple responses should be aggregated into the required categories.

Results

In an analysis of ECHORN data from 1211 participants, 901 (74.40%) selected 1 racial category. Of those that selected only 1 category, 13.0% (117/901) selected Caribbean; 6.4% (58/901), Puerto Rican or Boricua; and 13.5% (122/901), mixed or multiracial. A total of 17.84% (216/1211) of participants selected 2 or more categories, with 15.19% (184/1211) selecting 2 categories and 2.64% (32/1211) selecting 3 or more categories. The participants who selected more than one category included but were not limited to white Hispanic, black Hispanic, black Asian, black East Indian, and Caribbean Hispanic individuals. Based on OMB data standards, by collapsing those who selected multiple groups and those who selected only the multiracial and mixed category, 27.91% (338/1211) of the ECHORN participants are placed in the "more than one race" category. The nuanced race and ethnicity data become simply "more than one race, black or African American, white, Hispanic or Latino, Asian, or not reported/unknown."

Discussion

Principal Findings

Data standards for race and ethnicity need to reflect and evolve with the scientific advances around the measurement and mechanisms by which race and ethnicity can affect health [17,18]. The stated goals of the OMB standards are to harmonize the collection and presentation of population race and ethnicity information across federal databases and to facilitate comparisons and analyses [16]. To achieve the objectives of precision medicine, ECHORN data on those who selected multiple categories, such as the white Hispanic, black Hispanic, black Asian, black East Indian, or Caribbean Hispanic individuals, could be aggregated with other data sources with defined granular race and ethnicity data on this population. For example, the US Census Bureau has developed granular data collection standards on race and ethnicity, quantifying the growth of these multiracial and multiethnic populations. The State of Massachusetts, along with other states, has for several decades mandated the collection of more granular race and ethnicity information, with over 30 categories on many data collection forms, including birth certificates and clinical data [19-21]. However, it is not specified how multiracial and multiethnic populations' granular data can be harmonized to facilitate comparisons and analyses across any datasets collected using different standards. Current research collaborations, such

as Observational Health Data Sciences and Informatics, that are focused on facilitating harmonization and sharing data by using standard ontologies such as Systematized Nomenclature of Medicine - Clinical Terms and Logical Observation Identifiers Names and Codes, have no agreed-upon standard for granular race and ethnicity data or a mechanism to map across data standards [22].

Standards have not been refined or expanded adequately to accommodate studies collecting granular race and ethnicity data on mixed or multiracial individuals [23,24], and these imprecise standards have unmeasured effects on health. Current standards may contribute to health disparities by providing insights on persons privileged by these data structures and by further marginalizing persons whose racial and ethnic identity is obscured in suboptimal data standards for classification and harmonization. While the OMB standards clearly state that “the racial and ethnic categories set forth in the standards should not be interpreted as being primarily biological or genetic in reference,” [16] current standards used in health sciences continue to support the conflation of the social categories of race and ethnicity with the biologic and genetic categories in day-to-day practice. This conflation has powerful implications for population-level biomedical discoveries and clinical care and treatment [25]. For example, inherent inequities in data standards are reflected in the continued use of monoracial guidelines as the standard of care in clinical practice, in spite of knowledge that suggests the fallacies of this framework [26,27]. It also has implications for population genetics and the translation of discoveries. These social constructs are used to develop standards for genetic population norms, wherein outlier data are discarded and study findings are associated with a singular racial group, influencing the development of biologic treatments directed at mutations that are predominantly in a particular racial group [28,29]. However, there is no biological origin for much of what we define as health inequities [30]. At the individual level, understanding how contextual factors, such as racism and discrimination, affect how a multiracial and multiethnic person understands and addresses their own health risks is significantly limited because of the lack of data and data standards that organize and share granular data in a viable way [31]. Importantly, multiracial and multiethnic populations are only one example of diverse subgroups affected by this lack of evolved standards; we risk the loss of rich information on the

individuals who select more than one category for their race and ethnicity.

Several incremental changes can be instituted to improve these data standards on race and ethnicity. In addition to standardizing the definitions and collection of more granular race and ethnicity data across research studies, as advocated by numerous prior researchers [10-13], the standards need to be developed and adopted by funding agencies, such as the NIH, so that researchers from different groups who are collecting granular data can share and aggregate data [32,33]. These comprehensive data standards need to specify how to systematically categorize self-identified granular race and ethnicity data for those who have selected 2 or more categories. The standards can provide mechanisms to map race and ethnicity data collection standards to other standards over time, such as the Centers for Disease Control and Prevention Race and Ethnicity Code Set, Version 1.0, or the United States Census Bureau [32-34]. As data are collected and shared between regional and national entities, this mapping between standards will enable the aggregation of smaller data about underrepresented populations across studies and global contexts [32,35,36] and will provide a systematic method for individuals who have collected granular data to organize and map their data to less-evolved data collection standards.

Conclusion

Comprehensive data standards for race and ethnicity throughout the life course of health science research studies are critical to identifying and achieving health equity for populations differentially affected by discrimination [23,24,37]. Partnerships with relevant stakeholders in the development and mapping of standards are essential and will likely increase availability of meaningful and usable data [38]. Multidisciplinary research teams that focus on health equity (eg, informaticists, data scientists, information scientists, geneticists, sociologists, and public health researchers) need to adapt standards and advance the theory and systems for organizing, storing, and analyzing complex data. These standards are urgently needed to ensure the sustained value of data collected about diverse populations and their health. With the status quo, we will continue to privilege one group's data over another's, lack meaningful and useable information of diverse racial and ethnic population groups, and likely further perpetuate health inequities.

Acknowledgments

We acknowledge Ms Hannah Friedman, who was a research assistant on this project, and Ms Mary Miller and Ms Natasha Wenner for their editorial assistance.

Abstract

Background: An increasing number of studies suggest that web-based interventions for patients with depression can reduce their symptoms and are expected to fill currently existing treatment gaps. However, evidence for their efficacy has mainly been derived from comparisons with wait-list or treatment as usual controls. In particular, designs using wait-list controls are unlikely to induce hope and may even have placebo effects, making it difficult to draw conclusions about the intervention's efficacy. Studies using active controls are rare and have not yielded conclusive results.

Objective: The main objective of this study is to assess the acute and long-term antidepressant efficacy of a 6-week, guided, web-based self-management intervention building on the principles of cognitive behavioral therapy (iFightDepression tool) for patients with depression compared with web-based progressive muscle relaxation as an active control condition.

Methods: A total of 348 patients with mild-to-moderate depressive symptoms or dysthymia (according to the Mini International Neuropsychiatric Interview) were recruited online and randomly assigned to 1 of the 2 intervention arms. Acute antidepressant effects after 6 weeks and long-term effects at 3-, 6-, and 12-month follow-up were studied using the Inventory of Depressive Symptomatology–self-rating as a primary outcome parameter and change in quality of life (Short Form 12) and user satisfaction (client satisfaction questionnaire) as secondary outcome parameters. Treatment effects were assessed using mixed model analyses.

Results: Over the entire observation period, a greater reduction in symptoms of depression ($P=.01$) and a greater improvement of life quality ($P<.001$) was found in the intervention group compared with the active control group. Separate tests for each time point revealed significant effects on depressive symptoms at the 3-month follow-up ($d=0.281$; 95% CI 0.069 to 0.493), but not after 6 weeks (*main outcome*: $d=0.192$; 95% CI -0.020 to 0.404) and 6 and 12 months. The intervention was significantly superior to the control condition with respect to user satisfaction (25.31 vs 21.97; $t_{259}=5.804$; $P<.01$).

Conclusions: The fact that antidepressant effects have been found for a guided self-management tool in comparison with an active control strengthens the evidence base for the efficacy of web-based interventions. The antidepressant effect became most prominent at the 3-month follow-up. After 6 weeks of intervention, significant positive effects were observed on life quality but not on depressive symptoms. Although the effect size of such web-based interventions on symptoms of depression might be smaller than that suggested by earlier studies using wait-list control conditions, they can be a cost-effective addition to antidepressants and face-to-face psychotherapy.

Introduction

Web-Based Interventions in the Treatment of Depression

Web-based interventions for people with depression have been evaluated positively in numerous randomized controlled trials (RCTs). They raise the hope of offering a cost-effective and easily disseminated intervention via the internet [1] for one of the most common disorders worldwide [2]. Cognitive behavioral therapy (CBT) is an evidence-based treatment for depression recommended in national and international treatment guidelines, but access to this treatment is limited [3]. Especially in primary care, where the majority of patients with diagnosed depression are treated [4], access to psychotherapy is problematic. Web-based interventions are promising for closing this treatment.

The majority of web-based interventions for depression are based on techniques derived from CBT, consist of 5 to 15 modules, and incorporate psychoeducational material as well as interactive elements or tasks [5]. Their efficacy seems to have been confirmed by several reviews and meta-analyses finding statistically significant, moderate effect sizes ($d=0.56$ [6] and $d=0.59$ [7]; Hedges $g=0.50$ [8]; $d=.67$ [9]) when comparing internet-based interventions with treatment as usual (TAU) or with wait-list controls. A consistent finding is that interventions that incorporate some kind of guidance (through personal contact or via email support) turn out to have better retention rates and antidepressant effects than self-guided interventions [8,10]. Web-based interventions across several disorders also have been found to produce stable effects for up to 3 years in a review incorporating 14 trials with 902 participants, 3 of which dealt with depression and found positive effects after 2-3.5 years [11].

Although these studies and meta-analyses appear to provide consistent evidence for the efficacy of web-based interventions, an important limitation sheds doubts on this area of research: Effect sizes observed in trials investigating web-based interventions are dependent on the control condition used [12]. Studies with wait-list controls produce larger effect sizes (Hedges $g=0.9$) than those using care as usual or other control conditions (Hedges $g=0.38$) [10]. One possible explanation for this phenomenon is the influence of patients' expectations regarding the success of the intervention. Especially for patients with depression (a condition in which hopelessness and a negative view of the future are part of the symptomatology), becoming aware of *only being in the control condition* does not induce hope but might instead produce placebo effects [12].

A Critical Review of the Evidence

So far, most trials on web-based interventions have relied on wait-list and care as usual controls [13], with comparisons to wait-list control likely overestimating the real efficacy. To date, only a few studies have compared web-based interventions for

depression with active or placebo control interventions and even fewer report on follow-up data.

Mackinnon et al [14] tested 2 active treatments (a web-based intervention and an information website) against an attention control condition, in which participants discussed certain aspects of their lifestyle with the study team. Although varying in content (depression-specific content vs aspects about lifestyle), all 3 groups received the same amount of telephone contact with the study team [15]. The observed effect sizes for the web-based intervention ($d=0.38$) and the information website ($d=0.29$) were statistically significant but smaller than those in wait-list-controlled studies.

Johansson et al [16] tested a tailored and standardized version of the same web-based intervention against an active control condition (an online discussion forum) and found moderate to large effects with regard to symptoms of depression ($d=0.84$ and $d=0.57$). However, patients randomized into the control arm first received the invitation to join an online discussion forum and, after the intervention period, received the standardized treatment. In this design, patients knew when they were randomized into a control and wait-list condition and might have been disappointed or felt set back by this, potentially leading to less hope induction or even placebo effects.

Glozier et al [17] conducted a double-blind study on an internet-based cognitive behavioral therapy (iCBT) program. The iCBT intervention was compared with an internet-delivered health intervention for depression in patients with cardiovascular disease and both, participants and study assistants assessing the outcome measure, were unaware of which condition was the active intervention. The iCBT program led to a significantly greater reduction in symptoms of depression, but the effect size in this well-controlled design was small (Cohen $d=0.16$).

Taken together, when using more valid control conditions, the evidence for the antidepressant efficacy of web-based interventions relies on a limited number of studies, and reported effect sizes appear to be small. The best available evidence for antidepressant efficacy thus far stems from a meta-analysis comparing internet-based interventions for depression with face-to-face psychotherapy. Andersson et al [18] combined 5 studies that directly compared guided internet-based interventions with face-to-face psychotherapy (often in a group setting) and found a small effect size in favor of web-based intervention (Hedges $g=0.12$), which was not significantly different from zero.

However, not only the direct intervention effects should be subjected to critical examination. The existing results on long-term efficacy might also be influenced by the choice of controls. Psychotherapeutic interventions are claiming long-term positive effects resulting from the learning of new behavioral and cognitive patterns. Although the first results thus far seem positive, the number of studies incorporating longer follow-up

periods is limited and often stems from wait-list-controlled trials. From the 40 high-quality RCTs that were included in a recent meta-analysis for web-based interventions targeting depression [8], only 3 studies contained data on a follow-up of at least 12 months. All 3 studies used within-group comparisons of symptom severity following the intervention to later time points and reported stable effects over the respective follow-up periods [19-21]. This statistical comparison is mainly used in wait-list-controlled trials, which have the disadvantage of not enabling between-group comparisons at follow-up. As symptoms of depression usually fluctuate spontaneously and episodes of depression are usually remitting after several months even when untreated, it is unclear if the results found at follow-up are due to a successful treatment, an initial placebo effect plus spontaneous remission, further treatment options participants took, or other external factors. So far, only a few studies with smaller samples have reported between-group comparisons at follow-up. For example, in one study on 69 participants, using a face-to-face intervention as a comparator, data from a long-term follow-up confirmed that after 3.5 years both groups still did not differ in a statistically significant way [20]. Through the design of this study, it will be possible to expand our understanding of the long-term effects of web-based interventions for depression.

This Study

The general objective of this study is to strengthen the evidence base for web-based interventions and to close the described gaps in the previous results. To this end, we implemented a web-based active control condition. This control condition was designed to be as similar as possible to the intervention concerning credibility, hope induction, and contact with the study assistants. Furthermore, a 12-month follow-up was implemented.

The main objective was to compare changes in self-rated symptom severity occurring during the trial period up to 12 months for patients with mild-to-moderate depression, who either used a CBT-based, web-based self-management tool (iFightDepression [iFD]) or took part in an active control condition (progressive muscle relaxation [PMR]). We expected the iFD tool to be superior to an active control in terms of symptom reduction. Our main outcome of intervention effects after the 6-week intervention period (as predefined in the study protocol) was supplemented by long-term data to extend the relevance of our conclusions.

Further objectives focused on a more in-depth analysis of the effects of both interventions by doing the following:

- Considering possible covariates such as age, gender, or amount of guidance that might influence the intervention effect.
- Examining the differences between both interventions with respect to changes in self-rated quality of life.
- Examining possible differences between the 2 conditions concerning user experience as well as the amount of usage and the duration and content of guidance in a descriptive and explorative manner.

Methods

Trial Design

This study is an RCT assessing the efficacy and usability of a guided web-based self-management intervention (iFD) compared with an active control condition (PMR) after 3 and 6 weeks of intervention as well as after 3, 6, and 12 months postintervention. The trial was conducted in accordance with the Declaration of Helsinki. The complete study protocol was published elsewhere [22] and is in line with the Consolidated Standards of Reporting Trials statement [23].

Recruitment and Selection of Participants

The study participants were recruited throughout Germany via the website, social media channels, appearances in other media, and newsletters of the German Depression Foundation (DF). Furthermore, newsletters of associated organizations were used for distribution. Interventions were offered free of charge, and no reimbursement was offered to participants.

Individuals interested in taking part in the study were directed to a website providing general information on the study procedures and a web-based questionnaire assessing several inclusion and exclusion criteria. In the study information provided to the participants, both interventions were described as equivalent offers to not induce a bias in expectations. After successfully passing the screening questionnaire, contact details could be left for the main screening that took place via telephone. This procedure led to the preselection of individuals with sufficient internet literacy to meet the minimal study requirements. All screening procedures and guidance during the trial were carried out by psychologists or psychotherapists. If the screening was successful, participants were asked to provide written informed consent for participating in the study and to provide the telephone number of a confidant, whom the study team could contact in case of a suspected crisis (for further details on the screening and inclusion procedures see Oehler et al [22]).

Inclusion criteria were outpatient status, a diagnosis of depressive disorder with presently mild or moderate severity (F32.0, F32.1, F33.0, and F33.1) or dysthymia (F34.1) according to the Mini International Neuropsychiatric Interview (MINI) and patient health questionnaire-9 (PHQ-9; score 5-14, indicating mild-to-moderate symptoms), aged 18 years and above, sufficient language skills to meet the study requirements, and internet access. Outpatient status was taken as one of the inclusion criteria, so that patients could be referred to their local care provider in case of a crisis. Exclusion criteria were dementia, drug or alcohol abuse within the last 6 months, drug or alcohol addiction, schizophrenia, manic episodes or bipolar disorder, obsessive-compulsive disorder (all according to the MINI), known personality disorders (F60.2 and F60.31), acute suicidal tendencies, severe somatic disorders requiring immediate treatment, pregnancy, and participation in another clinical trial within the past 4 weeks.

All participants who provided written informed consent and matched the inclusion and exclusion criteria were randomized using the minimization algorithm by Pocock [24] and stratified

for gender (male/female), depression severity (mild/moderate according to PHQ-9), and CBT experience (present/absent) with an 80% chance of using the algorithm's recommendation.

To the best of our knowledge, no comparable studies were available for power calculation at the time. Therefore, power calculation was based on the results of a study [25], which compared face-to-face CBT with an active control condition (guided self-help group) in depressed primary care patients and found a difference of 5.3 points on the Inventory of Depressive Symptomatology—clinician rated after 10 weeks. For this study, the difference was estimated to be 4.0 points on the Inventory of Depressive Symptomatology—self-rating (IDS-SR), as we expected the difference to be slightly smaller in a web-based trial compared with face-to-face interventions. On the basis of this estimation, 122 patients per group are needed to detect a difference with a power of 80% ($\alpha=.05$). It was planned to include 360 participants to obtain at least 250 complete data sets after an expected dropout of approximately 30%.

Ethics and Trial Registration

The protocol for this study was reviewed and approved by the Ethics Committee at the Faculty of Medicine, University of Leipzig, on February 11, 2015.

The trial was registered under the identification code DRKS00009323 at the German Register for Clinical Trials, with the title *Efficacy of an Internet-Based Self-Management Intervention for Adult Primary Care Patients With Mild and Moderate Depression or Dysthymia*. The international registration of the study was carried out via the *International Clinical Trials Registry Platform* with the secondary ID 080-15-09032015.

Assessments

There were 3 main assessment points during the intervention period (before the intervention and after 3 and 6 weeks of intervention) and 3 follow-up assessments (3, 6, and 12 months after the end of the intervention period). During this period, the primary and secondary outcome measures were collected.

Measures

Primary Outcome

The IDS-SR was used as the primary outcome measure in this study (range 0-84) to assess changes in depression severity. The scale has been shown to be useful in detecting symptom change as well as residual symptoms in patients with depression [26]. The concordant validity with the Beck Depression Inventory and the Hamilton Rating Scale for Depression has been shown to be appropriate ($r\geq.88$) [27], and the internal consistency at baseline was acceptable (Cronbach $\alpha=.78$).

Secondary Outcomes

To assess changes in the perceived health-related quality of life, Short-Form 12 (SF-12) was used. It was developed as a practical short form of the Short-Form-36. A mental and a physical component score (both ranging from 0 to 100) can be calculated from the questionnaire answers for which moderate to high convergent validity has been shown in several studies [28,29].

The German version (Fragebogen zur Messung der Patientenzufriedenheit) of the client satisfaction questionnaire-8 (CSQ-8) was used to assess acceptance and feasibility of the interventions. As the questionnaire was originally developed for the evaluation of hospital stays, the wording was slightly adapted to fit web-based interventions. A similar adaptation yielded good internal consistency ($\omega=.95$) [30].

The usage of the intervention was assessed each week during the intervention period using a self-report measure with 2 items. Participants were asked how often they had worked with the intervention during the last week and how much time they had spent on it.

Tracking the objective usage was possible only for the iFD group through the log files of the iFD tool website. Offline use in the form of printed worksheets cannot be tracked. For the PMR group, it was registered if participants downloaded the weekly changing intervention audios. The actual use could not be tracked. Owing to these limitations, both objective measures only served as an approximation and validation of the subjective measures.

Monitoring Instrument

To monitor changes and detect possible deteriorations in depressive symptoms over the course of the intervention, the 9-item (PHQ-9; range 0-27) was used. The PHQ-9 is a short, well-validated, and widely used measure [31,32]. The internal consistency at baseline was below the values usually reported for this scale (Cronbach $\alpha=.66$). During the intervention, patients reporting symptoms indicating severe depression for 3 weeks in a row or acute suicidality were contacted by the study assistants via telephone or email and, if necessary, advised to seek appropriate clinical support. This was necessary in 12 cases. A protocol for managing acute suicidality was established. If patients reported severe symptoms of depression but wanted to continue using the intervention, their cases were discussed with the supervising physician.

Adverse Events

At the beginning of the study (T0), after 3 weeks (T1), and after 6 weeks (T2), adverse events were recorded. Every new event that led to the inability to work or that needed medical treatment was recorded, and a possible connection to the intervention was assessed. Events that led to unplanned inpatient treatment or were life-threatening or lethal were classified as serious adverse events. Serious adverse events were passed on to the supervising physician for review.

Documentation of Guidance

The duration of all planned calls made by the study assistants during the intervention period was recorded and added to provide a sum score for the overall guidance received by each patient. Additionally, the content and perceived quality were rated by the study assistants. Adverse events were recorded and topics relevant to the study, for example, date of next appointment, were discussed. Additional calls to ensure patient safety after they reported suicidal thoughts or severe symptoms of depression in the questionnaires as well as the follow-up calls at T3 to T5 were not counted as guidance.

Interventions

The iFightDepression Tool

The iFD tool is a guided web-based self-management tool based on the principles of CBT. It includes 6 core workshops, each comprising written information, worksheets, exercises, and a mood rating. For this study, participants were asked to use the tool for 6 weeks and to complete 1 workshop per week. Each week's workshop covered a different topic (eg, an activity diary, monitoring and adapting one's sleep, or challenging automated negative thoughts). The content and development are described in more detail elsewhere [22,33]. iFD offers the opportunity to complete worksheets on the web or to use a printed version. Patients were asked to try out each workshop and, if helpful, continue using the learned techniques. The iFD tool did not change during the study period, except for a news box on the landing page that was updated approximately once a month.

Progressive Muscle Relaxation

In this study, PMR was used as the control condition. During the 6 weeks of intervention, participants were encouraged to practice PMR and to learn how to deliberately induce physical relaxation to reduce stress and mental tension. Lessons range from 13 to 33 min and build on one another, adding more muscle groups every week. At the beginning of each week, participants received a link to download the next lesson. They were instructed to practice on a daily basis, if possible, but at least two or 3 times a week and to integrate the practice into their daily routine.

PMR was chosen as a credible control intervention and is widely used in therapeutic settings, for example, as part of CBT or in the treatment of sleep disorders. The method is also highly accepted by the public as a form of self-help for depression [34,35] and is rated to be helpful for clinically depressed patients ($n=736$; 38.6%) very or moderately effective and ($n=749$; 39.2%) slightly effective [36].

In a systematic review of several relaxation techniques (PMR or similar methods), relaxation was recommended as the first-line treatment in a stepped care approach. Antidepressant effects were visible shortly after relaxation interventions, superior to wait-list and no treatment but inferior to psychotherapy [37], making PMR a suitable choice as a control condition.

Guidance

Guidance was provided during 5 telephone calls by the study assistants (psychologists and psychotherapists) from the Research Center of the DF, supervised by a senior psychiatrist who was involved in the development of the iFD tool. Comparable with iFD guides outside of the study setting, all study assistants were qualified using the standard web-based seminar and used a guideline for the calls based on the webinar content. The focus of the guidance calls was to motivate the participants rather than discuss the intervention content.

To keep contact with the study staff comparable across both intervention groups, the same guideline was used in the guidance calls for both the iFD and PMR groups, and calls were carried out by the same study assistants.

Statistical Analysis

To pursue the main objective, changes over time in the primary outcome measure were investigated using a mixed model analysis, which included a random intercept and random slope for each participant. The variance-covariance structure was set to unstructured to avoid any constraints. This approach was adopted to make the best use of incomplete data while minimizing the bias to the parameter estimations [38,39]. All analyses were performed on the intent-to-treat sample using data from all randomized participants. As a sensitivity check, the analysis of the main outcome was repeated for a per-protocol sample (only participants having finished at least four workshops in the iFD tool or downloaded 4 sessions of PMR) and using an imputed data set. The parameter of interest for each model was the time \times group interaction, specifying the differential change of symptoms over time attributable to the group assignment. A quadratic term and its interaction with the group variable was added (time \times time \times group) to allow for parabolic trends over time. Within- and between-group effect sizes (Cohen d) were calculated using the difference in means between intervention groups at posttreatment and follow-up for imputed data (with 50 imputations) taking into account the dependence of data collected within participants to avoid the loss of power due to incomplete cases [40] and employing the pooled standard deviation as the standardizer. Confidence intervals of the between-group effect sizes were examined to check for intervention effects at each time point.

Several studies have shown that certain covariates at the participant level, such as adherence to the intervention, participant age, or gender [41-43], can influence dropout rates and intervention success. It is also of interest whether the use of the intervention or the amount of contact with the study team influenced the changes in the outcome measures. Therefore, to meet our second objective, possible covariates (chosen based on the literature on covariates influencing the outcome of interventions for depressed patients) were added stepwise to the mixed model (base model), which contained fixed effects for time, time \times time, and a dichotomous variable for the intervention group and their interactions, and were kept in the model if they improved the model fit as measured by the restricted maximum likelihood (REML) criterion at convergence. The following covariates were tested: the amount of guidance received (sum of minutes spent on guidance call per participant), sex (female vs male), age, self-reported amount of time spent working with the intervention (sum score of hours spent on intervention), and self-reported frequency of use (sum of self-reported times worked with the intervention). To control for possible effects of other treatments, a dichotomous variable for *taking antidepressants or receiving psychotherapy at screening vs not taking antidepressants or receiving psychotherapy at screening* was added as a possible covariate. Covariates and interactions that did not improve the model fit were excluded from the model.

For the third objective, an equivalent analysis was repeated for quality of life using the SF-12 data.

For all models described, model assumptions were checked using graphical inspections of the plotted residuals and the

normal Q-Q plot. The assumptions of normality and homoscedasticity were not violated in any of the models. The inspection of Cook distance estimates yielded several influential data points, but the model results remained unchanged after excluding these. Therefore, in this paper, mixed models using the full sample are reported.

To assess our final objective, descriptive analyses were performed on key features of intervention use and the results of the expectation questionnaire. Group differences in the contents of the guidance calls were tested for significance using a two-sample Z test for proportions to compare the frequency of each topic. A two tailed t test was performed on the CSQ-8 sum scores (user satisfaction) to assess the group difference statistically.

All analyses were performed using R [44]. For the mixed model calculations, the packages lme4 and lmerTest were used to estimate the model coefficients and corresponding P values. Results were calculated using REML estimation and the

Kenward-Roger approximation to calculate the denominator degrees of freedom for the performed t statistics, as this has been reported to be the most robust way to determine the statistical significance of parameters in mixed models [45].

Results

Enrollment and Baseline Characteristics

Recruitment for the trial commenced in June 2016 and was completed in August 2018. Follow-up data were collected until August 2019.

The participant flow chart (Figure 1) provides an overview of the screening and enrollment numbers of the patients ($n=347$) who were included in the study and randomized into 1 of the 2 treatment arms. The current sample can be described as treatment experienced and, in most cases, with recurrent depression. The levels of both education and internet literacy were high (Table 1).

Figure 1. Participant flow chart; a participant was counted as having completed 1 measurement point when either the telephone interview had taken place or the questionnaire had been filled out. Single measures might be reported with slightly differing sample sizes. PHQ: patient health questionnaire; PMR: progressive muscle relaxation; iFD: iFightDepression.

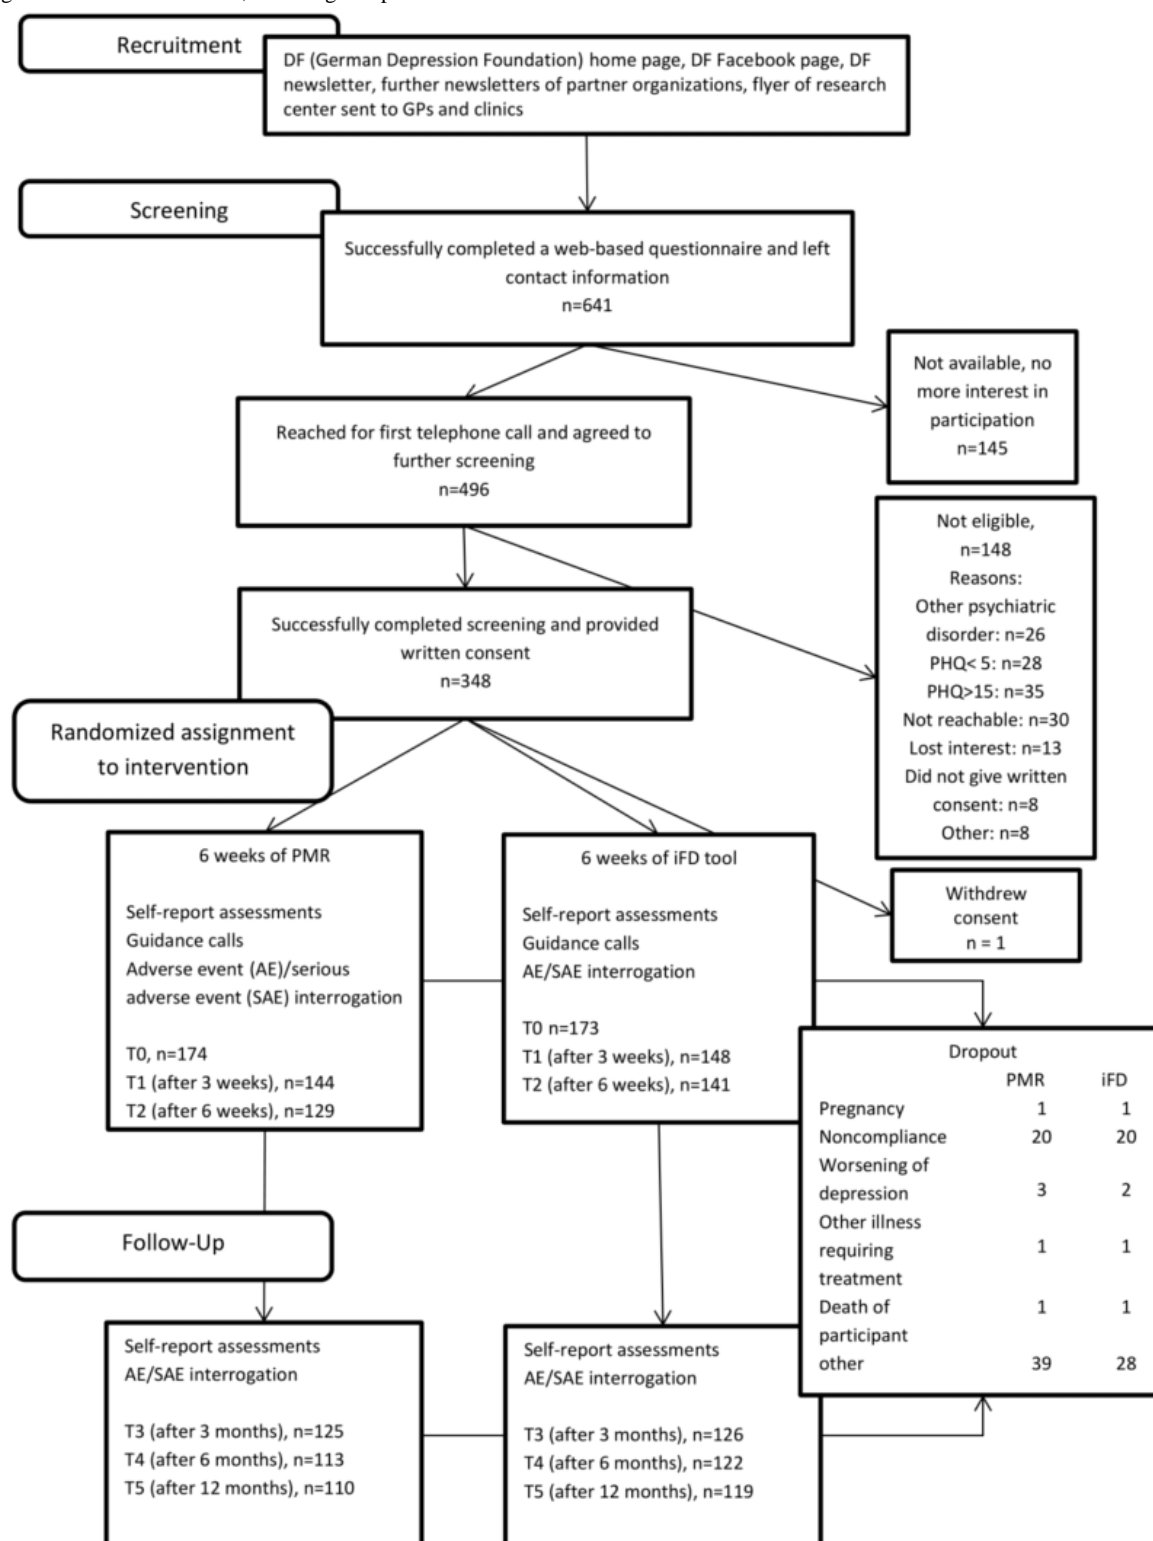

Table 1. Baseline characteristics.

Variable	Intervention group (n=173)	Control group (n=174)
Characteristics		
Age (years), mean (SD)	42.9 (12.4)	41.7 (12.4)
Female, n (%)	137 (79.2)	136 (78.3)
Acquired a university degree, n (%)	64 (37.0)	68 (39.1)
Internet usage <10 years, n (%)	157 (90.8)	155 (89.1)
Using the internet daily, n (%)	164 (94.8)	166 (95.4)
Inclusion diagnosis		
Major depression, n (%)	2 (1.2)	4 (2.3)
Recurrent major depression, n (%)	164 (94.8)	157 (90.2)

Generalized anxiety disorder, n (%)	8 (4.6)	6 (3.4)

Adherence

Of the 347 patients included, 288 filled out the T1 measure (after 3 weeks) and 262 completed T2 (after 6 weeks). The follow-up measures were completed by 251 participants 3 months after the treatment ended, 235 participants after 6 months, and 229 participants after 12 months. Some of the measures reported have deviating sample sizes (n) due to a small number of participants omitting one or more of the measures.

According to self-report, participants in the intervention group used the iFD tool 23.6 (SD 12.6) times on average and participants in the PMR group practiced 22.4 (SD 9.5) times over the course of the 6-week intervention period. They reported to have spent an average of 6.2 (SD 4.7) hours using the iFD program and an average of 6.5 (SD 5.4) hours using PMR. Neither of these differences reached significance ($t_{303.26}=0.606$, $P=.55$ and $t_{334.91}=0.620$, $P=.54$, respectively).

Objective data, taken from the back end of the iFD tool and the download page of the PMR website, confirmed regular use and downloads of both interventions. The iFD users completed an average of 5.5 (SD 2.1) workshops and spent a mean of 3.8 (SD 3.0) hours using the tool on the web over the course of 18.7

sessions (the end of a session was defined by >30 min of idle time after the last click; time after the last click has not been included in average usage time). PMR users downloaded an average of 4.2 (SD 1.86) of the 6 relaxation lessons (n=165; for 10 participants, downloads had to be enabled differently due to technical problems and were not trackable).

Main Objective

Considering intervention effects on the IDS-SR as the primary outcome measure over the entire observation period (6 weeks of intervention + 12 months of follow-up), a significant difference in the symptom change over time was found, favoring the iFD group (an overview of the main and secondary outcomes over time is shown in Table 2). In the base model specified without covariates, the estimated fixed effect of interest (group x time interaction) differed statistically significant from zero ($t_{1157.2}=-2.519$; $P=.01$). A significant main effect of time ($t_{1196.2}=-3.934$; $P<.001$) was also observed, indicating a significant symptom reduction over time in both groups, as well as a significant interaction of time² x group caused by the greater curvature of the trajectory in the iFD group ($t_{1099.0}=2.686$; $P=.007$). Figure 2 depicts the changes in the main outcome variable as well as the values predicted by the base model.

Figure 2. Changes over time in mean IDS-SR. Points of measurement: T0: before the intervention; T1: after 3 weeks of intervention; T2: after intervention period; T3 to T5: follow-up measurements after 3, 6, and 12 months; error bars: standard errors of the mean; and IDS-SR: Inventory of Depressive Symptomatology–self rating. Model results refer to the estimates of the base model including fixed effects for time x group and time x time + group.

As a measure of the model's ability to describe the data, R^2 was calculated. The base model yielded a conditional R^2 of 0.59 and a marginal R^2 of 0.08, indicating that 59% of the variance in the dependent variable was described by the model and 8% of variance can be explained by the fixed effects alone. The results did not change when using a per-protocol sample or the imputed data set and are therefore not reported separately (results for all models can be found in the [Multimedia Appendix 1](#)).

The between-group effect sizes and their confidence intervals, calculated from imputed data sets, are shown in [Table 3](#) and

provide an estimate of significance for the group differences at every assessment point. Group differences in the IDS-SR were not statistically significant following the 6-week intervention period (T2) but were so at the 3-month follow-up (T3). Within-group effect sizes comparing T0 and T2 measures ([Table 2](#)) can be described as medium according to the rough categorization proposed by Cohen [46] (iFD: $d=-0.718$; PMR: $d=-0.619$). After the intervention period, the IDS-SR scores remained stable in the iFD group and decreased further in the PMR group.

Table 3. Between-group effect sizes, results of the mixed models with and without covariates.

^aES: effect size; between-group effect sizes were corrected for unequal sample size and could therefore also be referred to as Hedges *g*. Effect sizes are calculated based on imputed values to make use of the full data set. Positive values indicate a higher score in the PMR group, and negative values indicate higher scores in the iFD group.

^bIDS-SR: Inventory of Depressive Symptomatology--self-rating.

^cSF-12 MCS: Short-Form 12 mental component score.

^dSF-12 PCS: Short-Form 12 physical component score.

Secondary Objectives

Covariate Analysis

The final model built to predict the IDS-SR scores included the original fixed effects of time, time², and group as well as their interaction as predictors (the full model results are shown in the [Multimedia Appendix 1](#)). In addition, fixed effects for self-reported frequency of use, amount of guidance received over the course of the intervention, and the interaction of amount of guidance with the group variable were kept in the model. These covariates were chosen because they improved the model fit (as indicated by a smaller REML criterion at convergence). The significant effect of the amount of guidance ($t_{216.7}=3.58$; $P<.001$) showed that higher overall IDS-SR scores were associated with a greater amount of contact with the study team (model parameter for the fixed effect: 0.20 [SD 0.06]). In addition, the significant interaction of the group and amount of guidance ($t_{216.4}=-2.13$; $P=.04$) mirrors the fact that this was especially the case in the PMR condition.

The fixed effect for frequency of use did not reach statistical significance ($t_{216.2}=0.58$; $P=.72$) but improved the model fit and was therefore kept in the model. The fixed effects of sex, age, taking antidepressants or receiving psychotherapy at screening, and self-reported amount of time spent working with the intervention were not significantly different from zero and did

not improve the overall model fit; thus, they were not added to the final model.

None of the other interactions between the covariates and the time or the group variable was significantly different from zero; therefore, the model was specified without additional interactions. This implies that, in this study, the intervention effect was not affected by the covariates named above in a way that was detectable with the current design. The final model yielded a conditional R^2 of 0.60 and a marginal R^2 of 0.10.

Quality of Life

In the mixed model describing the changes in quality of life (mental component score), the significant interaction of group x time ($t_{1198.4}=-1.967$; $P=.049$) reflects an intervention effect in favor of the iFD tool, indicating a greater improvement in the quality of life for iFD users compared with participants in the PMR group. A statistically significant time² x group interaction indicates greater curvature in the iFD group ($t_{904.8}=-3.900$; $P<.001$). The mental component score was significantly associated with the group variable ($t_{859.9}=-2.274$; $P=.02$; [Figure 3](#)), indicating an overall lower score on the SF-12 in the iFD group. The base model yielded a conditional R^2 of 0.55 and a marginal R^2 of 0.06.

The between-group effect sizes after the intervention (T2) and at the 3-month follow-up (T3) showed statistically significant intervention effects ([Table 3](#)).

Figure 3. Changes over time in mean SF-12. Points of measurement: T0: before the intervention; T1: after 3 weeks of intervention; T2: after intervention period; T3 to T5: follow-up measurements after 3, 6, and 12 months; error bars: standard errors of the mean; and SF-12: Short-Form 12 (mental component score). Model results refer to the estimates of the base model including fixed effects for time x group and time x time + group.

In an extended mixed model containing self-reported frequency of use and the amount of guidance, the covariates themselves did not have a significant effect on the SF-12 scores, but improved the model fit. In addition, the group variable was no longer assigned a significant fixed effect, meaning the model did not yield a significant main effect of intervention group. The final model yielded a conditional R^2 of 0.64 and a marginal R^2 of 0.06.

In the mixed model using the physical component score as a dependent variable, none of the relevant fixed effects significantly differed from zero. As expected, the physical component score was not affected by the intervention and

remained unchanged over time (full model results are shown in the [Multimedia Appendix 1](#)).

Guidance

The mean time spent on the 5 guidance and study calls was 38.5 (SD 9.9) min per participant for the iFD group and 28.9 (SD 15.0) min per participant for the PMR group, with the difference being statistically significant ($t_{314.41}=5.078$; $P<.001$). The subjective quality as rated by the guiding study assistants was *positive* or *mostly positive* for 96.7% (736/761) of the calls in the iFD group and for 96.5% (691/716) in the PMR group. The relative occurrence of specific topics during the guidance calls, as recorded by the guides, are reported in [Table 4](#).

Table 4. Frequency of specific topics that occurred in the telephone calls, rated by guide, raw values, and percentage (calculated with number of observations/interviews as 100%).

Topic ^a	iFD ^b (n=761 observations), n (%)	PMR ^c (n=716 observations), n (%)	Chi-square value (df)	P value ^d	Holm-corrected P value
Comprehension problems	54 (7.0)	4 (0.6)	40.1 (1)	<.001	<.001
Current state of health	658 (86.5)	626 (87.4)	0.2 (1)	.64	.76
Content support	247 (32.5)	126 (17.6)	42.4 (1)	<.001	<.001
Motivation of participant	121 (15.9)	137 (19.1)	2.5 (1)	.12	.59
Dissatisfaction with intervention	83 (10.9)	159 (22.2)	33.6 (1)	<.001	<.001
Positive feedback on the intervention	301 (39.6)	206 (28.8)	1.4 (1)	.23	.76
Questions about released content (only iFD)	27 (3.5)	N/A ^e	N/A	N/A	N/A
Study organizational topics	639 (84.0)	596 (83.2)	0.1 (1)	.76	.76
Irregular participation in intervention	78 (10.3)	61 (8.5)	1.1 (1)	.29	.76

^aMultiple topics could be the subject of each call; therefore, percentages do not add up to 100.

^biFD: iFightDepression.

^cPMR: progressive muscle relaxation.

^dP values corrected for multiple testing using Hochberg correction.

^eNot applicable.

User Satisfaction

The mean sum score of the CSQ-8, a measure of user satisfaction, was 25.31 in the iFD group and 21.97 in the PMR group out of a possible 32, the difference being statistically significant ($t_{259}=5.8044$; $P<.01$). Satisfaction with the iFD tool seems to be in the expected range, with a sum score similar to those of other studies on internet interventions (26.26 major depression [MD] prevention [30], 26.05 stress management, 24.51 MD treatment in routine psychiatric care [47], 24.96 guided internet-based intervention for depression [48], 22.88 unguided internet-based intervention for depression, and 22.4 happiness training [49]).

Adverse Events

During the course of the intervention, 159 adverse events and 4 serious adverse events were recorded. Three adverse events were rated as *possibly related* to the intervention, 2 in the iFD group, and 1 in the PMR group. The *possibly related* adverse events were all deteriorations of the patient's mood. One patient in each group described the feeling of trying one more intervention that did not help as a contributing factor to the deterioration, and 1 participant in the iFD group reported worse symptoms of depression after reducing her antidepressants without consulting her physician, as she expected to get better by using iFD. Of the serious adverse events, 2 occurred in each intervention group and none were rated as related or possibly related to the intervention. None of the adverse or serious adverse events recorded during the follow-up period were related or possibly related to the intervention.

Discussion

Principal Findings

This study is one of the first studies on the antidepressant effects of iCBT using a control condition that is both credible and comparable with the iCBT group in the form of delivery, terms of duration, and contact with the study team. To this end, we assessed between-group differences concerning changes in symptom severity over time as the main objective and possible covariates influencing the intervention effect as well as differences in health-related quality of life as a further objective.

The results concerning our main objective (decrease in symptoms of depression as measured with the IDS-SR) differed significantly between the intervention and control groups according to the mixed model results, favoring the iFD group. This effect was especially apparent at the 3-month follow-up ($d=0.281$, reduction on the IDS-SR was 8.2 points for iFD and 4.8 for PMR), whereas the group difference was only approaching significance after 6 weeks (following the intervention, the main outcome as predefined in the study protocol, $d=0.192$). These effect sizes are considerably smaller than those reported in a meta-analysis for trials using wait-lists as controls ($d=0.56$) but more similar to studies using TAU controls ($d=0.23$) [10]. Finding smaller effects or even no effect, when using an active control condition instead of a wait-list control, is to be expected as placebo effects should affect both groups in a similar manner and nocebo effects should be reduced to a minimum, thereby (mostly) ruling out expectation effects and greater hope induction driving the effect. As studies on depressed patients have been shown to be very susceptible to placebo [50], our finding of significant effects compared with a possible active control that is known to be helpful for depressed patients is noteworthy. The effect sizes are in accordance with the studies by Mackinnon et al [14] and

Johansson et al [15], who observed small but significant effects when comparing internet-based interventions to active and attention control conditions.

For further interpretation of the current results, the composition of the sample should be considered. The current sample was a self-selected community sample with a high rate of very educated, internet-affine patients who had experienced several episodes of depression in the past (iFD: median 6; PMR: median 5), who had already gained experience with psychotherapy (past: 330/347, 95.1%; present: 190/347, 54.8%), and who were receiving some kind of treatment at the beginning of the study. The mean age at the onset of depression was 21.8 (SD 12.1) years, indicating that, on average, participants had been experiencing episodes of depression for about 20 years before participating in this study.

This implies that the participants in this study could have already gained a lot of experience in therapeutic techniques and in managing their symptoms, which might have attenuated the treatment effects in comparison to studies treating patients with a first episode of depression or less treatment experience. This might indicate that even experienced patient groups can benefit from this type of intervention. On the other hand, some patients might assume that PMR is less likely to be effective than iCBT and will perceive less hope induction. iFD might be perceived as a new and promising treatment option. This can result in overestimation of the true antidepressant effect.

Patient characteristics such as gender and age as well as the amount of use and guidance did not significantly influence the intervention effect in this study. This is in line with the results on sociodemographic data having no predictive value in an individual patient data meta-analysis by Karyotaki et al [51]. However, Karyotaki et al [51] and Donkin et al [42] reported a positive association between the intervention effect and the amount of intervention received, which could not be replicated in this study. A possible explanation for the lack of this association is that patients might regulate uptake according to their needs, that is, one person might feel that they have received sufficient help after 2 modules, whereas a different person might feel that they need all 6 modules. If this holds true, the total amount of intervention received might not predict the outcome, as it did not in this study. In contrast to previous findings [8,15], the amount of guidance provided in this study did not predict treatment success in the mixed model analysis, possibly due to the fact that the mean amount of guidance (33.7 min) was at the lower end of the 30 to 180 min, which Baumeister et al [52] had previously proposed as an optimal amount of guidance in a review of 14 studies on the impact of guidance in web-based interventions. Larger variation in the amount of guidance, for example, in meta-analysis incorporating several studies with differing designs, might reestablish this effect.

In this study, the 1-year follow-up allowed the analysis of the long-term effects of the interventions. The current results show that although the improvement in the intervention group remained stable, the control condition caught up after 6 months and was not significantly different after 12 months. Our sample had a high proportion of patients with recurrent depressive

disorders; therefore, spontaneous remission over the course of the 1-year follow-up is plausible.

For our third objective, assessing changes in quality of life, a statistically significant effect for intervention was found. Although both groups reported improved quality of life concerning their mental health, this increase was significantly more pronounced in the group assigned to the iFD tool with a small but statistically significant between-group effect size after 6 weeks of intervention ($d=-0.343$) and 3 months ($d=-0.359$) postintervention. In their overview of several studies on internet-based interventions for depression, Andrews and Williams [53] reported several trials showing positive effects on both quality of life and disability with moderate to large effect sizes. Our results are in line with this, the smaller magnitude of the effect possibly being caused by the stronger control condition.

To address our fourth objective, this study explored key features of the provision of a web-based intervention with guidance according to a practice-oriented guideline. The average time spent on guidance was 9.6 min longer in the iFD group, and content-related support and comprehension problems were significantly more often part of the guidance calls in the iFD group than in the PMR group. These differences in the amount and content of the guidance calls might reflect a differential need within the groups. Although the PMR training was extended a bit each week, the iFD tool offered new topics and new tasks each week and might have been intellectually more challenging. However, it was also perceived as more positive by the participants, leading to significantly fewer complaints about the intervention during the telephone calls and to a higher score on the satisfaction rating.

In addition to improving treatment outcomes, guidance and contact with the study team are often referred to in the literature as important factors to improve adherence to the intervention. In this study, dropout was acceptable and subjective, and objective measures indicated that usage was high in both groups, with most participants completing the majority of weekly assignments. This implies that this rather small amount of guidance was sufficient, raising hopes that iFD might also prove effective in routine care where guidance will be offered by therapists and physicians. However, the highly structured study environment with an extensive screening interview (not counted as guidance time in this study) and regular questionnaires might have further improved adherence. This should be kept in mind when implementing iFD in routine care.

Limitations

Several limitations must be considered. First, the active control condition cannot be considered a placebo because there are studies pointing toward an antidepressant effect of PMR [37]. This can lead to an underestimation of the true antidepressant effect of the iCBT intervention. As Hart et al [54] argued, it is almost impossible to construct a psychosocial or behavioral intervention that is a true placebo, that is, an intervention that is harmless, completely inactive or inert, and comparable with the intervention tested. Therefore, we decided to choose an active control that might have affected the outcome measures, but that is thought to be less effective in treating depression

while still resembling the web-based intervention in its form and the amount of time patients spend on it. However, this design has the disadvantage of not disentangling spontaneous remission from the effects produced by the control condition.

Second, the amount of guidance was significantly longer in the iFD group despite our best efforts to keep it parallel. Although the amount of guidance was not related to outcome, it cannot be ruled out that this difference had a certain impact on our results.

Third, the generalizability of the results is limited by the fact that the results were obtained within the context of an RCT, which differs from implementation in routine practice. Johansson and Andersson [15] showed that even adding a structured screening interview to otherwise unguided web-based interventions led to increased effects of the intervention, so it is plausible that for the current trial, the study procedures had an impact on the effects reported here. Furthermore, our sample was self-selected and is not representative of all patients with depression. This might have led to more motivated participants, who were more interested in web-based interventions than the average patient. In addition, the trial was conducted by the institution implementing iFD in Germany; thus, the presence of allegiance bias cannot be excluded.

Finally, we did not collect data on additional treatment options that patients might have utilized during the follow-up period. Therefore, we cannot control for possible treatment differences between the iFD and PMR groups during follow-up.

Conclusions

This study is one of the few studies that used a valid control condition (PMR) as well as a 12-month follow-up. The results confirm that with active controls, the effect sizes are smaller than those in wait-list-controlled designs. Nevertheless, the results strengthen the evidence base for the efficacy of web-based CBT interventions in patients with depressive disorders. Over the entire observation period, the iFD tool was superior to an active control in the reduction of symptoms of depression ($P=.01$) and in the improvement of quality of life ($P<.001$). Although the predefined primary outcome (reduction of symptoms of depression on the IDS-SR after 6 weeks) was not statistically significant, the secondary outcome (quality of life, measured through the mental component score on the SF-12 after 6 weeks) was. Patients in the intervention group reported an accelerated symptom improvement most prominent 3 months after the intervention and, on average, transitioned from moderate to mild symptoms of depression (according to the cutoff values of the IDS-SR [55]). The intervention effects remained stable for up to 12 months, with the control participants continuing to improve and catch up with the intervention group from month 6 onward. A total guidance time of 38.5 min with an acceptable adherence indicates that iFD has the potential to be an efficient complement to treatment and to help reduce treatment gaps in psychosocial interventions. The fact that iFD is free of charge and available in 12 languages makes it an option in many countries worldwide.

Acknowledgments

The authors would like to thank the project team of Preventing Depression and Improving Awareness through Networking in the EU for the development of the iFD tool and the European Alliance Against Depression, especially Juliane Hug, Elisabeth Kohls, and Pia Driessen for their support concerning the iFD tool and their scientific contribution.

Finally, the authors would like to express their gratitude to all participants taking part in the study.

The trial was funded within the framework of cooperation between the DF and the *Deutsche Bahn Stiftung gGmbH*.

Authors' Contributions

CR-K and FG developed the study design, wrote the ethics proposal, developed the quality control plan (inspection plan), and revised the manuscript. FG and CO performed the final testing and adaptation of the study procedures. FG, MR, and CO conducted the study and provided guidance for web-based interventions. CO performed the data analysis, wrote the first draft of the manuscript, and supervised the editing process. UH and CR-K supervised the data analysis and, together with MR and FG, revised the manuscript for important intellectual content. All authors approved the final version of the manuscript.

Conflicts of Interest

UH is a member of the advisory board for Janssen Pharmaceutica, received travel costs and honorarium as speaker and research grant for an investigator-initiated trial from Medice, and travel costs and honorarium as speaker for Servier. CR received lecture honoraria from Servier and was part of an advisory board for RECORDATI. UH, CR, MR, FG, and CO work or have worked for the DF, implementing the iFD tool in Germany. UH and CR have been part of the project in which the iFD tool was developed.

Abstract

Background: Data coordination across multiple health care facilities has become increasingly important for many emerging health care applications. Distrust has been recognized as a key barrier to the success of such applications. Leveraging blockchain technology could provide potential solutions to build trust between data providers and receivers by taking advantage of blockchain properties such as security, immutability, anonymity, decentralization, and smart contracts. Many health technologies have empirically proven that blockchain designs fit well with the needs of health care applications with certain degrees of success. However, there is a lack of robust architecture to provide a practical framework for developers to implement applications and test the performance of stability, efficiency, and scalability using standard blockchain designs. A generalized blockchain model is needed for the health care community to adopt blockchain technology and develop applications in a timely fashion.

Objective: This study aimed at building a generalized blockchain architecture that provides data coordination functions, including data requests, permission granting, data exchange, and usage tracking, for a wide spectrum of health care application developments.

Methods: An augmented, 3-layered blockchain architecture was built on a private blockchain network. The 3 layers, from bottom to top, are as follows: (1) incorporation of fundamental blockchain settings and smart contract design for data collection; (2) interactions between the blockchain and health care application development environment using Node.js and web3.js; and (3) a flexible development platform that supports web technologies such as HTML, https, and various programming languages. Two example applications, health information exchange (HIE) and clinical trial recruitment, were developed in our design to demonstrate the feasibility of the layered architecture. Case studies were conducted to test the performance in terms of stability, efficiency, and scalability of the blockchain system.

Results: A total of 331,142 simulated HIE requests from accounts of 40,000 patients were successfully validated through this layered blockchain architecture with an average exchange time of 11.271 (SD 2.208) seconds. We also simulated a clinical trial recruitment scenario with the same set of patients and various recruitment criteria to match potential subjects using the same architecture. Potential subjects successfully received the clinical trial recruitment information and granted permission to the trial sponsors to access their health records with an average time of 3.07 seconds.

Conclusions: This study proposes a generalized layered blockchain architecture that offers health technology community blockchain features for application development without requiring developers to have extensive experience with blockchain technology. The case studies tested the performance of our design and empirically proved the feasibility of the architecture in 2 relevant health application domains.

KEYWORDS

blockchain; smart contract; health information exchange; electronic health records; health care application

Introduction

Background

The health care industry generates abundant health data from various sources [1]. The meaningful use of health data can improve the decisions of health care providers and patient outcomes [2]. The increasing adoption of digitalized health care records such as electronic health records (EHRs) provides the opportunity for health care data analytics and the coordination of results with care of patients [3,4]. Many health care applications are designed to maximize the potential benefits of EHR usage, such as analyzing epidemiological disease patterns to improve public health across the nation or timely health information exchange (HIE) to provide patients with coordinated and efficient care across health care facilities. Data sharing is needed when required data are distributed and stored in different sources [5,6]. However, multiple barriers to data coordination exist: (1) data privacy and security concerns during HIE [7,8], (2) the limitations of institutional privacy rules [3,9], and (3) the time-consuming process of generating agreements on data exchange between institutions [10,11]. There are security and privacy concerns about the exchange of sensitive health data [8]. Due to the Health Insurance Portability and Accountability Act, legislation limits EHR access without patient authorization [3,12]. Therefore, there needs to be a sustainable and secure data collection mechanism by which each data owner can maintain control of their data and only if the owner of the data allows it to occur [13].

Blockchain Approaches

Facing the challenges of data coordination, blockchain is considered to be a disruptive technology that fits the needs of many health care applications [14,15]. Blockchain is a distributed ledger technology that was first applied in the financial sector [16]. Bitcoin is one of the most popular applications of blockchain that shows its security, durability, and robustness. All the users in the blockchain are anonymous and represented by unique pairs of randomly generated 256-bit public and private keys [16]. This feature of protecting user privacy is one of the reasons for the success of Bitcoin and is also why blockchain is considered for potential health care applications without concerns for patient privacy issues [17]. Similar to the public blockchain used for Bitcoin, blockchain can be implemented privately, also known as a *permissioned chain* for different applications [18]. Users need to gain permission to join the private chain, which limits the data access of the blockchain to only authorized users. Blockchain is a chain of blocks that contain current and former block numbers and validated transactions occurring in a short period [19]. Generation of blocks follows a certain consensus protocol, such as Proof of Work (PoW), which requires miners to provide

computing power to validate the legitimacy of the transactions and generate new blocks. Data owners can use blocks to track the timestamps and requesters of their data. All transactions are publicly auditable. Any malicious transaction is expected to be detected by the users in the blockchain and will be discarded thereafter [20]. Once a transaction is made, all the users will validate the identity of the sender and the legitimacy of the transaction. There is no trusted third party to perform the validation process. Rather, the legitimacy of the transaction data accuracy and data provenance is ensured by all the users in a transparent manner [21]. Verified transactions will be written into the subsequent block, and the contents of the transaction can never be erased or changed [16]. The Ethereum blockchain keeps all the original blockchain features and adds a function of programmable self-executing computer protocols to the blockchain system with agreements between the requester and receiver called *smart contracts* [19]. Smart contracts are coded in Turing-complete languages such as Solidity in the Ethereum blockchain that can solve any computational problems [22]. For example, using smart contracts can regulate transactions such as enforcing the interoperability standard of exchanged data [23].

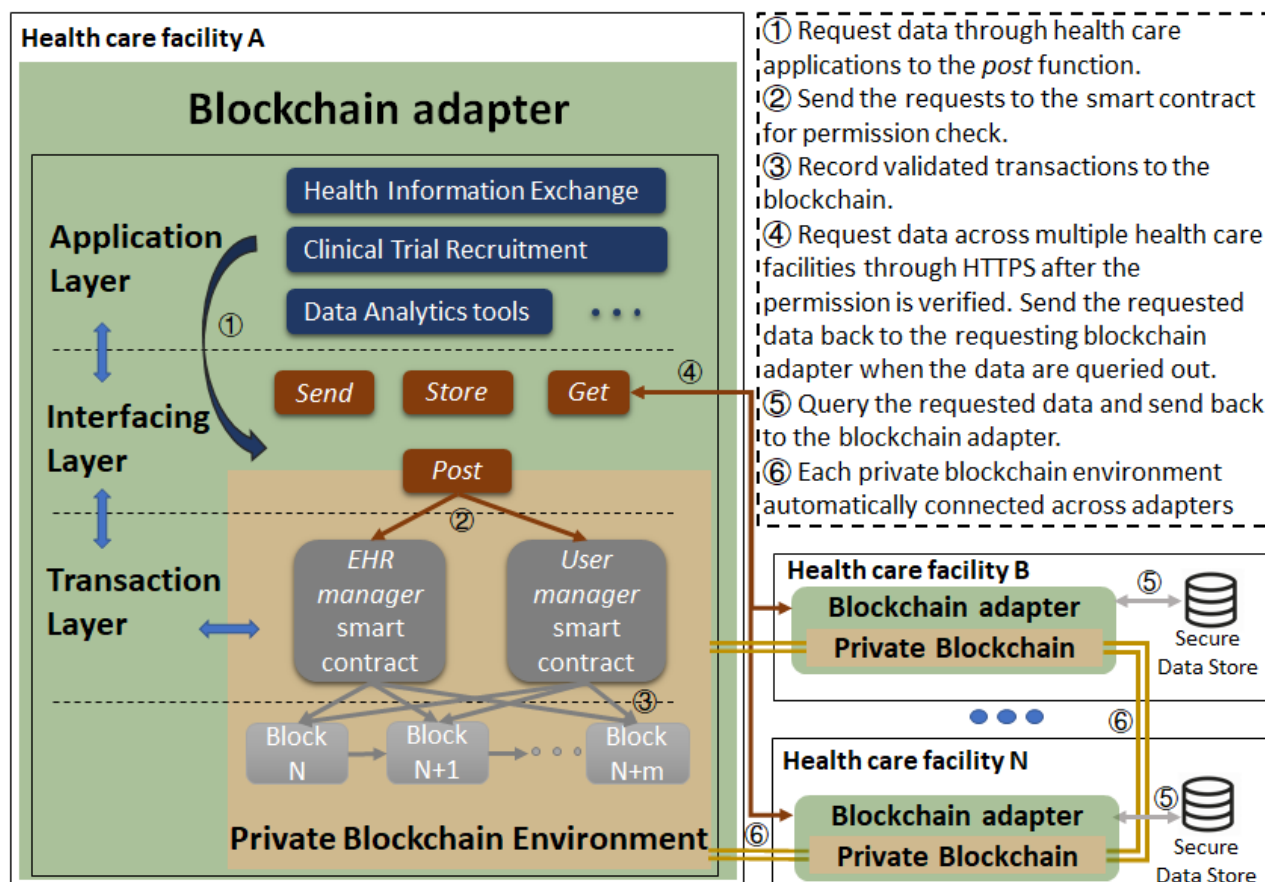

As the features of decentralized transaction validation—ensured data provenance, data sharing, data integration, and flexibility of smart contracts—fit well with the needs of many health care applications, there have been many efforts to apply blockchain to areas of health care, such as HIE, pharmaceutical supply chains, and clinical trial management [24,25]. However, most blockchain applications in the health care area are still in the early stages of implementation [15].

Objectives

This was an extended study of previous blockchain application designs and an exploration of a new generalized layered architecture, as shown in Figure 1. We built a private blockchain environment, implemented the layered architecture, and built 2 prototype applications based on this architecture: HIE and subject recruitment for clinical trials.

Compared with traditional blockchain architecture, this study proposed a generalized blockchain system that fits a wide spectrum of health care applications for cross-site data coordination. The layered architecture provides a blockchain platform with predefined functions for data collection for developers to implement health care applications without an extensive experience of blockchain. We explained the blockchain environment setup and the new layered architecture in the Methods section, followed by case studies and simulation results in the Results section to demonstrate the feasibility, scalability, and compatibility of the architecture for health care application development.

Figure 1. Overall layered blockchain architecture. The transaction layer consists of 2 smart contracts to manage data access tasks. The interfacing layer interacts with the blockchain environment, graphical user interfaces, and other blockchain adapters. The application layer provides a flexible platform for health care application development. The figure shows the general process of data requests using the architecture. EHR: electronic health record.

Methods

Augmented Three-Layered Blockchain Architecture

The blockchain network offers advantages in managing digital assets [26,27]. A well-known digital asset managed by blockchain is Bitcoin or, in general, cryptocurrency [25]. In health care applications, EHR access is a digital asset in management. The health data for patients who opt to participate in the blockchain are encrypted and stored in secured off-blockchain databases located in health care facilities protected by their own firewalls. The foundation private blockchain is used to store all transactions referring to EHR requests and exchanges and the metadata that contain pertinent health care data with the identifications of patients and health care facilities. In addition, the following components are captured in the metadata: time of creation, data set location, access permission and control, data decryption, and data authenticity.

As blockchain is a fully distributed system, we have built 3 layers on the top of the private blockchain network: *transaction layer*, *interfacing layer*, and *application layer*. As shown in Figure 1, the *transaction layer* consists of 2 types of smart contracts coded in Solidity, namely, *EHR manager* smart contracts and *user manager* smart contracts, to manage the storage of and access to metadata that are encrypted with decentralized validity and authenticity checks using blockchain

security [28]. These 2 smart contracts are fixed in the system and are not permitted to change.

Data requests from one health facility to another trigger certain functions of smart contracts through the *interfacing layer*. Only through the information in the trustable metadata can original data be retrieved and verified for authenticity by the *interfacing layer*. Applications such as subject recruitment for clinical trials, EHR management, and artificial intelligence (AI)-based data analytics tools can be built on the *application layer*. This layered architecture has the following benefits compared with the previous blockchain systems used for health care applications: (1) compatibility of most health care applications that require data exchange, (2) semipublicity to fix the blockchain settings and smart contract functions but retain most blockchain features, (3) security settings of each layer to protect the identities and data of patients during an exchange, and (4) traceability of who have accessed the data and how they used the data.

Environment Setup

To build the blockchain system, each health care facility is required to provide at least one blockchain node, which is an electronic device that can install the blockchain system. In our setting, each node runs the official Go implementation of the Ethereum protocol on an Ubuntu Linux server. To connect the blockchain with EHR systems, we have developed a blockchain adapter, which is a blockchain node designed to abide by the

local data access policies set by individual health care facilities [29].

To ensure the security of health care data and meet the needs of current EHR operations, our blockchain system does not store patient data. There are two main reasons for this. First, it is not practical to store a large chunk of health care data in a blockchain because of the health care facilities' policies of sharing health information and blockchain storage constraints [25]. Second, the health care industry is still unreceptive to allowing patient data to move across the blockchain network [12]. A metadata set containing pertinent information of the original EHR data is created and submitted to the blockchain platform. The creation and updating of metadata are recorded into a chain of data blocks in the blockchain. These transactions executed via smart contracts are immutable and traceable, thus creating a trustable metadata transaction. As there are different interoperability standards, such as Fast Healthcare Interoperability Resources and Health Level 7 version 3, there will be different metadata points of different data stores for the receiver to choose from. The receiver can choose the compatible interoperability standard of their home department's standard during the HIE process [30,31]. The metadata owner, who is the same as the data set owner, can grant, reject, or revoke access permission automatically via smart contract or interactively by means of electronic notification and confirmation. For example, smart contracts can be programmed to grant or reject access permission based on time or data type or to delegate access permission to a specific user. In all cases, because a third-party intervention is not necessary for granting or rejecting permissions, the time efficiency of data sharing can be greatly improved. This is the decentralized feature of the blockchain network that enables peer-to-peer HIE.

Each blockchain user, including the blockchain adapter, is represented by a hash value (account address) derived from the public key generated by the blockchain [32]. The private key is kept private by the user, and the public key is used for internal and external transactions and communications. Any transaction related to the account address must be signed by the signature, which is the private key. All transactions need to ensure the public key and the private key matched before transactions are recorded in the blockchain. The patients need to go to the health care facilities to opt into the system so that they can claim ownership of their data. A user can create a username and password or use biometric information that is mapped to the public and private key instead of memorizing the real key's value. The metadata permission control carried out by smart contract is anonymous, which ensures privacy. The metadata used for locating encrypted data are communicated with the secured data stores via the https protocol, and the result is communicated back to the user via the same protocol; thus, it is considered to be a secure data transfer.

Foundation Private Blockchain Network

The foundation of our layered architecture is a private Ethereum blockchain, which involves an immutable chain of data blocks consisting of committed ledgers and multiple blockchain nodes synchronously maintaining the same chain of data blocks. In the overall architecture, this layer ensures data immutability,

decentralized consensus, data transparency, and traceability. The private blockchain is initiated from a starting node with special settings to make the blockchain unique. The smart contracts are deployed through the starting node when the private blockchain is built. All the participating nodes from health care facilities must obtain permission from the starting node to join the system. This procedure will disallow unauthorized parties from joining the system. As the participating nodes joined into the system, the blockchain will automatically generate accounts for their blockchain adapters. All other users, such as patients and health care providers, need to opt into the system through health care facilities. The blockchain accounts will be generated for the users from each health care facility as soon as the applicants' identities are proven.

The private blockchain stores all the transactions for (1) patients and health care facilities granting, revoking, and denying access to their EHR data; (2) authentication of patients and health care providers to retrieve the EHR data; and (3) health care facilities to store metadata for patient visits. The transactions will record the receiver, sender, contained data, and the timestamp into the blocks through blockchain adapters. Users can also make transactions in the backend blockchain console through the blockchain node. These transactions still need to pass smart contract regulations to become effective. Most users will interact with the graphical user interfaces (GUIs) built on the *application layer* to execute functions in the blockchain system.

Transaction Layer

The *transaction layer* consists of 2 smart contracts that specify a metadata model for health care records and methods that regulate data access rights, permission policies, and data encryption. Two smart contracts, the *EHR manager* smart contract and the *user manager* smart contract, are deployed to the blockchain to securely accomplish the basic EHR management tasks. The *EHR manager* smart contract can only be used by health care facilities to submit the EHR metadata to the blockchain. The *user manager* smart contract is used by patients or facilities to manage access to their data. Once a patient has opted into the system from a health care facility, the health care facility's blockchain adapter will automatically encrypt his or her patient ID and public key using the patient's private key and input to the *user manager* smart contract. Health care facilities will have adapter IDs stored in the *user manager* smart contract. The following scenarios demonstrate the use of smart contracts for the EHR metadata input and HIE.

Electronic Health Record Manager Smart Contract for Submitting Metadata to the Blockchain

The *EHR manager* smart contract (as shown in Figure 2) defines several structures to record patient information: *EHRDataID* and *EHRdata* define the metadata components, *PatientID* stores the patient ID and health care facility ID for the registered patients, and *patientData* maps the different health care facility visit records of patients with the patients' IDs. Once the blockchain adapter receives a record from the EHR system, the blockchain adapter automatically performs the following steps to submit the metadata to the blockchain through an *addEHR* function:

Figure 2. Main part of the electronic health record manager smart contract code that defines the metadata structure. Blockchain adapters must extract the information and calculate the encrypt keys and then store them into the smart contract. The record will automatically associate with the adapter's blockchain ID.

```

1  pragma solidity ^0.4.13;
2  contract EHRMgrContract {
3
4      struct EHRDataID {
5          bytes32 datasetID;    // Dataset ID
6          string datasetDesp;   // Dataset description
7          bytes32 timeOfCreation; // dataset creation time
8      }
9
10     struct patientID {
11         bytes32 patient_ID;    // patient ID in a hospital
12         bytes32 hospital;      // hospital ID
13         bytes32 patientName;   // patient name
14     }
15
16     struct EHRData {
17         EHRDataID ehrdataID;   // dataset ID struct
18         string datasetLoc;      // an URL or a data object hash
19         bytes32 keycipher;      // cipher of the encryption key for EHR

21     }
22     struct patientData {
23         patientID patientid;    // patientID in a hospital
24         mapping (bytes32 => EHRData) ehrCollection; // all EHRs for a patient in a hospital
25     }
26
27     mapping (address => patientData ) patientDataSet; // user info for the EHR datasets
28
29     function addPatient(bytes32 _patient_ID, bytes32 _hospital, bytes32 _patientName, address _patient) public {
30         patientDataSet[_patient].patientid.patient_ID=_patient_ID;
31         patientDataSet[_patient].patientid.hospital=_hospital;
32         patientDataSet[_patient].patientid.patientName=_patientName;
33     } // to add a patient to blockchain
34
35     function addEHR(string _loc, bytes32 _keycipher, bytes32 _datasetID, string _datasetDesp, bytes32 _timeOfCreation, address _patient) public{
36         patientDataSet[_patient].ehrCollection[_datasetID].ehrdataID.datasetID=_datasetID;
37         patientDataSet[_patient].ehrCollection[_datasetID].ehrdataID.datasetDesp=_datasetDesp;
38         patientDataSet[_patient].ehrCollection[_datasetID].ehrdataID.timeOfCreation=_timeOfCreation;
39         patientDataSet[_patient].ehrCollection[_datasetID].datasetLoc=_loc;
40         patientDataSet[_patient].ehrCollection[_datasetID].keycipher=_keycipher;
41         patientDataSet[_patient].ehrCollection[_datasetID].bcAdapter=msg.sender;
42     } // to submit an EHR metadata to blockchain
43
44 }

```

1. Extract the patient ID from the EHR data set.
2. Find a public key associated with the patient from the *user manager* smart contract.
3. Generate a random *data key* for encrypting the EHR data set.
4. Encrypt the EHR data set using data key and store the encrypted data to an *off-chain* secured data store.
5. Use the patient's public key to encrypt the data key. Call the encrypted data key "key cipher."
6. Submit the following metadata to the blockchain:
 - Patient ID.
 - Encrypted data set location as a URL.
 - Key cipher.

- Associated blockchain adapter ID.

The blockchain adapters will generate public and private key pairs following the Diffie-Hellman protocol using Node.js. The data encryption and decryption settings ensure that the data belonging to the patient is only decrypted by the health care facility that produced the data. The key cipher makes the data key more secure and can only be computed when the data owner is known. Figure 3 shows one patient's decoded metadata retrieved through blockchain using the Remix integrated development environment, which is an open-source visualization tool used for interacting with blockchain nodes and smart contract development and deployment.

Figure 3. Example of a patient's metadata retrieved through blockchain. The information is decoded by the Remix web-based integrated development environment, which is connected to the retrieving blockchain node. The patient's metadata contain data location, key cipher, data set ID, data set description, and creation time.

User Manager Smart Contract for the Health Information Exchange Process

A scenario is described in this section to show the process of health care provider X retrieving patient A's EHR. Through a mobile application or web browser with biometric authentication, Patient A can grant access privileges to health care provider X using the application program interface (API) to set data permission on the *interface layer*. In some cases, more than one clinician is involved in the patient's care. The health care facility needs to create a shared blockchain account for the provider's department so that all involved clinicians can access the patient's data with one-time authentication [33]. Blockchain adapters will record who has accessed the data and submit it to the blockchain. The blockchain adapters from the receiver's home health care facility will perform the following steps for the data retrieval process:

1. Verify health care provider X's permission to access patient A's records through the *EHR manager* smart contracts.
2. Retrieve patient A's metadata from the *EHR manager* smart contract.
3. Request the encrypted EHR data set from the remote health care facility via an https service provided by blockchain adapter.
4. Retrieve the encrypted data using encrypted data set location information in EHR metadata.

5. Decrypt the EHR data set. This step involves decrypting the key cipher using the patient's private key to obtain the data key that decrypts the EHR data set.

Similar processes will be used for sharing data between health care facilities and for patients retrieving their own EHR records. The entire process will be performed automatically through the blockchain adapter.

Interfacing Layer

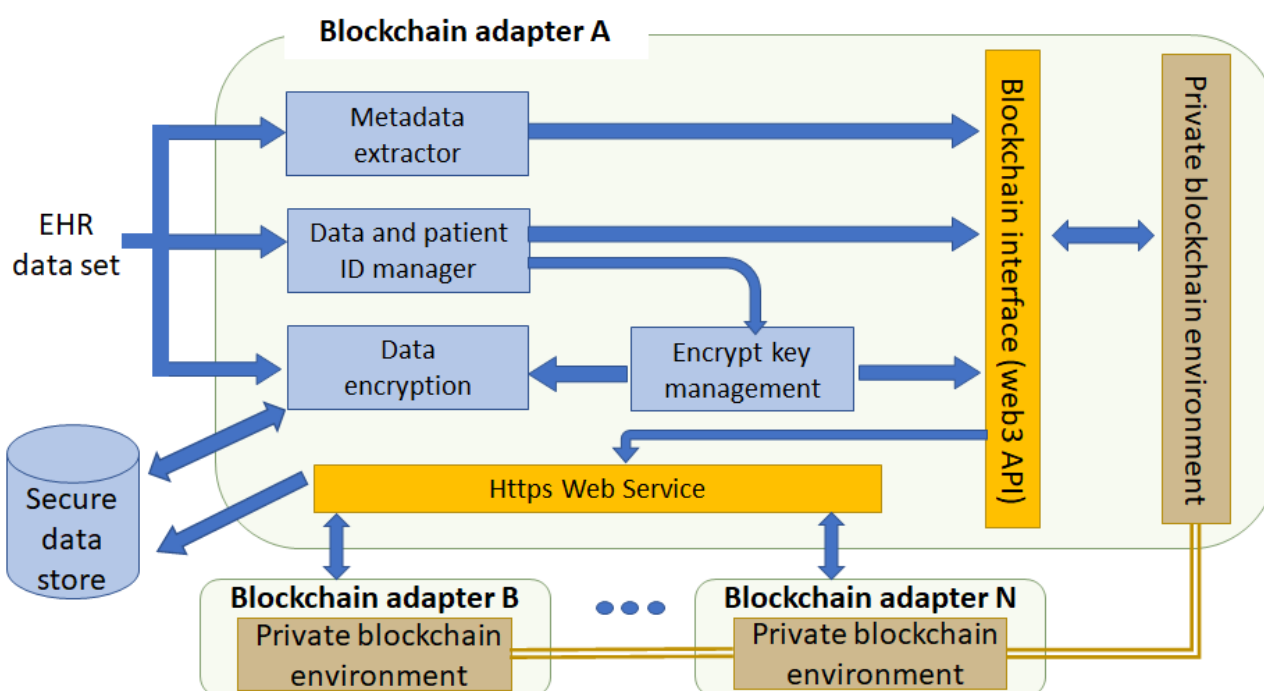

The *interfacing layer* provides 4 high-level methods: *get* the health care data from different facilities, *store* the encrypted data securely, *post* metadata or data request to the blockchain via smart contracts in the *transaction layer*, and *send* the encrypted data to the receiver who has gained permission from the data owner. Using the functions in this layer, application developers can implement distributed data applications (DApps) without the knowledge of smart contracts and the underlying blockchain network. This layer consists of APIs and https web services to define a set of primitive coordinate functions: (1) submit data, (2) set data permission, and (3) retrieve data. The data submission API will extract metadata from the original data and call the *transaction layer's* smart contracts to record it to the blockchain. It will also encrypt the original data and store the encrypted version to a secure off-blockchain data store. The data retrieval API will call smart contracts to retrieve metadata from blockchain, verify encrypted data authenticity with metadata, and decrypt the encrypted data in the off-blockchain data store to obtain the original data. The data

permission setting API will call the *transaction layer's* smart contracts to set access policies and methods for a piece of metadata. Information contained in metadata is used to retrieve and decrypt data. The https web services provide secure data transport when data are to be transported through a channel and can potentially be eavesdropped. Using the blockchain adapter to serve as a gateway to the EHR system minimizes the concerns of data exchange security.

We implemented blockchain adapters as a Node.js application and used the web3.js package for interfacing with a blockchain node and https.js package for https secure web services. web3.js is also available in the Python library as web3.py. The

https-based web services are mainly used for communication among blockchain adapters. The blockchain adapter is embedded as software that will install the missing component automatically, such as node.js and web3.js. Figure 4 shows a high-level block diagram of a blockchain adapter. The metadata extractor extracts metadata such as patient ID and data set ID from the EHR data set for data identification purposes in the blockchain. The data and patient ID manager maps the patient ID to the data set ID and records the information in both the *user manager* smart contract as well as the *EHR manager* smart contract. The data set encryption block in Figure 4 encrypts the EHR data set and stores away in the secure data store with a URL or a data object hash for future access.

Figure 4. Blockchain adapter components and functions. Blockchain adapter extracts the metadata from the electronic health record, encrypts the electronic health record, stores the encrypted electronic health record into the secured data store, and maps the patient ID and data ID to the blockchain account. Blockchain adapters use https to interact with other adapters and communicate with the foundation private blockchain network through a blockchain interface. API: application program interface; EHR: electronic health record.

From the security and reliability point of view, the following design guidelines are strictly followed for the blockchain adapter:

1. Blockchain adapter is modeled as a nonhuman blockchain user and has its own private and public key pair when the blockchain account or address is established. The public key is made public via the *user manager* smart contract. The private key is kept in a blockchain adapter.
2. The https service uses a separate key and certificate file.
3. The Diffie-Hellman key agreement protocol is used for data set encryption.
4. When one blockchain adapter fails, transactions (data set exchange) with the associated organization will be interrupted, but transactions among all other organizations will not be affected.

Application Layer

With the above *interfacing layer* architecture and smart contract setup, many health care applications involving data exchange

can be developed in the *application layer*. This layer will rely on the *interfacing layer* to securely collect the data and then perform data analytics. Applications will not change the existing blockchain settings. These applications can allow researchers or data owners to have better use of the EHR data. For example, personal health records management can be developed on the *application layer*. A patient's identity will be verified through smart contracts in the blockchain. All patient records can be retrieved through the *interfacing layer*. In addition to the HIE application, subject recruitment for clinical trials could also be developed in this layer. Clinical trial sponsors need to obtain permission from the patients through blockchain adapters from clinical trial sites before the matching process [34]. After the patients grant the sponsors permission to gather their data, clinical trial sponsors can use the data analytics tools developed in the *application layer* to match the patients with their recruitment criteria automatically. We implemented these 2 sample applications on our private blockchain system. The

Results section shows the interactions of the *application layer* and the blockchain system and the simulation results.

Results

Case Studies

To test the feasibility of our layered architecture, we built a blockchain environment that contains 1 starting node and 4 health care facility nodes. All the nodes have installed an Ubuntu 18.04.2 operating system and Go Ethereum with the default PoW setting. A blockchain adapter has been installed to each node to communicate with the blockchain and its own secured data store, which was implemented using MongoDB. We created 100 accounts for health care providers and 10,000 patient accounts on each health care facility node of patients' records from the Surveillance, Epidemiology, and End Results database [35]. A total of 2431, 2587, and 2505 patients have multiple records distributively stored in 2, 3, and 4 health care facility nodes, respectively. The remaining patients' records were stored in a single facility node. Selected records were stored in each secured data store using an automated script following the same procedure described in the *EHR manager* smart contract. The ownerships have been claimed when the metadata were pushed into the blockchain using the smart contract in the *transaction layer*.

After setting up the environment, we implemented 2 applications to interact with our blockchain system. The applications are built off-chain but can communicate with the blockchain system using node.js. These 2 applications are examples of the potential use of the layered blockchain architecture. We tested the accuracy, scalability, and speed of our system. We made the following assumptions to simulate the 2 processes: (1) each clinical site has provided at least one node to the system, (2) each clinical site agrees to connect the blockchain adapter to the secured data store, and (3) patients have authorized the blockchain system as well as the 2 applications to access their health records.

Health Information Exchange

This application provides an interface for users to manage access to personal health care records through the *transaction layer*. Patients can use this application to grant and revoke access to their records. Patients can also track how many times their records have been accessed through this application. To test the accuracy, speed, and scalability of our system, we simulated

the process of patients granting permission to health care providers of their EHR. We developed 5 scripts to automate the simulation process by (1) randomly selecting 1 patient to grant 1 health care provider permission to their EHR per second for an hour and recording the timestamp, (2) recording the timestamp when the health care providers received the permission, (3) recording the timestamp when the health care providers received the data, and (5) adding 1 patient per second to script 1 then repeating scripts 1 to 4 until reaching the system limitation because of the known scalability constraints of Ethereum [36].

The simulation only contains the period of interactions with the blockchain. Retrieving data is an off-chain process through the https portal and varies with different health care facilities. From our simulation results, the system breaks at a certain point when the scale reaches 14 transactions per second (TPS). We simulated 331,142 access-granting transactions. All the transactions have successfully retrieved the records except the last second's 14 transactions due to reaching the Ethereum scalability limitation. The average time of writing a transaction to a block is 11.271 (SD 2.208) seconds. We did not find a correlation between TPS and validation time. All health care providers received the metadata in an average of 1.73 seconds.

In this study, the scalability of the blockchain using various transaction frequencies from 1 to 14 TPS through blockchain adapters was tested. Figure 5 shows the time spent granting permission from different scales (the 14 TPS group was excluded because of incomplete results). Once the permission is granted by writing the transactions into blocks, the receiver can retrieve the metadata from the smart contract through the blockchain adapter without making another transaction for users to validate the legitimacy. This means that the average time of receiving metadata is much shorter than the grant permission. The script of the 9 TPS group runs slowly compared with the former groups. All the blockchain nodes were restarted separately, and the script was restarted with the 10 TPS group. The speed is affected by the processing speed of the blockchain nodes and Ethereum performance. The starting node's blockchain adapter was used to control the overall frequency. All transactions from the blockchain adapters of health care facility nodes will queue in the starting node's adapter until the earlier batches of transactions have been executed by each blockchain adapter. We controlled the overall frequency as 13 TPS, which avoids the Ethereum's scalability constraints by spacing the transactions.

Figure 5. Box plot of simulation results for 1 to 13 transactions per second groups. The boxes show the different quantiles of time cost related to different scales of transactions per second.

Subject Recruitment for Clinical Trials

To prove the compatibility of our layered blockchain system, another application was implemented as subject recruitment for clinical trials. This application involves posting criteria, granting permission, and data exchange. To use this application, each clinical trial sponsor needs to provide at least one blockchain node with a blockchain adapter installed. All patients who want to participate in clinical research are required to opt into the application so that they can receive the recruitment criteria. This application involves the following procedures:

- Clinical research recruiters will send recruitment criteria to the opted-in patients in the *interfacing layer*. The criteria also contain the recruiters' blockchain address used for patient authentication.
- Patients who received the criteria can check whether they are matched. If they are interested in clinical research, they can authenticate the clinical research recruiter to access their EHR.
- Recruiters will be notified by the blockchain of whether any patients have granted their permissions to access their data. Then, they will retrieve patient data for precise matching.

- The recruiters will notify the patients if they are matched and send further instructions.

We have implemented a GUI to demonstrate the usage of this application. Patients need to opt for this application to receive the current clinical trial recruitment information. We randomly selected 4 sponsors to post their recruitment criteria using their blockchain adapters through the blockchain *interfacing layer*. Only patients who opted will receive recruiting clinical trial information. Figure 6 shows the GUI for a simulated patient with ID 1721653. It will provide basic information for the patient, such as blockchain address and registered health care facility ID. The recruiting criteria include the sponsor ID, basic inclusion criteria such as age and gender, and study disease (in this case, we used the primary site for the study disease in our simulation). Patients can use the GUI to grant the sponsors access to receive their data to have a precise match with their clinical trial criteria. This action will automatically send a transaction to the *user manager* smart contract to add the sponsor's blockchain address to their access list. Through our simulation, 2 sponsors successfully received permission in an average of 3.07 seconds.

Figure 6. Graphical user interface for patients to permit clinical trial sponsors to access their data. The graphical user interface shows the patient's blockchain address, opt-in status, current recruiting trials' basic recruitment criteria, and permission options. When the patients select the recruiting trial and click submit, the sponsor will be added to their access list in the USER manager smart contract through the blockchain adapter.

Discussion

Conclusions and Future Work

This paper described an augmented layered blockchain system in development for most health care applications involving data coordination across multiple health care facilities. The design of this layered architecture provides generic functions and methods for application developers to securely collect data from different sources without requiring extensive experience of the blockchain technology. The layered architecture allows users the ability to audit the legitimacy of previously occurring transactions but prevents users from modifying any components in the blockchain. The features of blockchain provide a solution to current data coordination challenges. The blockchain-based approach extends the ownership of the EHR data set to each patient. On the basis of decentralized features of blockchain technology for peer-to-peer transactions, this approach can greatly reduce the health care data set sign-off and release. Data security and authenticity are also guaranteed by the immutability of the blockchain and smart contract-regulated data exchange.

Through our simulation process, our system empirically proved the feasibility of the architecture for health care applications.

We also tested the scalability of our blockchain system and provided an optimal solution to avoid blockchain scalability constraints. Our future work will continue to evaluate the validation mechanism to improve the blockchain performance and add an AI component on the *application layer* for data analytics to maximize the use of EHRs based on the layered blockchain system.

Limitation

The main limitation of our approach is the setup requirement from each participating site. Each health care facility is required to provide at least one blockchain node to the system and keep an encrypted EHR outside of the operation EHR for registered patients into the secured data stores that can communicate with blockchain adapters. Patients will potentially also need to provide blockchain nodes such as mobile devices to exchange and store their personal health records generated by their personal medical devices. The performance of the model can be affected by the properties of the blockchain node. If a single node creates a mass of transactions at the same time through the blockchain adapter, this action will use up all the memory and break the node before it is sent to the blockchain.

Correction of: <https://www.jmir.org/2020/4/e17734/>

(*J Med Internet Res* 2020;22(7):e21027) doi:[10.2196/21027](https://doi.org/10.2196/21027)

The authors of “Optimizing Text Messages to Promote Engagement With Internet Smoking Cessation Treatment: Results From a Factorial Screening Experiment” (*J Med Internet Res* 2020;22(4):e17734) noticed several errors in their published manuscript which had been introduced after proofreading. The following corrections have been implemented:

The symbols μ and ϕ were presented as m and f , respectively, in the following sentence of the Methods section; additionally, in this section, the negative sign was incorrectly subscripted:

SMDs for frequency counts were calculated as $(m_1 - m_2) / [f(m_1 + m_2)]^{1/2}$, where m_1 and m_2 were the sample means of each comparison group.

This has been revised to:

SMDs for frequency counts were calculated as $(\mu_1 - \mu_2) / [\phi(\mu_1 + \mu_2)]^{1/2}$, where μ_1 and μ_2 were the sample means of each comparison group.

In the same paragraph, the negative sign was again incorrectly subscripted in the following sentence:

SMDs for binary outcomes were calculated as $(p_1 - p_2) / [p_1 \times q_1 + p_2 \times q_2]^{1/2}$, where $p_1 = 1 - q_1$ and $p_2 = 1 - q_2$ were the sample outcome prevalence of each comparison group.

This has been revised to:

SMDs for binary outcomes were calculated as $(p_1 - p_2) / [p_1 \times q_1 + p_2 \times q_2]^{1/2}$, where $p_1 = 1 - q_1$ and $p_2 = 1 - q_2$ were the sample outcome prevalence of each comparison group.

Additionally, due to a technical error the following sentence was published in the Results section of the Abstract:

As no SMD >0.30 was observed for main effects on any outcome, results suggest that for some outcomes, the combined intervention was stronger than individual factors alone.

This has been revised to:

As no SMD >0.30 was observed for main effects on any outcome, results suggest that for some outcomes,

the combined intervention was stronger than individual factors alone.

The correction will appear in the online version of the paper on the JMIR website on July 28, together with the publication of

this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Submitted 03.06.20; this is a non-peer-reviewed article; accepted 03.06.20; published 28.07.20.

Related Article:

Correction of: <https://www.jmir.org/2020/5/e13980/>

(*J Med Internet Res* 2020;22(7):e21381) doi:[10.2196/21381](https://doi.org/10.2196/21381)

In “A Facilitated Web-Based Self-Management Tool for People With Type 1 Diabetes Using an Insulin Pump: Intervention Development Using the Behavior Change Wheel and Theoretical Domains Framework” (*J Med Internet Res* 2020;22(5):e13980) the authors noted several errors.

In the Results section of the Abstract, the text was revised from:

“(4) professional responsibility and associated risks and dangers, whereas HCPs are fearful of the consequences of promoting non-NHSSM support, and they question whether SM support fits into their role.”

to

“(4) professional responsibility and associated risks and dangers, whereas HCPs are fearful of the consequences of promoting non-NHS SM support, and they question whether SM support fits into their role.”

In the Discussion section, one sentence has been updated to correct reference citations. The text was revised from:

“In addition, there has been a recent drive for the integration of psychosocial support into routine

diabetes care [19,22], and this study provides an initial engagement with the factors that would impact how psychosocial support is taken up with HCPs and the priorities for patients.”

to

“In addition, there has been a recent drive for the integration of psychosocial support into routine diabetes care [18,21], and this study provides an initial engagement with the factors that would impact how psychosocial support is taken up with HCPs and the priorities for patients.”

Multimedia Appendices 1 and 2 contained tracked changes comments. These files have now been replaced and no longer contain the comments.

The corrections will appear in the online version of the paper on the JMIR Publications website on July 30, 2020, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories

Submitted 12.06.20; this is a non-peer-reviewed article; accepted 12.06.20; published 30.07.20.

Abstract

Background: Coronavirus disease (COVID-19) is a type of pneumonia caused by a novel coronavirus that was discovered in 2019. As of May 6, 2020, 84,407 cases and 4643 deaths have been confirmed in China. The Chinese population has expressed great concern since the COVID-19 outbreak. Meanwhile, an average of 1 billion people per day are using the Baidu search engine to find COVID-19-related health information.

Objective: The aim of this paper is to analyze web search data volumes related to COVID-19 in China.

Methods: We conducted an infodemiological study to analyze web search data volumes related to COVID-19. Using Baidu Index data, we assessed the search frequencies of specific search terms in Baidu to describe the impact of COVID-19 on public health, psychology, behaviors, lifestyles, and social policies (from February 11, 2020, to March 17, 2020).

Results: The search frequency related to COVID-19 has increased significantly since February 11th. Our heat maps demonstrate that citizens in Wuhan, Hubei Province, express more concern about COVID-19 than citizens from other cities since the outbreak first occurred in Wuhan. Wuhan citizens frequently searched for content related to “medical help,” “protective materials,” and “pandemic progress.” Web searches for “return to work” and “go back to school” have increased eight-fold compared to the previous month. Searches for content related to “closed community and remote office” have continued to rise, and searches for “remote office demand” have risen by 663% from the previous quarter. Employees who have returned to work have mainly engaged in the following web searches: “return to work and prevention measures,” “return to work guarantee policy,” and “time to return to work.” Provinces with large, educated populations (eg, Henan, Hebei, and Shandong) have been focusing on “online education” whereas medium-sized cities have been paying more attention to “online medical care.”

Conclusions: Our findings suggest that web search data may reflect changes in health literacy, social panic, and prevention and control policies in response to COVID-19.

KEYWORDS

COVID-19; China; Baidu; infodemiology; web search; internet; public health; emergency; outbreak; infectious disease; pandemic; health literacy

Introduction

In December 2019, a severe public health emergency was induced by the outbreak of a novel coronavirus, which has since

been named coronavirus disease (COVID-19) by the World Health Organization (WHO) [1]. Since the first-level response by government officials to COVID-19 across China's provinces and cities, governmentally imposed social isolation has provided

the Chinese population with ample time to search online for the latest COVID-19–related news [2]. Baidu, as the most widely used Chinese search engine, accounts for two-thirds of China's search engine market share [3]. At the time of the COVID-19 outbreak, we found that the number of searches for COVID-19 had increased exponentially, despite the fact that its incidence and mortality rates were much lower than those of some noncommunicable diseases, such as cancer. Hence, this phenomenon is worthy of further attention and discussion.

Methods

We obtained web search data from the Baidu Index [4]. As of May 2020, Baidu accounts for 71.23% of the search engine market share in China [5] and is the most widely used search engine in the country. It is a well-known and extensive platform for information/resource sharing that Chinese internet users rely on.

Search data, dating to as early as 2004, were derived from search frequencies on Baidu. Frequencies were calculated based on the search volumes of specific search terms entered by internet users, and data on a daily, monthly, and yearly basis were obtained for the search terms we chose from the Baidu Index.

We entered the formal Chinese names for “lung cancer,” “liver cancer,” “esophageal cancer,” “colon and rectum cancer,” and “breast cancer,” respectively, and acquired their search data history from January 1, 2020, to March 17, 2020. The Baidu Index provides search term analysis; it also uses a process to scientifically determine related search terms based on the mode through which the searchers initiate a search request. This means that other relevant search terms will be provided automatically once the internet users enter a search term. Thus, we entered “COVID-19” into the Baidu Index and obtained its related search terms from February 11, 2020, to March 17, 2020 (search volumes for “COVID-19” can only be obtained from February 11, 2020 onward). The search terms mainly included health literacy, social panic, and prevention and control measures relating to COVID-19. All search data were downloaded free of charge on March 17, 2020.

We performed descriptive analyses to describe and compare the overall search situation under the context of the pandemic from different aspects. Statistical analysis was conducted using Excel 2016 (Microsoft Corporation) and IBM SPSS (version 22.0, IBM Corporation). We used Tableau (version 2018.3, Tableau Software) and Excel 2016 (Microsoft Corporation) to create heat maps.

Results

Mapping of Health Literacy and Social Panic Via Web Search Data During a Public Health Emergency

The COVID-19 pandemic necessitates requirements for public health literacy. Despite China's active response in combating this outbreak, a proportion of the Chinese population has remained afraid, which may seriously affect progress in controlling and preventing future outbreaks. This phenomenon is particularly striking on the internet and within social media, and investigating COVID-19–related health literacy and social panic via these platforms may yield important insights.

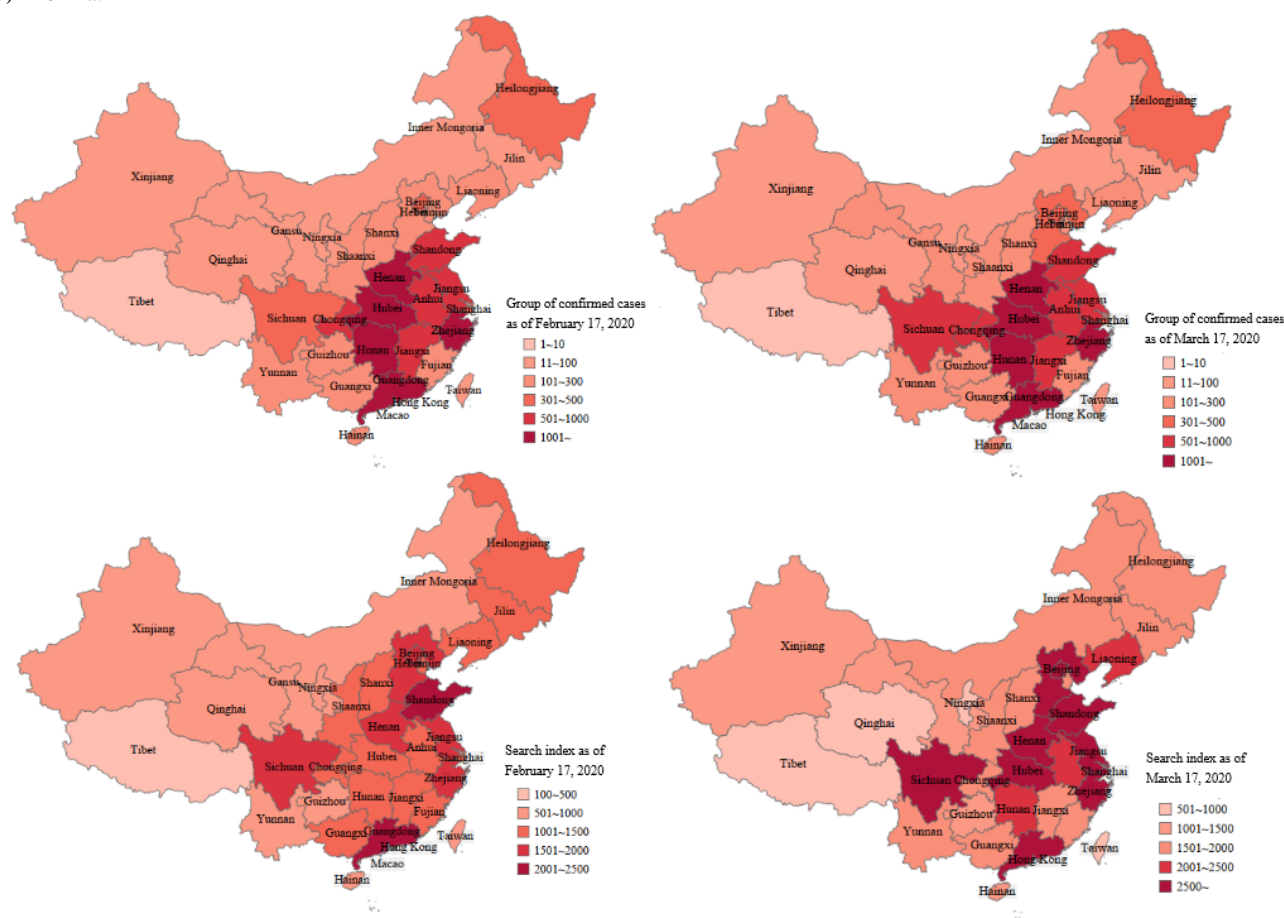

Taking the COVID-19 outbreak as an example, spurious information disseminated via social media by nonexpert individuals has included false claims on how to kill the COVID-19 virus (severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2]), for example, by drinking alcohol, smoking, aromatherapy, essential balms, use of a hair dryer, or taking a hot bath [2]. The internet has figuratively become a double-edged sword in the context of the COVID-19 outbreak.

Concerns of Internet Users During the COVID-19 Outbreak

By summarizing web searches for COVID-19, the most searched content has focused on the progression of the pandemic and tips on how to protect oneself from infection [6]. Web searches on COVID-19 have mainly included the following: the latest news on the pandemic; relevant knowledge about COVID-19 infection prevention and control; basic, as well as more comprehensive, information describing SARS-CoV-2; and rumors and suggested policies from unqualified sources [6].

Citizens in Wuhan, Hubei Province, have been more concerned about COVID-19 compared to citizens from other cities during the same period since the outbreak first occurred in Wuhan (Figure 1). Wuhan citizens searched for content related to “medical help” 22% of the time, followed by searches for “protective materials” and “pandemic progress.” Medical help refers to special assistance and support provided to the citizens of Wuhan during the pandemic, which included the deployment of 42,000 trained medical workers from across the country to Wuhan and other cities in Hubei Province, and donations of medical supplies (medical masks, medical protective clothing, ventilators, etc).

Figure 1. The cumulative number of confirmed cases of coronavirus disease (COVID-19) (top row) and the change in COVID-19's search index (bottom row) in China.

Since the COVID-19 outbreak, web searches for wild animals have reached a historical peak—the Baidu topic “refuse to eat wild animals” has reached nearly 100 million views [7]. Content related to “harm to wild animals” has received considerable attention. At the early stage of the pandemic, there were some speculation that wild animals may have spread the coronavirus to people in Wuhan, although there is no scientific conclusion regarding the origin of COVID-19 [8-10]. In this context, on February 24, 2020, on the basis of the *Law of the People's Republic of China on the Protection of Wildlife*, China established a comprehensive system to prohibit the consumption of wild animals [11].

With the pandemic now gradually under control in China, public concerns have changed accordingly [12]. Web searches for “when to return to work and start school” have increased eight-fold from those during the previous month based on the web search data in the Baidu Index. Searches for content related to “closed community and remote office” have continued to rise, and searches for “remote office demand” have risen by 663% from the previous quarter. Individuals from first-tier cities such as Beijing, Shanghai, Shenzhen, Guangzhou, and Chengdu have paid more attention to telecommuting. Employees who

have returned to work have mainly engaged in web searches on “return to work and prevention measures,” “return to work guarantee policy,” and “time to return to work.” Men have been half as attentive as women regarding protective measures related to returning to work.

Previously, the four major industries most discussed by Chinese netizens have been online education, online medical care, online entertainment, and fresh electronic commerce (e-commerce) (Table 1) [6]. During the pandemic, provinces with large populations of educated individuals (eg, Henan, Hebei, and Shandong) have been focusing on “online education.” In contrast, fourth-tier cities have been paying more attention to “online medical care” (in China, cities are usually graded according to various levels such as city development, comprehensive economic strength, talent attractiveness, information exchange capability, international competitiveness, technological innovation capability, and transportation accessibility. First-tier cities refer to metropolises that are important for social, political, and economic activities [eg, Shanghai, Beijing]. Most fourth-tier cities are medium-sized cities.). Additionally, young and middle-aged groups exhibited greater search volumes for “online medical care” [10].

Table 1. Growth rate of search volumes of the four major industries discussed by netizens [6].

Industry	Search growth rate (%)
Online education	248
Online medical care	200
Online entertainment	170
Fresh electronic commerce	120

Impact of a Lack of Health Literacy on the COVID-19 Outbreak

COVID-19 is a novel and highly infectious disease [13,14], but in the early days of the outbreak, people had limited knowledge of it and did not know how to prevent it, which concomitantly caused panic. Despite the COVID-19 pandemic becoming gradually controlled in China, most people still remain under high alert. Some misinterpretations of discussions on the resumption of work on the internet have caused another wave of panic among some groups and cities since returning to work. This phenomenon can be observed on Weibo, a social media platform based on information sharing, dissemination, and acquisition in real time (similar to Facebook). Many people are worried about whether a large number of people returning to work will reinitiate the spread of COVID-19. However, individuals in areas with no outbreaks of the disease or low incidence of infections have also expressed this concern. However, if cities continue to stagnate, such stagnation may lead to a higher mortality rate than that attributed to COVID-19. Zhang Wenhong, head of a Shanghai medical treatment expert group, stated the following in an interview [15]:

If the hospital does not return to work, cancer patients cannot receive chemotherapy and surgery, and other infected people cannot be treated. Patients with trauma cannot get a good treatment. Under such circumstances, the number of patients dying from other diseases will far exceed the number of people dying from the new coronavirus.

Why Are Public Health Emergencies of Greater Concern Than Highly Fatal Chronic Diseases Like Cancer?

Cancer-related deaths in China account for approximately 27% of all global cancer-related deaths [16,17]. As presented in Table 2, except for esophageal cancer, the search frequencies of all other cancers have decreased since the COVID-19 outbreak. Meanwhile, the search frequency of COVID-19 has increased significantly [4]. Dr Tedros Adhanom Ghebreyesus, Director-General of the WHO, reported that the global mortality rate of COVID-19 is approximately about 3.4% [18]. According to the latest data from the National Health Commission of the People's Republic of China on February 3, 2020, the mortality rate of COVID-19 in Hubei Province is 3.1%, while the national COVID-19 mortality rate is even lower at 0.2% [19].

Table 2. Changes in the search index of the top five cancers and coronavirus disease (COVID-19) in China from January 27, 2020, to March 17, 2020.

Disease	Incidence rate (per 100,000 persons) ^a	Mortality rate (per 100,000 persons) ^a	Daily mean value		Overall search index ^b		Mobile search index ^b	
			Overall search index	Mobile search index	Year-on-year change (%)	Month-on-month change (%)	Year-on-year change (%)	Month-on-month change (%)
Lung cancer	58	49	3849	3538	−23	−1	−19	— ^c
Liver cancer	37	30	1301	1128	−63	−22	−65	−18
Esophageal cancer	17	15	1108	957	11	3	14	3
Colon and rectum cancer	31	13	215	120	−12	−9	−21	−16
Breast cancer	26	6	2235	2034	−50	−15	−50	−13
COVID-19	—	—	25,256	19,614	—	4263	—	3784

^aIncidence and mortality rates for the five cancers were obtained from the Global Burden of Diseases Database [20].

^bNegative values represent decline.

^cNot available.

The death rate associated with cancer is much higher than that of COVID-19. If we use the national data (excluding Hubei Province), the mortality rate of COVID-19 is comparable to that of the general influenza, and the total incidence rate is far lower than that of influenza [21,22]. There are several reasons

that may explain the relatively high mortality rates of COVID-19 in Wuhan and in Hubei Province in general, including the stronger virulence of SARS-CoV-2 in Wuhan, more cross-infection, and the prevalence of patients with mild symptoms who did not see a doctor [23].

Discussion

Principal Findings

Health literacy includes two aspects: (1) knowledge, which comprises basic health knowledge and skills; and (2) ability, which refers to one's ability to acquire, understand, screen, and apply health information [24,25]. Health information literacy represents the core of health literacy—it can greatly improve the public's capacity for self-protection in order to improve the overall response to public health emergencies.

The health literacy rate of Chinese residents in 2018 was 17.06% [26]. It mainly covers basic health knowledge and concept literacy, healthy lifestyle and behavior literacy, and basic health skills literacy. Although the health literacy rate of residents has improved, the uneven distribution of health literacy levels between urban and rural areas, and across regions and populations, still exists. The health literacy levels of rural residents, residents in the Midwest, and the elderly are relatively low. As mentioned above, with the rapid development of internet technology, people can easily use the internet to search for health information. However, the new coronavirus that caused the recent pandemic was previously unknown. Since the COVID-19 outbreak, the related transmission characteristics, symptoms, transmission channels, and methods for protection have been gradually communicated to the public via recent publications on COVID-19-related research. Public health emergencies have the characteristics of urgency and paroxysm since they require the public to respond quickly. At such times, the ability to acquire, understand, and use health data will enable individuals to more quickly facilitate disease control and prevention in the face of a public health emergency.

People use the internet for almost everything they do nowadays. By uploading and downloading information, everyone can be a publisher and conveyor of the immense quantity of information available on the internet. Search engines facilitate the acquisition and learning of health information from a variety of sources, which provides the public with more diversified content, autonomy, and greater control over choices. However, search engines also lead to many problems. For example, they may disseminate data from unreliable sources, making it difficult for the public to distinguish between high-quality and low-quality health information [27-29]. In these unprecedented times, people are more vulnerable and credulous to the impact of new information related to COVID-19. Hence, the vast amount of information available on the internet undoubtedly has a considerable impact on public health literacy and may influence the control and prevention of further outbreaks.

Improving health information literacy is the primary component of improving overall health literacy. First, it is necessary to raise awareness of the important role of health information literacy, and to realize how it can improve public health and promote the development of health services. Second, the state should take the lead in setting up a network containing national health information and support services from multiple sources (eg, the public, medical organizations, governmental sectors) to ensure that the public can receive assistance in obtaining health information and related skills. Because health information

involves professional knowledge and also concerns the health of every citizen, the release of authoritative information from professional agencies during the pandemic is particularly important. During the COVID-19 pandemic, many users of social media often cited the words of academician Zhong Nanshan, a trusted public academic, to spread information from a credible source. This pattern demonstrates that individuals need authoritative health information. Timely and authoritative information may be one of the most effective ways to eliminate doubt and reduce panic, especially in the face of public health emergencies. Third, education should be strengthened to improve the level of public health literacy throughout schools, communities, and villages. Individual education levels and education systems are important factors affecting public health information literacy, and health information literacy education through comprehensive linkage represents the most inclusive and cost-effective precautionary measure [30,31]. As recommended by the WHO, the following response strategies are required: rapidly establishing international coordination and operational support; scaling up of national readiness and responses to operations; and accelerating priority research and innovation [32].

In addition to face-to-face communication, the online role of health care providers in public health communications is also important for mitigating medical misinformation. Examples of such online public health communications are WebMD in the United States, AskDr in Singapore, HaoDF in China, etc. Through these outlets, health care authorities can communicate with the public via the internet and provide professional and reliable health information.

While classic public health measures still play very important roles in tackling the current COVID-19 pandemic, there are also many new potentially enabling technological domains that can be applied to help monitor, survey, detect, and prevent such pandemics, including the Internet of Things, big data analytics, artificial intelligence, and blockchain technology. Therefore, we should make full use of these emerging technologies to contain the current COVID-19 outbreak, as well as future pandemics in a timely and effective manner [33-39].

Conclusions

Since the Chinese New Year, the COVID-19 outbreak has become the most important issue in China. Fear of an unknown virus represents the beginnings of panic, and the internet and social media networks have since become incubators and catalysts of panic. Individual cases can be shared by tens of millions of people in a single day through social media dissemination. Hundreds of millions of people are eagerly absorbing information about the novel coronavirus, but reading about new cases is undoubtedly causing concerns among citizens about their own health status.

The pandemic has diverted attention from other health issues. China accounts for 19% of the global population, and its incidence of cancer accounts for 22% of the total global prevalence of cancer. Nevertheless, these diseases have never caused panic at the level of COVID-19. The mortality rate of COVID-19 cannot be compared with that of any other major noncommunicable disease. Despite this discrepancy, the Chinese

population continues to be horrified by COVID-19 but at ease with other known diseases. We need to collectively alter our minds about COVID-19 in order to manage such public health emergencies more rationally. This change requires a more

logical use of information obtained from social media and the internet during public health emergencies, as well as improvements in health literacy and the ability to cope with social panic.

Abstract

Background: Most patients with coronavirus disease (COVID-19) who show mild symptoms are sent home by physicians to recover. However, the condition of some of these patients becomes severe or critical as the disease progresses.

Objective: The aim of this study was to evaluate a telemedicine model that was developed to address the challenges of treating patients with progressive COVID-19 who are home-quarantined and shortages in the medical workforce.

Methods: A telemedicine system was developed to continuously monitor the progression of home-quarantined patients with COVID-19. The system was built based on a popular social media smartphone app called WeChat; the app was used to establish two-way communication between a multidisciplinary team consisting of 7 medical workers and 188 home-quarantined individuals (including 74 confirmed patients with COVID-19). The system helped patients self-assess their conditions and update the multidisciplinary team through a telemedicine form stored on a cloud service, based on which the multidisciplinary team made treatment decisions. We evaluated this telemedicine system via a single-center retrospective study conducted at Tongji Hospital in Wuhan, China, in January 2020.

Results: Among 188 individuals using the telemedicine system, 114 (60.6%) were not infected with COVID-19 and were dismissed. Of the 74 confirmed patients with COVID-19, 26 (35%) recovered during the study period and voluntarily stopped using the system. The remaining 48/76 confirmed patients with COVID-19 (63%) used the system until the end of the study, including 6 patients whose conditions progressed to severe or critical. These 6 patients were admitted to hospital and were stabilized (one received extracorporeal membrane oxygenation support for 17 days). All 74 patients with COVID-19 eventually recovered. Through a comparison of the monitored symptoms between hospitalized and nonhospitalized patients, we found prolonged persistence and deterioration of fever, dyspnea, lack of strength, and muscle soreness to be diagnostic of need for hospitalization.

Conclusions: By continuously monitoring the changes in several key symptoms, the telemedicine system reduces the risks of delayed hospitalization due to disease progression for patients with COVID-19 quarantined at home. The system uses a set of scales for quarantine management assessment that enables patients to self-assess their conditions. The results are useful for medical staff to identify disease progression and, hence, make appropriate and timely treatment decisions. The system requires few staff

to manage a large cohort of patients. In addition, the system can solicit help from recovered but self-quarantined medical workers to alleviate shortages in the medical workforce and free healthy medical workers to fight COVID-19 on the front line. Thus, it optimizes the usage of local medical resources and prevents cross-infections among medical workers and patients.

KEYWORDS

telemedicine system; home quarantine; quarantine management assessment; progressive COVID-19 patients; COVID-19

Introduction

Since its outbreak in December of 2019, coronavirus disease (COVID-19) has spread worldwide, causing more than 5 million infections and tens of thousands of deaths in the course of three months [1]. In cities that were severely affected by COVID-19, such as Wuhan (China), Lombardy (Italy), and New York City (United States) [1], local medical capacities were quickly depleted by large numbers of patients who hurried to hospitals for treatment. Many medical workers were infected, and medical care supplies were further exhausted [2]. To prevent collapse of the global health care system, many countries have advocated for infected patients with mild symptoms to stay home and self-quarantine [3]. However, it has been observed that the condition of some home-quarantined patients becomes severe or critical as the disease progresses. Home quarantine can delay timely treatment and hospitalization of these patients, which may lead to their death.

In this paper, we report a telemedicine model that we developed to address the challenges outlined above. This telemedicine system enabled close monitoring of 74 home-quarantined COVID-19 patients from January 6 to 31, 2020. Of the 74 patients, 6 (8%) were admitted to hospital when signs of deterioration were detected by the system. One patient received extracorporeal membrane oxygenation (ECMO) treatment for 17 days. All 74 patients recovered.

The telemedicine model was built based on WeChat, a popular smartphone app for instant messaging and social media. The WeChat app established two-way communication between the home-quarantined patients and a multidisciplinary team. The multidisciplinary team contacted the patients regularly to receive

information updates. The information was subsequently analyzed to determine the latest status of the patients. Home-quarantined patients could also initiate communication to report any abnormalities in addition to receiving feedback about their medical conditions. The system we developed is the first to quantify subjective symptom descriptions with objective numerical scales. In addition, this telemedicine system helps alleviate the workload of overwhelmed medical staff [4], as we found that excessive laboratory data and physical examinations were not strictly necessary to identify the prognoses of patients with mild symptoms. Furthermore, the telemedicine model minimizes the risk of infection among caregiving staff by reducing their direct physical contact with patients. In this paper, we summarize the procedures of the telemedicine model and present clinical evidence of its success.

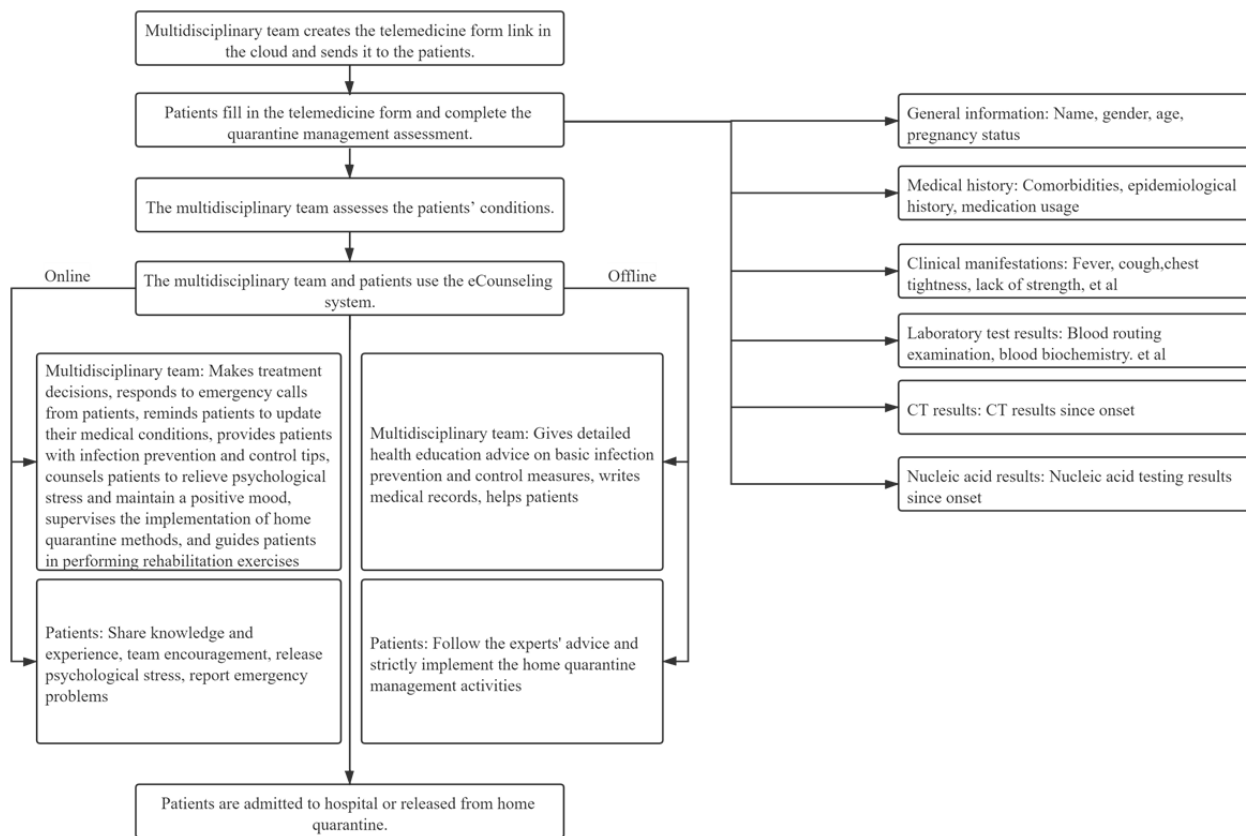

Methods

We evaluated the telemedicine system via a single-center retrospective study conducted at Tongji Hospital in Wuhan, China, between January 6 and January 31, 2020. The study was approved by the Tongji Hospital Ethics Committee before data were collected retrospectively.

Procedure and Information Flow of the Telemedicine System

Below, we outline the procedure of the telemedicine system. When a patient signed up for the telemedicine system, the multidisciplinary team created a patient-specific telemedicine form in the cloud. The telemedicine form was then sent to the patient through a link via the WeChat app to the patient's mobile phone or by email. The patient began the process by filling in the telemedicine form (Figure 1).

Figure 1. Flowchart of the telemedicine system, including the steps to enroll a patient, conduct self-assessment via the quarantine management assessment, and update conditions using the eCounseling system. CRP: C-reactive protein; CT: computed tomography; eCounseling: electronic counseling; PCT: procalcitonin.

The patient first answered a set of standardized questions, which included general demographic information (name, gender, age, occupation, and pregnancy status), medical history (comorbidities, epidemiological history within the past 14 days, and medication usage), clinical manifestations (eg, fever, cough, chest tightness, lack of strength), various laboratory tests, computed tomography (CT) images, and nucleic acid test results for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) detection (Figure 1).

Next, the patient underwent quarantine management assessment. This assessment was based on a set of medical observation scales developed by the multidisciplinary team based on both a literature review [5-9] and input from 34 medical experts from our medical school or its affiliated hospitals (Multimedia Appendix 1). The quarantine management assessment helped the multidisciplinary team assess the patients' conditions.

Based on the assessment, the multidisciplinary team determined whether the patient should be hospitalized immediately or placed under medical observation at home. If the patient was placed under medical observation, the patient would then begin using the electronic counseling (eCounseling) system, which facilitated close observation by and efficient communication with the multidisciplinary team. Specifically, the patient was required to update their conditions on a daily basis using the telemedicine

form. Due to the convenience provided by the cloud service, the information could be instantly accessed by pertinent multidisciplinary team members. They subsequently provided feedback and guidance on the telemedicine form, which then could also be accessed by the patient immediately.

In addition, the patient was invited to join a WeChat group consisting of patients participating in the telemedicine system and multidisciplinary team members. In this way, the patient could receive health tips from the multidisciplinary team and conduct a group chat with other patients and multidisciplinary team members. The patient could also initiate a one-to-one chat or telephone call with any multidisciplinary team member using built-in functions in the WeChat app.

The multidisciplinary team adjusted their observational attention based on the progression of each patient's condition. If a patient's condition continued to worsen (eg, repeated and persistent fever >38.5 degrees Celsius, cyanosis or CT image deterioration >50% within 48 hours) or their mental state scores continued to decline, the patient was flagged as "red." The multidisciplinary team then determined that the patient should be admitted to hospital to be treated. The detailed decision-making process regarding hospitalization is presented in Figure 2. Figures 3 and 4 provide screenshots of the interfaces in which the telemedicine form is created and used, respectively.

Figure 2. Decision tree of patient treatment for MDT based on patients' condition updates via the eCounseling system. °C: degrees Celsius; BP: blood pressure; bpm: beats per minute; CT: computed tomography; mmHg: millimeters of mercury; SpO₂: oxygen saturation.

Composition of the Multidisciplinary Team

The multidisciplinary team consisted of multidisciplinary medical workers, including 2 physicians, 3 nurses, 1 rehabilitation physician, and 1 psychologist. The physicians gave treatment advice according to the patients' condition updates through the eCounseling system. The nurses guided the methods of quarantine and disinfection, supervised the patient's regular work, rest, nutrition, and diet, and urged the patients to update their conditions in the telemedicine form on a daily basis. The rehabilitation physician helped the patients develop practical rehabilitation plans, and the psychologist helped them maintain a positive mood.

Participating Patients

The system initially recruited 188 individuals through word of mouth and physician referrals. Of these individuals, 114/188 (60.6%) showed no symptoms of COVID-19 during the 14-day quarantine period. These individuals were dismissed from the telemedicine system. The remaining 74 patients were confirmed COVID-19 cases. Among these patients, 26/74 (35%) left the system prematurely.

The multidisciplinary team followed up with every patient who dropped out; they found that all 26 patients had recovered and felt that their continued participation in the telemedicine system was unnecessary.

The observation endpoints for the patients in the telemedicine system were set as follows: patients were clinically cured (normal CT imaging reports plus a minimum of 2 rounds of negative results for SARS-CoV-2 nucleic acid detection), patients were admitted to hospital because of progression of the disease, or patients were deceased (although this did not occur in our study).

Diagnostic Criteria, Inclusion Criteria, and Exclusion Criteria of Patients With COVID-19

The diagnostic criteria for confirmed cases were defined as the presentation of either 1 of 2 pieces of etiological evidence: testing positive for SARS-CoV-2 nucleic acid in respiratory or blood samples by reverse transcriptase–polymerase chain reaction (RT-PCR) or virus sequences detected in respiratory or blood samples sharing high homology with the known sequence of SARS-CoV-2.

The inclusion criteria of the telemedicine system were set as confirmed or suspected cases of COVID-19 and voluntary

participation in medical observation. Patients who were not diagnosed with COVID-19 with certainty, pregnant or breastfeeding women, patients younger than 18 years or older than 75 years, and patients who were unable to cooperate with the data reporting were excluded from the analysis.

Results

Development of the Quarantine Management Assessment

We designed the quarantine management assessment scales using common symptoms presented by the patients with COVID-19 we treated at the Tongji Hospital clinic. We then gradually added new symptoms to the scales as our understanding of the disease advanced. The final version of the quarantine management assessment was designed based on these scales, which consisted of 5 primary indicators, 22 secondary indicators, and 83 tertiary indicators ([Multimedia Appendix 1](#)).

To calibrate the validity of the quarantine management assessment scales, they were submitted to 34 medical experts for evaluation. Two rounds of expert consultations were conducted. In each round, 17 experts from the emergency

department, respiratory department, intensive care unit (ICU), and infectious disease department were invited to evaluate the scales. Statistical analysis of the consultation results showed that the response rates of the two rounds of expert consultations were 100% and 88.24%, respectively; the mean authoritative coefficient was 0.855. The *W* values for the degree of coordination of the expert opinions were 0.204 and 0.293 for the two rounds, respectively. The *W* values were also statistically significant ($P=.003$).

Demographics and Baseline Characteristics on Admission

Of the 48 patients in the study, 35 (73%) were female. The median age was 37.5 years (IQR 30.00–45.00). Fever was the most common initial symptom among the 48 patients (28, 58%), followed by cough (16, 33%), lack of strength (6, 13%), muscle soreness (5, 10%), and nasal congestion (3, 6%) ([Table 1](#)). One patient had no symptoms upon their initial clinic visit. Six patients were admitted to hospital later because their conditions worsened during home quarantine; all these patients had fever. Of the hospitalized patients, 3 had coughs and 3 also showed infiltration in both lungs at the time of diagnosis. However, 2 hospitalized patients exhibited normal CT imaging at initial diagnosis ([Table 2](#)).

Table 1. Demographics, baseline characteristics, and clinical outcomes of the home-quarantined patients with COVID-19 (N=48).

Characteristic	All patients (N=48)	Nonhospitalized patients (n=42)	Hospitalized patients (n=6)
Age (years), median (IQR)	37.50 (30.00-45.00)	35.50 (29.50-44.25)	55.00 (37.25-70.25)

Decreased	28 (58)	22 (52)	6 (100)

^aCT: computed tomography.

Of the 6 hospitalized patients, 2 patients (33%) progressed to critical condition. One patient (labeled as Patient No. 3 in [Table 2](#)) was directly admitted to the ICU. ECMO support was provided to this patient for 17 days. He was transferred to the general ward when his condition stabilized. Eventually, the patient recovered ([Table 2](#)). Another hospitalized patient (labeled as Patient No. 4 in [Table 2](#)) was found to have a persistent fever on day 5 of observation. The patient's CT results identified ground-glass opacities in both lungs ([Figure 5](#)). Emergency hospital admission was requested for the patient. Noninvasive ventilation was provided, and the patient's condition gradually improved. This patient was discharged from hospital after 30 days of treatment ([Table 2](#)).

Based on the information collected through the eCounseling system, we found that there were differences in disease progression between patients with mild conditions and the patients who were hospitalized. The hospitalized patients had appreciably elevated body temperature at onset, which scored between 3 and 4 points (approximately 38–40 °C) and persisted longer than that of nonhospitalized patients. The mean body temperature of the nonhospitalized patients became normal by day 4 or 5 ([Figure 6A](#)). In comparison, the body temperature of the hospitalized patients remained elevated on day 5 to 6 along with exacerbated cough ([Figure 6B](#)).

The results of the quarantine management assessment of symptom progression also provided direct insight into timely intervention for patients whose conditions deteriorated over time. The separation between the dyspnea curves was very distinct between nonhospitalized and hospitalized patients. For nonhospitalized patients with mild symptoms, dyspnea peaked on day 6 with a score of 2 to 3, which manifests as shortness of breath when hurrying on a level surface. However, these patients' symptoms gradually improved over time. In contrast, hospitalized patients had sustained dyspnea that continued to worsen over time ([Figure 6C](#)).

Although the degree of lack of strength appeared to be unrelated to disease severity at onset, this symptom was never alleviated among hospitalized patients and continued to worsen over time. In comparison, among nonhospitalized patients, strength was nearly normal by day 4 ([Figure 6D](#)). In addition, we observed that the mental state of hospitalized patients gradually deteriorated over the course of the disease, showing a similar pattern to lack of strength ([Figure 6E](#)). Furthermore, while muscle soreness was alleviated on day 4 for all patients, the degree of muscle soreness in hospitalized patients continued to be higher than normal ([Figure 6F](#)). The progression of diarrhea was inconsistent for both groups ([Figure 6G](#)). This may be due to the side effects of certain antiviral drugs. We also found that 4 days after the onset of illness, the chest tightness of hospitalized patients gradually worsened ([Figure 6H](#)).

Table 2. Clinical characteristics of the participating patients admitted to hospital (n=6) based on the medical observation scales described in Multimedia Appendix 1.

Characteristic	Patient No. 1	Patient No. 2	Patient No. 3	Patient No. 4	Patient No. 5	Patient No. 6
Age (years)	38	67	43	35	71	70
Gender	Female	Male	Male	Male	Female	Female
Presenting symptoms and signs at onset

Discussion

Principal Findings

World Health Organization (WHO) emergency guidelines recommend considering alternative quarantine methods, including homecare and isolation, for patients with COVID-19 who have mild symptoms in cases of insufficient hospitalization conditions or medical resources [3]. However, these guidelines do not provide details on how this home quarantine should be conducted, nor do they offer instructions on what to do when patients' conditions become severe or critical. A notable example is the British Prime Minister Boris Johnson, who was admitted to the ICU after 11 days of home quarantine [10]. More concerning, based on initial clinic symptoms and laboratory tests, it is difficult to distinguish patients whose

conditions will later become severe or critical. For example, CT results were normal for 7/48 (15%) of the patients in our study during initial diagnosis, including 2 patients who were hospitalized. Our results were consistent with the findings of Guan et al [11], who reported that CT images were normal for 17.9% of patients with mild conditions and 2.9% patients with severe conditions, respectively. Thus, it may be a common challenge to identify patients during an initial clinic screening whose conditions are prone to become severe or critical. Constant observation of home-quarantined patients by medical staff may therefore be of lifesaving importance.

The telemedicine model presented in this paper not only fills the gap in the WHO guidelines on home quarantine but also mitigates the subsequent threats of the disease caused by a lack of initial symptoms. Specifically, through the quarantine

management assessment, the telemedicine system can complement the initial clinic screening and, hence, greatly increase the accuracy of diagnosis. Through the eCounseling system, the telemedicine system can detect any newly emerged symptoms; then, the multidisciplinary team can be promptly informed to make appropriate treatment decisions.

To demonstrate the merits of the telemedicine system, fever can be considered as an example. Current studies list fever as an indispensable or highly prevalent symptom during the initial phase of COVID-19 infection [12-16]. However, in the study by Guan et al [11], fever was only present in about half (48.7%) of the patients during initial diagnosis. The telemedicine system proposed in this paper helped patients report their elevated body temperatures later to medical staff, who then could monitor the changes in body temperature over time to detect any alarming patterns. We found that hospitalized patients had elevated body temperature that was sustained considerably longer than that of nonhospitalized patients. In contrast, the body temperature of nonhospitalized patients returned to normal by day 4 to 5. This difference can be detected only through continuous observation implemented by the telemedicine system or another similar system. Thus, the telemedicine system greatly aids medical staff in making correct treatment decisions without being misguided by the initial clinic diagnosis.

The telemedicine system also contributes to clinical practice by identifying the key roles of dynamic changes in four diagnostic symptoms: fever, dyspnea, lack of strength, and muscle soreness. Dyspnea peaked on day 6 for nonhospitalized patients but persisted in hospitalized patients and was exacerbated over time. Similarly, both lack of strength and muscle soreness returned to normal by day 4 for nonhospitalized patients but not for hospitalized patients. When a patient reported via the eCounseling system that she was still experiencing the symptoms listed above after day 4, the multidisciplinary team went on alert and paid closer attention to that patient.

Further, these symptoms have not been fully studied in the literature on COVID-19. Therefore, tracing dynamic changes in the abovementioned symptoms paves the way for future studies to investigate whether these time markers can serve as turning points of the disease. In comparison, we found that excessive laboratory data and physical examination were not strictly necessary to evaluate patients with mild symptoms. Instead, the evaluation could be performed through patients' subjective initiative and active participation through self-monitoring of the disease.

Another contribution of this telemedicine system is the quarantine management assessment scales. This set of scales

provides hands-on and easy-to-use self-diagnosis tools for home-quarantined patients. It also helps medical staff obtain more details about the clinical symptoms of the patients without the need for close physical contact in a clinic. We found that the quarantine management assessment worked well in identifying patients with disease progression.

From the resource management perspective, the telemedicine system enabled management of 188 individuals initially and 74 patients later by a team consisting of only 7 medical workers. None of the patients died, and none of the multidisciplinary team members were infected with COVID-19. Efficiency is important for regions whose medical workforce has been impacted by medical worker infection. Many infected medical workers were required to remain at home for at least two weeks after recovery. One merit of the telemedicine system is that medical staff who have recovered from COVID-19 and are self-quarantined can be enlisted to help. Thus, the shortage in the medical workforce can be alleviated, and other medical workers can be freed to fight COVID-19 on the front line. In conclusion, the implementation of such a system can optimize the usage of local medical resources and reduce cross-infection among medical workers and patients.

Limitations and Future Work

One limitation of this study is that its scope was restricted by the suddenness and complexity of the COVID-19 outbreak as well as the diversity and latency of the clinical manifestations of the disease. As a result, we were unable to obtain a larger sample size to achieve a higher level of validity of the findings. It is worth mentioning that we are currently testing the telemedicine system globally. As of April 9, 2020, 1421 patients worldwide are using this system, including 804 in Italy, 250 in the United Kingdom, 181 in France, and 168 in the United States. More than 60% of the participating patients are quarantined at home. We expect to report further findings in the future.

Conclusion

Continuous monitoring of patients with COVID-19 quarantined at home with a telemedicine system helped greatly reduce the risks of delayed hospitalization due to disease progression. Through this system, medical workers can trace changes in several key symptoms and intervene in the home quarantine in time for hospitalization. The telemedicine system proposed in this study was proven to be effectual and efficient. Implementation of this system will optimize the usage of local medical resources and reduce cross-infection among medical workers and patients.

Acknowledgments

This study was supported by the Special Fund for Novel Coronavirus Pneumonia from the Science and Technology Department, Hubei Province (Grant No. 2020FCA035) and the COVID-19 Prompt Response Research Special Project from Huazhong University of Science and Technology (Grant No. 2020kfyXGYJ023). The funding organizations had no role in the study design, data collection, analysis, interpretation, or writing of the paper.

Authors' Contributions

HX and SH designed the study, had full access to all data in the study, and take responsibility for the integrity of the data and the accuracy of the data analysis. HX and SH contributed equally and share first authorship. CQ, SL, JD, HX, and LY contributed to the data analysis, data interpretation, literature search, and writing of the manuscript. BJ, LA, YX, MB, and LY had roles in patient recruitment, data collection, data acquisition, and clinical management. All authors reviewed and approved the final version of the manuscript.

Abstract

Background: Public health surveillance experts are leveraging user-generated content on social media to track the spread and effects of COVID-19. However, racial and ethnic digital divides, which are disparities among people who have internet access and post on social media, can bias inferences. This bias is particularly problematic in the context of the COVID-19 pandemic because due to structural inequalities, members of racial and ethnic minority groups are disproportionately vulnerable to contracting the virus and to the deleterious economic and social effects from mitigation efforts. Further, important demographic intersections with race and ethnicity, such as gender and age, are rarely investigated in work characterizing social media users; however, they reflect additional axes of inequality shaping differential exposure to COVID-19 and its effects.

Objective: The aim of this study was to characterize how the race and ethnicity of US adults are associated with their odds of posting COVID-19 content on social media and how gender and age modify these odds.

Methods: We performed a secondary analysis of a survey conducted by the Pew Research Center from March 19 to 24, 2020, using a national probability sample (N=10,510). Respondents were recruited from an online panel, where panelists without an internet-enabled device were given one to keep at no cost. The binary dependent variable was responses to an item asking whether respondents “used social media to share or post information about the coronavirus.” We used survey-weighted logistic regressions to estimate the odds of responding in the affirmative based on the race and ethnicity of respondents (white, black, Latino, other race/ethnicity), adjusted for covariates measuring sociodemographic background and COVID-19 experiences. We examined how gender (female, male) and age (18 to 30 years, 31 to 50 years, 51 to 64 years, and 65 years and older) intersected with race and ethnicity by estimating interactions.

Results: Respondents who identified as black (odds ratio [OR] 1.29, 95% CI 1.02-1.64; $P=.03$), Latino (OR 1.66, 95% CI 1.36-2.04; $P<.001$), or other races/ethnicities (OR 1.33, 95% CI 1.02-1.72; $P=.03$) had higher odds than respondents who identified as white of reporting that they posted COVID-19 content on social media. Women had higher odds of posting than men regardless of race and ethnicity (OR 1.58, 95% CI 1.39-1.80; $P<.001$). Among men, respondents who identified as black, Latino, or members of other races/ethnicities were significantly more likely to post than respondents who identified as white. Older adults (65 years or older) had significantly lower odds (OR 0.73, 95% CI 0.57-0.94; $P=.01$) of posting compared to younger adults (18-29 years), particularly among those identifying as other races/ethnicities. Latino respondents were the most likely to report posting across all age groups.

Conclusions: In the United States, members of racial and ethnic minority groups are most likely to contribute to COVID-19 content on social media, particularly among groups traditionally less likely to use social media (older adults and men). The next step is to ensure that data collection procedures capture this diversity by encompassing a breadth of search criteria and social media platforms.

Introduction

Background

Amid the novel coronavirus disease (COVID-19) pandemic of 2020, US adults are turning to social media to consume and share information [1]. Public health surveillance experts are already leveraging the data created by social media users to track the spread and effects of COVID-19 across populations [2-6]. Sets of social media data are also appearing in open access repositories to facilitate this work [7]. In light of COVID-19, several scientific journals are fast-tracking the peer-review process, creating an unprecedented pace of publication for new social media surveillance studies [8,9]. This in turn is accelerating the availability of analyses that can be used to inform interventions and policies aimed at combating the direct and indirect effects of COVID-19 in society.

Despite the potential benefits of social media data in providing real-time insight into COVID-19, important limitations remain. As noted in prior studies, representativeness is an ongoing challenge for social media surveillance systems [10-12]. Among the factors shaping the representativeness of social media data are racial and ethnic digital divides [13-15], in which members of racial and ethnic minority groups are less likely to access the internet and use social media [16]. In turn, the absence of social media data from racial and ethnic minority groups may bias findings from social media surveillance systems. In the context of the COVID-19 pandemic, biases due to the underrepresentation of social media data from members of racial and ethnic minority groups are particularly problematic because structural inequalities have generated an environment in which these groups are among the most vulnerable [17-23].

In this study, we analyzed a nationally representative survey of US adults conducted in late March 2020 to determine how race and ethnicity, and their intersections with gender and age, are associated with posting content related to COVID-19 on social media. Demographic intersections of age and gender with race and ethnicity are rarely inspected in studies characterizing social media users to understand potential biases in data sets [13,15]. However, it is particularly critical to examine these intersections during the COVID-19 pandemic because age and gender are additional fault lines shaping both social media use and the risk of experiencing direct and indirect effects of COVID-19. This analysis of digital divides can potentially offer guidance to researchers conducting public health surveillance studies who are concerned about biases in the social media data they are analyzing.

Inequalities in Social Media Use and Effects of COVID-19

At present, little is known about how social media posting about COVID-19 varies across racial and ethnic groups. This is particularly problematic given the context of the COVID-19 pandemic. Within the United States, members of racial and ethnic minority groups experience heightened susceptibility to

serious complications from COVID-19 because of underlying health and health care inequalities predating the pandemic [17-19]. Racial and ethnic minority groups are also overrepresented among essential workers, which elevates their risk of exposure to COVID-19 [21]. Further, they are more susceptible to indirect effects of the pandemic, such as job loss or pay cuts [20].

Digital divides raise questions about whether members of racial and ethnic minority groups are posting COVID-19 content on social media. Racial and ethnic minority groups in the United States have only recently made gains in internet access, narrowing the advantage held by white people [14,24]. Among people with internet access, members of racial and ethnic minority groups use social media at approximately the same rate as white people or more, depending on the platform [13,15,25]. Further, it has been suggested that the COVID-19 pandemic will exacerbate existing digital divides, due in part to the economic impacts of the pandemic and reduced access to public, workplace, and school internet connections [26]. The findings of public health surveillance tools leveraging social media data to track the COVID-19 pandemic may thus be biased toward underrepresenting the experiences of racial and ethnic minority groups.

Alternatively, members of racial and ethnic minority groups may be most likely to post COVID-19 content on social media. Given their higher risk of contracting COVID-19 and experiencing its deleterious effects, members of these groups are also more likely to struggle with mental health during the pandemic [23,27]. In response, they may turn to social media as a coping mechanism or to seek social support [28,29]. Social media data would then offer an opportunity for public health surveillance systems to understand racial and ethnic inequities during the pandemic.

Age is another axis of inequality for both social media use and complications arising directly and indirectly from COVID-19. Older adults (65 years and older) are less likely to access the internet and use it to share content on social media [30,31]. However, this demographic group was identified early in the pandemic as being at high risk for complications from COVID-19 [32] as well as for experiencing social isolation from mitigation efforts such as stay-at-home restrictions [33,34]. The intersection between race/ethnicity and age is also important because the older adult population is currently majority white but will become increasingly diverse in the next few years [35]. Public health surveillance tools relying on social media data must consider the impacts of these shifting demographics on digital divides.

Lastly, gender inequalities are also critical for identifying potential biases present in social media data. Women in the United States have outgained men in internet access [14,36]. Among internet users, women are generally more likely than men to use social media [13,15]; thus, it is probable that they are overrepresented in social media data. This digital divide in which women make greater use of social media may be

problematic given that men appear to be at increased risk from COVID-19 complications [37]. Regarding the indirect effects of COVID-19, there are compelling reasons to expect distinct experiences for men and women. For example, men are more likely than women to rely on the workplace for confidants [38,39]. As a result, men who are working remotely during the pandemic, lose their job, or experience a reduction in work hours may have mental wellness impacts caused by diminished access to their usual sources of social support. By contrast, women are more likely to work as frontline nursing staff and to suffer indirect effects due to changing work patterns, increased exposure to intimate partner violence, and increased childcare obligations [40,41]. Race and ethnicity likely further modify these gender differences in experiences during the pandemic [42]; thus, an intersectional approach is required when analyzing which people are likely to post content on social media.

To date, no studies have considered how social media posting about COVID-19 differs by race and ethnicity, how these differences intersect with gender and age, or the implications of these patterns for public health surveillance efforts. Accordingly, the current study reports findings from a secondary analysis of a nationally representative survey fielded late March 2020.

Methods

Data Source

The data we analyzed were obtained from the Pew Research Center, a nonpartisan think tank that conducts regular surveys to track demographic trends. We analyzed the Wave 64 survey of their American Trends Panel, which is a probability-based online panel of US adults (people aged 18 years or older) [43]. Of the 15,433 invited panelists, 11,537 responded (74.8% response rate) in either English or Spanish from March 19 to 24, 2020. Among these panelists, 164/11,537 (1.4%) did not have an internet-enabled device but received an internet-enabled tablet to keep at no cost. The results shown are from analyzing 10,510 respondents, with complete responses on all measures used. Missing values for any measure were <1%, except for income, for which 3% of values were missing. An analysis using a multiple imputed data set (10 iterations) to fill in missing income values afforded results that are comparable to those shown here.

Posting COVID-19–Related Content

The dependent measures were responses to an item asking whether they “used social media to share or post information about the coronavirus” (1=yes, 0=no).

Race/Ethnicity, Gender, and Age

We measured these three demographics using the original groupings provided in the data set. Race and ethnicity were based on the respondent’s identification with one of four mutually exclusive categories (white, black, Latino, other). Gender was measured as a sex binary (female, male). Age was measured using four categories (18 to 29 years, 30 to 49 years, 50 to 64 years, 65 years or older).

Covariates

Other measures associated with social media use and differential exposure to the direct and indirect effects of COVID-19 served as covariates in the multivariable analysis. The set of covariates directly measures experiences with economic hardship and struggles with mental health during the pandemic along with sociodemographic factors shaping differential exposure to these and other stressors, such as additional household labor and misinformation [13,15,29,30,44,45]. Covariates were respondents’ marital status (never married; currently married/cohabitating; divorced, widowed, or separated), annual family income (less than US \$30,000, US \$30,000–\$74,999, greater than US \$75,000), educational attainment (high school or less, some college, college graduate), political leaning (very liberal, liberal, moderate, conservative, very conservative), and mental health, which is an average of five items modified from the Center for Epidemiologic Studies Depression Scale [46] and General Anxiety Disorder Scale [47] asking how frequently (less than 1 day, 1 to 2 days, 3 to 4 days, 5 to 7 days) they experienced the following during the seven days preceding the survey ($\alpha=.73$): nervous, anxious, or on edge; depressed; lonely; hopeful about the future; trouble sleeping. Higher values indicate poorer mental health. Household characteristics were census division, metropolitan area (yes, no), presence of a child less than 12 years of age (yes, no), presence of a household member who was laid off (yes, no), and presence of a household member who received a pay cut (yes, no). All groupings are original to the data set.

Statistical Analysis

After describing the analytical sample, we present results from three multivariable logistic regressions estimating the odds that respondents would report that they used social media to post COVID-19 content. The first estimated the association of respondents’ race and ethnicity on the odds of posting content, adjusted for gender, age, and the covariates. The second examines how the intersection of race/ethnicity with gender shapes the odds of posting by estimating interactions between the racial and ethnic categories with gender. The estimated odds were adjusted for age and the covariates. The estimates were then used to compare the presence and severity of the gender divide by racial and ethnic group. The third regression followed a parallel procedure, enabling an assessment of the presence and severity of the age divide by racial and ethnic group. Specifically, we examined the intersection of race/ethnicity with age by estimating interactions between the racial and ethnic categories and the age groups. In these last two regressions, we corrected for making multiple comparisons.

All results shown (except for frequencies when describing the analytic sample) are based on weighting the data using the set of svy commands available in the statistical program Stata 16. The survey weights used in this process were provided by the Pew Research Center to reflect known US population counts on the following characteristics: age, race and ethnicity, gender, education, census region, metropolitan status, internet access, political party identification, volunteerism, registered voter, and years living in the United States.

Results

Descriptive data for the analytical sample appear in [Table 1](#). Means and percentages are survey-weighted, but frequencies reflect the unweighted sample. Of the respondents in the weighted sample, 4383/10,510 (39.4%) reported posting COVID-19 content on social media. The majority of the 10,510 respondents (7012, 65%) were white, and most (6700, 63.7%) were between 30 and 64 years of age. A slight majority of respondents were women (5724/10,510, 51%).

[Table 2](#) shows the associations between respondents' race and ethnicity and the odds of posting COVID-19 content on social media based on a multivariable logistic regression that adjusts for all covariates. Compared to the odds of posting for white respondents, black respondents had 29% higher odds ($P=.03$), Latino respondents had 66% higher odds ($P<.001$), and respondents identifying with other races or ethnicities had 33% higher odds ($P=.03$).

[Table 2](#) also shows the independent associations of respondents' gender and age with their odds of posting. Estimates depict a gender divide favoring women and an age divide favoring respondents aged 18 to 29 years. Women had 58% higher odds than men to report that they posted COVID-19 content ($P<.001$). Compared to respondents aged 18 to 29 years, respondents who are 65 and older were significantly less likely to report posting ($P=.01$).

The next two steps in the analysis examined the intersections between race/ethnicity and gender and age by estimating statistical interactions. Full estimation results are available in [Multimedia Appendix 1](#). Here, we summarize key findings using figures plotting predicted probabilities and discrete changes in predicted probabilities, showing 95% confidence intervals around estimates.

The first two figures summarize how the intersections of race and gender are associated with reports of posting COVID-19 content on social media. [Figure 1](#) plots the predicted probabilities of posting COVID-19 content on social media for each cross-section. Among men, who were less likely to post ([Table 2](#)), respondents who identified as black ($P=.009$), Latino ($P<.001$), or other races/ethnicities ($P=.003$) were more likely to post than respondents who identified as white. Among women, only Latino respondents were significantly more likely to post than white respondents ($P=.001$). [Figure 2](#) summarizes how the severity of the gender divide in posting COVID-19 content among respondents who identified as black, Latino, or other races/ethnicities compares to that of respondents who identified as white. Values crossing zero indicate comparable severity, while negative values indicate an attenuation of the divide. The figure shows a tendency for the gender divide to be slightly narrower among respondents identifying as either black ($P=.06$) or other races ($P=.03$); these findings did not hold when adjusting for multiple comparisons.

Figure 1. Predicted probabilities of posting (95% CI) for each gender by race and ethnicity. Pr(Posting): probability of posting.

Figure 2. Differences in the gender divide in posting (95% CI) among respondents who identified as black, Latino, or other races/ethnicities relative to that of respondents who identified as white. Pr(Posting): probability of posting.

The remaining two figures offer a parallel summary of the intersections between the race of the respondents and their ethnicity and age. [Figure 3](#) shows the predicted probabilities of posting for all four age groups by race and ethnicity of the respondents. Latino respondents were significantly more likely than white respondents across all age groups to report posting COVID-19 content on social media (18 to 29 years: $P=.01$, 30 to 49 years: $P=.04$, 50 to 64 years: $P<.001$, ≥ 65 years: $P=.001$).

While respondents aged 65 years or older were less likely to post COVID-19 content than respondents aged 18 to 29 years ([Table 2](#)), those who did post content were likely to identify as Latino. The only other significant finding from this analysis was that among respondents aged 18 to 29 years, respondents identifying as a race/ethnicity other than black, white, or Latino had a higher probability of posting than white respondents ($P<.001$).

Figure 3. Predicted probabilities of posting (95% CI) for each age group by race and ethnicity. Pr(Posting): probability of posting.

Figure 4 continues the summary of the intersections between race and age by displaying the additional contributions of race and ethnicity to the age divide among respondents who post COVID-19 content on social media. The figure shows how the differences in the predicted probability between respondents aged 18 to 29 years and each of the older age groups change for respondents who identified as black, Latino, or other races/ethnicities relative to respondents who identified as white. A value crossing zero indicates comparable predicted differences in probability, with positive values indicating a wider age divide

among the group compared to white respondents. Age divides were significantly intensified among respondents identifying as other races (31 to 49 years: $P<.001$, 50 to 64 years: $P=.04$, ≥ 65 years: $P=.001$), perhaps because of the heightened tendency of respondents aged 18 to 29 years from this racial/ethnic group to post (Figure 1). When adjusting for multiple comparisons, these conclusions held except among respondents aged 50 to 64 years. The severity of the age divide was comparable in all other cases.

Figure 4. Differences in the age divide in posting (95% CI) among respondents who identified as black, Latino, or other races/ethnicities relative to respondents who identified as white. Pr(Posting): probability of posting.

Discussion

Principal Findings

US public and public health surveillance analysts are both turning to social media during the COVID-19 pandemic. Specifically, members of the public are posting content related to the pandemic; in turn, analysts are using this content to track the spread of the virus and its effects across the population. However, racial and ethnic digital divides raise questions about the representativeness of the social media data that analysts are using to make inferences and projections. We found that among a nationally representative sample of US adults, members of racial and ethnic minority groups were most likely to report posting COVID-19 content on social media. Further, among men and older adults, who are traditionally less likely to use social media, members of racial and ethnic minority groups were also most likely to report posting content. Studies like this one that examine digital divides are critical to understanding the characteristics of people posting content to better infer the presence of biases in social media data. Other steps are likely necessary to fully address issues of representativeness in data,

such as ensuring that data collection processes and search criteria are designed to capture diversity in the data.

Respondents who identified as black, Latino, or other races and ethnicities were more likely to report posting COVID-19 content on social media than respondents who identified as white. This finding may simply be an artifact of a reversal of digital divides, whereby white people are now least likely to use social media. A reversal is possible given trends observed during February 2019 in the United States [25]. While the estimated racial and ethnic differences from February 2019 cannot adequately account for the odds ratios in the current study, it is difficult to rule out this possibility without a demographic profile of social media users during the days preceding the pandemic. Alternatively, members of racial and ethnic minority groups may be most likely to post because the specific pandemic context (in which they are at higher risk of direct and indirect effects of COVID-19) inspires a stronger motivation to post. Specifically, our model controlled for financial ramifications from COVID-19 and mental health; however, there may be other COVID-19-related factors driving posting. Uses and gratifications theory suggests that social media use is often driven by a desire for self-expression, self-documentation, and

social connection [48]. Social media also offers a space for seeking social support and coping with stress [28,29]. Although there may be culturally driven distinctions in posting behaviors related to uses and gratifications, there is little prior research considering how these distinctions differ across race and ethnicity [49]. More work is needed to understand differences in posting behaviors, particularly to better understand COVID-19.

Regardless of the reason that members of racial and ethnic minority groups are most likely to post about COVID-19 on social media, our findings suggest that public health surveillance tools relying on social media data may be well positioned to capture their pandemic experiences and how they are related to structural inequalities within the United States. It will be critical for researchers to continue to both reflect on the overall representativeness of social media data and consider the nuances of social media use and data collection strategies when seeking data on specific populations. For example, a higher proportion of the Latino population than the white population uses Instagram, while these rates are more consistent for Facebook [25].

The intersections with gender and age were also enlightening for understanding digital divides during the pandemic. Women are generally more likely than men to use social media [13,15], and we saw this divide reflected across all racial and ethnic groups with respect to posting about COVID-19. Among men, those in racial and ethnic minority groups were most likely to report posting. These racial and ethnic differences are important to bear in mind depending on which gender disparities in COVID-19 experiences researchers seek to understand. With respect to age, studies consistently show that older adults are less likely to use social media [30], which was reflected in the findings of this study. This is important because of the elevated risks older adults face during the pandemic. Among respondents 65 years or older, Latino respondents are significantly more likely to post, suggesting an opportunity to leverage their social media data to understand their experiences. Such intersections with race and ethnicity are rarely investigated in studies on digital divides.

Limitations

This study is not without limitations. The dependent measure (posting content on social media related to COVID-19) is self-reported; thus, it is susceptible to recall bias. However, the survey was administered shortly after the outbreak occurred in the United States, which mitigates some of the potential bias. The measure also does not allow us to determine the content of posts or which social media platforms were used. Previous work

showing racial and ethnic demographic variation by platform can offer some guidance [15]. Moreover, we cannot distinguish between users who post original content versus users who repost others' content (eg, a retweet on Twitter). Other datasets combining a user's social media data with their demographic profile are better suited for identifying users who are likely to repost [44]. Limitations such as these are common within studies relying on a secondary analysis of nationally representative data.

Conclusions

Despite limitations, the results of this examination of digital divides offer key insights into who is contributing to the social media content related to COVID-19 that analysts are studying. Because COVID-19 is exacerbating previously existing inequalities in the United States, members of racial and ethnic minority groups experience elevated risk of experiencing the deleterious health and economic effects of the virus. These populations are also most likely to post COVID-19-related content. There is also evidence of a heightened tendency to post among members of racial and ethnic minority groups who are members of other vulnerable groups that are usually less likely to use social media (people aged 65 years and older, men). These patterns suggest that social media data offer opportunities for public health researchers seeking to understand the impacts and spread of COVID-19 among racial and ethnic minority groups in the United States. We further suggest that it is not sufficient for researchers to rely only on broad social media usage demographics when reflecting on the representativeness of their data, as COVID-19 posting does not perfectly mirror what would be anticipated based on usage statistics alone [25].

To ensure that public health surveillance efforts take digital divides into account, studies like this one are a critical first step in that they provide demographic context for user-generated data. Additional steps are needed to realize this opportunity fully and mitigate bias. For example, collecting data in several languages, including Spanish, may ensure that the data reflect the patterns observed here among Latino respondents. A publicly available dataset of tweets associated with the pandemic is currently being collected [7]. The data collection process must incorporate a breadth of social media platforms and ensure that search criteria are reflective of the linguistic diversity in discourse about COVID-19. Given that the selection of search criteria shapes social media research findings [50], it is also critical for future research to map language use and how it differs across demographics. These steps are critical to meeting the challenges presented by the COVID-19 pandemic and understanding its lasting effects on the US population.

Abstract

Background: The emergence of the coronavirus disease (COVID-19) pandemic in March 2020 created unprecedented challenges in the provision of scheduled ambulatory cancer care. As a result, there has been a renewed focus on video-based telehealth consultations as a means to continue ambulatory care.

Objective: The aim of this study is to analyze the change in video visit volume at the University of California, San Francisco (UCSF) Comprehensive Cancer Center in response to COVID-19 and compare patient demographics and appointment data from January 1, 2020, and in the 11 weeks after the transition to video visits.

Methods: Patient demographics and appointment data (dates, visit types, and departments) were extracted from the electronic health record reporting database. Video visits were performed using a HIPAA (Health Insurance Portability and Accountability Act)-compliant video conferencing platform with a pre-existing workflow.

Results: In 17 departments and divisions at the UCSF Cancer Center, 2284 video visits were performed in the 11 weeks before COVID-19 changes were implemented (mean 208, SD 75 per week) and 12,946 video visits were performed in the 11-week post-COVID-19 period (mean 1177, SD 120 per week). The proportion of video visits increased from 7%-18% to 54%-72%, between the pre- and post-COVID-19 periods without any disparity based on race/ethnicity, primary language, or payer.

Conclusions: In a remarkably brief period of time, we rapidly scaled the utilization of telehealth in response to COVID-19 and maintained access to complex oncologic care at a time of social distancing.

Introduction

The emergence of the coronavirus disease (COVID-19) pandemic in the United States in March 2020 created unprecedented challenges in the provision of scheduled health care and, in particular, ambulatory cancer care. The rapid spread

of COVID-19 has renewed focus on telehealth [1], including video consultations [2], as a means of continuing ambulatory care without increasing the risk of potential exposure for patients, clinicians, and staff.

Telehealth is the provision of health care remotely by means of a variety of telecommunication platforms such as messaging, audio, and video [3]. While the use of telehealth to deliver cancer care is not new [4] and has already been well described [5], delivering it at the current scale as a result of the COVID-19 pandemic is unprecedented.

University of California, San Francisco (UCSF) Health established a telehealth program in 2015, which offers video visits in all practices. In response to the evolving pandemic, leadership challenged the organization to transition all in-person clinic visits, beginning March 15, 2020, to video visits with exceptions only for specific, urgent cases.

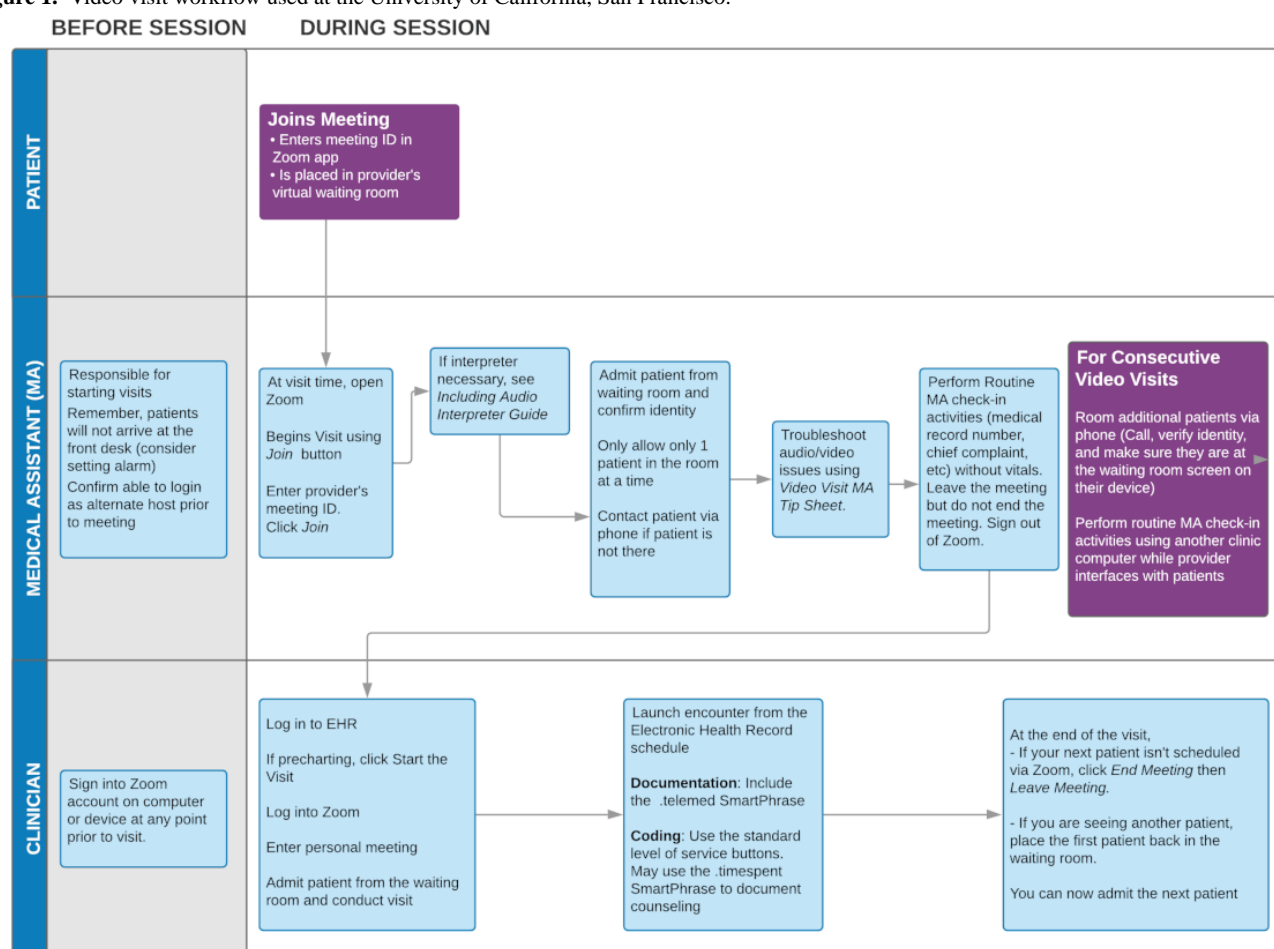

In this study, we analyze the change in video visit volume at the UCSF Comprehensive Cancer Center in response to COVID-19 and compare demographics and appointment data

from January 1, 2020, and in the 11 weeks after the transition to video visits.

Methods

Demographics and appointment data (dates, visit types, and departments) were extracted from the electronic health record reporting database. The pre-COVID-19 period was defined as the 11 weeks from January 1 to March 13, 2020, prior to the transition, and the post-COVID-19 period as the 11 weeks following the transition to video visits on March 16, 2020, up to May 31, 2020. All video visits were performed using a HIPAA (Health Insurance Portability and Accountability Act)-compliant video conferencing platform (Zoom Video Communications Inc) with a pre-existing workflow (Figure 1). The statistical program R (version 3.5.3, R Foundation for Statistical Computing) was used for analysis [6] and a *P* value less than .05 was considered significant.

Figure 1. Video visit workflow used at the University of California, San Francisco.

Results

In the pre-COVID-19 period from January 1 to March 13, 2020, there were a total of 23,988 ambulatory care episodes, with a mean of 2181 (SD 522) episodes per week across 17 departments and divisions at the UCSF Cancer Center (Figure 2). During this period, 2284 video visits were performed, with a mean of 208 (SD 75) video visits being performed per week. The proportion of video visits ranged from 7%-18% whereas

the proportion of in-person visits ranged from 76%-86% (Figure 3). In the post-COVID-19 period from March 16 to May 31, 2020, there was a total of 20,567 ambulatory care episodes (mean 1870, SD 200 per week). A total of 12,946 video visits were performed in the post-COVID-19 period (mean 1177, SD 120 per week). The proportion of video visits increased to 54%-72%. The proportion of episodes during which a procedure was performed ranged from 4%-7% in the pre-COVID-19 period and 1%-5% in the post-COVID-19 period.

Table 1 displays the demographic data of patients who had a video visit in the pre-COVID-19 period ($n=2284$) and patients who had a video visit in the post-COVID-19 period ($n=12,946$). In the post-COVID-19 period, more black/African American (531 [4.1%] vs 78 [3.4%]; $P<.001$), Hispanic/Latino (1450 [11.2%] vs 215 [9.4%]; $P<.001$), and Asian (1903 [14.7%] vs 197 [8.6%]; $P<.001$) patients received care via video visits compared to the pre-COVID-19 period. There was increased

post-COVID-19 utilization of video visits for patients in urban areas (12,014 [92.8%] vs 2026 [88.7%]; $P<.001$). We did not find any difference in the insurance status of patients using video visits during either period. In the post-COVID-19 period, first clinic encounter (2822 [21.8%] vs 417 [18.3%]; $P<.001$) and physician-provided visits (10,590 [81.8%] vs 1538 [67.3%]; $P<.001$) increased.

Figure 2. Number of clinic encounters stratified by visit type (in-person visits, procedural visits, video visits, and phone visits) from January 1 to May 31, 2020, with March 16, 2020, denoting the institution-wide transition to video visits in response to coronavirus disease (COVID-19).

Figure 3. Relative weekly trends in clinic encounters, stratified by visit type (in-person visits, procedural visits, video visits, and phone visits) from January 1 to May 31, 2020, with March 16, 2020, denoting the institution-wide transition to video visits in response to coronavirus disease (COVID-19).

Table 1. Demographics of patients who had video visits pre- and post-COVID-19.

Characteristic	Pre-COVID-19 period (n=2284)	Post-COVID-19 period (n=12,946)	P value
Age (years), median (IQR)	64.3 (54.9-71.5)	63.6 (52.8-71.8)	.11
Female, n (%)	844 (37)	6123 (47.3)	<.001

Advanced practice provider	746 (32.7)	2356 (18.2)	

Discussion

Principal Findings

We demonstrate a rapid expansion (from <20% to 72%) in telehealth use in a comprehensive cancer center over a remarkably brief time period in response to COVID-19 without differences in race or insurance type. Medicare telehealth visits have increased by more than 25% annually for the past decade [7], yet absolute adoption numbers remain low and fragmented with concerns about potentiating disparities in health care access [8]. The vast majority of cancer care cannot be delayed and the COVID-19 pandemic has presented new challenges that telehealth is uniquely situated to solve. Changes that would typically encompass months of planning, pilot testing, and education have been compressed into days. The use of telehealth has grown exponentially with some practices transitioning to near-complete virtual care in as little as a few days [9-11].

Several factors have likely enabled the rapid expansion of video visits at our institution. First, we had an established telehealth structure and workflow familiar to providers and practice staff. Second, UCSF made a strategic decision to provide work Relative Value Unit (wRVU) credit to providers for telehealth visits since 2015, irrespective of payer reimbursement. Third, new regulatory changes at the federal and state levels as a response to COVID-19 have reduced barriers, including the ability to see new patients (including Medicare beneficiaries) without a prior in-person visit to establish care and reimbursement for telehealth encounters by the Centers for Medicare & Medicaid Services (CMS) at parity with in-person visits beginning March 17, 2020 [12]. Finally, CMS now permits providers licensed in any state to provide telehealth services across the country [13].

Limitations

There are a number of limitations to this study that need to be acknowledged. We did not evaluate the outcome of the video

visits (eg, patient satisfaction and qualitative or clinical outcomes). The study is from a single, large, urban academic cancer center in the United States and our findings may not be generalizable to other specialties, practices, or locations. We believe that this is the first report of the utilization of video visits in a comprehensive cancer center in response to COVID-19 with a detailed description of the changing demographic of patients utilizing video visits before and after the COVID-19 pandemic.

Conclusions

Overall, the proportion of video visits increased from 7%-18% to 54%-72% between the pre- and post-COVID-19 periods while maintaining access to complex oncologic care at a time of social distancing. The COVID-19 pandemic has forced us to radically rethink and change our cancer care delivery models. In many health systems, there will undoubtedly be many lessons learned from this "natural experiment," which has the potential to permanently change care delivery patterns.

Authors' Contributions

AYO had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. AYO, PEL, and SLW were responsible for study concept and design; and acquisition, statistical analysis, and interpretation of data. PEL and SLW drafted the manuscript. Administrative, technical, and material support was provided by LB, and supervision was provided by PRC, RSP, and AYO. All authors critically reviewed the manuscript for important intellectual content.

Conflicts of Interest

AYO was a consultant for VSee from December 2019 to January 2020.

Abstract

Background: Existing health disparities based on race and ethnicity in the United States are contributing to disparities in morbidity and mortality during the coronavirus disease (COVID-19) pandemic. We conducted an online survey of American adults to assess similarities and differences by race and ethnicity with respect to COVID-19 symptoms, estimates of the extent of the pandemic, knowledge of control measures, and stigma.

Objective: The aim of this study was to describe similarities and differences in COVID-19 symptoms, knowledge, and beliefs by race and ethnicity among adults in the United States.

Methods: We conducted a cross-sectional survey from March 27, 2020 through April 1, 2020. Participants were recruited on social media platforms and completed the survey on a secure web-based survey platform. We used chi-square tests to compare characteristics related to COVID-19 by race and ethnicity. Statistical tests were corrected using the Holm Bonferroni correction to account for multiple comparisons.

Results: A total of 1435 participants completed the survey; 52 (3.6%) were Asian, 158 (11.0%) were non-Hispanic Black, 548 (38.2%) were Hispanic, 587 (40.9%) were non-Hispanic White, and 90 (6.3%) identified as other or multiple races. Only one symptom (sore throat) was found to be different based on race and ethnicity ($P=.003$); this symptom was less frequently reported by Asian (3/52, 5.8%), non-Hispanic Black (9/158, 5.7%), and other/multiple race (8/90, 8.9%) participants compared to those who were Hispanic (99/548, 18.1%) or non-Hispanic White (95/587, 16.2%). Non-Hispanic White and Asian participants were more likely to estimate that the number of current cases was at least 100,000 ($P=.004$) and were more likely to answer all 14 COVID-19 knowledge scale questions correctly (Asian participants, 13/52, 25.0%; non-Hispanic White participants, 180/587, 30.7%) compared to Hispanic (108/548, 19.7%) and non-Hispanic Black (25/158, 15.8%) participants.

Conclusions: We observed differences with respect to knowledge of appropriate methods to prevent infection by the novel coronavirus that causes COVID-19. Deficits in knowledge of proper control methods may further exacerbate existing race/ethnicity disparities. Additional research is needed to identify trusted sources of information in Hispanic and non-Hispanic Black communities and create effective messaging to disseminate correct COVID-19 prevention and treatment information.

Introduction

A novel coronavirus, severe acute respiratory syndrome 2 (SARS-CoV-2), was identified in Wuhan, China, in December 2019; the virus quickly spread worldwide and was labeled a pandemic by the World Health Organization on March 11, 2020 [1]. SARS-CoV-2 can result in severe respiratory infection, causing coronavirus disease (COVID-19). The rapid spread and high estimated infectivity of SARS-CoV-2 coupled with the severity of COVID-19 led to widespread shuttering of businesses and implementation of mandatory stay-at-home orders across the United States. Although reported cases are not stratified by race and ethnicity in all US jurisdictions or may be incompletely reported due to missing information, available data indicate the emergence of racial and ethnic disparities in the occurrence of COVID-19 [2], mirroring disparities that have been well characterized in other disease processes.

Racial and ethnic disparities in COVID-19 occurrence may be due to multiple factors. Asian, Black, and Hispanic Americans are all more likely to be uninsured than non-Hispanic White Americans [3], resulting in reduced access to health care. Increased prevalence of preexisting conditions that are known to be associated with poor outcomes in COVID-19 patients, including diabetes [4,5] among Black and Hispanic people and hypertension [5-7] among Black people, may increase susceptibility and disease severity in these populations. The long-term effects of structural racism and income inequality that cause larger proportions of people of color to work in conditions that are not conducive to social distancing [8] or to live in crowded conditions [8,9] also facilitate efficient transmission of the virus. In addition to combatting these existing disparities, in a rapidly evolving pandemic, accurate information is necessary for individuals to exercise appropriate prevention and care-seeking behavior. We examined whether there were racial or ethnic differences in knowledge, stigma, and experience of symptoms during the early stages of the COVID-19 pandemic.

Methods

Advertisements on Facebook, Snapchat, and Twitter were used to conduct a nationwide web-based survey with US adults aged 18 years or older from March 27 through April 1, 2020 [10]. Participants were eligible to participate if they were at least 18 years of age. We sought to obtain a racially and ethnically diverse sample by overrecruiting people of color and Hispanic participants. Therefore, because a sufficient number of non-Hispanic White participants had been enrolled, enrollment of non-Hispanic White participants was stopped on the final day of recruiting to increase the representation of communities of color in the survey. Participants were not compensated for completing the survey. All study procedures were reviewed and approved by the Emory University Institutional Review Board.

The survey included questions on knowledge of effective prevention methods, a COVID-19 stigma scale, and current

COVID-19-related symptoms (see [Multimedia Appendix 1](#)). We used chi-square tests with Holm Bonferroni correction to account for multiple comparisons to assess differences across these domains based on race and ethnicity (Asian, Hispanic, non-Hispanic Black, non-Hispanic White, and other/multiple race). Corrected *P* values <.05 were considered statistically significant. The full survey is included in [Multimedia Appendix 1](#). All analyses were conducted using SAS 9.4 (SAS Institute).

Results

A total of 1435 participants consented to participate and completed the survey. Of the 1435 participants, 52 (3.6%) were Asian, 548 (38.2%) were Hispanic, 158 (11.0%) were non-Hispanic Black, 587 (40.9%) were non-Hispanic White, and 90 (6.3%) were of other or multiple races. There were race and ethnicity differences in gender, annual income, educational status, and geographic region of residence across categories of race and ethnicity ([Table 1](#)).

When asked whether they were currently experiencing symptoms possibly related to COVID-19, a plurality of participants (635/1435, 44.3%) reported no symptoms ([Table 2](#)). Of those experiencing COVID-19 symptoms, the most frequently reported symptoms were cough (328/1435, 22.9%), sneezing (322/1435, 22.4%), and headache (311/1435, 21.7%). The only symptom that differed by race/ethnicity was sore throat. Racial/ethnic differences were observed in perceived likelihood of currently having COVID-19 by race/ethnicity. Hispanic (192/544, 35.3%) and non-Hispanic Black (54/157, 34.4%) participants were more likely to report that it was somewhat likely, likely, or very likely that they currently had COVID-19 compared to Asian (11/51, 21.6%) and non-Hispanic White (121/580, 20.9%) participants.

When asked about their knowledge of numbers of cases and COVID-19 deaths, non-Hispanic White (376/587, 64.1%) and Asian (32/52, 61.5%) participants were more likely to correctly estimate that there were currently 100,000 or more cases in the US compared to Hispanic (269/548, 49.1%) and non-Hispanic Black (73/158, 46.2%) participants. No differences were observed in the estimated number of deaths expected from COVID-19 by the end of 2020.

Non-Hispanic White (180/587, 30.7%) and Asian (13/52, 25.0%) participants were more likely to answer all 14 COVID-19 knowledge scale questions correctly compared to Hispanic (108/548, 19.7%) and non-Hispanic Black (25/158, 15.8%) participants. Overall, 46.6% of participants endorsed at least one stigmatizing statement related to COVID-19, with no difference by race.

Overall, 954/1247 participants (76.5%) indicated willingness to participate in future research studies of diagnostic and serologic testing for SARS-CoV-2, with no differences by race and ethnicity.

Table 1. Demographic characteristics of participants in a cross-sectional web-based survey of COVID-19 symptoms and knowledge from March 27 through April 1, 2020 (N=1435).

Characteristic	Total (N=1435)	Asian (n=52, 3.6%)	Hispanic (n=548, 38.2%)	Non-Hispanic Black (n=158, 11.0%)	Non-Hispanic White (n=587, 40.9%)	Other/multiple race (n=90, 6.3%)	<i>P</i> value ^a
Age (years), median (IQR)	33 (24-57)	25 (21-31)	30 (22-44)	25 (20-38)	54 (31-64)	31 (21-58)	.002

^bCOVID-19: coronavirus disease.

^cCategory total does not sum to the column total due to missing data.

^dValues greater than the population of the United States (328 million) were excluded. At the beginning of the study period (March 27, 2020), there were 107,000 cumulative confirmed cases in the United States. At the end of the study period (April 1, 2020), there were 213,400 cumulative confirmed cases in the United States.

Discussion

Principal Findings

We observed few differences in prevalent symptoms consistent with COVID-19 among a web-based sample of adults in the United States at the end of March through the beginning of April 2020. With respect to estimating the extent of the epidemic in the United States during the study period, there were 101,700 cumulative confirmed cases and 1600 cumulative deaths as of March 27, 2020 and 213,400 cumulative confirmed cases and 5000 cumulative deaths by April 1, 2020 [11].

Despite the similarity in experiences of COVID-19 symptoms, we did observe differences in participants' self-assessed likelihood of having COVID-19 at the time of survey completion. Hispanic and non-Hispanic Black participants were more likely to suspect that they were currently infected, which may reflect an awareness of the differential impact of the pandemic on communities of color in the United States or a better understanding of the potential for asymptomatic infection. These differential self-assessments of the likelihood of current infection may translate to differential testing and care-seeking behavior. Trends in self-assessment of symptoms and knowledge of appropriate prevention strategies should be continuously monitored to identify any persistent differences based on race and ethnicity.

Limitations

This study has limitations. Participants were recruited on the internet via advertisements on social media sites and are not representative of all adults in the United States. Participation in an uncompensated survey may reflect a prior interest in COVID-19; therefore, the respondents may have more COVID-19 knowledge compared to the general population. However, we do not think that this selection bias would be differential by race or ethnicity.

Conclusions

Racial and ethnic disparities in morbidity and mortality due to COVID-19 are already apparent. Black and Hispanic populations bear a disproportionate burden of medical conditions across their lifespans, including obesity, diabetes, and heart disease [4,5,12]. Worse health outcomes are exacerbated by structural racism, which in turn impacts housing, economic opportunities, education, transportation, food availability, and health care access [13]. Previously existing disparities in chronic disease incidence and prevalence due to unequal access and treatment [14] that are at least partially contributing to the observed COVID-19 disparities could increase if people are relying on incorrect prevention methods. Knowledge gaps in effective prevention methods and an inability to adhere to known best prevention methods due to crowding and work conditions have the potential to exacerbate these underlying disparities.

Addressing the structural racism that results in differential access to care will necessarily involve structural changes to health care delivery [15]. Universal access to COVID-19 testing, treatment, and if available, a SARS-CoV-2 vaccine will be critical but not sufficient. Medical mistrust must also be addressed [16]. Lack of trust in the medical establishment is an artifact of historical mistreatment of populations of color and of misinformation. It will be necessary to identify methods to overcome medical mistrust to ensure acceptance of treatment and prevention measures. Additionally, research is needed to identify trusted sources of information, as well as modes and mechanisms of communication, in Black and Hispanic communities to ensure that correct prevention and treatment information can be disseminated most effectively. Reducing disparities in knowledge, health care access, prevention, and treatment will be necessary conditions for successfully combatting the COVID-19 pandemic.

Acknowledgments

We appreciate and acknowledge the contributions of our study participants. This work was supported by the National Institute of Allergy and Infectious Diseases (3R01AI143875-02S1). The study was facilitated by the Center for AIDS Research at Emory University (P30AI050409). Abstract

Background: An extensive amount of information related to the novel coronavirus (COVID-19) pandemic was disseminated by mass and social media in China. To date, there is limited evidence on how this infodemic may influence psychobehavioral responses to the crisis.

Objective: The aim of this study is to assess the psychobehavioral responses to the COVID-19 outbreak and examine their associations with mass and social media exposure.

Methods: A cross-sectional study among medical and health sciences students from the Fujian Medical University in Fuzhou, China, was conducted between April 6-22, 2020.

Results: A total of 2086 completed responses were received. Multivariable analyses demonstrated that four constructs of the Health Belief Model (HBM)—higher perception of susceptibility (odds ratio [OR] 1.44; 95% CI 1.07-1.94), severity (OR 1.32; 95% CI 1.10-1.59), self-efficacy (OR 1.61; 95% CI 1.21-2.15), and perceived control or intention to carry out prevention measures (OR 1.32; 95% CI 1.09-1.59)—were significantly associated with a higher mass media exposure score, whereas only three constructs—higher perception of severity (OR 1.43; 95% CI 1.19-1.72), self-efficacy (OR 1.85; 95% CI 1.38-2.48), and perceived control or intention to carry out prevention measures (OR 1.32; 95% CI 1.08-1.58)—were significantly associated with a higher social media exposure score. Lower emotional consequences and barriers to carry out prevention measures were also significantly associated with greater mass and social media exposure. Our findings on anxiety levels revealed that 38.1% (n=795; 95% CI 36.0-40.2) of respondents reported moderate-to-severe anxiety. A lower anxiety level was significantly associated with higher mass and social media exposure in the univariable analyses; however, the associations were not significant in the multivariable analyses.

Conclusions: In essence, both mass and social media are useful means of disseminating health messages and contribute to the betterment of psychobehavioral responses to COVID-19. Our findings stress the importance of the credibility of information shared through mass and social media outlets and viable strategies to counter misinformation during a pandemic.

KEYWORDS

psychobehavioral; COVID-19; mass media; social media; medical students; China

Introduction

With rapid increases in the number of internet users, both mass and social media have a prominent role to play in modern society. In China, there were approximately 688 million internet users, of whom 75.1% were aged 10-39 years, in 2015 [1]. As the general public becomes more health conscious, the popularity of social media as a means of acquiring health-related information has been growing in recent years [2,3]. Of note, social media tools are readily accessible on the internet and have become even easier to access via apps on smartphones. As a result, the role of social media as a pathway to news is very popular [4]. However, social media users may be exposed to untrustworthy news or information of questionable accuracy. Inaccurate information acquisition could have detrimental effects, since passive acquisition through social media, particularly through WeChat Moments, is an important medium for health information acquisition among college students in China [2]. (WeChat is the most popular social media platform in China and includes instant messaging and service platforms to carry out payment, marketing, and promotion activities. WeChat Moments is an interactive platform that allows users to share information/news articles, photos, and video.) Moreover, almost 60% of social media users admitted that internet-based health information impacted their health management strategy [5]. Mass media, in contrast, provides more credible information and has been used as a means of communication of scientifically accurate information about health more often than social media. Mass media can influence health behaviors and promote health behavior change in the public [6].

In late December 2019, an unknown form of pneumonia—caused by a novel coronavirus—surfaced in Wuhan, China, and rapidly spread across the globe. By the end of April, the overall number of the coronavirus disease (COVID-19) cases worldwide increased to 2,878,196 and the death count reached 198,668 [7]. China, after over 3 months of battling COVID-19, has managed to control the outbreak. Nonetheless, the community at large in China remains vulnerable, and prevention from rebound is essential since lockdown regulations have been relaxed. During the early phase and the peak of the COVID-19 epidemic in China, various issues surrounding mental distress among the general public caught the attention of researchers. Studies showed that a great proportion of the general public was found to have severe depressive symptoms, even during the early phase of the outbreak [8,9]. It is important to address mental health issues during a disease outbreak, as it may weaken social and other areas of functioning, including an impairment in prevention measures [10,11]. Psychobehavioral responses have been understudied after the cessation of the COVID-19 outbreak in China and this warrants attention. The lay public's psychobehavioral responses during a disease outbreak play an important role in bringing the outbreak under control [10]. Hence, to avoid a resurgence of infections, investigation into preventive behavioral responses in addition to the psychological well-being of the public post-COVID-19 warrant attention. Attitude is a key factor that determines behavioral intention.

The Health Belief Model (HBM) has been used as the theoretical framework to explain the health behaviors of individuals. It includes the following concepts: perceived susceptibility, perceived severity, perceived benefits, perceived barriers, cues to action, and self-efficacy [12,13]. Adopting the HBM to explain psychobehavioral changes during the COVID-19 outbreak is essential.

One study in China, conducted during the early phase of the outbreak, found a high prevalence of mental health problems among the public, which was positively associated with frequent exposure to social media [14]. To the best of our knowledge, little research has been conducted on social or mass media exposure now that China has entered the downward trend of COVID-19 transmission. Thus, an investigation of exposure to both mass and social media and linkage to the psychobehavioral health outcomes of the public is needed. Accurate information-seeking behaviors during the COVID-19 outbreak has important implications for health-related behavior change and may strengthen infection prevention and control. The traditional mass media is message-driven; in contrast, social media is conversation-driven, and during the COVID-19 outbreak, it is unclear which form of media influences the public and shapes their psychobehavioral responses. Therefore, this study aimed to (1) assess the level of mass and social media exposure related to COVID-19 and (2) identify the association between both forms of media exposure with HBM constructs, psychological and behavioral responses, and anxiety levels.

Methods

Participants and Study Design

An anonymous internet-based, cross-sectional, open survey was distributed to medical and health sciences students at Fujian Medical University, Fuzhou, China, between April 6-22, 2020. Convenience sampling was used to recruit subjects for this study. The link to the survey questions was sent to administrators or lecturers of all departments to be disseminated to registered students at the university. In an attempt to reach comprehensive recipient coverage, the link to the survey was also sent to students' social media groups and forums. All respondents were informed that their participation was voluntary, and consent was implied through their completion of the questionnaire. No incentives were provided to the study participants.

The questionnaire was developed in English, then translated into Chinese. Local experts performed face validation on the content of the questionnaire. The online questionnaire was subsequently pilot tested for readability and clarity of items on 30 participants from the general public. A minor revision was made based on the results of the pilot study. The revised questionnaire was further pretested before field administration. The survey consisted of questions that assessed demographic background, mass media and social media exposure, constructs from the HBM, psychological and behavioral responses, and anxiety levels associated with the COVID-19 outbreak.

Instruments

Mass Media and Social Media Exposure

Questions on mass media (8 items) and social media (10 items) exposure queried participants about types of information acquisition. The response options were scored on a 4-point Likert scale (0=never, 1=rarely, 2=sometimes, and 3=often). The scores were summed, with higher scores representing higher usage. The possible score range for mass media exposure and social media exposure was 0-24 and 0-30, respectively. The participants were informed that the term “mass media” refers to both traditional and online mass media (written or broadcast), including television, radio, advertising, newspapers, magazines, and newsfeeds. In contrast, “social media” refers to websites and apps such as WeChat, Weibo, and Youku, which are among the most commonly used social media platforms in China. Weibo shares features similar to Twitter (eg, allows users to share content up to a 140-Chinese-character limit). On the other hand, Youku, often called the YouTube of China, is an online video and streaming service platform.

HBM Constructs

Questions related to HBM constructs include perceived severity, perceived susceptibility, perceived efficacy, and perceived control or intention [12,13,15]. Perceived severity was measured using a 1-item question (*How serious do you think COVID-19 is?*) on a 4-point scale (*not at all serious* to *very serious*). Perceived susceptibility was a 1-item question (*What do you think are your chances of getting COVID-19?*) on a 4-point scale (*not at all* to *very large chance*). Perceived efficacy was measured using a 1-item question (*Do you think that you will manage to carry out prevention measures currently recommended by the authorities?*) on a 4-point scale (*certainly cannot* to *most certainly yes*). Perceived control or intention was measured using a 1-item question (*Would you carry out prevention measures currently recommended by the authorities?*) on a 4-point scale (*certainly cannot* to *most certainly yes*).

Psychological and Behavioral Responses

Psychological responses measure the emotional consequences of the COVID-19 outbreak. The emotional consequences consist of questions about feelings of fear, avoidance, keeping a secret, embarrassment, and stigma associated with COVID-19 (5 items). Optional answers were on a 4-point Likert scale, with the items scored as 1 (strongly disagree), 2 (disagree), 3 (agree), or 4 (strongly agree). The possible total emotional consequences score ranged from 5-20, with higher scores representing higher levels of emotional consequences.

Behavioral response measures relating to preventive barriers consist of 5 sections (8 items) that comprise questions about personal protection (3 items), cough etiquette (3 items), and contact precautions (2 items). The question queried participants' level of difficulty in practicing physical prevention measures. A 4-point Likert scale was used to report responses, with scores of 1 (very easy), 2 (easy), 3 (difficult), or 4 (very difficult). The total physical prevention barriers score ranged from 8-32, with

higher scores representing higher difficulty levels of physical prevention.

Anxiety

Anxiety was measured using the 6-item state version of the State-Trait Anxiety Inventory (STAI-6) [16,17]. The respondents rated the frequency of experiencing 6 emotional states (ie, being calm, tense, upset, relaxed, content, and worried) as a result of the COVID-19 outbreak. A 4-point scale was used (ie, 1=not at all, 2=somewhat, 3=moderately, and 4=very much). The scores on the 3 positively worded items were reverse-coded. The total summed scores were prorated (multiplied by 20/6) to obtain scores that were comparable with those from the full 20-item STAI (giving a range of 20-80) [17]. A cut-off score of 44 was used to indicate moderate-to-severe symptoms [10,18].

Statistical Analysis

The reliability of the scales used was evaluated by assessing the internal consistency of the items representing the scores. The mass media and social media exposure items had a reliability (Cronbach α) of 0.958 and 0.940, respectively. The emotional consequences and prevention barrier behavior items had a reliability (Cronbach α) of 0.794 and 0.840, respectively. The reliability computed for the STAI-6 items in the assessment of anxiety was 0.793.

Multivariable logistic regression analysis, using a simultaneous forced-entry method, was used to determine the factors influencing mass media and social media exposure. Multivariable logistic regression analyses were performed on all variables found to have a statistically significant association (two-tailed, $P<.05$) in the univariable analyses. Odds ratios (ORs), 95% CIs, and P values were calculated for each independent variable. All statistical analyses were performed using SPSS, version 20.0 (IBM Corporation). The level of significance was set at $P<.05$.

Ethical Considerations

This research was approved by the Research Ethics Committee of the Fujian Medical University. Written informed consent was not acquired from participants. The committee approved that consent was implied through questionnaire completion and submission.

Results

A total of 2086 completed responses were received. Figure 1 shows the number of daily new cases in China since the beginning of the COVID-19 outbreak [19] and the duration of our data collection period. As shown in Figure 1, data collection was carried out past the peak of the COVID-19 outbreak.

As shown in Table 1, more than half of the participants were 18-20 years old ($n=1197$, 57.4%). Nearly two-thirds of the birthplaces of participants were in rural areas ($n=1369$, 65.6%). Most participants reported that their annual family income was below CNY 50,000 ($n=978$, 46.9%) or in the CNY 50,000-120,000 category ($n=775$, 37.2%). The distribution by university year was approximately equal.

Mass Media and Social Media Exposure

Figure 2 shows the proportion of *often* responses and its corresponding 95% CIs for mass and social media use. The majority of participants relied on mass media for staying up-to-date with information about the number of confirmed COVID-19 cases or deaths ($n=1224$, 58.7%), followed by information seeking related to prevention ($n=1204$, 57.7%), transmission ($n=1145$, 54.9%), symptoms ($n=1105$, 53%), and risk ($n=1012$, 48.5%) associated with COVID-19. The most common reasons to use social media were to obtain information about prevention ($n=1065$, 51.1%), transmission ($n=1048$, 50.2%), and symptoms ($n=1015$, 48.7%) of COVID-19.

The mean total mass media exposure was 19.3 (SD 4.9; range 0-24) out of a possible score of 24. The median was 20.0 (IQR 16.0-24.0). The total mass media exposure scores were categorized into two groups (20-24 or 0-23), based on the median split; as such, a total of 1113 (53.5%; 95% CI 51.2-55.5) were categorized as having a score between 20-24 and 973 (46.6%; 95% CI 44.5-48.8) had a score between 0-23. The mean total social media exposure was 23.2 (SD 5.8; range 0-30) out of a possible score of 30. The median was 23.0 (IQR 20.0-29.0). The total social media exposure scores were categorized into two groups (23-30 or 0-22), based on the median split; as such, a total of 1096 (52.5%; 95% CI 50.4-54.7) were categorized as having a score between 23-30 and 990 (47.5%; 95% CI 45.3-49.6) had a score between 0-22.

Figure 2. Proportion of participants who "often" used mass media and social media ($N=2086$).

HBM Constructs

In total, 1558 participants (74.7%; 95% CI 72.8-76.5) reported *certainly yes/probably yes* for perceived susceptibility of getting infected with COVID-19. A relatively lower proportion perceived COVID-19 as very serious ($n=985$, 47.2%; 95% CI 45.1-49.4). The majority also reported *certainly yes* ($n=1506$, 72.2%; 95% CI 70.2-74.1) in their ability to carry out recommended prevention measures. A relatively lower proportion reported *certainly yes* ($n=1298$, 62.2%; 95% CI 60.1-64.3) about their intentions to carry out the recommended prevention measures.

Psychological and Behavioral Responses

Figure 3 shows the proportion and corresponding 95% CIs of responses for items on emotional consequences. Nearly half of the participants answered *strongly agree/agree* in regard to avoidance behavior ($n=962$, 46.1%); 21.2% ($n=443$) and 17.9% ($n=374$) strongly agreed or agreed that they felt embarrassment or fear, respectively. The mean total emotional consequences score was 9.4 (SD 2.7; range 5-20). The median was 10 (IQR

7-11). The total emotional consequences scores were categorized into two groups (10-20 or 5-9), based on the median split; as such, a total of 1082 (51.9%; 95% CI 49.7-54.0) were categorized as having a score between 10-20 and 1004 (48.1%; 95% CI 46.0-50.3) were categorized as having a score between 5-9.

The proportions of *difficult/very difficult* responses and the corresponding 95% CIs for difficulties in carrying out preventive measures are also shown in Figure 3. The greatest difficulty reported was avoiding touching one's eyes, nose, and mouth ($n=1000$, 47.9%). Difficulties in avoiding proximity with other people and wearing a mask all the time were also reported by 21.8% ($n=454$) and 12.8% ($n=267$) of participants, respectively. The mean total score for barriers to carry out preventive measure was 15.0 (SD 3.7; range 8-32). The median was 16 (IQR 12-17). The total score for barriers to carry out preventive measures was categorized into two groups (16-32 or 8-15), based on the median split; as such, a total of 1100 (55.7%; 95% CI 50.6-54.9) were categorized as having a score between 16-32, and 986 (47.3%; 95% CI 45.1-49.4) were categorized as having a score between 8-15.

Figure 3. Proportion of participants who answered "agree/strongly agree" for questions related to emotional consequences and "difficult/very difficult" for questions related to carrying out preventive measures (N=2086).

Anxiety

The mean overall anxiety score was 40.4 (SD 10.8; range 20-80). Using a cut-off score of 44 for the STAI score, a total of 38.1% (n=795) (95% CI 36.0-40.2) of participants reported moderate-to-severe anxiety (score=44-80). Participants in the 18-20 years age group (n=477, 39.8%) reported the highest amount of moderate-to-severe anxiety, followed those who were 21-22 years old (n=270, 37.8%) and 23-29 years old (n=48, 27.4%) ($\chi^2_2=10.027$, $P=.007$). There was a gradual decrease in the proportion of moderate-to-severe anxiety by university year, whereby 41.4% (n=274) of year 1 participants reported moderate-to-severe anxiety compared to 40.0% (n=196) among year 2, 39.8% (n=241) among year 3, and only 25.6% (n=84) among year 4 ($\chi^2_3=26.198$, $P<.001$).

Influence of Mass and Social Media on Psychobehavioral Responses

As shown in Table 2, multivariable regression analysis of factors influencing a higher score of mass media exposure showed significant associations with all the HBM constructs. Higher perception of severity (OR 1.33; 95% CI 1.10-1.60),

self-efficacy (OR 2.03; 95% CI 1.64-2.52), and perceived control or intention to carry out prevention measures (OR 1.29; 95% CI 1.07-1.56) were significantly associated with a higher mass media exposure score. Lower emotional consequences (OR 1.51; 95% CI 1.25-1.83) and barriers to carry out preventive measures (OR 1.50; 95% CI 1.26-1.84) were also significantly associated with a higher mass media exposure score.

Multivariable regression analysis of factors influencing a higher score of social media exposure showed significant associations with 3 of the HBM constructs. Higher perception of severity (OR 1.41; 95% CI 1.17-1.69), self-efficacy (OR 2.01; 95% CI 1.67-2.58), and perceived control or intention to carry out prevention measures (OR 1.27; 95% CI 1.05-1.53) were significantly associated with a higher social media exposure score. Likewise, lower emotional consequences (OR 1.50; 95% CI 1.24-1.67) and barriers to carry out preventive measures (OR 1.39; 95% CI 1.15-1.67) were also significantly associated with a higher social media exposure score.

A lower anxiety score was significantly associated with higher mass and social media exposure in the univariable analyses; however, the associations were not significant in the multivariable analyses.

Table 2. Factors associated with mass media and social media exposure (N=2086).

Discussion

Principal Findings

This study assessed both mass and social media exposure related to COVID-19 and investigated the association between media exposure and HBM constructs, psychological and behavioral responses, and anxiety levels. This study targeted university students, as university students are among the biggest users of the internet and social media [20]. Since this study was conducted when the country was experiencing a decline in COVID-19 cases, it has the advantage of identifying detrimental psychobehavioral factors to provide insight for interventions to prevent a resurgence of infections. Of note, during the data collection period, the nationwide lockdown and movement control had started to ease; nevertheless, schools and universities in China had not yet reopened.

The high mean total exposure score implies that university students have high exposure to both mass media and social media during the COVID-19 outbreak. This finding replicates evidence from previous research, indicating high use of online media (particularly social media) by the younger generation and specifically university students [21-24]. In this study, we also found that university students were exposed to equal amounts of COVID-19-related information from both mass and social media. Both mass and social media were equally used

as information sources for the prevention of infection, symptoms, risk, and mode of transmission.

Despite China's downward COVID-19 trend, the study participants demonstrated a high perceived risk of COVID-19 infection. However, a relatively lower perception of the severity of COVID-19 infection was observed. Many participants also reported high self-efficacy in carrying out recommended prevention measures. During the early phase of the outbreak, the country carried out aggressive public health interventions, such as early detection of cases, contact tracing, and population behavioral changes, which have been reported to have contributed enormously to containing the epidemic [25]. The positive psychobehavioral responses found in this study indicate that population behavioral change interventions have brought about positive behavioral as well as attitudinal changes up to the present time, which is reflected in the success in curbing the spread of the virus to the wider community as observed in the continuous slowdown of COVID-19 cases in China.

The study also found an overall low level of emotional consequences among participants during the off-peak period of the COVID-19 outbreak, as shown by the low mean value of the total emotional consequences score. Despite the low level of emotional consequences, it should be noted that continuous mitigation of the emotional well-being of the public during an infectious disease outbreak is important in controlling

transmission [26]. During the severe acute respiratory syndrome (SARS) epidemic, fear and stigma may have instigated people to delay seeking care and remain in the community undetected. Also, a noteworthy finding is that the most prominent emotional consequence found was avoidance behavior, as it was reported by nearly half of the study participants. It is important to note that cognitive avoidance contributes to a delay in taking precautions to prevent the spread of COVID-19. The implication of this is that prompt action by the public and immediate seeking of medical care upon suspicion of COVID-19 infection are still needed, regardless of the downward trend.

This study's participants found minimal difficulty in carrying out preventive measures. The most prominent difficulty encountered was avoiding touching one's eyes, nose, and mouth; nearly half the participants reported having experienced this difficulty. The importance of refraining from touching one's eyes, nose, and mouth with unwashed hands to prevent the transmission of COVID-19 has been noted previously [27]. Since habitual face-touching behavior has been commonly reported [28], hand hygiene compliance should be encouraged to avoid this route of transmission. Public health interventions to promote and encourage desirable hand-hygiene-compliant behaviors are crucial even though the outbreak is largely under control.

During the early phase of the pandemic, more than half (53.8%) of the general public in China reported the psychological impact associated with COVID-19 as being moderate or severe [8]. In this study, slightly over one-third (38.1%) of university students reported moderate-to-severe anxiety. Although relatively lower anxiety levels were observed after the peak of the outbreak, our results indicate that COVID-19 is still spurring fear in some parts of society. In the case of the Ebola outbreak, anxiety and depression were still prevalent 1 year after the outbreak, especially among those who had been in quarantine and witnessed death associated with the disease [29]. Findings from this study imply that COVID-19-related anxiety among university students warrants special attention. Therefore, it is suggested that continuous assessment and monitoring of COVID-19-associated mental health issues is essential when students resume their studies on campus. Mental health service provision or psychological intervention services to help students who experience loss of family members or friends to COVID-19 should be encouraged in all universities across the country, especially in Wuhan, China's coronavirus epicentre. Furthermore, the study also found that younger university students were more vulnerable to moderate-to-severe anxiety; more attention from university authorities should be allocated to monitor the mental well-being of these students.

The results of the multivariate analyses of this study provide evidence of the important role of both mass and social media in shaping individual health beliefs using the HBM constructs. Substantial mass media exposure was associated with having a higher perception of illness severity and a higher perceived control or intention to carry out prevention measures. Similarly, social media exposure shapes individual health beliefs using the HBM constructs. However, high social media exposure was associated with all the HBM constructs investigated, except for the perception of risk.

Previous reports have noted that emotional consequences such as fear, stigma, and discrimination during the COVID-19 outbreak among people in China were fuelled by misinformation and unfounded rumors [30]. In our study, multivariate analyses revealed that greater mass and social media exposure were also associated with lower emotional consequences, namely, perception of avoidance, embarrassment, fear, and keeping the infection a secret. This perhaps implies that our study participants were exposed to credible and accurate information from both mass and social media, and hence were not negatively impacted. Of note, the Chinese government implemented viable strategies to counter misinformation and fake news during the pandemic such as immediate removal of fake news in the media and strict penalties for offenders.

The behavioral influence of both mass and social media were evident in this study. More mass and social media exposure was also associated with lower barriers to carrying out prevention practices. The findings imply the importance of continuously providing the public with accurate and credible information through mass and social media to enhance emotional well-being and prevention behaviors. It is also vital for media authorities to ensure the credibility of information shared in during an infectious pandemic to elevate negative psychological impact and enhance prevention behaviors. It has been suggested that quick and targeted interventions oriented to delegitimize sources of fake information in the media are important to reduce negative consequences [31]. As such, the findings of this study provide insights into the importance of developing prompt strategies to counter misinformation.

In short, our findings suggest that both mass and social media are useful means of getting health messages across and contribute to improving psychobehavioral responses to COVID-19. Although traditionally the trustworthiness and authenticity of information sourced from social media in relation to mass media has been an issue of concern, this study demonstrated contrary results. Both mass and social media contributed similarly to favorable psychobehavioral responses to COVID-19.

Interestingly, the univariable analyses also observed that both high levels of mass and social media usage were significantly associated with lower anxiety levels. However, the association was not significant in the multivariable analyses. Our finding contradicts recent findings that reported a high prevalence of mental health problems among the public in China that was positively associated with frequent exposure to social media [14]. Of note, our study participants were medical and health sciences students, and this perhaps implies that they were more proficient at identifying and consuming credible information on social media than the general public. In addition, our study has also demonstrated that students with higher exposure to mass and social media tend to have lower negative emotional consequences and fewer barriers to carrying out prevention measures, which might partly contribute to their lower anxiety level. Thus, their increased social media usage does not result in a higher level of mental health problems. This possibly suggests that the proper use of social media for information purposes is beneficial in shaping psychological and behavioral responses during an infectious disease outbreak.

Limitations

This study has several limitations that should be considered. The first pertains to the use of convenience sampling and its cross-sectional nature. It cannot, therefore, be used to infer causality. Despite of the recruitment of a large and diverse sample, the relatively high proportion of young participants in this study may introduce a bias toward greater social media usage. Second, the responses were based on self-report and may be subject to recall bias, self-reporting bias, and a tendency to report socially desirable responses. A third limitation is that the participants were medical and health sciences students; this warrants careful interpretation owing to their comprehensive knowledge and attitude about COVID-19 as well as their higher affinity for health information. Next, the associations found in this study should be interpreted with caution as the psychobehavioral responses were obtained during the off-peak period of the COVID-19 outbreak. Despite these limitations, the study data contribute tremendously to the understanding of the influence of both mass and social media on psychobehavioral responses to the COVID-19 outbreak in China.

Conclusions

Higher exposure to both mass and social media related to the COVID-19 outbreak increased positive attitudes in all the domains of the HBM. Emotional consequences and behavioral prevention barriers also reduced with higher exposure to both mass and social media. In conclusion, based on our results, both mass and social media are useful means of disseminating health-related information to the public and contribute to improvements in psychobehavioral responses to COVID-19. Our findings imply that university students are proficient at identifying and consuming credible information on social media. With much information circulating on the internet, it is challenging for the public to stay informed with reliable, credible, and trustworthy information from the internet. The general public should be informed about proper online health information seeking during disease outbreaks to avoid detrimental psychological and behavioral impacts that may deter outbreak management and control.

Acknowledgments

This study was supported by The Pilot Project of Fujian Provincial Department of Science & Technology (No. 2020Y0005), and Fujian Medical University's Rapid Response Funding Call for COVID-19 Related Research (No. 2020YJ003).

Authors' Contributions

LPW, YL, and ZH conceived the study. YL collected data. LPW and HA analyzed the data. LPW wrote the manuscript. All authors have approved the manuscript.

Abstract

Background: Coronavirus disease (COVID-19) is a worldwide epidemic, and various countries have responded with different containment measures to reduce disease transmission, including stay-at-home orders, curfews, and lockdowns. Comparative studies have not yet been conducted to investigate the impact of these containment measures; these studies are needed to facilitate public health policy-making across countries.

Objective: The aim of this study was to describe and evaluate the impact of national containment measures and policies (stay-at-home orders, curfews, and lockdowns) on decelerating the increase in daily new cases of COVID-19 in 54 countries and 4 epicenters of the pandemic in different jurisdictions worldwide.

Methods: We reviewed the effective dates of the national containment measures (stay-at-home order, curfew, or lockdown) of 54 countries and 4 epicenters of the COVID-19 pandemic (Wuhan, New York State, Lombardy, and Madrid), and we searched cumulative numbers of confirmed COVID-19 cases and daily new cases provided by health authorities. Data were drawn from an open, crowdsourced, daily-updated COVID-19 data set provided by Our World in Data. We examined the trends in the percent increase in daily new cases from 7 days before to 30 days after the dates on which containment measures went into effect by continent, World Bank income classification, type of containment measures, effective date of containment measures, and number of confirmed cases on the effective date of the containment measures.

Results: We included 122,366 patients with confirmed COVID-19 infection from 54 countries and 24,071 patients from 4 epicenters on the effective dates on which stay-at-home orders, curfews, or lockdowns were implemented between January 23 and April 11, 2020. Stay-at-home, curfew, and lockdown measures commonly commenced in countries with approximately 30%, 20%, or 10% increases in daily new cases. All three measures were found to lower the percent increase in daily new cases to <5 within one month. Among the countries studied, 20% had an average percent increase in daily new cases of 30-49 over the seven days prior to the commencement of containment measures; the percent increase in daily new cases in these countries was curbed to 10 and 5 a maximum of 15 days and 23 days after the implementation of containment measures, respectively.

Conclusions: Different national containment measures were associated with a decrease in daily new cases of confirmed COVID-19 infection. Stay-at-home orders, curfews, and lockdowns curbed the percent increase in daily new cases to <5 within a month. Resurgence in cases within one month was observed in some South American countries.

KEYWORDS

COVID-19; national containment; lockdown; curfew; stay-at-home; epidemic curve

Introduction

The coronavirus disease (COVID-19) epidemic is caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2); it is the third coronavirus-associated epidemic to emerge from a species leap from wild animals to humans, after severe acute respiratory syndrome (SARS) in 2003 and Middle East respiratory syndrome (MERS) in 2012 [1,2]. Coronavirus infection causes acute respiratory illness that is usually self-limiting but can be severe in some cases [3]. Coronaviruses primarily infect the upper respiratory and gastrointestinal tracts of birds and mammals. However, once a human is infected, they can transmit the coronavirus to other humans through respiratory droplets and aerosols from coughing and sneezing, like other respiratory pathogens [4]. In Wuhan, China, it was estimated that the basic reproductive number for SARS-CoV-2 was 2.68 (95% CI 2.47-2.86) and its doubling time was 6.4 days (95% CI 5.8-7.1) [5] in the early phase of the pandemic. Since January 2020, following the lockdown of Wuhan, increasing numbers of SARS-CoV-2-infected cases have been reported outside the city [6]. The COVID-19 pandemic began with small chains of transmission in China and nearby cities, which then became large chains of extensive spread in countries worldwide. As of July 2, 2020, over 10 million confirmed cases and more than 510,000 deaths have been recorded globally [7]. National responses of containment measures, such as stay-at-home orders, curfews, and lockdowns, have varied across countries with different characteristics. To our knowledge, there is no comparative study investigating the impact of these containment measures on COVID-19 transmission in countries with respect to geographical location, income status, containment measures imposed, and early and late responses to the COVID-19 pandemic.

From the perspective of public health, principles of controlling contagious disease transmission focus mainly on early detection via testing and contact tracing, in addition to prevention of transmission by containment measures such as stay-at-home orders, curfews, lockdowns, quarantine of exposed individuals [8], and travel or trade restrictions [9]. Additionally, behavioral interventions such as personal protective measures (such as hand hygiene and respiratory etiquette) and social or physical distancing measures (such as isolation of sick individuals, school measures and closures, workplace measures and closures, and avoiding crowding) should be advocated at the community level to facilitate the flattening of the epidemic curve [10].

Quarantine has been used as an effective tool to control communicable disease outbreaks throughout history [11]. The quarantine period provides ample time for the incubation period to complete; therefore, asymptomatic cases will become symptomatic and can therefore be identified. Quarantine is most successful in settings where there is prompt detection of new cases, where contacts can be listed and traced within a short time frame, followed by a prompt issuance of quarantine with

voluntary compliance. This may not be applicable to the case of COVID-19 infection because the science and epidemiology of the disease are still largely unknown. At the time of preparation of this paper, in a rapid review assessing the effects of quarantine (alone or in combination with other measures) of individuals who had contact with confirmed cases of COVID-19 infection, who travelled from countries with a declared outbreak, or who lived in regions with high transmission of the disease, it was concluded that insufficient evidence was available [12].

Initial analysis of data from China collected in February 2020 suggested that the epidemic did not expand exponentially. Public response to the epidemic in addition to containment policies was found to be effective despite the initial increase in the number of confirmed cases [13]. The initial transmission rate (R_0) was reduced from 2.6 to 0.62 (95% CI 0.37-0.89) due to the stay-at-home order in the United Kingdom [14]. Similar changes in effective transmission rate (R_t) were observed in the United States and many European countries after population-level containment interventions were implemented [15,16]. However, worldwide evidence to guide policy makers on effective control of the pandemic is still lacking.

Nonpharmaceutical public health measures at the individual level (physical distancing, use of face masks, and wearing of eye protection to reduce person-to-person transmission) have been studied by the COVID-19 Systematic Urgent Review Group Effort (SURGE) [17]. However, the effectiveness of measures implemented at the national level is a knowledge gap that should be filled. In this study, we aimed to describe and evaluate the impact of national containment measures and policies (stay-at-home orders, curfews, and lockdowns) on decelerating the increase in daily new cases of COVID-19 infection in 54 countries and 4 epicenters of the pandemic in different jurisdictions worldwide.

Methods

Data Source

We used an open, crowdsourced, daily-updated COVID-19 data set provided by Our World in Data [18]. This public domain repository provides numbers of cumulative confirmed cases, confirmed cases per 1 million people, confirmed daily new cases, cumulative deaths, and daily deaths for each country associated with the European Centre for Disease Prevention and Control and the total number of tests for COVID-19 performed per 1000 people as reported by the health authority of each country. Because the most common test for COVID-19 is the polymerase chain reaction (PCR) test, our data source tracked the number of tests for COVID-19 in terms of the number of PCR tests performed or the number of individuals who were tested for COVID-19 reported by the health authority of each country. Cumulative confirmed cases and daily new cases in four epicenters (Wuhan, the Lombardy region of Italy, New York State, and Madrid) were obtained from the websites

of national health authorities. Commencement dates of countrywide containment measures were gathered from the national health ministries and health authorities by authors CW and EHMT and were cross-checked by the last author (AW). Characteristics including the continent, income level classified by the World Bank [19], types of containment measures (stay-at-home order, curfew, or lockdown), effective dates of containment measures, and numbers of confirmed cases on the effective dates of containment measures were retrieved for each country and epicenter. All crowdsourced data were available up to June 20, 2020.

Regarding the three containment measures under investigation, a stay-at-home order was defined as limited outdoor movement except essential activity, curfew was defined as a stay-at-home order during specific time periods, and lockdown was defined as restriction of population mobility within a specific region or country. Acknowledging that variations in the adoption of containment measures may exist across regions or countries, the main difference between a stay-at-home order and a lockdown was denoted as the restriction of people moving in or out of a region being imposed with the latter but not the former. Accordingly, the containment measure introduced in the United States would be classified as a stay-at-home order.

Ethics Approval

This study used open-sourced, secondary dataset, and was exempted from ethics review of Institution Review Board.

Outcome Definitions

The primary outcome of this study was the percent increase in daily new cases from 7 days prior (day -7) to 30 days after (day $+30$) the commencement of measures in countries and epicenters. This specific timeframe between day -7 and day $+30$ ensured that complete daily new case data were obtained for all included countries and epicenters. The percent increase in daily new cases on day t was defined as the daily new cases on day t divided by the cumulative confirmed cases on day $t - 1$, where t was between -7 and 30 . When estimating the percent increase in daily new cases by characteristic group, estimates were calculated as the total daily new cases in the locations within the group on day t divided by the total cumulative confirmed cases of the locations within the group on day $t - 1$. The denominator and numerator in the fraction were two summations; the summations were taken over the countries with nonmissing numbers of cases on days t and $t - 1$, respectively. This percent increase can be represented by the weighted sum of the percent increase of the component locations, where the weight is calculated based on the cumulative cases in the country on day $t - 1$:

Average increase in daily new cases from day -7 to day -1 was calculated by method of geometric mean.

Data Analysis

We used line graphs to represent the trends in the percent increase in daily new cases for each type of containment measure and by the measure start date, continent of the country

or epicenter, income level, and average percent increase in daily new cases before the start of containment measures. The formula proposed by Waller et al [20] was used to estimate the 95% CI for the weighted proportion. The 95% CI for the percent increase of a location was estimated by the method of the binomial proportion confidence interval, while that for a group was estimated by the method of the weighted binomial proportion confidence interval. The calculation of the percent increase in daily new cases at time t was excluded in a particular group and country if the daily new cases data were missing at time $t - 1$ and time t . Scatter plots were used to visualize the percent increase in daily new cases at day $+7$, day $+14$, day $+21$ and day $+30$ for each country or epicenter by the average percent increase in cases before the commencement of the containment measures and after the start dates of the containment measures. The relationship between the number of diagnosed cases and the number of tests performed for each location was also assessed using line graphs.

All statistical analyses and figure generations were performed using Stata version 16.0 (StataCorp LLC).

Results

This study included 122,366 patients with confirmed COVID-19 infection from 54 countries and 24,071 patients from 4 epicenters on the days when stay-at-home orders, curfews, or lockdowns were implemented between January 23 and April 11, 2020. The containment measures at the national level are summarized in [Multimedia Appendix 1](#). Of the 54 countries, 31 (57%) adopted lockdowns, 17 (32%) adopted curfews, and 6 (11%) adopted stay-at-home orders. All countries initiated their containment policies after March 9, 2020, except for China (January 23, 2020).

Regarding the type of containment measure, countries adopting stay-at-home orders, curfew, and lockdown demonstrated a decreasing trend in percent increase in daily new cases of COVID-19 infection after the commencement of the measures ([Figure 1](#)). In countries with stay-at-home orders, curfews, or lockdowns, the percent increase was observed to be curbed to <5 within one month. The percent increase in daily new cases decreased from 26.9 (95% CI 25.7%-28.0%) at baseline to 20.3 (95% CI 19.8%-20.7%) at day $+7$, 12.8 (95% CI 12.6%-13.0%) at day $+14$, 7.29 (95% CI 7.17%-7.41%) at day $+21$, and 4.03 (95% CI 3.96%-4.10%) at day $+30$ for countries introducing stay-at-home orders. For countries introducing curfew, the percent increase in daily new cases decreased from 11.4 (95% CI 10.9-11.9) at baseline to 5.93 (95% CI 5.61-6.26) at day $+7$, 3.73 (95% CI 3.47-3.98) at day $+14$, 2.60 (95% CI 2.38-2.81) at day $+21$, and 1.89 (95% CI 1.71-2.07) at day $+30$. Meanwhile, the percent increase in daily new cases decreased from 20.6 (95% CI 19.2-22.1) at baseline to 16.6 (95% CI 15.9-17.4) at day $+7$, 10.8 (95% CI 10.4-11.2) at day $+14$, 8.32 (95% CI 8.06-8.57) at day $+21$ and 2.88 (95% CI 2.73-3.02) at day $+30$ for countries introducing lockdown. For the start date of the intervention ([Figure 2](#)), a persistent drop in the percent increase in daily new cases was also observed at the initial stage of the containment measures, except in China.

Figure 1. Percent increase in daily new cases vs days since containment measure by type of containment measure.

Figure 2. Percent increases in daily new cases vs days since implementation of containment measures by the start date of the containment measure.

Within seven days of commencement of the containment measures, a decreasing trend in the percent increase in daily new cases was observed across continents (Figure 3). The introduction of a new COVID-19 case classification in China at day +21 led to a spike in the percent increase in daily new cases in Asia. Resurgence in COVID-19 cases in South

American countries was observed with a spike in percent increase in daily new cases at day +25, more than two weeks after the implementation of containment measures. By income level (Figure 4), a decreasing trend in the percent increase in daily new cases was observed for high-income countries since the initiation of containment measures.

Figure 3. Percent increases in daily new cases against days since implementation of containment measures by continent.

Figure 4. Percent increases in daily new cases vs days since implementation of containment measures by income level.

Among countries with an average percent increase in daily new cases above 10 over seven days prior to the commencement of containment measures, a decreasing trend in percent increase in daily new cases was identified following the implementation of a stay-at-home order, curfew, or lockdown (Figure 5). Among the countries studied, 20% (n=11) had an average increase in daily new cases of 30-49% a week before intervention, while 13% (n=7) had an average increase in daily new cases of $\geq 50\%$. For countries with an average percent increase in daily new cases between 30-49%, 15 and 23 days were required to reduce the percent increase in daily new cases to 10 and 5, respectively. The distributions of percent increases of daily new cases at day

+7, day +14, day +21 and day +30 by average percent increase before the commencement of containment measures in countries and epicenters are shown in Figure 6. A majority of countries (n=45, 83%) experienced a lower percent increase in daily new cases at day +7 than their respective average percent increases before the commencement of measures, whereas only 2 countries had a higher percent increase in daily new cases at both day +14 and day +21 than that prior to containment intervention. The percent increases in daily new cases at day +7, day +14, day +21, and day +30 for each type of containment measure were similar regardless of the start date of the stay-at-home order, curfew, or lockdown (Figure 7).

Figure 5. Percent increases in daily new cases vs days since implementation of containment measures by average percent increase in daily new cases before the containment measures.

Figure 6. Percent increases in daily new cases at day +7 (A), day +14 (B), day +21 (C) and day +30 (D) against average percent increase in daily new cases before intervention by country and epicenter.

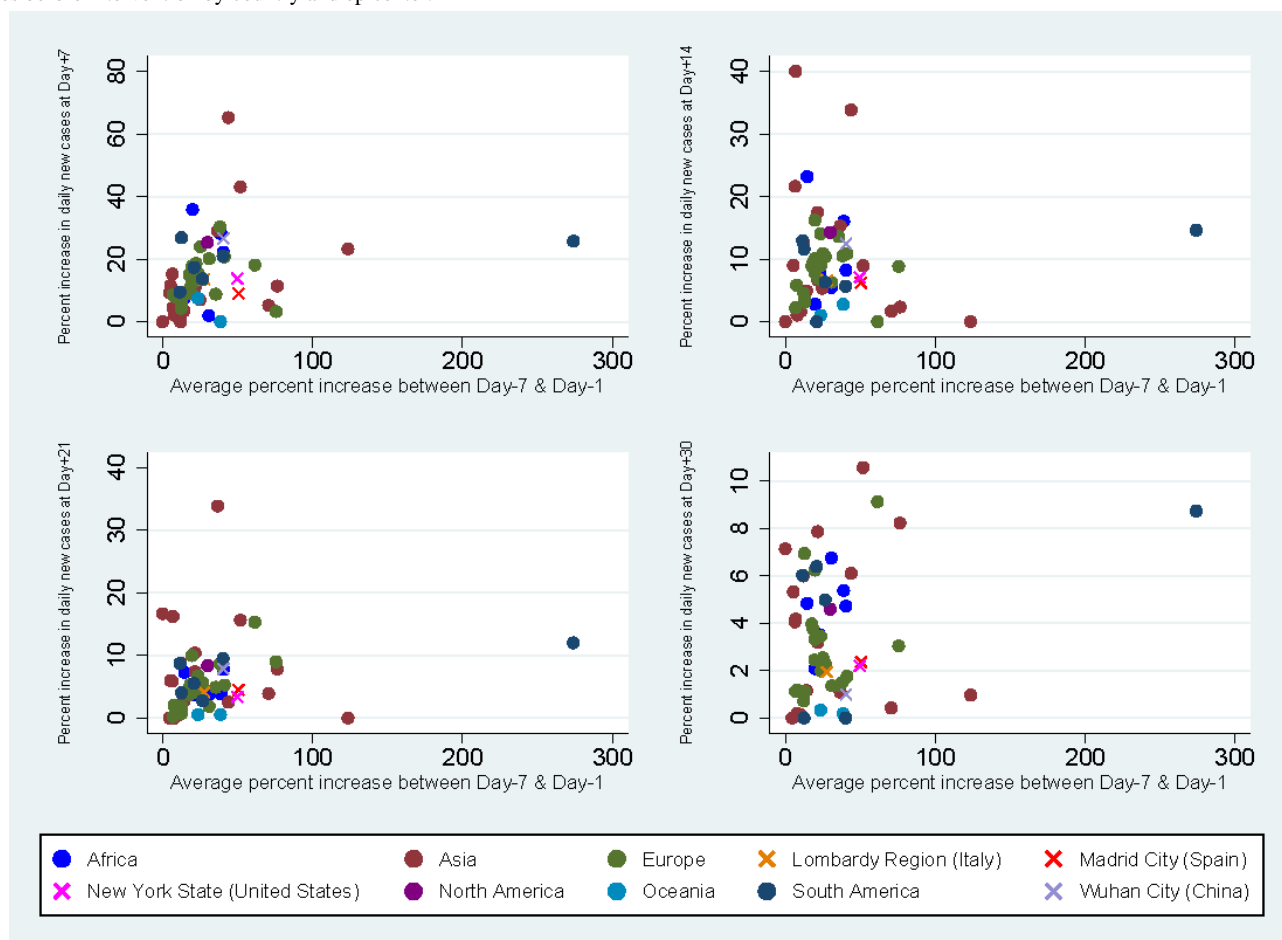

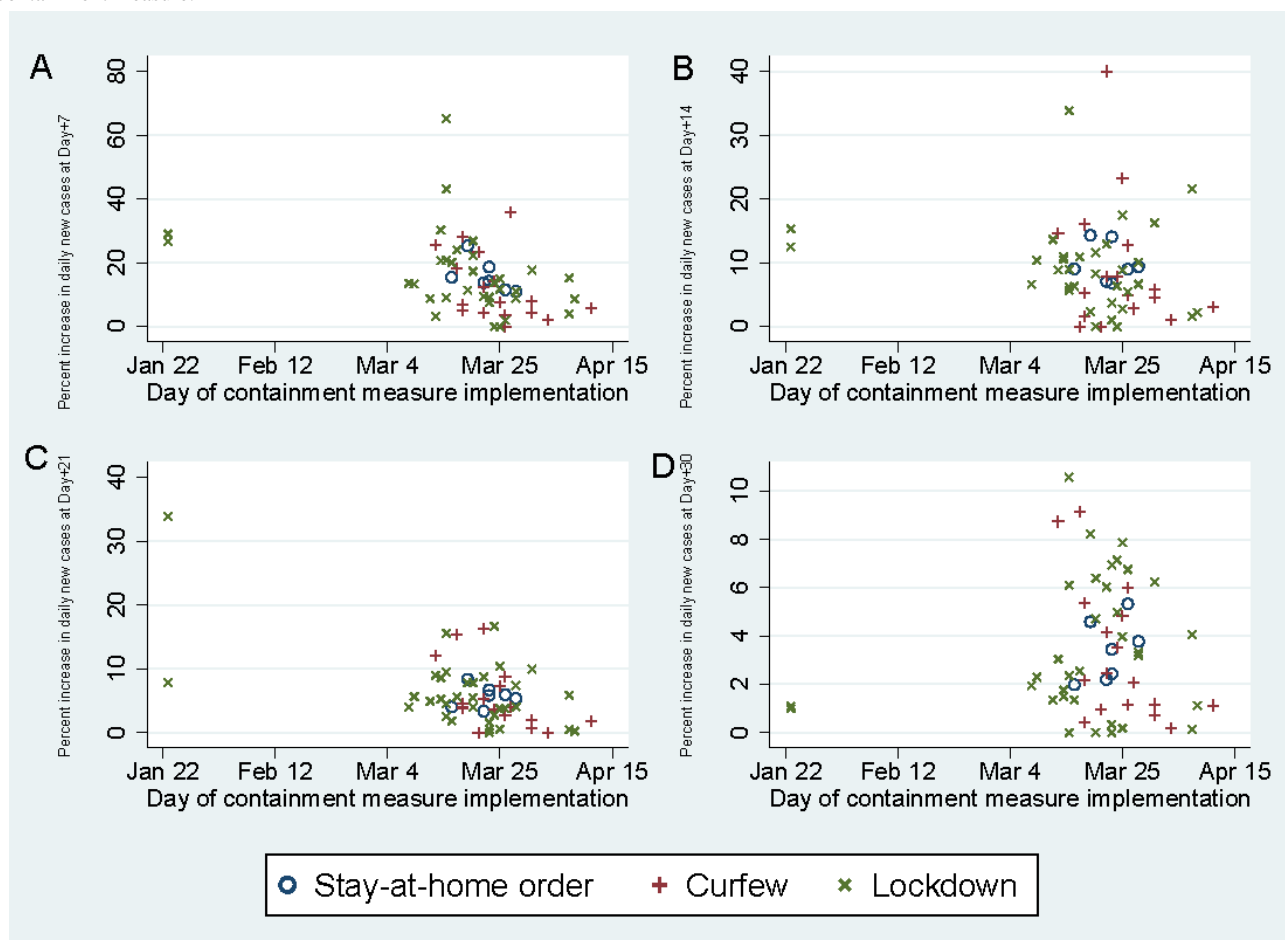

Figure 7. Percent increases in daily new cases at day +7 (A), day +14 (B), day +21 (C), and day +30 (D) vs start date of containment measure by type of containment measure.

With respect to the type of containment measures, Figure 8 illustrates the relationship between the number of COVID-19 tests performed per 1000 people and the number of confirmed cases per 1 million people as reported by the health authority of each country. Countries that initiated lockdown demonstrated flattened curves, implying a reduction of the number of new confirmed cases per 1 million people, while these countries

greatly expanded their scope of PCR testing. Countries adopting stay-at-home orders or curfews demonstrated a linear relationship between the number of COVID-19 tests performed and the number of confirmed cases. Increasing the number of COVID-19 tests performed had adjunctive effects on curbing the increase in daily new cases among locked-down countries.

Figure 8. Total confirmed cases per 1 million people vs total tests for COVID-19 per thousand people in 54 countries by type of containment measure. COVID-19: coronavirus disease.

Discussion

Principal Findings

Our findings suggest that different national containment measures, namely stay-at-home orders, curfews, and lockdowns, are associated with a decrease in the percent increase in daily new cases of confirmed COVID-19 infection. This is consistent with our previous understanding that the virus can be transmitted through respiratory droplets; hence, reducing social contact and population movement may help reduce the spread of this infectious disease. Among countries adopting a lockdown approach, increasing the number of COVID-19 tests may have had adjunctive effects on curbing the increase of confirmed daily new cases. The effects of stay-at-home orders, as described in this study, were contributed by the United States, the United Kingdom, Belgium, Germany, Ireland, and Japan. However, the effects of these orders were likely underestimated on a global scale, given that residents in many regions and countries (such as South Korea [21], Vietnam, Taiwan [22], and Hong Kong [23]) were strongly advised to stay home rather than being ordered to do so, which also appears to have been effective in reducing disease transmission [24]. Lockdown serves to prevent movement of infected individuals between regions. Therefore, lockdown was implemented in epicenters as an altruistic measure to contain the epidemic. While lockdown can cause severe disruption of international interactions, especially in this globalized era, further research is warranted to investigate

whether entry screening and quarantine would achieve similar outcomes to those of lockdown. It is our view that stay-at-home orders are adopted to minimize community transmission, and lockdowns (or border restrictions) aim to reduce the number of imported cases. Curfew, however, only limits physical contact among individuals during specific time periods; this may lead to a less observable effect, if any.

In the United States, the most prominent country in North America, there was no single effective date of a stay-at-home order at the country level, as containment measures and government responses to the COVID-19 pandemic varied from state to state (ranging from March 19 to April 11). California was the earliest state to enact a stay-at-home order, on March 19, 2020; this was assumed to be the effective date of national containment measures for the United States in this study. Most states in the United States subsequently imposed stay-at-home orders, leading to a time lag between the effective date and actual disease control. It can be speculated that the delay in commencing these containment measures across the country contributed to the spike in percent increase in daily new cases with stay-at-home orders for the first few days immediately following the first effective date of implementation, as the United States accounted for almost half the percent increase in daily new cases during the peak observed.

A persistently low percent increase in daily new cases was observed in Asia throughout the study period. An upsurge of

the number of COVID-19 cases alerted the health authorities in Asian countries and their residents during the early phase of the pandemic. With reference to the lessons learned during the SARS outbreak in 2003, Asian communities adopted various nonpharmaceutical measures to minimize disease transmission even before the announcement of health policies by local governments. This is evident in a report suggesting that nonpharmaceutical measures (such as hand hygiene, use of face masks, respiratory etiquette, and social distancing) have been incorporated into the local culture of Asian regions [25]. Countries in South America, however, showed signs of potential resurgence or a second wave of COVID-19 cases at the end of the study period. It is very concerning that containment measures did not appear to be effective in flattening the epidemic curve for individual countries in the region or that the health literacy of the public regarding COVID-19 infection should be improved. These concerns appear to be valid in light of the several subsequent spikes of percent increase in daily new cases identified across several South American countries (such as Argentina, Colombia, and Peru) following the lifting of containment measures before the disease was brought under control.

In addition to substantially lowering the percent increase in daily new cases in countries and regions with severe surges ($\geq 100\%$), the investigated containment measures could also help less prevalent areas ($<10\%$) to maintain a stable low percent increase in daily new cases. Accordingly, these interventions can be initiated at an early stage to flatten the curve and protect local health services from overwhelming demand. In view of the considerable economic cost associated with restriction of population movement, early public health interventions may also help alleviate the impact of prolonged recession and massive disruption of economic activities posed by mounting crises of newly confirmed cases and fatalities.

In this study, the relationships between the number of COVID-19 tests performed per 1000 people and the number of confirmed cases per 1 million people were examined by country and type of containment measures. These relationships were more obvious when the number of confirmed cases per million people was relatively small (around 1000 confirmed cases per 1 million people), which indicates the importance of leadership and coordination by local governments to make rapid expansion of PCR testing feasible and achievable in areas affected by the COVID-19 pandemic. Once the number of confirmed patients exceeded 1000, the effect of the same testing-to-population ratio almost disappeared; this may have occurred because health care facilities were overwhelmed by symptomatic patients, leaving no capacity to contact potential cases and conduct tests to identify an even larger number of carriers. Additionally, a country may fail to expand its testing capacity if the availability of testing agents becomes a rate-determining factor. Meanwhile, adoption of curfews and stay-at-home orders in countries did not appear to control the rise of new confirmed cases; hence, it can be postulated that testing must be coupled with other nonpharmaceutical public health control measures, such as quarantine and isolation, to exert effects on disease control.

The COVID-19 pandemic revealed how wealth inequity is associated with differential outcomes among countries. In our study, it was observed that high-income countries achieved a greater reduction in percent increase in daily new cases following the implementation of a stay-at-home order, curfew, or lockdown. This decline was more gradual among low-income and lower-middle-income countries, potentially because the crowded living conditions in these countries pose inherent risk of disease transmission. Moreover, other public health measures such as quarantine of exposed individuals may not be as effective in these countries because low-income employees who rely on their wages to meet financial obligations may avoid COVID-19 testing and subsequent forced quarantine. Therefore, development of a comprehensive public health intervention should be part of the strategic plan to manage the outbreak of infectious diseases alongside the promotion of health literacy of individuals, particularly in low-income countries and among people of lower social classes.

Limitations

The current study has several limitations. First, in an attempt to control the disease outbreak, many governments implemented multiple public health interventions simultaneously or within a short timeframe [26]; thus, individual strategies could not be evaluated independently. Second, the effects of different containment measures on disease transmission can vary depending on the patterns of social contact at home, schools, and workplaces, which would likely be influenced by local cultures and the enforcement of public regulations. Third, the observational design of this study precluded causal inference. However, clinical trials are neither feasible nor ethical during the current public health emergency, and compelling evidence comparing the experience of one outbreak area with another in which different policies were adopted is still lacking.

During the pandemic, crowdsourced data collection has played an increasingly important role in providing timely and accurate data for disease surveillance [27]. A number of local crowdsourcing platforms, such as *Ushahidi* [28], have been working together to deliver real-time reports to the public to raise public awareness and facilitate the development of local contingency measures. This collaboration represents a potential advancement in the publication of timely epidemiological analyses and reports; however, the accuracy, ethics, and confidentiality of research data should not be undermined [29].

Conclusion

National containment measures are essential to controlling the COVID-19 pandemic. In this study using crowdsourced data, countries that implemented stay-at-home orders, curfews, and lockdowns managed to curb the percent increase in daily new cases within a month; however, a resurgence in cases was observed in several South American countries two weeks after the commencement of containment measures. While no vaccine or effective treatment is yet available, the findings of our study can shed light on the impact of different containment measures and the priority of their implementation during this pandemic.

Acknowledgments

The authors would like to thank *Our World in Data* for providing open-source data on confirmed COVID-19 cases and tests and Mr Owen Chu for statistical assistance. There was no funding source for this study.

Authors' Contributions

CW, JW, and AW contributed equally to all aspects of the study design and conduction, data interpretation, and writing of the manuscript. CW, ET, CHA, and KL contributed to the data extraction, analysis, and interpretation. AW contributed to the data validation. All authors approved the final version for submission.

Conflicts of Interest

None declared.

Abstract

Background: Timely allocation of medical resources for coronavirus disease (COVID-19) requires early detection of regional outbreaks. Internet browsing data may predict case outbreaks in local populations that are yet to be confirmed.

Objective: We investigated whether search-engine query patterns can help to predict COVID-19 case rates at the state and metropolitan area levels in the United States.

Methods: We used regional confirmed case data from the New York Times and Google Trends results from 50 states and 166 county-based designated market areas (DMA). We identified search terms whose activity precedes and correlates with confirmed case rates at the national level. We used univariate regression to construct a composite explanatory variable based on best-fitting search queries offset by temporal lags. We measured the raw and z-transformed Pearson correlation and root-mean-square error (RMSE) of the explanatory variable with out-of-sample case rate data at the state and DMA levels.

Results: Predictions were highly correlated with confirmed case rates at the state (mean $r=0.69$, 95% CI 0.51-0.81; median RMSE 1.27, IQR 1.48) and DMA levels (mean $r=0.51$, 95% CI 0.39-0.61; median RMSE 4.38, IQR 1.80), using search data available up to 10 days prior to confirmed case rates. They fit case-rate activity in 49 of 50 states and in 103 of 166 DMA at a significance level of .05.

Conclusions: Identifiable patterns in search query activity may help to predict emerging regional outbreaks of COVID-19, although they remain vulnerable to stochastic changes in search intensity.

Introduction

Early detection of regional coronavirus disease (COVID-19) outbreaks is essential for efficient medical resource allocation, public health messaging, and implementation of infection prevention and control strategies [1]. It is particularly important given the probability of future waves of COVID-19 cases and

the difficulty of applying traditional epidemiological forecasting models in areas with low case levels [2,3]. However, laboratory testing capacity is limited, and confirmed case reports lag behind underlying infections, decreasing their predictive capacity in the early days of an outbreak or resurgence.

Internet browsing data, such as search-engine query results, can provide a real-time indication of symptoms in a population and

have been used extensively to predict and model outbreaks like influenza and dengue [4-7]. Such methods generally assume that specific and detectable patterns in internet behavior, such as search trends or social media postings, reflect health-seeking behavior in real time at the population level. Forecasting models based on search queries, such as Google Flu Trends, have shown predictive value without direct reliance on formal case reports, although historical inaccuracies mean that they can only supplement, not replace, traditional forecasting methodologies based on confirmed cases [8-10].

COVID-19 case rates display significant regional heterogeneity that requires locally tailored containment strategies. Google search trends, encompassing a majority of internet queries in the United States and publicly available through Google Trends (GT), provide a powerful resource for systematic comparison of browsing behavior between US regions. We hypothesized that keyword libraries could be screened for specific terms whose aggregate activity would reflect regional differences in COVID-19 case rates, as has been demonstrated for influenza [4]. While several studies have previously attempted to model the COVID-19 pandemic using search query data, such attempts have largely focused on specific regions, like Taiwan and Iran, and a limited number of individually selected search terms [11-14]. We explored the potential of large-scale, publicly accessible search query data to signal new COVID-19 cases at the state and metropolitan-area levels in the United States.

Methods

Data Collection and Processing

We obtained confirmed case data for US states and counties from the New York Times (NYT) data set from January 21, the date of the first confirmed US case, to April 2, 2020, comprising county-specific, lab-confirmed COVID-19 case reports compiled daily from local and state health authorities [15]. We used the NYT data set because of both its inclusion of county-level case geotags and its strong correlation with other case tracking sources [16]. Next, we used GT to compile a library of 463 unique search queries and their associated daily activity levels over the same time period. Library terms were automatically retrieved based on the likelihood of user association with a set of prespecified coronavirus-related seed terms ([Multimedia Appendix 1](#)), using the GT “Related Queries” function.

We compared the z-transformed correlation of each query’s search activity with an in-sample data set comprising daily confirmed national cases rates for days through March 10 with >100 new cases per day. Each query’s search activity was offset by temporal lags of between 0 and 14 days, generating a list of best-fitting queries and their associated optimal lag times. To focus on terms with early predictive power, we excluded queries

whose optimal lag was less than 9 days. We selected the five best-fitting queries and constructed a single explanatory variable by summing the lag-adjusted, relative activity levels of each query. Finally, we linearly fit the explanatory variable to national data through March 10 to generate a single scalar coefficient.

Data Analysis

We measured the correlation of state-specific activity levels for our explanatory variable with daily reported case levels in individual states using out-of-sample data from March 11 through April 2. We also measured how well the explanatory variable explained out-of-sample case rates in 166 designated market areas (DMA), which are collections of approximately 15 counties each constituting the highest-resolution regional data available on GT. Means and confidence intervals for correlation coefficients were calculated using the inverse z-transformation of the averaged z-transformed coefficients. The strength of model predictions over time was measured using a partial correlation of first confirmed case dates with z-transformed correlation coefficients in all regions with >100 cases, controlling for regional population. We used root-mean-square error (RMSE) as an additional measure of model performance. Model predictions were adjusted for regional population and internet access [17]. All data were anonymous, and the study protocol was approved by the institutional review board of the Icahn School of Medicine at Mount Sinai.

Results

Search Query Characteristics

Queries incorporated into the final explanatory variable were highly correlated with national case data, with correlation coefficients ranging from 0.996 to 0.999 on the in-sample data. The optimal temporal lags for incorporated queries were from 11 to 12 days, indicating a prediction horizon of up to 10 days (assuming that a day’s full GT query results become available on the subsequent day). The final variable, the linear sum of weighted, lag-adjusted activity levels for the five best-fitting terms from the 463-term library, fit the in-sample data with a correlation of 0.998.

Characteristics of additional screened queries validated our methodology. For instance, acute topics like medical care and testing had smaller associated lag times with confirmed case rates, as would be expected for urgent inquiries ([Table 1](#)). Queries unrelated to COVID-19 had correspondingly weaker correlations with the observed data. The best-fitting category of queries was “COVID-19 guidance,” which included terms related to coronavirus-specific medical advice from health authorities. Relative levels of search activity had no significant effect on fit with case data.

Table 1. Characteristics of query topics screened for fit with coronavirus disease (COVID-19) case data.

Search query category	Unique queries ^a , n (%)	Correlation with national case rate ^b , mean	Associated lag time (days) ^c , mean	Activity weighting ^d
COVID-19 guidance	32 (6.9)	0.96	9.1	0.38
COVID-19 news	57 (12.3)	0.96	8.3	1.00
COVID-19 symptoms	91 (19.7)	0.94	8.9	0.41
Medical treatments	34 (7.3)	0.93	10.1	0.31
COVID-19 testing	58 (12.5)	0.89	5.4	0.11
Medical care	33 (7.1)	0.89	7.2	0.60
Nonspecific symptoms	62 (13.4)	0.89	6.8	0.57
Economic effects	28 (6.0)	0.86	5.9	0.12
Unrelated to illness	51 (11.0)	0.86	6.6	0.76
Symptoms of other illnesses	17 (3.7)	0.84	8.3	0.77

^aNumber of queries of each type in the query library (eg, the category “COVID-19 testing” would include the specific query “coronavirus test near me,” and the category “nonspecific symptoms” would include the query “cough”).

^bExpressed as the inverse z-transformation of the averaged z-transformed correlations with in-sample national data.

^cMean lag time between best-fitting query activity and confirmed case rate, in days.

^dRelative mean search activity levels, normalized.

Regional Case-Rate Predictions

The query-based predictions fit well with out-of-sample case rate data at the national level, with a correlation of 0.84 ($P<.001$) for out-of-sample data and 0.83 ($P<.001$) for all available data. The predictions were also well correlated at the state level in nearly all cases, fitting case data in 49 of 50 states at a significance level of $\alpha=.05$ and 41 of 50 states at $\alpha=.005$ (mean $r=0.69$; 95% CI 0.51-0.81; [Figure 1A](#); [Multimedia Appendix 2](#)). RMSE was less than 4 cases per 100,000 residents for model predictions in 44 of 50 states (median 1.27; IQR 1.48; [Figure 1B](#)).

At the DMA level, the query-based predictions fit with daily case data for 62% (103/166) of regions at $\alpha=.05$, or 79% (84/107) excluding DMA with fewer than 100 cases (mean r

for all DMA=0.51; 95% CI 0.39-0.61; [Multimedia Appendix 3](#)). RMSE was slightly higher for DMA-level compared to state-level predictions but was less than 7 for 92% (152/166) of DMA (median 4.38; IQR 1.80). Furthermore, at both the state and DMA levels, the strength of the correlation was not significantly associated with the date of a region's first confirmed case ($P=.51$ for states and $P=.71$ for DMA for partial correlations in regions with >100 cases, controlling for population), suggesting that predictive search behaviors may precede new cases regardless of the timing of a regional outbreak ([Figure 1C](#) and [D](#)). The explanatory variable consistently produced well-fitting predictions with data available 10 days in advance of predicted new case activity ([Figure 2](#)), even in regions where fewer than 100 new cases were confirmed per day.

Figure 1. Correlation of query predictions with regional coronavirus disease (COVID-19) confirmed case rates. (A) Correlation of predicted case rates with actual case rates for the 50 states. Values are Pearson correlation coefficients. * indicates significance at $\alpha=.05$; ** at $\alpha=.01$; *** at $\alpha=.005$. (B) Root-mean-square error (RMSE) between predicted case rates and actual case rates for the 50 states, in units of daily new cases per 100,000 population. (C) Prediction correlations at the state level do not depend on outbreak timing, as measured by the date of the first confirmed case. Circle size indicates the relative population of the state. Color indicates US census-designated region (blue: Northeast; orange: Midwest; gray: South; green: West). (D) Prediction correlations at the designated market area (DMA) level do not depend on outbreak timing, as measured by the date of the first confirmed case. Circle size indicates the relative population of DMA. Color indicates the US census-designated region, as described. n.s.: not significant.

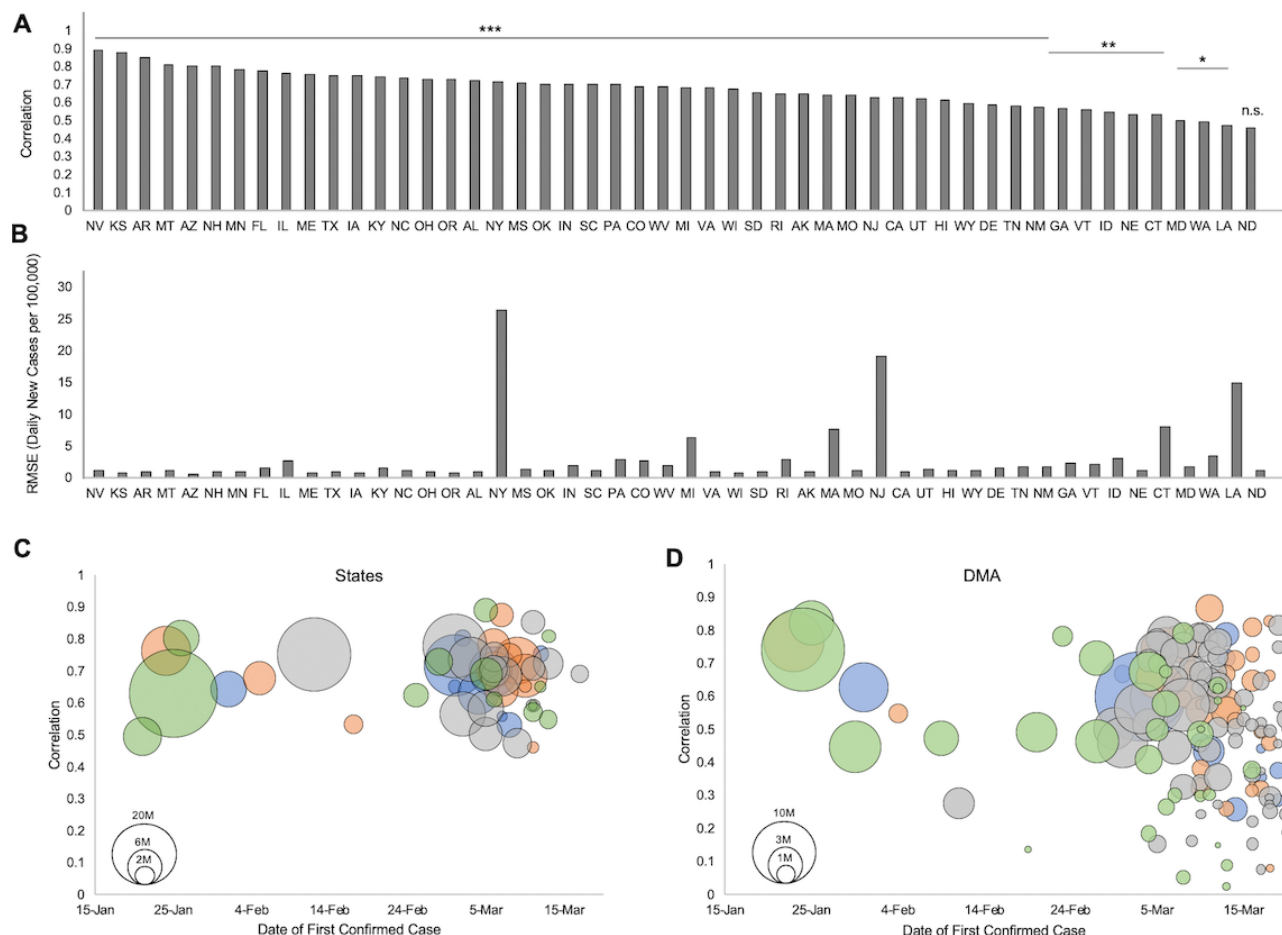

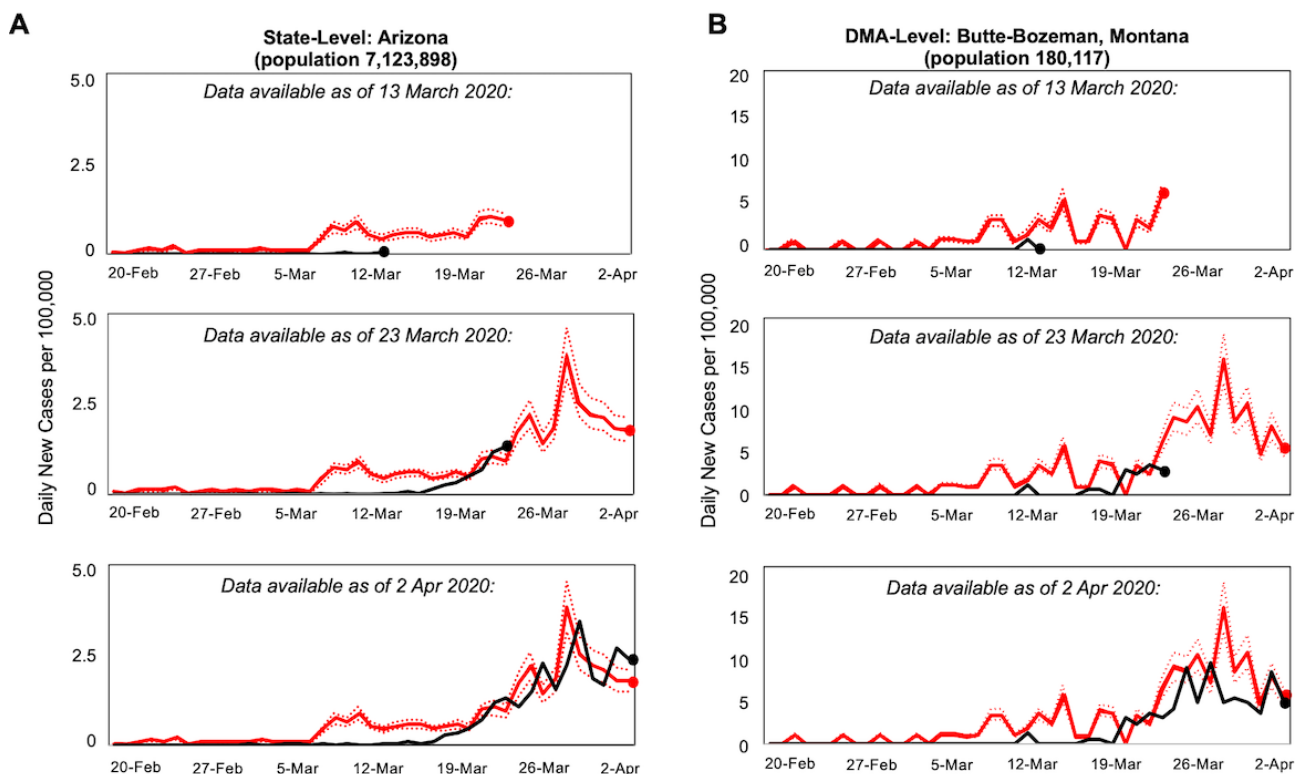

Figure 2. Correlation of query predictions (red) with regional coronavirus disease (COVID-19) case rates (black) at the state and designated market area (DMA) levels, February 20 to April 2, 2020. (A) Comparison of predicted case rates (red) with actual case rates (black) at the state level, with Arizona shown as an example. Dashed lines indicate 95% CIs. (B) Comparison at the DMA level, with the Butte-Bozeman area shown as an example of predictions in a low-population region.

Discussion

These data suggest that specific patterns of internet search behavior, which can be curated automatically from libraries of search terms, precede and correlate with regional case rates of COVID-19. Such patterns, which we captured using a single explanatory variable, remain correlated with case rates in regions with a broad range of populations, locations, and outbreak times, making aggregate search trends a useful tool for estimating regional COVID-19 outbreaks in the days preceding confirmed case reports. Correlation strengths were not significantly associated with the date of onset of regional outbreaks, making it unlikely that a single national event, such as a press release, could explain the strength of model predictions in all regions. Furthermore, search queries explicitly related to COVID-19 have more predictive power than unrelated keywords, and acute queries, such as those concerning testing or medical care, have smaller associated lag times.

Taken together, these results suggest that systematic screening of key term libraries can identify search queries reflecting real-time health-seeking behaviors at the regional level, expanding the suite of “infoveillance” methods that may assist in monitoring COVID-19 cases. This type of approach does not directly depend on either regional testing capacity or local media reports, making it particularly relevant in areas with small populations, limited medical infrastructure, or low case numbers. Such information can supplement traditional epidemiological approaches, such as estimates based on a compartmental

framework, to guide community health interventions in the early days of an outbreak.

Several aspects of query-based approaches to case estimation, such as this work, must be further characterized for COVID-19. First, while correlations were statistically strong across most US regions, elevated RMSE indicated lower accuracy for predictions in the New York City and New Orleans areas, both regions with major outbreaks. However, comparable losses in accuracy were not observed for other major outbreak sites, such as Philadelphia, Los Angeles, or Chicago. This may reflect region-specific differences in both internet browsing behavior and patterns of community infection and may be a limitation of query-based models using fixed terms. As evidenced by previous attempts to predict influenza outbreaks based on search data, browsing behavior will also likely change as public understanding evolves over the course of disease spread [18]. Therefore, search-term relevance is likely to vary with time, which may require continuous supplementation or reselection of query terms to ensure representativeness of current population behaviors. Furthermore, although we generally observed strong historical correlations, query-based models must also be monitored for sudden changes in COVID-related query activity due to external events, such as unrelated news reports. Such distortions would be particularly important in regions with limited internet access. Future models incorporating learning and real-time updating of region-specific search terms may improve query-based prediction efforts for future COVID-19 outbreaks.

Abstract

Background: Intervention measures have been implemented around the world to mitigate the spread of the coronavirus disease (COVID-19) pandemic. Understanding the dynamics of the disease spread and the effectiveness of the interventions is essential in predicting its future evolution.

Objective: The aim of this study is to simulate the effect of different social distancing interventions and investigate whether their timing and stringency can lead to multiple waves (subepidemics), which can provide a better fit to the wavy behavior observed in the infected population curve in the majority of countries.

Methods: We have designed and run agent-based simulations and a multiple wave model to fit the infected population data for many countries. We have also developed a novel Pandemic Response Index to provide a quantitative and objective way of ranking countries according to their COVID-19 response performance.

Results: We have analyzed data from 18 countries based on the multiple wave (subepidemics) hypothesis and present the relevant parameters. Multiple waves have been identified and were found to describe the data better. The effectiveness of intervention measures can be inferred by the peak intensities of the waves. Countries imposing fast and stringent interventions exhibit multiple waves with declining peak intensities. This result strongly corroborated with agent-based simulations outcomes. We also provided an estimate of how much lower the number of infections could have been if early and strict intervention measures had been taken to stop the spread at the first wave, as actually happened for a handful of countries. A novel index, the Pandemic Response Index, was constructed, and based on the model's results, an index value was assigned to each country, quantifying in an objective manner the country's response to the pandemic.

Conclusions: Our results support the hypothesis that the COVID-19 pandemic can be successfully modeled as a series of epidemic waves (subepidemics) and that it is possible to infer to what extent the imposition of early intervention measures can slow the spread of the disease.

Introduction

The coronavirus disease (COVID-19) pandemic has produced a great number of studies that aim to understand the dynamics of the disease spread and predict its future evolution (see, for example, [1-8]). Different types of models can be assumed to describe this dynamic evolution. In studying past epidemics, scientists have systematically applied “random mixing” models that assume that an infectious individual may spread the disease to any susceptible member of the population, as originally proposed by Kermack and McKendrick [9]. Recent approaches consider mobility and contact networks [10,11], epidemic waves attributable to community networks [12], subepidemic modeling [13], Bayesian modeling and inference [14], models of spatial contacts in large-scale artificial cities [15], and power-law models of infectious disease spread [16], to name but a few representative examples.

At present, there is a trove of data from different countries that can serve to put strict limits on plausible models. In this paper we use simulations from agent-based models and simple analytical solutions to fit reported data from a range of countries. This provides a comprehensive picture of likely scenarios of how the disease evolved in various countries. These scenarios can be useful in predicting the future spread of the disease and provide insight on how the imposition of social-distancing measures can be effective in containing or slowing its spread.

Our work is based on two premises. First, the apparent regular features in the reported infections in many countries are not random but rather contain useful information, as their persistence and regularity suggest. Second, there is a general underlying dynamic of the spread of the disease, *in spirit* similar to the original Kermack-McKendrick model of three populations [9], the “susceptible population” $S(t)$, the “infected/infectious population” $I(t)$, and the “removed/recovered population” $R(t)$, which are related by $S(t) + I(t) + R(t) = N$, where N is the total population. The time evolution of the *susceptible-infectious-removed* (SIR) populations is described by the equations:

Figure 1. Illustration of the agent-based simulation model on a 2D grid of size $L \times L$; in this illustration $L=7$, while in our simulations we considered $L=1000$. At $t=0$ (left panel) all the population is susceptible (blue dots), except for one infected individual (red dot). For a period $t < 1/\gamma$ (middle panel) the original infected individual can infect others in a neighborhood within a range $\pm D_0$ in each direction (shown by the dashed square), and each of those infected individuals also infects others within a corresponding range. For $t > 1/\gamma$ (right panel) some of the infected individuals have recovered (green dots), depending on when each was infected.

The size of this range turns out to be a crucial quantity, justifying the quest for social distancing measures to contain or slow down the spread of the disease. After being infected, an agent remains

The SIR model involves two positive parameters, β and γ , which have the following meanings:

- β describes the effective contact rate of the disease; an infected individual comes into contact with β other individuals per unit time (the fraction that are susceptible to contracting the disease is S/N).
- γ is the mean removal (recovery) rate, that is, $1/\gamma$ is the mean period of time during which an infected individual can pass it on before being removed from the group of the infected individuals.

However, the time evolution of the SIR populations, as captured by the linear first-order differential equations of the Kermack-McKendrick model, produce behavior that is much simpler than the actual reported data of infections. Therefore, more detailed (microscopic) models of how the disease is spread from one infected individual to others are required to produce features that can emulate real data. In this study, we consider the simplest possible microscopic model to motivate the reasons that underlie the common features of real data. We then use these results to propose a simple analytical model for fitting the data with a few parameters. Finally, we use the results of the fitting to draw some insights on the actual evolution of the disease in representative countries.

Methods

The Microscopic Agent-Based Model

To understand the dynamics of the epidemic in more detail, we use a more detailed model based on individual agents, which are also classified as susceptible S , infected/infectious I , and removed/recovered R , that exist on a 2D regular grid of points. Each of these agents starts as susceptible and can be infected by another infectious with probability β per unit time (which we take here to be 1 day), and once infected can infect other individuals within a range $\pm D_0$, as illustrated in Figure 1.

infectious for a period of $1/\gamma$ days, at which point the agent is removed (recovered) from the infectious population and can neither be infected again (has acquired immunity) or infect

others. We suggest that the “microscopic” model is likely to be closer to the actual evolution of the disease than the continuous populations model represented by equation (1). The size of the 2D model, a square of length L in the example discussed below, corresponds to a small, uniformly populated “virtual country” of population $N = L \times L$.

We first provided a comparison of the numerical solution of the continuous SIR populations, represented by equation (1) and the agent-based simulations. We chose a total population of $N=10^6$ for both cases and a number of $I(0)=4$ infected agents, distributed randomly on the 2D grid in the case of the agent-based simulations. In Figure 2, we give a comparison of the evolution of the three populations as a function of time for a total period of 150 days, by which time the infectious population has been reduced to zero and the susceptible and removed populations have reached their long-term asymptotic values in both models. Although the overall behavior of the three populations in the two models is similar, the tail of the $I(t)$ population is quite “fatter” for the solution of the differential equations. The behavior of the tail is important, as it determines

the rate at which the total number of infections (cumulative) grows with time, a subject of active research [17]. The value of the range D_0 in the simulations can be chosen at will up to $D_0=L/2$. The continuous SIR model contains no information on this range, which must be somehow included in the effective value of β . Keeping the value of β the same and adjusting the range D_0 and the initial condition for $I(0)$ in the continuous model, we can obtain reasonable agreement between the two models, as shown by an example in Figure 1. In this example, the evolution of the $S(t)$ population is captured well through the entire time range, except for the asymptotic value. This value is important, because it corresponds to the portion of the population that has not been infected at the end of the epidemic and is given by $N - R_{\text{tot}}$, where R_{tot} is the total number of removed; this is also equal to the time integral of the infected population divided by the mean period of infection, $1/\gamma$, as can be easily derived from equation (1c):

Figure 2. Comparison of the numerical solution to the susceptible-infectious-removed equations (solid lines) and agent-based simulations (points) for a population N . In both cases, we use $N=10^6$, $\beta=.25$ per day, and $1/\gamma = 14$ days. For the simulations, the range parameter is $D_0=50$ (see text for details).

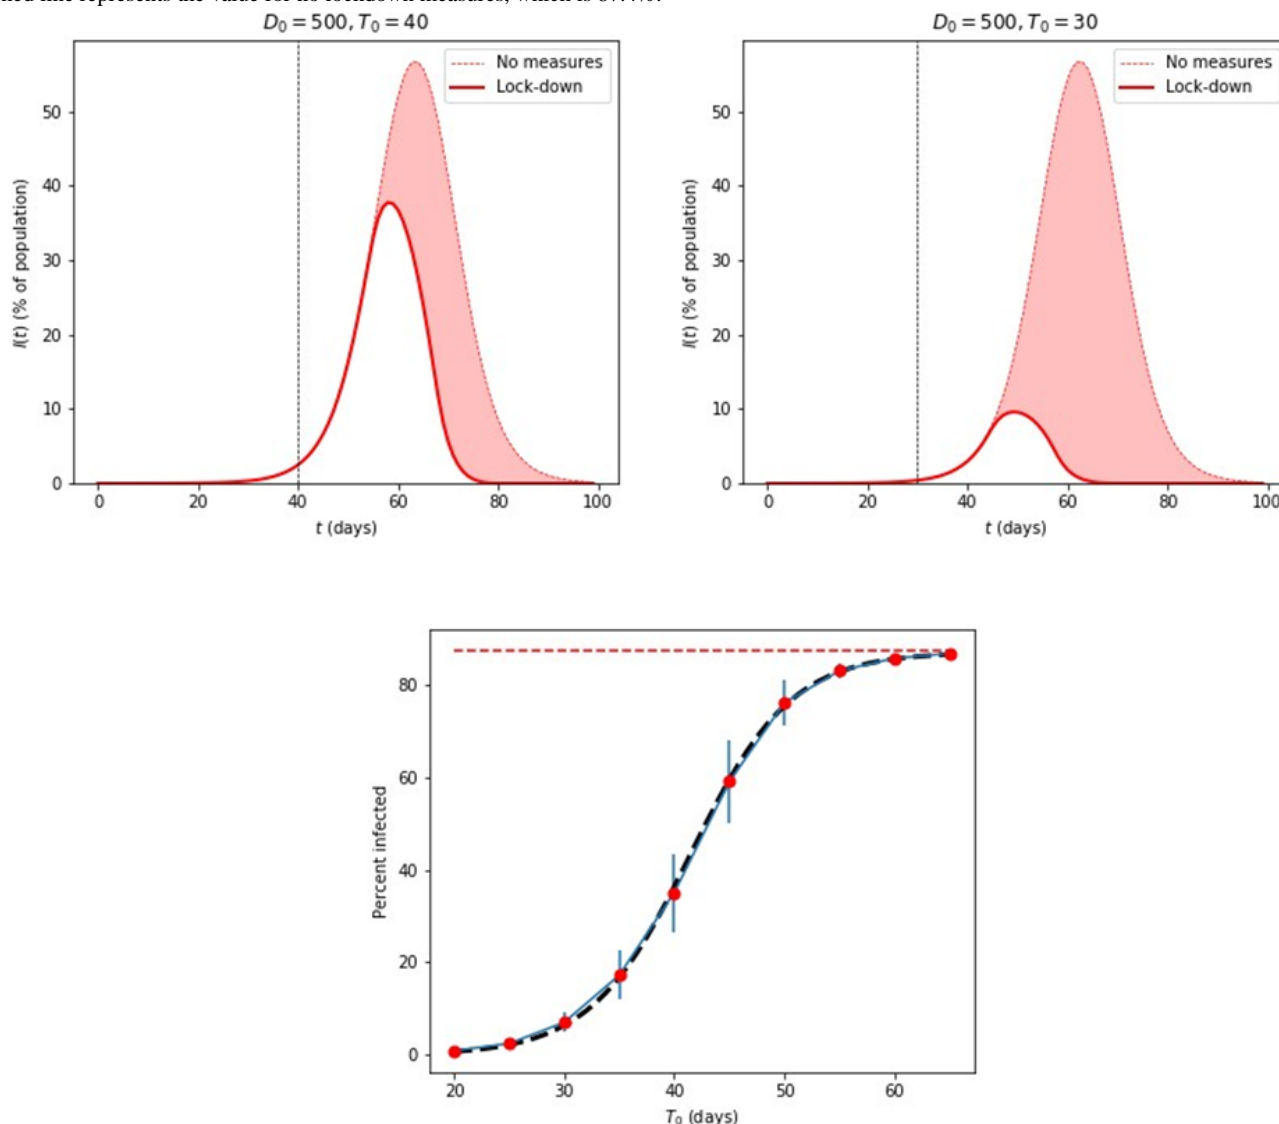

An important consideration in the dynamics of the disease is the effect of measures that restrict the movement of individuals in a population. This can easily be captured in the agent-based simulation model by taking a time-dependent value for the range that each infected individual has, namely:

where T_0 is the time at which the measures are imposed; both t and T_0 are measured from the time of the first infections, defined as $t=0$. Since $D(t) \rightarrow 0$ for $t \rightarrow \infty$ (assuming $\lambda > 0$) the behavior of the range corresponds to “lock-down” measures in which individuals are restricted to a small range and eventually cannot infect anyone else (they are in “quarantine”). We use $\lambda=2.5$ days in our simulations, which means that from the

moment that the measures are imposed ($t=T_0$), the initial range is reduced by a factor of ~ 20 for each week that passes. The effect of lockdown measures is quite dramatic, as shown in Figure 3. To provide a quantitative measure of this effect, we first let D_0 be the largest possible, $D_0 = L/2$ (half the size of the grid on which the agents live) and then consider several values of T_0 , from 20 to 65, the last value being the time where the maximum of $I(t)$ occurs in the case of no imposition of restrictions, such as lockdown. A useful measure to quantify this effect is the total population of infected individuals over the course of the epidemic scaled by the mean period of infection $1/\gamma$, which is the same number as the total population recovered, see equation (2). This quantity, given as a percent of the total population, is shown in Figure 3 for the whole range of T_0 values we considered.

Figure 3. Top: Epidemic disease simulations of the infected population, $I(t)$, as a percentage of the total population, using 1 million individual agents on a 2D grid, with different lockdown dates, T_0 , after the initial cases at $t=0$. The shaded curve in the background corresponds to $I(t)$ with no lockdown measures. For these simulations, $\beta=.25$, $1/\gamma=14$ days, and $\lambda=2.5$ days. Bottom: The percent of the total infected population, $R_{\text{tot}}(T_0)$ for different values of T_0 , ranging from 0.93%, for $T_0=20$ days, to 86.7%, for $T_0=65$ days. The error bars represent standard deviations from averaging over 30 samples in each case (for the largest and smallest values, the error bars are too small to be visible). The black dashed curve is the fit from equation (4). The red dashed line represents the value for no lockdown measures, which is 87.4%.

The asymptotic value, reached for $T_0=65$ is 86.7% ($\pm 0.33\%$), was almost equal to the value when no lockdown measures were imposed, 87.4% ($\pm 0.06\%$); this last value corresponds to the “herd immunity” limit for the parameters we have used in the present simulation. The smaller T_0 , the lower R_{tot} is, reaching the value of 0.93% ($\pm 0.34\%$) for $T_0=20$. The behavior of these values is well approximated by the expression:

$$R_{\text{tot}}(T_0) = R_{\text{tot}}^{\infty} \left(1 - e^{-\frac{T_0 - T_0^{\text{min}}}{\tau}} \right)$$

with $I_0=43.7$, $\tau=9.1$ days, and $T_1=41.5$ days. A clear conclusion from this set of results is that the early imposition of measures makes a significant difference in the total infected population; for example, in a country with a total population of 10 million, the imposition of measures 20 days after the first few reported cases can reduce the total number of infected from 8.74 million to 93,000. The assumptions in this example involve allowing free movement of all persons for the entire period of the disease

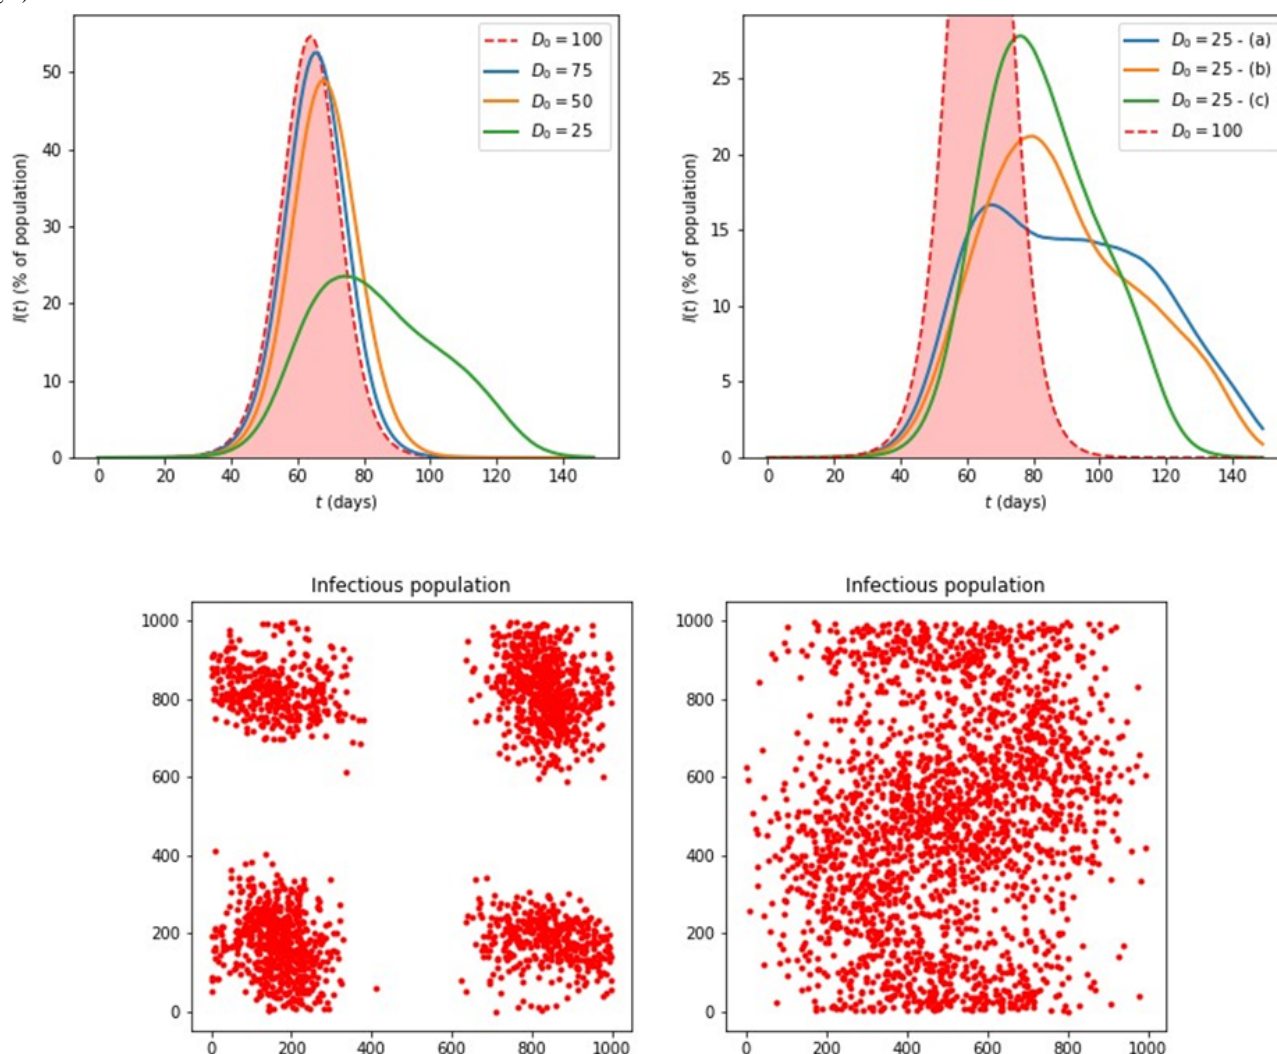

in the worst-case scenario to full quarantine within 2 weeks after imposing lockdown measures, which reduces the initial range spanning the entire country by a factor of 270, enough to essentially stop any disease transmission.

An interesting exercise is to consider what are the effects of *finite* D_0 much smaller than the size of the system (our “virtual country”). We give some examples of such simulations in Figure 4. For $D_0=100$ or larger, the result is essentially the same as that of the limiting case of free motion throughout the entire system, which was discussed in Figure 3 (background curves with no lockdown measures). For $D_0 \leq 75$, the curves start deviating from this behavior and even exhibit more interesting behavior, with additional “bumps” in the descending part and long tails, as the case $D_0=25$ shows. In fact, for $D_0=25$ the curves are not unique and depend on the initial random distribution of the infected individuals at $t=0$; we give an example in Figure 4. Within our simple microscopic model, this behavior arising from small

values of D_0 (like the case $D_0=50$ in Figure 4) can be easily explained; it corresponds to several small clusters of infections, which spread through the country in waves, as one cluster eventually becomes all removed, but before reaching this point, some infected individuals have moved to a region where there were no infections at all, starting a second wave of infections. We emphasize that, independent of the initial conditions that determine the number and time of the subsequent waves' occurrence, for a given value of small D_0 , the asymptotic value

of R_{tot} for $t \rightarrow \infty$ is always the same and of course depends on the specific value of D_0 . This simply means that the total number of infections is determined by the effective range of interactions and, given enough time, the disease will infect the same total number of agents no matter how it proceeds from one cluster to others. This behavior of disease evolution may be actually close to what is seen in reported data, as described in the following section.

Figure 4. Top row: Simulations based on individual agents with a finite range of spreading the disease, D_0 . Left: various values of D_0 ; the case $D_0=100$ already approaches the limit of free motion throughout the system, $D_0=L/2$, see also Figure 3. Right: several instances of $D_0=25$, labeled (a), (b), (c), exhibiting multiple bumps and long tails. Bottom row: the actual infected populations at the same time moment $t=30$ days, for $D_0=50$ (left) and $D_0=100$ (right).

In contrast to the situation for small values of D_0 , for larger values of D_0 all the curves for $I(t)$ are identical and the behavior is that of one wave smoothly spreading through the entire system, as shown also by an example ($D_0=100$) in Figure 4. The critical value separating these two regimes is between 100 and 75 in our simulations. It would be interesting to study what this critical value is and what is its relation to the system size L in a more systematic manner using methods from statistical physics.

The Multiple Wave Forced-SIR Model

Recently, the forced-SIR (FSIR) model was proposed by the authors and used to describe the evolution of the COVID-19 pandemic in a representative set of countries [18]. This model treated the evolution of the infected population as a single wave (single peak wave). It contains three adjustable parameters that are estimated for each country by fitting actual data. However, the single-wave assumption cannot explain the entire incidence curve (infected population curve) in each country. Wavy patterns (“bumps”) are evident in the actual data for many countries, which cannot be attributed to simply random fluctuations, due

to their regularity and similarity among several countries in which, at first glance, the disease was at different levels of severity. Here, we expand the analytical FSIR model to capture the multiple waves (subepidemics), underlying a country's overall incidence curve. This is akin to the case of finite D_0 discussed previously in the agent-based model. We applied this multiple wave analytical model to a representative set of 18 countries, in all of which the behavior of the infection as a function of time is accurately represented by our model.

In its original version, FSIR applies to a single epidemic wave, in which the infected population is given by the expression:

$$I(t) = N - S(t) - R(t) \quad (5)$$

with the approximate solution given by:

where N' , α_1 , α_2 , t_1 , t_2 are treated as adjustable parameters, with t_1 and t_2 representing the times at which the  and  populations reach their sigmoid midpoint values, respectively. Here, we extend this model to allow for multiple waves that capture the subepidemics in the infected population of a country. As argued in the agent-based microscopic model previously presented, several clusters of infections can appear in a country in waves; each cluster eventually becomes all removed, but before reaching this point, some infected individual has moved to a region where there were no infections at all, starting a second local wave of infections. In the extended model, we assume each wave is captured by a function described by equation (6), with different values of the parameters involved.

We apply this extended model to fit the multiple wave behavior of infected populations in different countries, as obtained from the European Centre for Disease Prevention and Control [19], for a period ending on May 16, 2020, which corresponds to 120 days from the onset of the exponential growth of reported cases in China. To obtain a meaningful fit, we had to consider data for each country that showed a monotonic increase at the beginning. This means that a few data points in each case were excluded, as they corresponded to sporadic reports of a few isolated cases, typically 1-10 in a given day, interspersed by several days of zero cases. In practice this means that the fitting begins at a certain cutoff day denoted as t_0 .

As in the case of the original FSIR model, to make the fit more robust and simpler, we chose the α_1 and α_2 parameters to have the same value $\alpha_1 = \alpha_2 = \alpha = 0.25$. We have found this to be the optimal value for the countries we considered. Moreover, a common value for the exponential decrease of the susceptible population, which is captured by the value of α_1 , and for the exponential increase of the removed population, which is captured by the value of α_2 , is actually more consistent with the agent-based simulations, as described in Section II.

Finally, instead of using t_1 and t_2 for each wave as independent parameters, we elected to use as independent parameters t_1 and

$\Delta t = t_2 - t_1$. To make the multiple-wave fit more robust, simpler, and systematic, we chose $\Delta t = 14$ (days) for all waves, which is a reasonable choice, as it corresponds to a common mean time period of 14 days before the infected individual is removed ($\Delta t = 1/\gamma$ in the agent-based microscopic model). This mean time-period has been imposed as a quarantine measure for the majority of countries imposing measures (interventions) and is consistent with a reported estimated median time of approximately 2 weeks from onset to clinical recovery for mild cases [20]. This condition leaves two adjustable parameters per subepidemic that can be varied to obtain the best fit to the data, namely the onset time t_1 , which corresponds to the midpoint of the sigmoid representing the decline of the susceptible population, and N' , which is a parameter representative of the number of daily cases near the peak of the infected population curve in the given wave. N_T , the total number of infected in the given wave, can readily be obtained. The best fit here is defined in the Root-Mean-Square (RMS) sense. The model parameters were determined by employing the Levenberg-Marquardt algorithm.

Results

Application to Representative Countries

We were able to obtain reasonable fits for over 30 countries from the entire database [19], primarily selecting countries for which the temporal COVID-19 evolution had reached peak intensity of the infection. Rather than including over 30 countries in the following discussion, we have chosen to focus on three groups, a total of 18 countries, that span the whole range of parameter values and could hopefully provide some insight to the multiple wave behavior of the pandemic. The choice of the 18 countries also aimed to represent parts of the world more heavily or less heavily impacted by the disease, as well as more typical cases. Here we defined the impact as the total number N_T of infected individuals during the first 120 days of the pandemic, as predicted by the FSIR model [18]; this number is scaled by the population of the country (N_P). In particular, we have included six countries in which the impact was small, China, Australia, Greece, Cyprus, Tunisia, and Japan for which $(N_T/N_P) < 1000$ infected per million; six countries in which the impact was moderate, Israel, Denmark, Germany, France, Canada, and Portugal for which $1000 < (N_T/N_P) < 3000$ infected per million; and six countries in which the impact was large, Sweden, Switzerland, United Kingdom, Italy, the United States, and Spain for which $(N_T/N_P) > 3000$ infected per million.

We fit 7-day running averages of the daily data, for all countries, with data up to May 16, 2020. For each country, we estimated the number of waves (subepidemics) in which the infected population curve could be analyzed, the model parameters of each subepidemic, and the expected number of cases for the first major wave ($N_T^{(1)}$) and for all waves (N_T). Table 1 presents the model parameters for the countries in our set.

^aThe ordering of the countries is discussed in Table 2.^bThe last column includes the values for the *expected* total number of cases N_T when the number of infections has dropped to near zero and is an *extrapolated* value.^cN/A: Not applicable, as there is no relevant wave (subepidemic) for the respective parameter value to be obtained.

In the following, we present results obtained by the multiple-wave FSIR model for selected countries that can be accurately fitted by 4 waves (Italy, Sweden), 3 waves (United States, Portugal, Greece), and a single wave (China). The countries selected fall in two distinct classes: the first class comprises countries, which implemented stringent intervention measures rather fast; the second class comprises classes that implemented measures at rather later times and not at a high stringency level. The stringency of the measures is tracked daily by the Oxford COVID-19 Government Response Tracker (OxCGRT) [21], which systematically collects information on several different common policy responses governments have taken, scores the stringency of such measures, and aggregates these scores into a common Stringency Index. OxCGRT collects publicly available information on 17 indicators of government responses, that is, eight policy indicators recording information on containment and closure policies such as school closures and restrictions in movement, four indicators recording economic policies such as income support to citizens or

provision of foreign aid, and five indicators recording health system policies. Italy, Portugal, Greece, and China had implemented high stringency measures rather fast, whereas Sweden, the United Kingdom, and the United States had not done so at that level.

Figure 5 presents the multiple wave fit for Italy, which was one of the most heavily impacted countries by COVID-19. An initial large subepidemic was followed by 3 declining subepidemics. The use of the term “declining” (or its opposite, “increasing”) refers to the peak intensity of the subepidemic. Italy has taken strong intervention measures, since the country’s maximum stringency level was 94.29 [21]. The shape of the curve is reminiscent of the shape of the curve produced by the agent-based microscopic model, Figure 4 for $D_0=25$. There is an excellent agreement between the 4-wave fit and the actual data in both daily and cumulative data. As can be seen, the single wave fit of the data, depicted by the green dashed lines, significantly underfits the data.

Figure 5. Results for ITA and PRT, obtained by fitting the multiple-wave forced-susceptible-infectious-removed (FSIR) model with data up to May 16, 2020. Top row: Red dots are the daily data reported by the European Centre for Disease Prevention and Control. The blue dots are 7-day running averages of the daily data. The green dashed line is the fit by the single-wave FSIR model. The black solid line is the 4-wave fit by the multiple-wave FSIR model. Middle row: Decomposition of the 7-day running average data (blue dots) in 4 waves for ITA and 3 waves for PRT. The black line represents the superposition of the multiple waves. The fit is in excellent agreement with the actual data. Bottom row: Blue dots are cumulative daily data (7-day running averages). The black line is the fit by the multiple-wave FSIR model, and it is essentially indistinguishable from the actual data. The green dashed line is the fit of the single-wave FSIR model, which clearly underfits the actual data. ITA: Italy; PRT: Portugal.

Figure 5 also presents the multiple wave fit for Portugal, which is a country experiencing a heavy impact by COVID-19. The country's government has implemented stringent measures, with the highest stringency level at 89.52 [21]. The country's incidence curve was fitted by 3 waves. An initial large subepidemic was followed by 2 declining subepidemics. Here too, the shape of the curve is reminiscent of the shape of the curve produced by the agent-based microscopic model, Figure 4 for $D_0=25$. There is an excellent agreement between the 3-wave fit and the actual data in both daily and cumulative data. As can be seen, the 1-wave fit of the data significantly underfits the actual data. Italy and Portugal are representative examples of countries where the initial major wave is followed by several waves of *declining* strength, suggesting that, despite the initial large impact, the countries were successful in eventually containing the epidemic. Germany, France, Spain, Switzerland, Denmark, and Spain are exhibiting similar behavior, namely

that of a major initial wave followed by several of declining strength.

Figure 6 presents the multiple wave fit for the United States, which appears to be the hardest hit country by COVID-19, in terms of total number of cases. The country implemented a series of intervention measures to stop the disease's transmission and impact, which were deemed not to be taken aggressively enough, with highest stringency level 73.57 [21]. The country's incidence curve was fitted by 3 waves. An initial large subepidemic was followed by subepidemics, with seemingly declining strength. However, the United States is a country comprising of more than 50 states and territories, and it is not clear if additional waves, possibly of strength comparable to the original ones, may materialize or not at later times. A study of decomposing the United States infected population curve per state is currently under way by the authors.

Figure 6. Results for the USA and SWE, obtained by fitting the multiple-wave forced-susceptible-infectious-removed model with data up to May 16, 2020. The meaning of symbols is the same as in Figure 5. SWE: Sweden; USA: United States.

Figure 6 also presents the multiple wave fit for Sweden, which was also one of the hardest hit countries by the disease. However, the Swedish Government decided not to impose strict intervention measures but to inform the citizens to adopt certain precautionary measures, in a mostly individualistic capacity; the country's maximum stringency level was 58.10 [21]. Thus, the country followed a different mitigation policy, with respect to the rest of Europe and most of the world. Sweden's incidence curve was fitted by 4 waves. An initial small subepidemic was followed by 3 increasing subepidemics. It seems that the disease is spreading in waves; once a cluster of infected people is all removed, another bigger one is getting infected. Thus, the adoption of voluntary policy makes multiple nondeclining subepidemics of the disease get hold of the country. Since there was no clear trend as of May 16, 2020, of the country getting over the intensity peak, the 1-wave fit predicts a linear increase of the total number of expected cases. The 4-wave fit estimates

a plateau of the total number of cases after the fourth wave, assuming that more waves do not materialize. According to the taxonomy of epidemic waves [13], COVID-19 in Sweden has generated an endemic wave; it remains to be determined if this is stationary or temporary.

Canada and the United Kingdom are among the countries exhibiting a similar subepidemics pattern, that of being impacted by a major wave followed by several waves of nondeclining strength.

Figure 7 presents the single wave evolution of the disease in China, which was the first country to be hit by COVID-19, and the Chinese Government implemented a series of rather fast and strict intervention measures to stop the disease's transmission and impact. The country's incidence curve was fitted by a single wave.

Figure 7. Results for CHN and GRC, obtained by fitting the multiple-wave forced-susceptible-infectious-removed (FSIR) model with data up to May 16, 2020. The meaning of symbols is the same as in Figure 5. CHN: China; GRC: Greece.

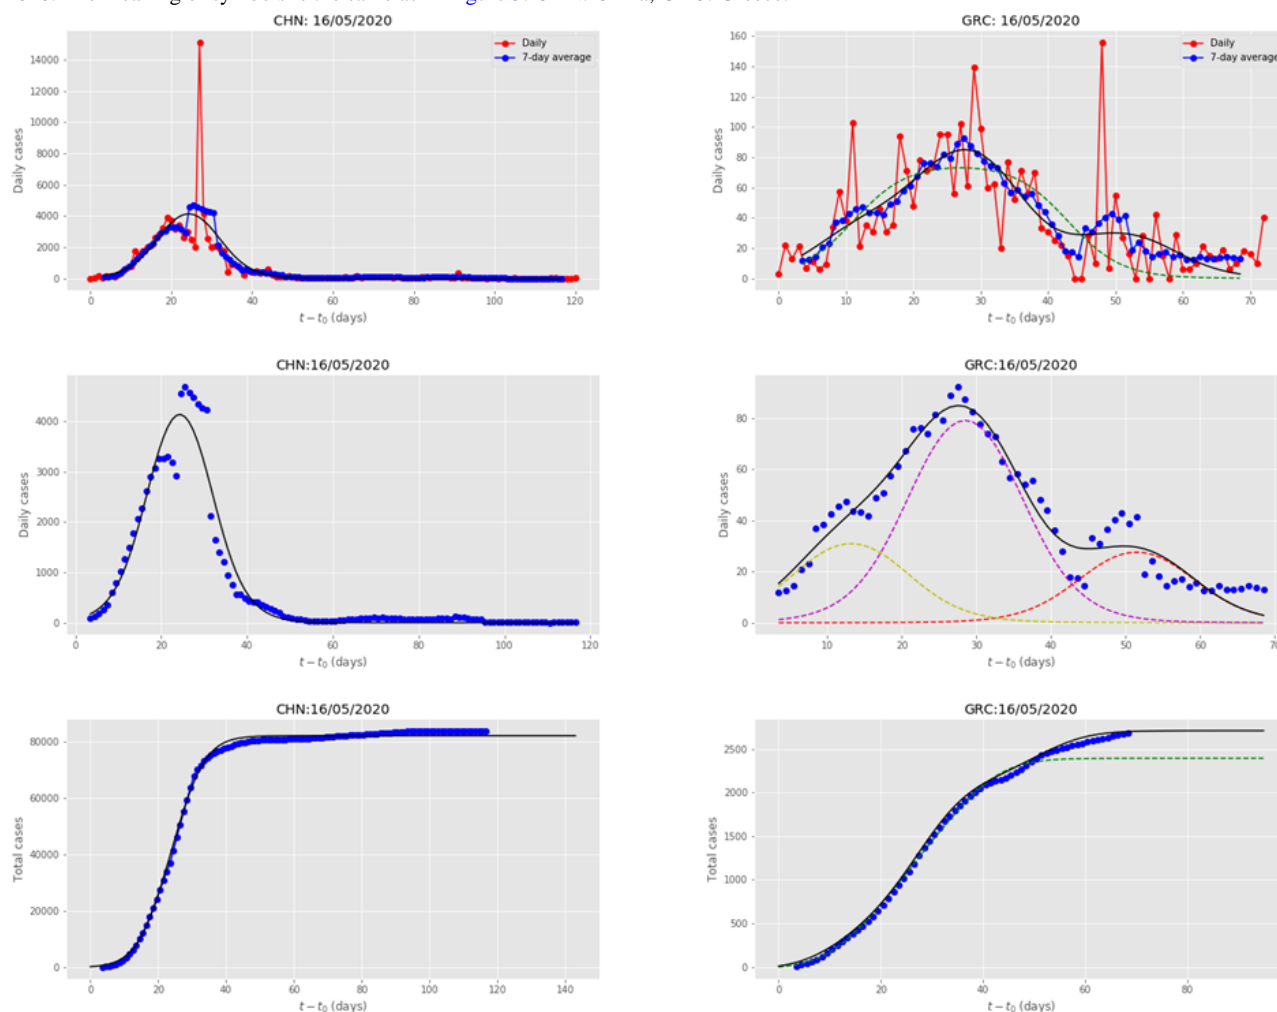

Figure 7 also presents the multiple-wave fit for Greece, whose government quickly implemented a series of intervention measures to stop the disease's transmission and impact, with highest stringency level 85.95 [21], keeping the total number of cases at very low levels. The country's incidence curve was fitted by 3 waves. An initial small subepidemic was followed by a larger one, which was followed by one of declining strength, suggesting that it contained the epidemic efficiently and fast. Greece is a representative example of countries, such as Sweden and Denmark, which also exhibit an initial small wave followed by a larger one. However, Greece and Denmark countered the epidemic before reaching high levels of cases. In terms of declining subepidemics, Greece follows the pattern of countries such as Japan, Israel, Cyprus, and Tunisia, in which the initial major wave was followed by a single subepidemic of declining strength.

Similar to China, the imposition of strict measures in countries such as Australia and New Zealand, shows that countries were able to reduce the disease's impact to a single wave. A quantitative estimate of the gain obtained is presented in the next-to-last column of Table 1, which presents the number of cases that could have been saved if countries had reduced the epidemic to a single wave rather than experiencing multiple ones; up to two-thirds of the total number of infections, as in

the case of the United States, could have been avoided. Recent findings on the differential effects of intervention timing on COVID-19 spread in the United States [22] strongly corroborate this picture.

The Pandemic Response Index

Countries respond to the pandemic in varied ways. It is an interesting question to quantify their varied response and make comparisons, which may be useful for contributing to the evaluation of the different policies followed. Based on the results of our model, it is possible to construct an index, the Pandemic Response Index (PRI), and assign a value to each country depending on its response to the pandemic.

To do this in an objective manner, we took into account two factors. First, the total number of infections as given by the quantity N_T of Table 1, divided by the population of the country N_p . The range of this quantity when multiplied by 100 is between 0 and 0.5 approximately. This is a measure of the overall impact of the pandemic on the population of the country, and as argued by our microscopic model, it is a reflection of how early measures to contain the epidemic were imposed. The second quantity we considered is ΔN_T , the number of cases that correspond to all the waves except for the first major one, which in some cases includes the earliest small wave (see Table 2).

Table 2. Ranking of the various countries according to the PRI, defined in equation (7).

Code	Country	ΔN_T (/million) ^a	N_T (/million) ^b	PRI ^c
CHN	China	0	59	9.94
AUS	Australia	0	271	9.73
GRC	Greece	50	252	8.76
CYP	Cyprus	121	690	8.44
TUN	Tunisia	28	88	8.32
JPN	Japan	56	118	7.51
ISR	Israel	594	1852	6.55
DNK	Denmark	757	1978	6.11
FRA	France	950	2106	5.64
DEU	Germany	1330	2163	4.76
CHE	Switzerland	1319	3565	4.59
PRT	Portugal	1495	2945	4.58
CAN	Canada	1440	2067	4.45
SWE	Sweden	2101	3189	3.52
ITA	Italy	2096	3689	3.47
GBR	United Kingdom	2633	3632	2.74
ESP	Spain	2155	5267	2.69
USA	United States	2818	4495	2.37

^a ΔN_T is the difference between N_T and the total number of cases that were infected by the first major subepidemic (for Sweden, Denmark, and Greece, both the small initial wave and the second wave have been taken into account). ΔN_T has also been normalized by the country's population in millions.

^b N_T is the asymptotic value after all waves have decayed, given in Table 1, normalized here by the country's population in millions.

^cPRI: Pandemic Response Index.

Arguably, this number of cases could have been avoided had the country imposed early and strict measures after the first wave of the epidemic was plainly evident; this was the case of single wave countries, for instance, China and Australia for which $\Delta N_T=0$. The larger this number is, the worse the performance of the country. This number, divided by $2N_T$, lies in the range 0-0.5. With these two quantities, we then define the “Pandemic Response Index” as:

a quantity that lies in the range from 0-10, the higher values corresponding to better performance. This provides a quantitative and objective way of ranking the countries according to their performance. The results of this comparison and the relevant numbers that enter in the evaluation of the PRI are given in Table 2. We note that the classification is consistent with our initial selection of the countries considered here, as being those on which the disease had greater impact as measured by the number of infections per million, with arbitrarily chosen cutoffs in the ranges (smaller than 1000, between 1000 and 3000, and larger than 3000 per million). The only country that changes category based on the PRI value is Switzerland, which is raised to higher performance (average, see Table 2); this is a result of the fact that, although Switzerland had a relatively large number of cases per million (3565 cases per million), most of those occurred in the first wave, leaving a rather small

percentage for subsequent waves. This remark suggests that the PRI is indeed a finer tool for evaluating performance, rather than relying on crude categorizations like the one based on the number of infections per million with arbitrary cutoff values between categories.

Discussion

Principal Findings

Reported cases of COVID-19 infections in various countries show features that are both common and regular, which we interpret as successive waves of transmission. We present evidence for this interpretation, using both agent-based simulations and a multi-wave model to fit the infected population data for many countries and give representative examples. This evidence supports the hypothesis that the COVID-19 pandemic can be successfully modeled as a series of epidemic waves (subepidemics). We analyzed the data from 18 countries based on this hypothesis and present the relevant parameters of a simple analytical model that accurately represents the data. Based on this analysis, it is possible to infer to what extent the imposition of early social distancing measures has slowed the spread of the disease. This analysis provides an estimate of how much lower the number of infections could have been, if early and strict intervention measures had been

taken to stop the spread at the first wave, as actually happened for a handful of countries.

Comparison With Prior Work

Recent works have emphasized more realistic approaches of human behavior and mobility involving larger transmission jumps by incorporating power-law decay of spatial interaction among human contacts [16], punctuated outbreaks as the disease progresses from one community to the next [12], and border effects [23]. In this study, our agent-based simulations start with 4 country-wide initial seeds for the disease onset in the “virtual country,” thus approximating in a reasonable way the effect of longer jumps before the imposition of the intervention measures such as social distancing and lockdown. Nevertheless, the microscopic model can be extended to encompass network and community structures as well as border effects by incorporating weighted interactions among the agents in the simulation grid.

The multiple-wave FSIR model can identify multiple waves (subepidemics), specifying *each one* by only three parameters, t_1 , Δt , and N' , all of which are obtained by directly fitting the reported data of daily populations of infected individuals. Each of these parameters can be assigned a physical meaning, which help quantify certain generally held views; a detailed discussion of the meaning of these parameters can be found in [18]. Moreover, the quantitative picture that emerges from the values of these parameters produces a rather accurate picture of the severity of the epidemic in the various countries, and the effect of the intervention measures if and when any were taken.

A limitation of the original FSIR model is that it provides the extrapolation to future cases of infection as only a *lower limit*; this point has been discussed in an elegant mathematical analysis of the data by Fokas et al [17], highlighting the need for the inclusion of nonlinear terms in the underlying differential equations to capture the slow rate of the infected population decay. This is evident in the countries that have long passed the peak of the reported cases; the tail does not asymptote to a constant value, as the sigmoid (logistic) model predicts, but the number actually keeps growing at a slow rate. The multiple-wave FSIR mitigates this limitation of the original FSIR model; by modeling more accurately the wavy behavior of the infected population curve, it can provide a better fit to

the daily data and to the cumulative actual data, and a better estimate to the cumulative number of cases (N_T), as can be seen in all the cases we examined, see [Figures 5 and 6](#).

Limitations

The multiple-wave FSIR model may suffer from the fact that the number of infections dies off exponentially as the last wave does, a feature that appears unrealistic according to several other models that attempt to capture the long-term behavior [24–29]. Another limitation relates to the fact that in many cases, when Δt is estimated as an adjustable parameter, it tends to provide an aggregate fit, that is, an initial large subepidemic tends to be followed by a longer in time and smaller in peak intensity averaged wave, which is the sum of smaller subepidemics. This wave can be characterized as a temporary endemic wave according to the taxonomy of [13]. To improve the resolution of the model and enable it to specify the underlying smaller subepidemics, an epidemiologically reasonable value for Δt is necessary. Furthermore, caution must be exercised in interpreting the subepidemics because they may constitute a superposition of even smaller ones, as in the case of the United States, a country comprising 50 states with varied responses to the epidemic.

Conclusions

Multiple waves of transmission during infectious disease epidemics represent a major public health challenge. Our agent-based simulations encompassing strong social distancing measures show epidemics with multiple wave structures. The analysis of reported data from 18 countries supports the hypothesis that the COVID-19 pandemic can be successfully modeled as a series of epidemic waves (subepidemics). The main strength of the simulations and the models developed and used in this work is the simplicity and the insight they offer on how the disease is transmitted in a country and on quantifying the effect of the intervention measures of the disease dynamics. Based on the model's results, the construction of a PRI provides a finer tool for evaluating each country's performance, instead of relying on crude categorizations like the one based on the number of infections per million with arbitrary cutoff values between categories.
