Abstract

Background: Various enhanced patient instructions (EPIs) have been used for bowel preparation (BP) and our previous meta-analysis also demonstrated the efficacy of EPIs in increasing the colonic polyp and adenoma detection rates; however, the optimal method for adequate BP has not yet been developed.

Objective: We performed a network meta-analysis to determine the optimal instructions.

Methods: We searched for randomized controlled trials (RCTs) comparing the effectiveness of EPIs with each other or standard patient instructions (SPIs) for BP. We performed direct and Bayesian network meta-analyses for all instructions and used the GRADE (Grading of Recommendations Assessment, Development and Evaluation) criteria to appraise the quality of evidence.

Results: We included 23 RCTs (7969 patients) comparing 10 different instructions. In direct meta-analyses, most of the EPIs, except visual aids and mobile apps, increased the adequate preparation rate (APR). Network meta-analyses showed that additional explanations were superior to visual aids (odds ratio [OR] 0.35, 95% CI 0.19-0.59), telephone calls (OR 0.62, 95% CI 0.37-0.99), educational videos (OR 0.79, 95% CI 0.5-0.77), and mobile apps (OR 0.33, 95% CI 0.14-0.68) with low-to-high-quality evidence; newly designed booklets (OR 3.28, 95% CI 1.59-6.16), SMS text messaging (OR 2.33, 95% CI 1.28-3.91), telephone calls (OR 1.86, 95% CI 1.03-1.78), educational videos (OR 2.33, 95% CI 1.40-3.65), and social media applications (OR 2.42, 95% CI 1.4-3.93) were superior to visual aids and mobile apps with low-to-high-quality evidence. SMS text messaging, telephone calls, and social media applications increase adherence to and satisfaction with the BP regime. Social media applications reduce the risk of adverse events (AEs). Telephone calls and social media applications increase the polyp detection rate (PDR).

Conclusions: Newly designed booklets, telephone calls, educational videos, and social media applications can improve the quality of BP. Telephone calls and social media applications improve adherence to and satisfaction with the BP regime, reduce the risk of AEs, and increase the PDR.

KEYWORDS

colonoscopy; bowel preparation; patient instruction; systematic review; network meta-analysis

Introduction

Colorectal cancer ranks third among the most common cancers and second in terms of the incidence and cause of cancer-related mortality worldwide, with 1.8 million new cases and 0.88 million deaths in 2018 [1]. Colonoscopy has been regarded as the criterion standard approach for early detection and safe removal of colorectal lesions [2-4]. In particular, screening colonoscopy has been associated with decreased colorectal cancer incidence and mortality [2,5]. The quality of bowel preparation (BP) is an important contributor toward successful and safe colonoscopy [6]. However, approximately 18% to 30.5% inadequate BP has been reported in previous studies [7-9]. It is discouraging that inadequate BP is associated with decreased polyp detection rates (PDRs), increased risk of adverse events (AEs), prolonged working time, and increased medical expenditure [10,11].

Previous studies have determined several factors that can influence the quality of BP, such as appropriate dietary restrictions and proper administration of preparation solutions [12]. Of all the factors, adequate comprehension of the BP and colonoscopy details is a critical contributor to adequate BP [13]. Patients usually receive written booklets or verbal instructions from professionals before colonoscopy for details regarding BP and dietary restrictions, which are defined as standard patient instructions (SPIs) [14]. However, the effect of SPIs on improving the quality of BP is not enough [15]. Therefore, researchers and practitioners have been developing most of the enhanced patient instructions (EPIs) by including cartoon pictures, SMS text messaging, telephone calls, mobile apps, and social media applications to improve the quality of BP prior to colonoscopy [14].

Thus far, several traditional pairwise meta-analyses investigating the comparative efficacy between EPIs and SPIs for the quality of BP have been published, and they have demonstrated improved BP [13,14,16-18]. Moreover, our previous meta-analysis also demonstrated the efficacy of EPIs in increasing the PDR and adenomas detection rate (ADR) [19]. However, only 2 3-arm randomized controlled trials (RCTs) investigated the comparative efficacy of telephone calls or WeChat versus SMS text messaging for BP in patients receiving outpatient colonoscopy. It is still unclear which EPIs should preferably be used by decision makers for BP before colonoscopy. To address those issues that could not be addressed by traditional pairwise meta-analysis, network meta-analysis, which can simultaneously assess the comparative efficacy of multiple interventions, has been developed [20,21]. Therefore, we performed direct pairwise and Bayesian network meta-analyses combining direct and indirect evidence comparing the relative efficacy of all patient instructions to determine the optimal educational instructions for BP before colonoscopy. We also used the GRADE (Grading of Recommendations Assessment, Development and Evaluation) criteria to appraise the quality of evidence.

Methods

We conducted this systematic review and network meta-analysis in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [22] and reported all the outcomes according to the International Society for Pharmacoeconomics and Outcomes Research Task Force on Indirect Treatment Comparisons Good Research Practices [23]. No formal protocol for the present study has been published. We registered our systematic review on the INSPLAY (International Platform of Registered Systematic Review and Meta-analysis Protocols) platform, and the trial registration number is INPLASY2020120103.

Search Strategy

We constructed the search strategy with the assistance of an experienced medical librarian using full-text words and MeSH (Medical Subject Headings). We also refined the search strategy according to the specific requirements of each database. All potential RCTs comparing EPIs to each other or SPIs for BP were captured in PubMed, the Cochrane Central Register of Controlled Trials, and Embase until December 2019. The last search was updated in February 2020. Details of the search strategies used for the 3 targeted databases are presented in Multimedia Appendix 1.

Study Selection

We first excluded duplicate records through running the Finding Duplicate function embedded in EndNote (version X9, Clarivate Analytics). Then, we checked the titles and abstracts of the articles to exclude irrelevant articles. Next, we screened the full texts to further check the eligibility of all the remaining studies. The inclusion criteria were as follows: (1) patients: adult patients who were assigned to receive selective outpatient colonoscopy; (2) interventions: all EPIs or SPIs for BP; (3) outcomes: the quality of BP assessed with the adequate preparation rate (APR), adherence to instruction (AI), satisfaction with the BP solution, willingness to repeat the same BP solution, PDR, and AEs including abdominal discomfort, nausea and vomiting, and sleep disturbance; (4) study design: RCTs. Language restrictions were not imposed. The exclusion criteria included (1) animal studies and (2) conference abstracts without sufficient data or unpublished studies.

The eligibility was checked by 2 investigators (XT and HC) independently, and any divergences were resolved through the consensus principle. When no agreement could be reached, a third investigator (WQC) was consulted for determining the eligibility.

Data Extraction

Essential data including the leading author, year of publication, study design, country where the study was conducted, age and sex of the patients, details of the BP regime, details of the instructions used, and outcomes of interest were extracted by 2 independent investigators (LJY and XT) using a data extraction sheet designed in advance. EPIs were classified as additional explanations, visual aids, new visual aids, newly designed booklets, SMS text messages, telephone calls, mobile apps, social media applications, and educational videos. The

classification and comparison of EPIs are documented in Multimedia Appendix 2.

The primary outcome of the present meta-analysis was the comparative efficacy of EPIs for improving the quality of BP before colonoscopy, which was assessed with respect to the APR. The secondary outcome was the comparative efficacy of EPIs with respect to the AI, satisfaction with the BP solution, willingness to repeat the same BP solution, PDR, and AEs.

Quality Assessment

We assigned 2 investigators to independently assess the risk of bias of each eligible study with the Cochrane risk of bias assessment tool [24]. We labeled each study as having low, unclear, or high risk of bias according to the match between the actual information and the following assessment criteria: random sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective reporting, and other biases. A third investigator (WQC) was consulted to solve any discrepancies.

Statistical Analysis

In traditional pairwise meta-analysis, we calculated the pooled odds ratio (OR) with 95% CI to express the dichotomous data [25]. We performed Cochran Q tests to qualitatively assess the heterogeneity and used the I^2 statistic to quantitatively estimate the level of heterogeneity [26]. All pairwise meta-analyses were performed based on the random-effect model because this model simultaneously incorporates within- and between-study heterogeneities. Publication bias is assessed using a funnel plot if the accumulated number of eligible studies for individual outcomes was more than 10 [27], and an asymmetry suggests the presence of publication bias [28]. Direct meta-analysis was conducted using Review Manager 5.3 (Cochrane Collaboration).

After completing direct meta-analysis, we conducted random-effect network meta-analyses to estimate all the relative effects using Markov chain Monte Carlo methods in OpenBUGS 3.2.3 (MRC Biostatistics Unit) following the methods described by Lu and Ades [29,30]. We used the initial value that was automatically generated from the software to fit the model [31]. To achieve convergence, we performed each Markov chain Monte Carlo method with 50,000 iterations and 20,000 burn-ins. We drew the comparison-adjusted funnel plot to assess the small-study effects when the number of studies included in one comparison pair exceeded 10 [32].

We assessed the probability that each instruction was the most efficacious one for improving quality of BP, the second best, the third best, and so on by calculating the OR for each instruction compared with an arbitrary common control group and counting the number of iterations of the Markov chain in which each instruction had the highest OR, the second highest OR, and so on [33].

Sensitivity Analysis

We designed several sensitivity analyses to evaluate the robustness of the summarized findings according to the following principles: (1) BP assessment scale (excluding studies in which uncommon scales were used except for the Boston Bowel Preparation Scale [BBPS], Ottawa Bowel Preparation Scale [OBPS], and Aronchick Bowel Preparation Scale [ABPS]); (2) risk of bias (excluding studies with high risk); (3) study design (excluding studies with multicenter design).

Quality of Evidence

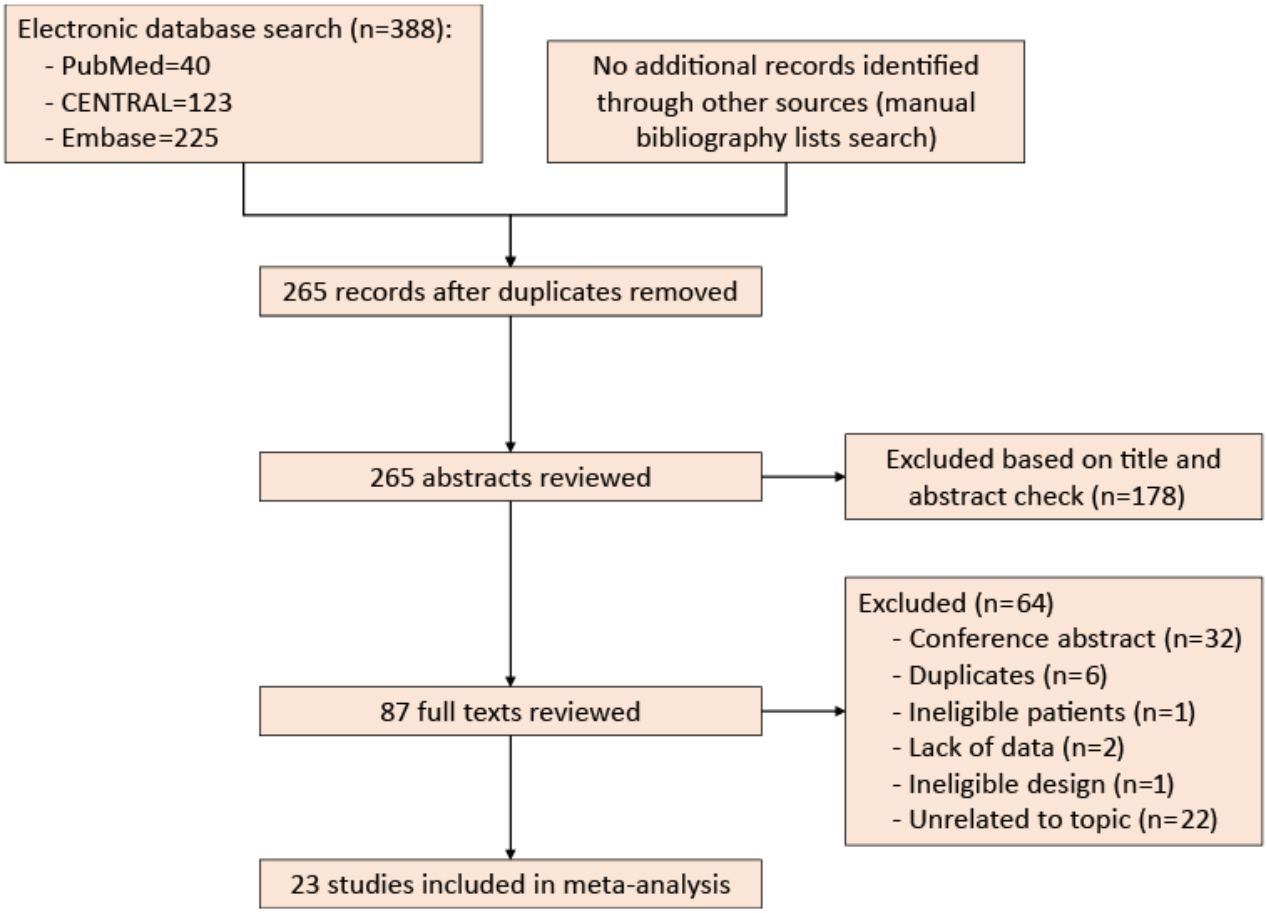
We rated the quality of evidence of the primary outcomes with the GRADE working group approach [34,35]. In this approach, the quality of direct evidence based on RCTs would be first rated as high and the level could be reduced to moderate, low, or very low according to 5 domains, including risk of bias, indirectness, imprecision, inconsistency, and publication bias [35]. The quality of indirect evidence was consistent with the level of the lowest rating of the 2 pairwise estimates that contribute as first-order loops to the indirect estimates and imprecision or intransitivity can further reduce the level [35]. If the assumption of coherence between direct and indirect estimates was confirmed, then the higher one of their levels would be assigned to the results from network meta-analysis [35].

Results

Study Selection

Figure 1 presents the schematic flowchart of the study selection process. From a total of 388 unique studies identified using the search strategy, we included 23 RCTs in this network meta-analysis [36-58]. Among these, 1 RCT involving a newly designed educational booklet was excluded (because of inpatient enrollment) [59]. Further, 1 RCT comparing modified BP protocols (multimedia education) to standard BP protocols was excluded owing to the design implementation using historical control data [60]. Moreover, 2 RCTs comparing educational videos or additional explanations with SPIs were excluded owing to the lack of essential data [61,62].

Figure 1. Flow diagram showing retrieval and selection of literature. CENTRAL: Cochrane Central Register of Controlled Trials.



Study Characteristics

The basic characteristics of the patients who were included in all eligible studies are summarized in Table 1. We have also documented the characteristics of the eligible studies in Multimedia Appendix 3. The studies were published between 2009 and 2019 [36-56,58]. The sample sizes of the individual studies ranged from 92 to 1018 with a total of 7969 participants. Among the 23 studies included, 2 were designed as 3-arm trials [41,55]; among these, Lee et al [41] compared the efficacy between SMS text messaging, telephone calls, and SPIs, and Wang et al compared the efficacy between SMS text messaging, social media applications and SPIs [55]. All other studies had 2-arm designs [36-40,42-54,56,58]. Further, 2 studies had multicenter designs [49,54]. All the studies reported the quality of BP assessed using the BBPS (9 trials) [36,41,45,50,53-57], OBPS (8 trials) [39,40,42,43,47-49,52], ABPS (4 trials) [37,38,51,58], Harefield Cleansing Scale (1 trial) [44], and Universal Preparation Assessment Scale (1 trial) [46].

Table 1. Basic characteristics of the patients included in studies on educational instructions for bowel preparation before colonoscopy.

Study	Country	Comparison	Sample size (male vs female participants)	Age (years, male vs female participants), mean (SD)	Male vs female participants (%)	Outcomes
Back et al 2018 [36]	Korea	Educational videos vs SPIs[a] (verbal instructions and instructional leaflets)	283 (139 vs 144)	55.4 (12.8) vs 57.6 (13.1)	53.4 vs 56.2	APR[b], AI[c], and SE[d]

[a]SPIs: standard patient instructions.
[b]APR: adequate preparation rate.
[c]AI: adherence to instruction.
[d]SE: satisfaction with the education.
[e]CIT: cecal intubation time.
[f]WT: withdrawal time.
[g]PDR: polyp detection rate.
[h]AEs: adverse events.
[i]n.r.: not reported.
[j]WRBP: willingness to repeat the same BP solution.
[k]ADR: adenomas detection rate.
[l]SDT: sleep disturbance.
[m]ICIBP: incomplete colonoscopy due to inadequate bowel preparation.
[n]CIR: cecal intubation rate.

Quality Assessment

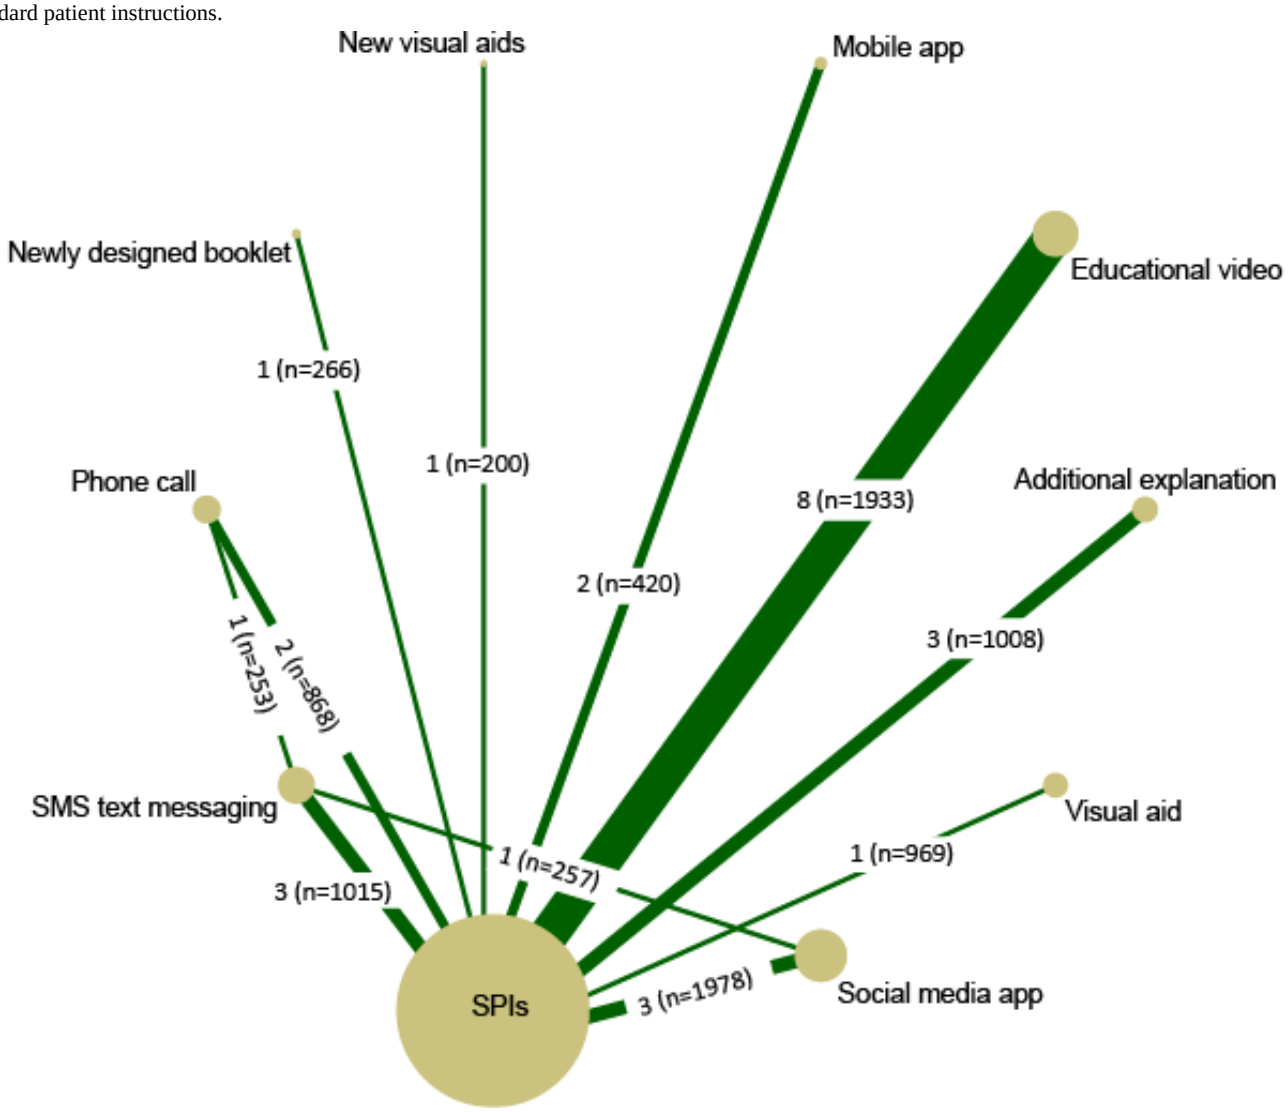
The overall and study-level quality assessments are outlined in Figure S1 of Multimedia Appendix 4. Overall, most of the studies (18/23, 78.3%) appeared to have been at low-to-moderate risk of bias, with 4 (17.4%) not reporting the details of generating the random sequence [45,47,49,56] and 8 (34.8%) not reporting the details for allocation concealment [36,38,45-48,53,57]. Further, 10 (43.5%) did not report the details of blinding the outcome assessor [39-41,43-45,47,51,53,54]. More importantly, 4 studies (17.4%) did not blind the assessors and were rated to be at high risk of bias [38,46,48,49]. In addition, 4 (17.4%) were rated to be at high risk of attrition bias [38,46,49,53]. Other bias sources were not detected in all studies.

Direct Treatment Effects

Primary Outcomes

Figure 2 demonstrates the available direct comparisons and network meta-analyses. Compared to SPIs, additional explanations (3 RCTs; OR 3.34, 95% CI 1.45-7.69), newly designed booklets (1 RCT; OR 3.63, 95% CI 2.15-6.12), new visual aids (1 RCT; OR 3.05, 95% CI 1.21-7.68), SMS text messaging (3 RCTs; OR 2.77, 95% CI 1.86-4.14), telephone calls (2 RCTs; OR 2.64, 95% CI 1.03-6.74), educational videos (8 RCTs; OR 2.82, 95% CI 1.83-4.35), and social media applications (3 RCTs; OR 2.70, 95% CI 1.75-4.18) adequately increased the BP rate, but not visual aids (1 RCT; OR 1.18, 95% CI 0.78-1.8) and mobile apps (2 RCTs; OR 1.85, 95% CI 0.15-23.24). Head-to-head meta-analysis showed that telephone calls (1 RCT; OR 1.25, 95% CI 0.33-4.77) or social media applications (1 RCT; OR 1.32, 95% CI 0.63-2.78) were not superior to SMS messaging. Significant heterogeneity was observed in trials comparing additional explanations (I^2=79%), telephone calls (I^2=60%), educational videos (I^2=62%), and mobile apps (I^2=68%). All the pooled results are delineated in Figure S2 in Multimedia Appendix 4.

Figure 2. Evidence network for adequate preparation rate. The numbers outside and inside parentheses refer to the number of trials and the total number of participants in these trials, respectively, and the thickness of the connecting lines corresponds to the number of trials between comparators. SPIs: standard patient instructions.



Secondary Outcomes

Compared to SPIs, additional explanations (1 RCT; OR 8.38, 95% CI 3.73-18.84), SMS text messaging (2 RCTs; OR 7.04, 95% CI 2.79-17.81), telephone calls (2 RCTs; OR 4.54, 95% CI 2.92-7.05), and social media applications (3 RCTs; OR 3.88, 95% CI 2.05-7.35) are associated with improved AI, but not educational videos (1 RCT; OR 3.16, 95% CI 0.99-10.06) or mobile apps (2 RCTs; OR 1.26, 95% CI 0.73-2.18). Head-to head meta-analysis showed that telephone calls (1 RCT; OR 1.25, 95% CI 0.33-4.77) and social media applications (1 RCT; OR 0.86, 95% CI 0.3-2.45) were not superior to SMS text messaging. Significant heterogeneity was observed in trials comparing social media applications (I^2=63%) to SPIs. All the pooled results are delineated in Figure S3 in Multimedia Appendix 4.

Compared to SPIs, social media applications (1 RCT; OR 2.56, 95% CI 1.35-4.87) and telephone calls (1 RCT; OR 1.85, 95% CI 1.01-3.41) indicated improved satisfaction with the

instructions but not SMS text messaging (2 RCTs; OR 1.92, 95% CI 0.94-4.05) or educational videos (1 RCT; OR 1.47, 95% CI 0.69-3.12). Head-to-head meta-analysis showed that telephone calls (1 RCT; OR 1.22, 95% CI 0.73-2.06) and social media applications (1 RCT; OR 0.95, 95% CI 0.52-1.72) were not superior to SMS text messaging. All the pooled results are delineated in Figure S4 in Multimedia Appendix 4.

Compared to SPIs, social media applications (3 RCTs; OR 2.16, 95% CI 1.51-3.09) and mobile apps (1 RCT; OR 2.48; 95% CI 1.22-5.04) were associated with improved willingness to repeat the same BP regime, but not additional explanations (1 RCT; OR 2.04, 95% CI 0.37-11.35), SMS text messaging (2 RCTs; OR 1.24, 95% CI 0.57-2.71), or telephone calls (2 RCTs; OR 1.58, 95% CI 0.67-3.69). Head-to-head meta-analysis showed that telephone calls (1 RCT; OR 1.44, 95% CI 0.61-3.37) and social media applications (1 RCT; OR 0.99, 95% CI 0.44-2.23) were not superior to SMS text messaging. Significant heterogeneity was observed in trials comparing telephone calls (I^2=69%) to SPIs. All the pooled results are delineated in Figure S5 in Multimedia Appendix 4.

Compared to SPIs, telephone calls (2 RCTs; OR 1.85, 95% CI 1.36-2.5) were associated with an increased PDR, but not visual aids (1 RCT; OR 0.99, 95% CI 0.76 -1.28), new visual aids (1 RCT; OR 0.99, 95% CI 0.57-1.73), SMS text messaging (3 RCTs; OR 1.07, 95% CI 0.81-1.41), educational videos (5 RCTs; OR 1.05, 95% CI 0.72-1.54), or social media applications (1 RCT; OR 1.25, 95% CI 0.65-2.41). Head-to-head meta-analysis showed that telephone calls (1 RCT; OR 1.61, 95% CI 0.97-2.68) were not superior to SMS text messaging. Significant heterogeneity was observed in the trials comparing educational videos (I^2=52%) to SPIs. All the pooled results are delineated in Figure S6 in Multimedia Appendix 4.

Compared to SPIs, social media applications were associated with reduced risk of abdominal discomfort (3 RCTs; OR 0.67, 95% CI 0.5-0.9), but not visual aids (1 RCT; OR 0.9, 95% CI 0.63-1.28), SMS text messaging (2 RCTs; OR 0.67, 95% CI 0.4-1.12), telephone calls (2 RCTs; OR 0.94, 95% CI 0.65-1.35), or educational videos (1 RCT; OR 1.01, 95% CI 0.37-2.76). Head-to-head meta-analysis showed that telephone calls (1 RCT; OR 0.83, 95% CI 0.47-1.48) or social media applications (1 RCT; OR 1.22, 95% CI 0.61-2.45) were not superior to SMS text messaging. All the pooled results are delineated in Figure S7 in Multimedia Appendix 4.

Compared to SPIs, social media applications indicated reduced risk of nausea and vomiting (3 RCTs; OR 0.7, 95% CI 0.55-0.88), but not visual aids (1 RCT; OR 1.27, 95% CI 0.67-2.41), SMS text messaging (2 RCTs; OR 0.64, 95% CI 0.27-1.53), telephone calls (2 RCTs; OR 0.8, 95% CI 0.56-1.13), or educational videos (1 RCT; OR 0.49, 95% CI 0.14-1.66). Head-to-head meta-analysis showed that telephone calls (1 RCT; OR 0.55, 95% CI 0.33-0.91) were superior to SMS text messaging, but not social media applications (1 RCT; OR 1.19, 95% CI 0.7-2.03). Significant heterogeneity was observed in the trials comparing SMS text messaging (I^2=74%) to SPIs. All the pooled results are delineated in Figure S8 in Multimedia Appendix 4.

Compared to SPIs, SMS text messaging (2 RCTs; OR 1.1, 95% CI 0.71-1.71), telephone calls (2 RCTs; OR 0.69, 95% CI 0.41-1.16), educational videos (1 RCT; OR 2.32, 95% CI 0.78-6.86), and social media applications (3 RCTs; OR 0.62, 95% CI 0.35-1.10) were not associated with increased risk of sleep disturbance. Head-to-head meta-analysis showed that telephone calls (1 RCT; OR 1.08, 95% CI 0.65-1.8) and social media applications (1 RCT; OR 1.08, 95% CI 0.66-1.77) were not superior to SMS text messaging. Significant heterogeneity was observed in the trials comparing telephone calls (I^2=55%) and social media applications (I^2=85%) to SPIs. All the pooled results are delineated in Figure S9 in Multimedia Appendix 4.

Network Meta-Analysis and Quality Assessment

Primary Outcomes

For the primary outcome of APR, the results of direct and indirect comparisons were largely similar with overlapping CIs, although differences were observed in the effect size and statistical significance in some cases, as shown in Table 2. In the network meta-analysis, we calculated the mixed-effect estimate as the weighted average of the direct (where available) and indirect treatment effects. In this analysis, when compared with SPIs, additional explanations (OR 3.56,95% CI 2.46-5; moderate quality of evidence), newly designed booklets (OR 3.81, 95% CI 2.19-6.3; very low quality of evidence), new visual aids (OR 3.61, 95% CI 1.29-8.63; very low quality of evidence), SMS text messaging (OR 2.7, 95% CI 1.85-3.86; high quality of evidence), telephone calls (OR 2.15, 95% CI 1.49-3.02; moderate quality of evidence), educational videos (OR 2.7, 95% CI 2.12-3.41; low quality of evidence), and social media applications (OR 2.81, 95% CI 2.07-3.73; high quality of evidence) increased the APR in patients undergoing colonoscopy, but not visual aids (OR 1.21, 95% CI 0.78-1.81; moderate quality of evidence) and mobile apps (OR 1.15, 95% CI 0.53-2.19; very low quality of evidence), as observed in Table 2.

Network meta-analysis demonstrated that visual aids (OR 0.35, 95% CI 0.19-0.59; high quality of evidence), telephone calls (OR 0.62, 95% CI 0.37-0.99; high quality of evidence), educational videos (OR 0.79, 95% CI 0.5-0.77; moderate quality of evidence), and mobile apps (OR 0.33, 95% CI 0.14-0.68; low quality of evidence) were inferior to additional explanations; newly designed booklets (OR 3.28, 95% CI 1.59-6.16; low quality of evidence), SMS text messaging (OR 2.33, 95% CI 1.28-3.91; high quality of evidence), telephone calls (OR 1.86, 95% CI 1.03-1.78; high quality of evidence), educational videos (OR 2.33, 95% CI 1.4-3.65; moderate quality of evidence), and social media applications (OR 2.42, 95% CI 1.4-3.93; high quality of evidence) were superior to visual aids; mobile apps were inferior to newly designed booklets (OR 0.32, 95% CI 0.12-0.7; low quality of evidence) or SMS text messaging (OR 0.44, 95% CI 0.18-0.9; low quality of evidence); social media applications (OR 0.43, 95% CI 0.19-0.85; low quality of evidence) were inferior to educational videos, and mobile apps (OR 0.42, 95% CI 0.18-0.83; low quality of evidence) were inferior to social media applications in increasing the APR.

Table 2. Pooled summary estimates and quality of evidence derived from direct and indirect estimates and network meta-analysis informing on comparative efficacy of educational interventions for improving quality of bowel preparation before colonoscopy[a].

[a]The italicized values indicate statistically significant differences.

[b]OR: odds ratio.

[c]One was rated with high risk.

[d]n.e.: not estimable.

[e]N/A: not applicable.

[f]Only one was captured.

[g]Point estimates between two studies were conflicting.

[h]One with only 266 participants was included.

[i]One with only 200 participants was included.

[j]A wide 95% CI was generated.

[k]Two were rated with high risk.

[l]One with only 257 participants was included.

For the primary outcome of APR, newly designed booklets had the highest probability of being ranked the best (85.8%), followed by additional explanations (80.6%), new visual aids (71.6%), social media applications (64.6%), educational videos (61.0%), SMS text messaging (60.4%), telephone calls (40.9%), visual aids (15.9), mobile apps (12%), and SPIs (7.2%), as shown in Figure S10 in Multimedia Appendix 4.

Secondary Outcomes

Network meta-analysis showed that when compared to SPIs, additional explanations (OR 9.84, 95% CI 4.13-21.78), SMS text messaging (OR 6.99, 95% CI 3.57-12.92), telephone calls (OR 8.48, 95% CI 3.08-7.42), educational videos (OR 4.24, 95% CI 1.12-12.61), and social media applications (OR 3.76, 95% CI 2.7-5.13) increased adherence to the preparation regime, but not mobile apps (OR 1.33, 95% CI 0.74-2.2), as shown in Table 3. Additional explanations significantly increased adherence to the preparation regime when compared to social media applications (OR 0.46, 95% CI 0.16-0.96) or mobile apps (OR 0.16, 95% CI 0.05-0.37). Moreover, SMS messaging (OR 0.21, 95% CI 0.08-0.44), telephone calls (OR 0.29, 95% CI 0.13-0.54), and social media applications (OR 0.36, 95% CI 0.18-0.65) significantly increased adherence to the preparation regime compared to mobile apps.

Table 3. Pooled relative risks of secondary outcomes based on combined direct and indirect evidence from Bayesian network meta-analysis with different educational instructions in patients undergoing colonoscopy[a].

Education instruction	Adherence to instruction	Satisfaction with BP_b	Willingness to repeat	Abdominal discomfort	Nausea and vomiting	Sleep disturbance	Polyp detection rate

[a]The italicized values indicate statistically significant differences.

[b]BP: bowel preparation.

[c]N/A: not applicable.

The analysis also demonstrated that besides educational videos, SMS text messaging (OR 1.79, 95% CI 1.22-2.55), telephone calls (OR 1.97, 95% CI 1.19-3.12), and social media applications (OR 2.03, 95% CI 1.17-3.34) indicated satisfaction with the BP regime when compared to SPIs.

Network meta-analysis also showed that when compared to SPIs, social media applications (OR 2.22, 95% CI 1.77-2.75) or mobile apps (OR 2.73, 95% CI 1.27-5.34) were associated with increased willingness to repeat the same BP regime. Social media applications (OR 1.69, 95% CI 1.1-2.48) significantly increased the willingness to repeat the same BP regime when compared to telephone calls.

Furthermore, telephone calls significantly increased the PDR when compared to SPIs (OR 1.86, 95% CI 1.4-2.44) and SMS messaging (OR 1.71, 95% CI 1.2-2.36). Social media applications (OR 1.73, 95% CI 1.01-2.77) were associated with an increased PDR compared to educational videos.

The analysis also showed that besides social media applications (OR 0.69, 95% CI 0.54-0.85), no other instructions were associated with decreased abdominal discomfort, when compared to SPIs. SMS text messaging (OR 0.66, 95% CI 0.46-0.9) or social media applications (OR 0.69, 95% CI 0.54-0.85) were superior to SPIs in reducing the risk of nausea and vomiting. Telephone calls or social media applications were associated with reduced risk of sleep disturbance but not SMS

text messaging or educational videos, when compared to SPIs. Moreover, SMS text messaging (OR 3.68, 95% CI 1.01-10.24) or telephone calls (OR 4.24, 95% CI 1.17-11.87) were also superior to educational videos in improving sleep disturbance. Social media applications were also superior to SMS text messaging (OR 0.68, 95% CI 0.47-0.95) or educational videos (OR 0.26, 95% CI 0.07-0.64) in reducing the risk of sleep disturbance

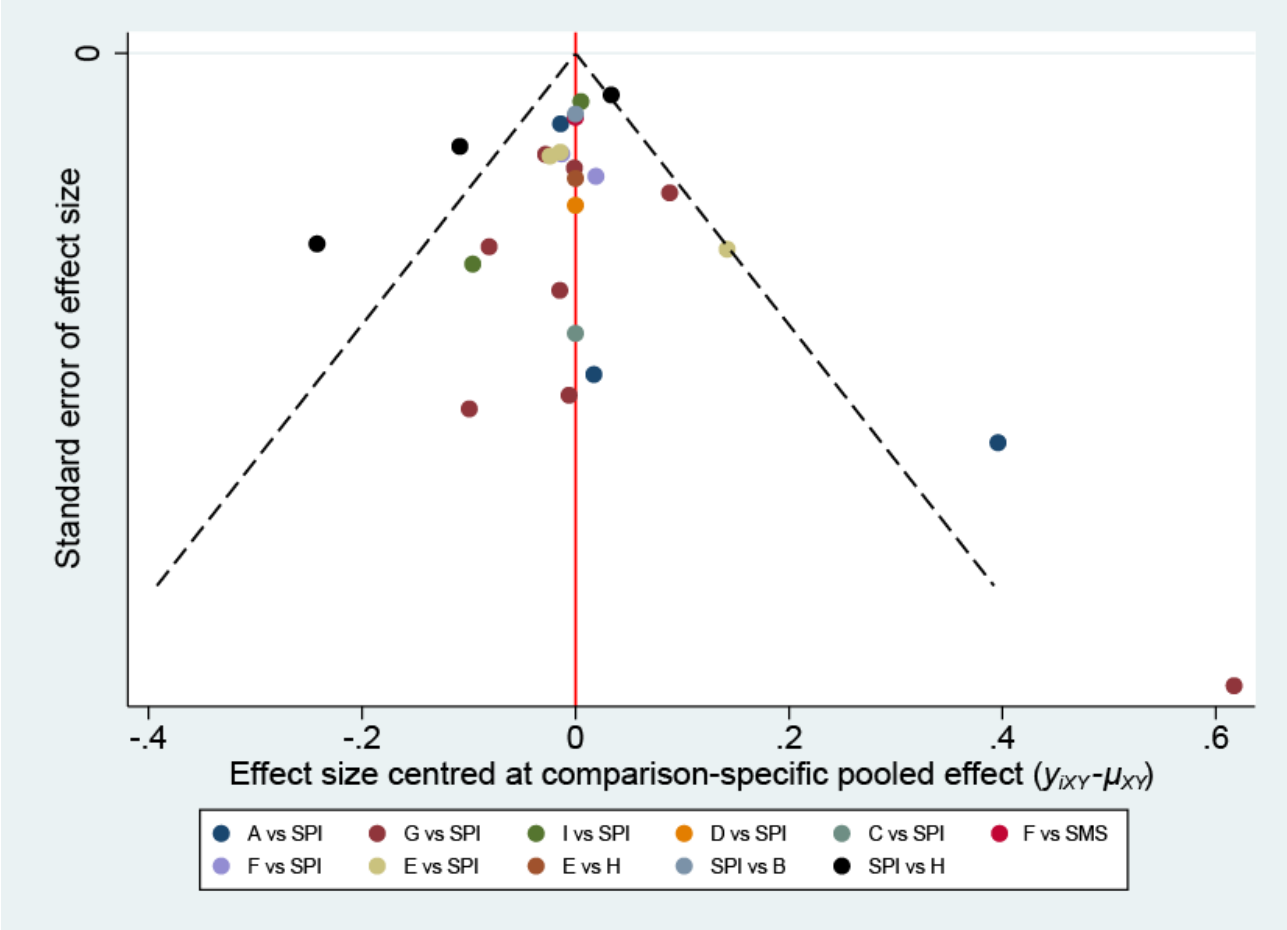
Sensitivity Analysis

Results from multiple prespecified sensitivity analyses are presented in Multimedia Appendix 5. Overall, for the primary outcome, the results were largely similar to the main analysis in the sensitivity analyses based on the (1) BP assessment scale (excluding studies in which uncommon scales were used except for BBPS, OBPS, and ABPS), (2) risk of bias (excluding studies with high risk), and (3) study design (excluding studies with multicenter designs). After excluding the studies using uncommon BP assessment scales, new visual aids (OR 3.16, 95% CI 1.02-8.01) were statistically superior to visual aids or mobile apps (OR 0.27, 95% CI 0.06-0.75) in increasing the APR; the difference (OR 0.49, 95% CI 0.2-1.03) between mobile apps and social media applications was not significant in increasing adherence to the BP regime. Excluding the studies with high risk also showed that telephone calls (OR 0.63, 95% CI 0.37-1.01) and educational videos (OR 0.79, 95% CI 0.5-1.19) were not inferior to additional explanations in increasing the APR. Excluding studies using uncommon preparation assessment scales showed that social media applications were not superior to mobile apps (OR 0.49, 95% CI 0.2-1.03) in increasing adherence to the BP regime. Furthermore, excluding the studies with high risk revealed that the difference (OR 1.59, 95% CI 0.88-2.66) between mobile apps and social media applications in increasing the PDR was not significant.

Publication Bias and Network Coherence

We did not find evidence of publication bias based on the funnel plot asymmetry in Figure 3, although the number of studies included in each comparison was very small, thereby making the available methods for evaluating publication bias somewhat unreliable. There were no significant differences between direct and indirect estimates where both were available, and the 2 methods had overlapping CIs for all interventions, as observed in Table 2.

Figure 3. Comparison-adjusted funnel plot for adequate preparation rate. The vertical axis represents the standard error of the effect size. The horizontal axis indicates the effect size centered at the comparison-specific pooled effect. The symmetrical funnel plot indicates the absence of publication bias. PDR: polyp detection rate; EPI: enhanced patient instruction; SPI: standard patient instruction; APR: adequate preparation rate; A: additional explanation; B: visual aid; C: newly designed booklet; D: new visual aids; E: SMS text messaging; F: telephone call; G: educational video; H: social media application; I: mobile app.



Discussion

Several meta-analyses [13,14,16-18] examined the quality of BP, colonic outcomes, and AEs including abdominal discomfort, nausea and vomiting, and sleep disturbance by comparing EPIs and SPIs. They concluded that EPIs are more effective and safer techniques for improving the quality of BP before colonoscopy. However, they did not completely explain which instruction is superior among the various EPIs because their analyses were based solely on direct comparisons between 2 given techniques. Our network meta-analysis of 23 RCTs involving 7969 patients is the first study that comprehensively analyzes direct and indirect evidence in EPIs for BP prior to colonoscopy.

In this systematic review and network meta-analysis, we made several key observations: (1) SMS text messaging and social media applications increase the APR, with high confidence in the estimates; additional explanations and telephone calls improve the APR with moderate confidence in the estimates; educational videos, newly designed booklets, and new visual aids also increase the APR but with low-to-very-low confidence in the estimates. (2) Based on high-to-moderate-quality evidence, additional explanations offer significant advantages over visual aids, telephone calls, and educational videos, but not SMS text messaging and social media applications; additional explanations are also superior to mobile apps but not to newly designed booklets and new visual aids, although the quality of evidence ranges from low to very low. (3) SMS text messaging, telephone calls, social media applications, and educational videos offer significant advantages over visual aids for increasing the APR, based on moderate-to-high-quality evidence; newly designed booklets also increase the APR with low-quality evidence. (4) According to low-quality evidence, newly designed booklets, SMS text messaging, educational videos, and social media applications significantly increase the APR but not new visual aids and telephone calls when compared to mobile apps. Overall, we observed that newly designed booklets had the highest probability of being ranked the best (for increasing APR), followed by additional explanations, new visual aids, social media applications, educational videos, SMS text messaging, telephone calls, and visual aids. (5) SMS text messaging, telephone calls, and social media applications increase adherence to and satisfaction with the BP regime; social media applications are associated with decreased risk of AEs; telephone calls or social media applications increase the PDR. It should be noted that we analyzed an inadequate number of eligible studies, and additional studies are warranted.

The quality of BP is the metric to determine if colonoscopy is successful and safe [63]. In this regard, 2 studies investigated the comparative efficacy of telephone calls and social media applications (WeChat) compared to SMS text messaging for BP and colonic outcomes. Lee and colleagues found no significant difference in the quality of BP between the telephone call and SMS text messaging groups, which is consistent with our finding (OR 0.82, 95% CI, 0.48-1.31; moderate quality evidence). However, the finding of Wang et al conflicts with the finding in the present study (OR 1.07, 95% CI 0.67-1.62; high quality of evidence), wherein social media applications are superior to SMS text messaging in increasing the APR. As a critically important quality metric of colonoscopy [63,64], the PDR was also assessed in these 2 studies, where no differences between the telephone call or social media application, and SMS text messaging groups were detected. However, our study demonstrates that telephone calls are associated with an increased PDR when compared to SMS text messaging (OR 1.71, 95% CI 1.2-2.36). Moreover, only 1 study with a small sample size was performed to compare telephone calls or social media applications to SMS text messaging. However, more studies performing indirect comparisons were included in our study to calculate the combined estimates. Further, this finding was supported by moderate- or high-quality evidence in our study.

The strengths of our analyses include the comprehensive and simultaneous assessment of the relative efficacy of all EPIs for BP prior to colonoscopy. Given the limited comparative effectiveness studies, it remains difficult for patients and physicians to make informed decisions about which instructions are most effective for improving the quality of BP. We used the GRADE methodology [34,35] to assess the quality of evidence for this network meta-analysis, which can be directly applied in guideline development.

However, there are certain limitations associated with direct comparative effectiveness related to network analyses and individual studies, which merit further discussion. First, there is a paucity of studies. Second, network meta-analysis may be vulnerable to misinterpretation. The biggest threat to the validity of network meta-analysis is conceptual heterogeneity, wherein there are considerable differences among the participants, interventions, background treatments, and outcome assessments, thus limiting the comparability of trials. It assumes that patients enrolled in all the included studies could have been sampled from the same theoretical population [20,35]. Although there were subtle differences in the patients (proportion of patients having undergone colonoscopy previously and those undergoing screening colonoscopy, diagnostic colonoscopy, or surveillance colonoscopy), BP solutions (such as polyethylene glycol [PEG] alone, PEG plus prokinetic agent, and low or standard doses), solution administration methods (split or single dose), and dietary restrictions (low residue, clear liquid, or low fiber), we tried to minimize this conceptual heterogeneity by performing multiple sensitivity analyses, including excluding trials using uncommon preparation assessment scales with high risk or multicenter design; the overall findings were unchanged, suggesting the robustness of these analyses. Third, the ranking probabilities may be challenging to interpret and do not always imply a clinically important difference. However, instead of focusing only on the summaries of the effect estimates, we used GRADE to rate the overall quality of evidence considering the risk of bias, imprecision, indirectness, inconsistency, and other biases for rating the confidence in the estimates [35].

There were similar limitations in the individual studies, which also undermine the strength of the meta-analysis. Most studies focused on the quality of BP, with a limited number of studies on colonic outcomes. BP-related AEs were poorly reported, limiting the assessments regarding the benefits of instructions; hence, a thorough assessment of risk-benefit profiles could not be performed. Studies were also at risk of detection bias with

suboptimal reporting of the blinding to assessor outcomes. Various dietary restrictions were imposed in different eligible studies; however, previous meta-analyses have demonstrated no difference between low residues and clear liquids [12,65], and thus, sensitivity analysis was not designed according to these aspects. Although BP solutions with different doses were used in the included studies, we did not design the subgroup or sensitivity analysis according to the dose of the BP solution because no significant difference between low and traditional doses was confirmed in our meta-analysis [6]. Split doses proved beneficial compared to single doses for improving BP [66] and increasing the PDR and ADR [67]; however, the insufficient number of eligible studies poses limitations for designing further sensitivity analyses. Moreover, 5 BP assessment scales were used in all the eligible studies; thus, we performed a sensitivity analysis to examine the robustness of the pooled results through excluding studies in which uncommon scales were used and found that most of the results were unchanged.

Despite these limitations, our network meta-analysis provides a better understanding regarding the comparative efficacy of EPIs for BP prior to colonoscopy. Newly designed booklets, telephone calls, educational videos, and social media applications can increase the quality of BP. Telephone calls or social media applications may be associated with improved adherence to and satisfaction with the BP regime, decreased risk of AEs, or an increased PDR.

Acknowledgments

This study was supported by the Medical Research Project which was jointly approved by the Chongqing Science and Technology Bureau and Health Commission of Chongqing Municipal City (approval number: 2020MSXM064). We also sincerely appreciate all the authors who performed the studies included in the network meta-analysis performed in this study.

Abstract

Background: Although relatively new, digital health interventions are demonstrating rapid growth because of their ability to facilitate access and overcome issues of location, time, health status, and most recently, the impact of a major pandemic. With the increased uptake of digital technologies, digital health has the potential to improve the provision of supportive cancer care.

Objective: This systematic review aims to evaluate digital health interventions for supportive cancer care.

Methods: Published literature between 2000 and 2020 was systematically searched in MEDLINE, PubMed, Embase, PsycINFO, Cochrane Central Register of Controlled Trials, and Scopus. Eligible publications were randomized controlled trials of clinician-led digital health interventions to support adult cancer patients. The interventions included were determined by applying a digital health conceptual model. Studies were appraised for quality using the revised Cochrane risk of bias tool.

Results: Twenty randomized controlled trials met the inclusion criteria for the analysis. Interventions varied by duration, frequency, degree of technology use, and applied outcome measures. Interventions targeting a single tumor stream, predominantly breast cancer, and studies involving the implementation of remote symptom monitoring have dominated the results. In most studies, digital intervention resulted in significant positive outcomes in patient-reported symptoms, levels of fatigue and pain, health-related quality of life, functional capacity, and depression levels compared with the control.

Conclusions: Digital health interventions are helpful and effective for supportive care of patients with cancer. There is a need for high-quality research. Future endeavors could focus on the use of valid, standardized outcome measures, maintenance of methodological rigor, and strategies to improve patient and health professional engagement in the design and delivery of supportive digital health interventions.

KEYWORDS

digital health; telehealth; eHealth; neoplasm; supportive care; systematic review; mobile phone

Introduction

Background

Approximately 18.1 million new cancer cases and 9.6 million cancer-related deaths occurred globally in 2018 [1]. The rising tide of cancer diagnoses in many developed countries has been attributed to both population aging and the increasing prevalence of primary risk factors, including physical inactivity, obesity, and metabolic disease [1,2]. As the cancer population continues to grow, there is an urgent need to improve supportive care services [2].

Supportive care focuses on assisting people with cancer and their families to cope with the disease and its treatment [3]. The management of cancer treatment-related symptoms and side effects and the maintenance of health-related quality of life from early diagnosis to end-of-life are key aims of supportive cancer care [3,4]. Supportive care interventions vary and may involve multidisciplinary team support, including doctors, nurses, pharmacists, and allied health professionals [5]. Recently, a shared follow-up approach between primary and secondary providers has been promoted to successfully meet increasing demands for survivorship care [6,7], as innovative methods for long-term cancer care are constantly needed [2].

There have been ongoing attempts to improve access to supportive care cancer services through the use of digital health technology [8]. Digital health interventions, with telemedicine as its oldest form dating back to the 1920s, have been increasing dramatically in recent years [9]. The terms *digital health* and *eHealth* are frequently used interchangeably, with numerous varied definitions. Eysenbach [10] defined eHealth as *an emerging field in the intersection of medical informatics, public health, and business, referring to health services and information delivered or enhanced through the internet and related technologies*. Elbert [11] and McLean et al [12] assert 3 key elements of digital health: (1) data obtained from the patient, (2) electronic transfer of data over a distance, and (3) patient-tailored feedback from a health care professional. Furthermore, a recent conceptual model proposed by Shaw et al [13] acknowledges the role of telehealth consultations, web-based forums, mobile devices and apps, and social media, in enabling real-time communication between health professionals and consumers.

Recent systematic reviews evaluating the impact of digital health interventions on health and health care costs provide promising evidence of effectiveness and cost-effectiveness [11,14]. Digital health has demonstrated potential in engaging people in their care [15], including as a tool for the treatment and self-management training of chronically ill patients [16,17]. Digital health interventions have been shown to be effective for managing cancer-related fatigue [18], may improve physical activity among cancer survivors [19], and can lead to positive effects addressing the supportive cancer care needs of individuals with different preferences and priorities [20]. Cancer survivors have been found to have a positive attitude toward digital health [21], suggesting that digital health interventions have the potential to overcome common challenges associated with access to supportive care in this population. Health professional-led, digital health–enabled, supportive care interventions may prove particularly useful in increasing accessibility of services to those with limited access because of location, health, time, and public health emergencies [22-30]. Despite the abundance of recent digital health literature, there remains an acknowledged lack of quality evidence regarding the effectiveness of supportive digital health care interventions for people with cancer [19,20,31-33].

Objective

Over the past several decades, studies have investigated the implementation and effects of digital health interventions in people with cancer. In previous systematic reviews evaluated in 2013, the design features of supportive digital health interventions for patients with cancer [20]; in 2014, the use of technology in cancer follow-up [31]; in 2015 and 2017, the effect of telehealth interventions in cancer survivors' general quality of life [32,34], and in 2020, the benefits and limits of digital health for optimal supportive care in oncology [35]. The last review by Aapro et al [35] conducted an article search up to November 2018 and focused on the technical features of digital technologies. This is a rapidly growing area of health care because of advances in information technology and the uptake of digital technologies by both health professionals and patients. Therefore, this systematic review aims to explore the effect of supportive care interventions assisted by digital technologies on the outcomes of patients with cancer.

Methods

Search Strategy

This systematic review was registered in the PROSPERO (International Prospective Register of Systematic Reviews) and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [36]. A search was performed in August 2020, using the following web-based databases: MEDLINE (OvidSP, Wolters Kluwer), PubMed (National Center for Biotechnology Information, US National Library of Medicine), Embase (OvidSP, Wolters Kluwer), PsycINFO (American Psychological Association), Cochrane Central Register of Controlled Trials (John Wiley & Sons), and Scopus (SciVerse, Elsevier). Three main keywords were searched: *supportive care*, *digital health*, and *cancer patients*. Additional search terms were included based on synonyms of these keywords and medical subject headings. Multimedia Appendix 1 indicates the search strategy used.

Inclusion Criteria

The inclusion criteria were as follows: (1) studies in English describing a randomized controlled trial (RCT), published between January 2000 and August 2020; (2) intervention recipients were adults with a diagnosis of cancer; (3) involved clinician-led digital health interventions; and (4) interventions implemented to provide supportive cancer care.

The determination of digital health interventions was on the basis of the conceptual model of Shaw et al [13], which consists of 3 core domains:

1. Health in our hands: Using digital technologies to monitor, track, and inform health, for example, smartphones, tablets, clinical devices, mobile sensors and wearables, apps, social media, and web-based information.
2. Interacting for health: Using digital technologies to enable health communication among practitioners and between health professionals and clients or patients, for example, traditionally dominated by teleconferencing and videoconferencing, this domain increasingly includes a range of synchronous and asynchronous tools, such as SMS and push notifications from mobile apps, dedicated portals, social media platforms, and virtual or simulated therapy tools.
3. Data enabling health: Collecting, managing, and using digital health data, for example, technologies that provide expanded knowledge and insights about the health of an individual, community, or population.

To be included in the review, it was essential that the intervention satisfied the 2 domains *health in our hands* and *interacting for health*. The third domain, *data enabling health* was deemed nonessential because of the known inconsistent reporting of these criteria. The essential criterion *health in our hands* was captured in the *Intervention* column and outlines the nature of digital health experience. *Interacting for health* was captured in the *Interactions* column of review data and outlines the individuals involved in any form of communicative exchange that supports the health and well-being of the patient and caregiver.

Studies with interventions involving automated systems, such as interactive voice response and similar web-based systems, to monitor symptoms were included if the intervention featured an internet or web-based component and triggered health professional or researcher involvement when a threshold, such as a pain score, was reached.

Exclusion Criteria

Studies were excluded if they were (1) not RCTs; (2) reported only self-managed interventions, patient-to-patient interventions, prevention tools, or alternative treatments, or (3) focused solely on interventions involving telephone delivery that replicated a clinical service.

Data Extraction and Synthesis

Two reviewers (MM and DM) independently reviewed the titles and abstracts, followed by a full-text review of all publications. In cases of disagreement, a consensus was sought through discussion. Disagreement persisted for 4 studies; therefore, a third reviewer (TS) was consulted to adjudicate.

Endnote software (Clarivate Plc) [37] was used to manage references, and Covidence software (Veritas Health Innovation Ltd) was used to import and extract studies [38]. Two reviewers (MM and DM) independently applied the revised Cochrane risk of bias tool (The Cochrane Collaboration) [39] to establish the quality of the included studies. A matrix was developed by the authors and applied in the collection and analysis of structured data. Matrix criteria also included whether a study adhered to the CONSORT (Consolidated Standards of Reporting Trials) eHealth Checklist [40], a tool developed to improve the standard of reporting in digital health trials.

Quality Assessment

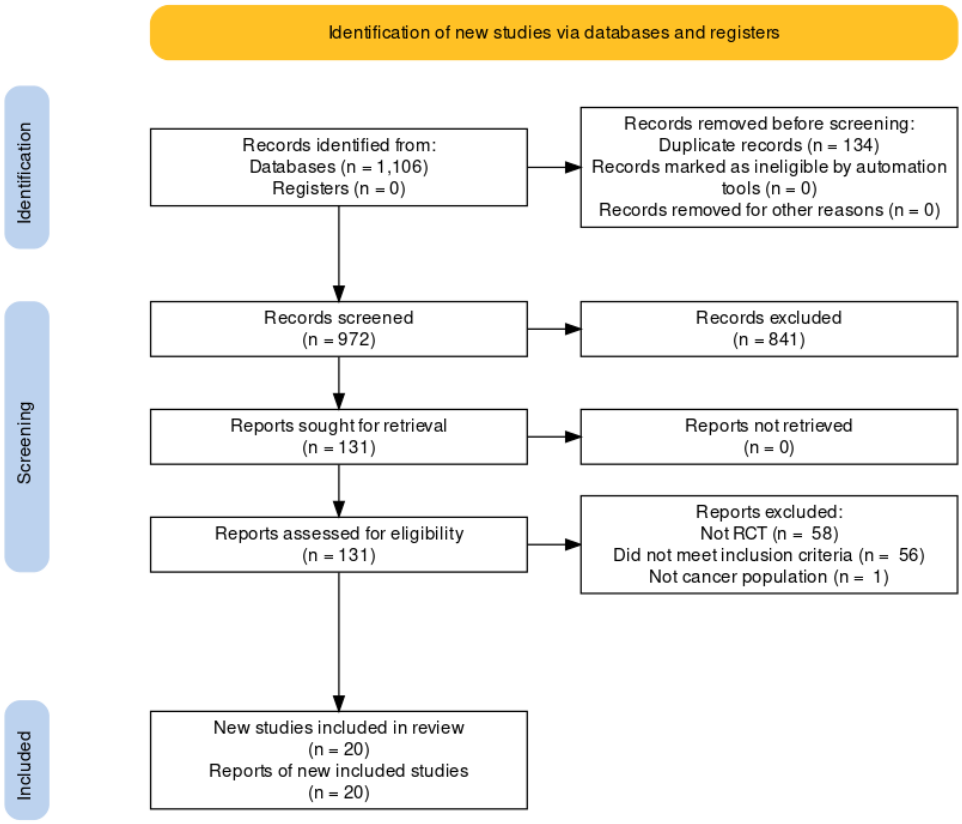
Using the revised Cochrane Collaboration's tool for assessing risk of bias (RoB) in randomized trials (Risk of Bias 2.0) [39], each study's methodological quality was assessed in 5 major domains: randomization process, deviation from intentional interventions, missing outcomes, measurement of outcomes, and selection of reported results. The RoB for each domain was rated as *some concerns*, *low*, or *high*. The overall RoB for each study was rated as *some concerns* or *high*.

Results

Study Selection

The initial search generated 972 records. After title and abstract review, 135 publications were retained. The full text for each of these 135 publications was reviewed for eligibility, resulting in the identification of 17 publications. Three additional studies were found using a reference search, generating a total of 20 digital health–enabled supportive cancer care interventions for inclusion in the review (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the search and study selection process. RCT: randomized controlled trial.



Study Characteristics

Population

Details of the study design and characteristics are given in Multimedia Appendix 2 [41-60]. Although the search was published in 2000, the earliest result identified was published in 2007, and the remaining included studies were published after 2009. A total of 20 studies were conducted across 8 countries [41-48], with 11 from the United States. The sample sizes ranged from 52 to 516 participants, with a median of 118.

Of the 20 included studies, 12 (60%) were designed for participants within a single tumor stream. Interventions for breast cancer were dominant, with a total of 9 studies [43,46-53]. A total of 2 studies identified were for lung cancer [54,55]. Of those targeting multiple tumor types, 1 recruited participants with breast or prostate cancer [45], and 1 recruited participants with lung, breast, or colorectal cancer [44]. The remaining 8 studies included several tumor types, such as participants living with any type or stage of cancer [42,56-58] or those with solid tumors attending ambulatory oncology clinics for chemotherapy [59,60].

Intervention Design and Features

The duration of interventions ranged from 4 weeks to 12 months, with a variable frequency of clinician-patient interactions ranging from biweekly to every 3 months. There were 5 studies involving the use of a web-based portal or web-based experience [45,46,48,55,57]; 8 studies included the use of a telephone or smartphone [43,44,47,52-54,59,60]; 2 studies used a combination of web-based and telephone interactions [51,58]; 2 studies used social media networks or social networks [51,55]; and 4 studies used wearable activity trackers [42,51-53]. Multidisciplinary care was identified in 30% (6/20) of the publications [44,46,47,55,56,58]. The study by Børøsund et al [46] was nurse-led, with referrals to either physicians or social workers. Uni-disciplinary interactions dominated, with 5 nurse-led [45,48,50,56,60], 1 social worker-led [49], and 1 led with a medical specialist experienced in mindfulness program delivery [42]. Bruggeman-Everts et al [41] involved a psychologist or physiotherapist assigned to participants in different arms of the study. Steel et al [57] outlined a collaborative care intervention, whereby a care coordinator provided information to the patient's medical team, as well as patients and caregivers. The interventions included digital health tutoring, psychotherapy, nursing support, remote exercise or rehabilitation program delivery, and digital mindfulness.

Digital supportive care interventions included interactive voice response, tele and video counseling, internet-based patient-provider communication, exercise based on the internet, support systems, symptom monitoring, and self-management, mobile phone-based remote monitoring, and activity monitoring with tracking devices. The programs included digital health tutoring, psychotherapy, nursing support, remote exercise, rehabilitation program delivery, and digital mindfulness interventions. All varied in terms of design, features, and use of multimedia components. Only 2 publications referred to the CONSORT Digital Health Checklist [46,55].

RoB Assessment

With regard to the overall RoB, no included studies were rated as *low* overall RoB; instead, 8 had *some concerns*, and 12 were *high risk*. A summary of the RoB assessment can be found in Multimedia Appendix 3 [41-60], describing the methodological quality of each domain according to the Cochrane tool for assessing RoB in randomized trials (RoB 2.0). Figures 2 and 3 describe a graphical representation of the RoB assessments. Figure 2 includes studies in which an intention-to-treat analysis was performed, whereas Figure 3 contains studies with a per-protocol analysis.

Figure 2. Risk of bias in studies with intention-to-treat analysis.

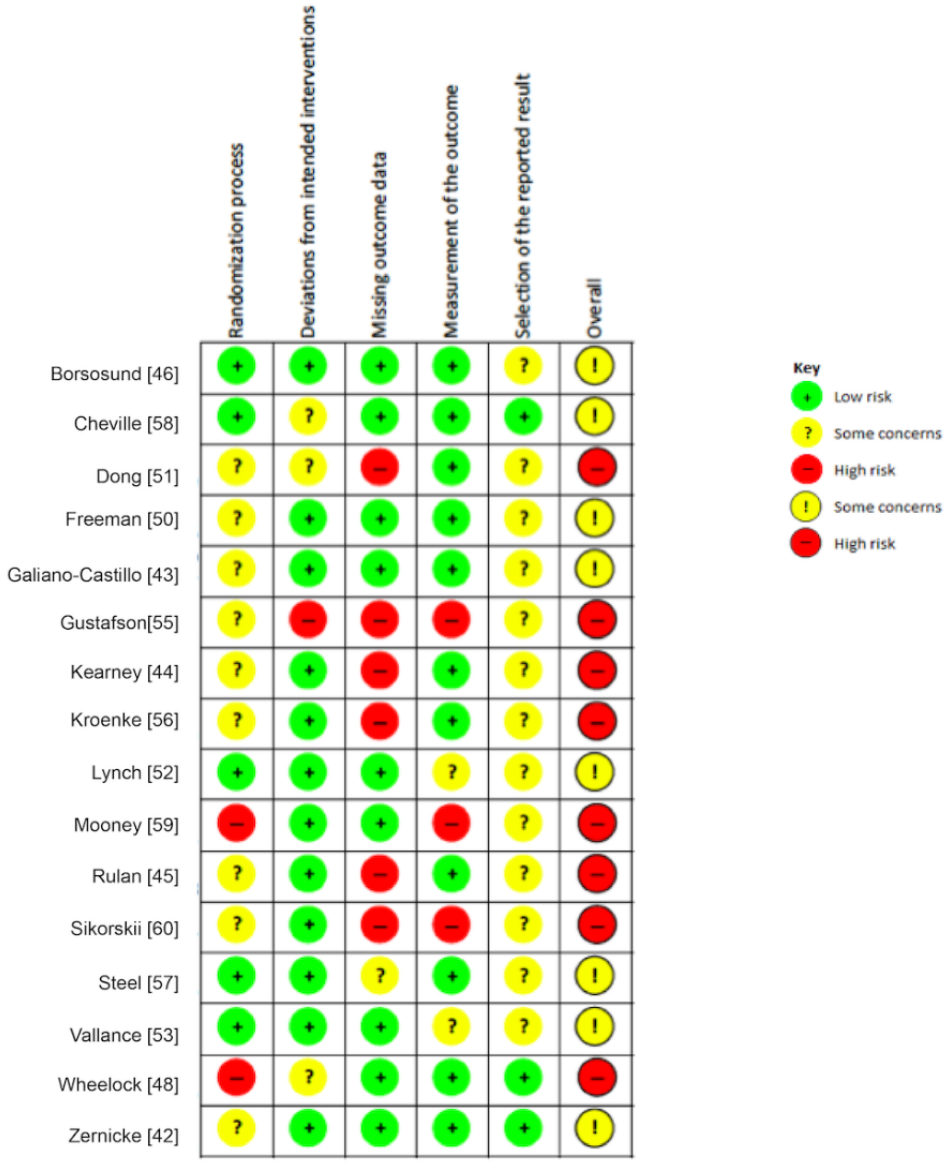


Figure 3. Risk of bias in studies with per-protocol analysis.

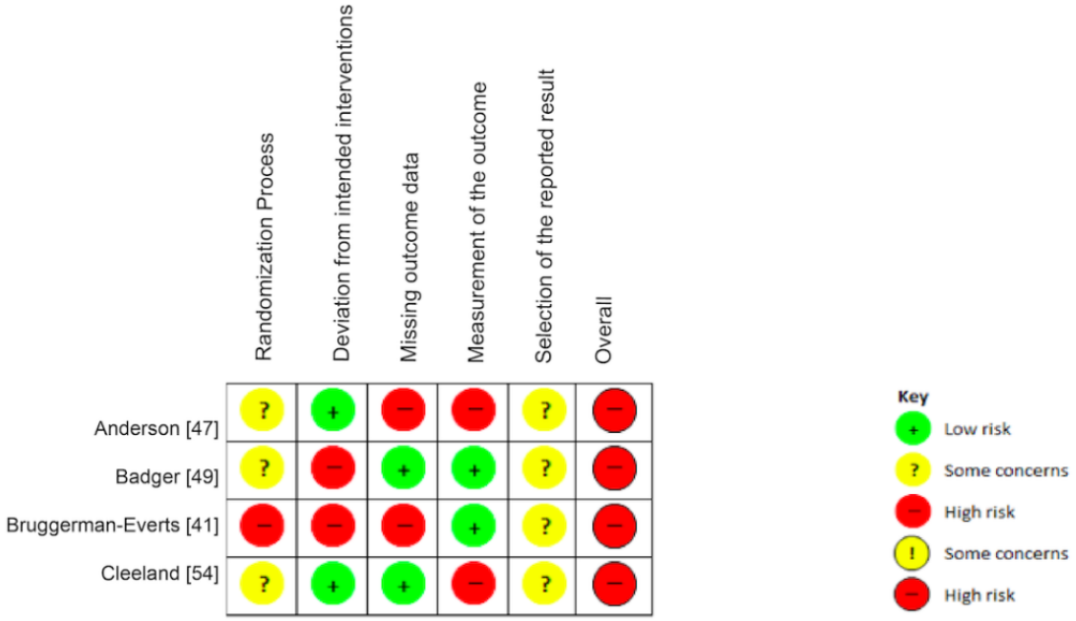

Intervention Outcomes

Overview

Interventions were analyzed according to the before-after test design, with most of the interventions including repeated measurement points. Although 20 studies were included, the interventions and outcomes were heterogeneous and did not enable meta-analyses. Outcomes were synthetized using a model for quality of life among cancer survivors developed by Ferrell and Dow [61,62]. The model encompasses dimensions of physical, psychological, social, and spiritual well-being, specifying the content for each dimension in the context of cancer survivors. Details of the intervention outcomes and statistically significant results are presented in Table 1.

Table 1. Intervention outcomes.

Author	Primary and secondary outcomes (grouped)	Measures	Results
Anderson et al [47]	• Pain • Sleep • Fatigue	• MDASI[a]	• Decreased pain severity from baseline to time point 1 (0.6 vs 2.3; *P*=.03; 95% CI 0.13 to 3.3) and from baseline to time point 2 (1.2 vs 3.5; *P*=.02; 95% CI 0.47 to 4.2) in the intervention group. • Improved reported sleep.
Badger et al [49]	• Depression • Symptom distress • Social well-being; spiritual well-being	• CES-D[b]; GSDS[c]; Social and spiritual; Well-being scales	• Depression, symptoms, and spiritual well-being improved in intervention groups (*P*=.01). No between-group differences. Social well-being improved for tele and video groups.
Børøsund et al [46]	• Symptom distress • Anxiety • Depression • Self-efficacy	• MSAS[d] • HADS[e] • CBI[f]	• WebChoice lower symptom distress (−0.16, 95% CI −.25 to −0.06; *P*=.001), anxiety (−0.79, 95% CI −1.49 to −0.09; *P*=.03), and depression (−0.79, 95% CI 1.18 to −0.05; *P*=.03) compared with control. • Internet-based communication group lower depression (−0.69, 95% CI −1.32 to −0.05; *P*=.03) compared with usual care. No change in symptom distress or anxiety.
Bruggeman-Everts et al [41]	• Fatigue severity • Mental health • Distress	• CIS-FS[g] • The positive and negative affect schedule • HADS	• Clinically changes in fatigue severity in 66% (41/62) of patients in home-based physiotherapist guided protocol (AAF[h]), 49% (27/55) of patients in web-based psychologist-guided intervention (eMBCT[i]), and 12% (6/50) of patients in psycho-education e-mails only.
Cheville et al [58]	• Functional capacity • Pain • HRQoL[j]	• AM-PAC[k] • BPI[l] • 5-item EQ-5D-3L	• Telerehabilitation by physical therapist-physician team (intervention group 1) improved function (difference, 1.3; 95% CI 0.08 to 2.35; *P*=.03) and quality of life (difference, 0.04; 95% CI 0.004 to 0.071; *P*=.01) compared with control. • Intervention groups 1 and 2 showed reduced pain interference and average intensity (intervention group 1, −0.4; 95% CI −0.78 to −0.07; *P*=.02; and intervention group 2, −0.5; 95% CI −0.84 to −0.11; *P*=.006).
Cleeland et al [54]	• Symptom threshold events • Cumulative distribution of symptom threshold events • Symptom severity	• MDASI	• Both groups had decreased symptom threshold events, control group reported more events at the end of the study period. For both groups together, the effect size of reduction in symptom severity was 0.72, effect size of 0.68 in the control group and 0.75 in the intervention group.

Author	Primary and secondary outcomes (grouped)	Measures	Results
Dong et al [51]	• HRQoL • Muscle strength • Cardiorespiratory capacity	• SF-36[m] • Stand-up or sit-down chair test and arm lifting test (30 seconds) • Modified Bruce treadmill protocol	• CEIBISMS[n] intervention showed improvements after 12 weeks in role-physical (P=.009), general health (P=.02), mental health (P=.01), vitality (P=.01) and health transition (P=.007). • In comparison with control group, differences in vitality (P=.009), mental health (P=.001), and health transition (P=.048).
Freeman et al [50]	• HRQoL • Functional capacity • Fatigue, sleep • Spiritual well-being	• SF-36 • FACT-B[o] • FACIT-F[p] and cog • FACT-Sp[q]	• Less fatigue (P=.002), cognitive dysfunction (P=.001), and sleep disturbance (P<.001) for both intervention groups compared with control. • No differences between live delivery and telemedicine delivery of therapy. • No group effect on overall quality of life; however, there was a time effect.
Galiano-Castillo et al [43]	• Functional capacity • Cognitive function	• 6-minute walk test • Trail making test • ACT[r]	• After intervention, the telerehabilitation group had significantly improved distances as well as percentage of predicted 6-minute walk test compared with the control group (P<.001).
Gustafson et al [55]	• Caregiver surveys reporting patient symptom distress	• Modified ESAS[s]	• Caregivers in the CHESS[t] arm consistently reported lower patient physical symptom distress than caregivers in the internet arm at 4 months (P=.03); and at 6 months (P=.004)
Kearney et al [44]	• 6 chemotherapy-related symptoms	• Common toxicity criteria adverse events chemotherapy symptom assessment scale	• Difference between groups in fatigue, higher in the control group (OR[u] 2.29, 95% CI 1.04 to 5.05; P=.04) and in hand-foot syndrome lower in control group (OR control or intervention 0.39, 95% CI 0.17 to 0.92; P=.03)
Kroenke et al [56]	• Depression • Pain severity	• HSCL-20[v] • BPI	• Improvements for the intervention group: >30% decrease in pain index (P<.001) and >50% decrease in the depression scale (P<.001). Effect size between-group differences at 3 months was 0.67 (95% CI 0.33 to 1.02) for pain and 0.42 (95% CI 0.16 to 0.69) for depression. • Intervention group had better outcomes for several HrQoL domains, including mental health, vitality, anxiety, and physical symptom burden.
Lynch [52][w]	• Vigorous physical activity (MVPA[x])	• Actigraph and activPAL accelerometers	• Between-group difference in MVPA at T2 (69 min/week; 95% CI 22 to 116); decreased total time of sitting 37 min/day (95% CI −72 to −2) and prolonged bouts of sitting 42 min/day (95% CI −83 to −2), favoring the intervention group
Vallance [53][w]			

Author	Primary and secondary outcomes (grouped)	Measures	Results
	• HRQoL • Fatigue	• FACT-B • FACIT-F	• Intervention group improvement in fatigue at T2 4.6 (95% CI 1.3 to 7.8). Within groups: intervention group, increase in fatigue at T2 5.1 (95% CI 2.0 to 8.2) and at T-3 3.3 (95% CI 0.1 to 6.41). No effects on HRQoL.
Mooney et al [59]	• Symptom severity • Distress	• Single item scale	• No significant difference between symptom severity or distress scores between groups.
Ruland et al [45]	• Symptom distress • Depression • Self-efficacy • HRQoL	• MSAS-SF[y] • Centre for Epidemiological Cancer Behavior Inventory Studies-Depression Scale 15 d	• Decreased distress on one subscale of MSAS. • Group differences on symptom distress were significant for the MSAS-SF (slope estimate, −0.052, 95% CI −0.101 to −0.004; t244=4.42; *P*=.04). There were no significant within- or between-group differences on the other MSAS-SF subscales.
Sikorskii et al [60]	• Symptom severity	• MDASI	• Decreased symptom severity across both intervention groups after 10 weeks. No between-group differences. Effect sizes were similar for NASM[z] (0.56) and ATSM[aa] (0.59)
Steel et al [57]	• Depression • Pain • Serum cytokine levels natural killer cell numbers	• CES-D • BPI • Functional assessment of cancer therapy–anemia, and hepatobiliary	• Reductions in pain (Cohen d=0.62), fatigue (Cohen d=0.26), depression (Cohen d=0.71), and significant changes in HRQoL with an effect size of Cohen d=0.99 at 6 months follow-up (*P*=.05) when compared with those in the enhanced usual care arm at 6 months.
Wheelock et al [48]	• Time between symptoms • Health care use	• Clinic visits • Health service use	• Did not meet primary objective, no difference in health service use
Zernicke et al [42]	• Feasibility • Mood • Stress • Posttraumatic growth inventory	• Monitoring interest, eligibility, and participation • Profile of mood states • CSOSI[ab]	• Significant improvements and moderate effect sizes in the web-based MBCR[ac] group relative to controls for mood disturbance (Cohen d=0.44; *P*=.049), stress (Cohen d=0.49; *P*=.02), spirituality (Cohen d=0.37; *P*=.04), and mindfully acting with awareness (Cohen d=0.50; *P*=.03).

[aa]ATSM: automated telephone symptom management

[ab]CSOSI: Calgary Symptoms of Stress Inventory.

[ac]MBCR: mindfulness-based cancer recovery.

Physical Well-being

Despite measuring similar outcomes, heterogeneous self-reported instruments were used across the studies. Control or reduction of symptoms and maintenance of function and independence comprise this domain. A total of 16 studies reported statistically significant changes in outcomes within the physical well-being domain [41,43-47,49,50,52-58,60]. Furthermore, 4 studies showed a significant reduction in pain [47,56-58], of which 3 used the Brief Pain Inventory [56-58]. Decreased fatigue was reported in 4 studies, favoring the intervention groups [41,44,50,53]. The most common outcome measure reported was clustered symptom changes, as referenced in 6 studies [45,46,49,54,55,60]. Finally, functional capacity-related outcomes were significant in 3 studies [43,52,58].

Health-Related Quality of Life

Health-related quality of life was the second most common domain, with significant improvements for the intervention group referenced in 4 studies [51,56-58].

Psychological Well-being

The most common outcome in this domain reporting significant improvements in the 4 interventions was depression [46,49,56,57]. Anxiety was reduced compared with the control group in one study [46], and significant improvements in mood disturbance were observed in one study [42].

Social and Spiritual Well-being

A single study reported a significant improvement in social well-being in the intervention group [49]. Badger et al [49] was also the only study that evaluated spiritual well-being changes, resulting in statistically significant improvements for the intervention group but no between-group differences.

Discussion

Principal Findings

Overview

In the studies integrated in this review, the interventions included digital health education, psychotherapy, nursing support, remote exercise, rehabilitation program delivery, and digital mindfulness interventions. All interventions satisfied the domains *health in our hands* and *interacting for health* of the digital health model by Shaw et al [13]. Digital supportive care interventions have been shown to improve cancer-related symptoms [45,46,49,54,55,60], pain [47,56-58], fatigue [41,44,50,53], health-related quality of life [51,56-58], functional capacity [43,52,58], and depression [46,49,56,57]. Only 2 RCTs included in this review did not report significant changes in one or more outcomes [48,59].

Digital Supportive Cancer Care Interventions

The digital interventions reviewed have been shown to be beneficial and independent of disease and demographic factors. This is similar to findings reported in other reviews [20,31,32,35,47,63] and meta-analyses [34]. In addition, the use of technology for cancer follow-up appears to be acceptable to patients, is clinically safe [31], and improves health knowledge and self-management practices [64]. However, such interventions vary in design and features, most lack or fail to report theoretical frameworks, and they use outcome measures making pooling or comparison between studies difficult. Another issue when comparing digital supportive care interventions is that it may be possible that interventions vary in their efficacy across different populations and technologies used for delivery. Furthermore, past studies have reported potential challenges impacting the implementation of digital health care, such as technical problems, lack of technology knowledge, and data security [65], which need to be considered when planning future studies. Recent systematic reviews concluded that a range of strategies should be implemented in digital supportive care [20,35,63] and general digital health interventions [66]. The study by O'Connor et al [66] recommends increasing public awareness of different

technologies and understanding of how they work, personalization of care, clinical accreditation of interventions, improving focus on health literacy, and safeguarding privacy of personal information as key areas for investigation. Key areas for digital supportive care design and implementation noted in previous cancer-related reviews that should be further explored are mechanisms for participant feedback to drive the co-design of digital interventions [20,67], the efficiency of delivering relevant and tailored health care information [65], and ways to integrate supportive care services at all stages of the cancer treatment pathway [35].

A supportive digital care intervention model should be underpinned by a theoretical framework that anticipates not only the outcomes and the tools to measure these, but also the process of achieving the outcomes from a particular intervention [20,63,68]. However, many studies do not address the validity of patient-reported health outcomes, and most of them use self-reported measures in pre-post test design, which leaves them at a RoB. This might be in part because one of the main challenges in the development of an evidence-based digital supportive cancer care intervention is the velocity of technology development in comparison with the often-long process of conducting and evaluating clinical trials.

Digital Health for Chronic Disease Care

Evidence from the research and implementation of digital health interventions across other disease groups may facilitate the transferability of digitally enabled supportive cancer care. Cancer is a chronic disease for many people [69]. Applications of research findings in other chronic diseases, such as cardiovascular disease [70], hypertension [12], and diabetes [71], which have a larger evidence base in digital health–enabled interventions with positive effects, should be used where possible. A recent systematic review [72] focused on the broader application of these symptom-reporting systems within multiple patient groups and concluded that although further research needs to be completed, most studies reported positive health outcomes. For example, in the case of diabetes, Greenwood et al [71] found that the most effective digital interventions incorporated all components of a technology-assisted self-management feedback loop, connected people with diabetes and their health care team using two-way communication, analyzed patient-generated health data, tailored education programs, and individualized feedback. A 2018 systematic review focused on using remote monitoring in people with a history of type 2 diabetes [73] significantly improved glycated hemoglobin and self-management. Evidence from diabetes research seems more cohesive, in part, because the outcomes of lowering glucose levels and glycated hemoglobin allow homogeneous measurement across studies.

Several successful digital health interventions focus on both behavior change and increasing patient engagement [74,75]. Barello [75] concluded that most studies failed to account for the complexity of patient engagement and that a more holistic approach might help maximize the potential of digital health technology [75]. Another recent review focused on mobile health apps for chronic disease management and found that regular symptom assessments, automated reminders, and feedback loops were common features, with most studies reporting significant improvement in health outcomes [73].

Current Challenges and Need for Quality Information

This review compiles evidence regarding the potential of digital health interventions for supportive cancer care in different settings, including remote areas and emergency situations [33]. However, the challenges facing public health systems worldwide in terms of emergencies, such as the COVID-19 pandemic, have rapidly increased the use of digital health interventions [29]. Health care systems, including cancer care, are adapting in response to the need for social distancing, lockdowns, and other public health initiatives. Cancer clinics have reduced clinical appointments, administration encounters, and postponed elective cancer surgeries [28], which has increased the need for follow-up and management without visiting hospitals [76]. This situation has advanced the use of digital health and telehealth apps and programs worldwide [30]. Digital supportive cancer care has been implemented out of necessity and is becoming a common delivery model [77]. Two of the suggested strategies to enable supportive cancer care during COVID-19 are (1) empowering patients and caregivers through the use of digital communication and (2) increasing the use of existing digital health platforms [28].

There is an urgent need to agree on relevant outcomes, methods of assessment, and there is a need for improved quality of primary studies and RCTs, as shown by our quality assessment. The lack of high-quality randomized trials identified in this review reflects the ongoing problem of low-quality research. Moreover, only 2 of the included publications referenced the CONSORT Digital Health Checklist, which was published in 2011. Only 3 included studies were published before 2011, making it disappointing that most later publications failed to reference this standard. Comments of Dickinson in BMC Cancer [31] remain relevant in 2020:

> *Nevertheless, there are surprisingly few randomized trials given the explosion in technological innovation in recent years. It could be that technology is evolving so fast that potential innovative technological interventions become outdated before they can mature sufficiently to be subjected to randomized trials.*

This insight has been recurrent in different systematic reviews [32,74].

Strengths and Limitations

Although the review was a rigorous evaluation of RCTs, there were a small number of included studies that indicated there may be significant literature in the phase I or II feasibility spectrum. Although 20 studies were included, the interventions and outcomes were heterogeneous and did not enable meta-analyses. Owing to the nature of this review, there was also a heterogeneous population, variable outcome measures, variable study quality, and methodological limitations. These characteristics have been found to contribute to a lack of evidence regarding the benefits of digital health [19]. It is difficult to draw conclusions and synthesize studies with inconsistent outcome measures, and a systematic approach to using standardized measures is required. The CONSORT Digital

Health Checklist should be used routinely. The review was limited to studies written in English. Therefore, it is possible that research papers published in other parts of the world were missed. As with many studies in oncology, this review found that breast cancer survivorship dominated. Thus, the development of supportive care interventions across other tumor streams is required. As most of the included studies were conducted in the United States and Europe, it is unclear whether the findings from these studies can be generalized to other countries and populations, particularly in developing nations.

Future Directions

Living well with cancer has gained greater relevance as the survival rates of many cancer types are increasing. The future of digital health in oncology supportive care brings a range of new and exciting possibilities. There is a need to evaluate the efficacy and efficiency of digital interventions in real-world conditions and standardize a core set of outcomes included in all studies to facilitate comparisons between interventions and digital technologies.

Conclusions

Digital health–enabled supportive cancer care is capable of improving health-related quality of life, symptom burden including self-report of pain and fatigue, depression, and, to a lesser extent, functional capacity. Supportive digital interventions in the field of cancer are being used and have been reported to be helpful for patients, independent of other factors. However, there is a need for higher quality research and clearer reporting than is evident in the current RCTs. Future research should focus on using valid, standardized outcome measures, increasing the methodological rigor of studies undertaken, and the development and evaluation of strategies to improve both patient and health professional engagement in the design and delivery of supportive digital health interventions.

Abstract

Background: Access to neurological care for Parkinson disease (PD) is a rare privilege for millions of people worldwide, especially in resource-limited countries. In 2013, there were just 1200 neurologists in India for a population of 1.3 billion people; in Africa, the average population per neurologist exceeds 3.3 million people. In contrast, 60,000 people receive a diagnosis of PD every year in the United States alone, and similar patterns of rising PD cases—fueled mostly by environmental pollution and an aging population—can be seen worldwide. The current projection of more than 12 million patients with PD worldwide by 2040 is only part of the picture given that more than 20% of patients with PD remain undiagnosed. Timely diagnosis and frequent assessment are key to ensure timely and appropriate medical intervention, thus improving the quality of life of patients with PD.

Objective: In this paper, we propose a web-based framework that can help anyone anywhere around the world record a short speech task and analyze the recorded data to screen for PD.

Methods: We collected data from 726 unique participants (PD: 262/726, 36.1% were women; non-PD: 464/726, 63.9% were women; average age 61 years) from all over the United States and beyond. A small portion of the data (approximately 54/726, 7.4%) was collected in a laboratory setting to compare the performance of the models trained with noisy home environment data against high-quality laboratory-environment data. The participants were instructed to utter a popular pangram containing all the letters in the English alphabet, “the quick brown fox jumps over the lazy dog.” We extracted both standard acoustic features (mel-frequency cepstral coefficients and jitter and shimmer variants) and deep learning–based embedding features from the speech data. Using these features, we trained several machine learning algorithms. We also applied model interpretation techniques such as Shapley additive explanations to ascertain the importance of each feature in determining the model’s output.

Results: We achieved an area under the curve of 0.753 for determining the presence of self-reported PD by modeling the standard acoustic features through the XGBoost—a gradient-boosted decision tree model. Further analysis revealed that the widely used mel-frequency cepstral coefficient features and a subset of previously validated dysphonia features designed for detecting PD from a verbal phonation task (pronouncing “ahh”) influence the model’s decision the most.

Conclusions: Our model performed equally well on data collected in a controlled laboratory environment and *in the wild* across different gender and age groups. Using this tool, we can collect data from almost anyone anywhere with an audio-enabled device and help the participants screen for PD remotely, contributing to equity and access in neurological care.

Introduction

Parkinson disease (PD) is the fastest-growing neurological disease worldwide. Unfortunately, an estimated 20% of patients with PD remain undiagnosed. This can be largely attributed to the shortage of neurologists worldwide [1,2] and limited access to health care. Early diagnosis and continuous monitoring, which allows medication dosage adjustment, are key to managing the symptoms of this incurable disease. The current standard of diagnosis requires in-person clinic visits where an expert assesses the disease symptoms while observing the patients as they perform tasks from the Movement Disorder Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS) [3]. The MDS-UPDRS includes 24 motor-related tasks to assess speech, facial expression, limb movements, walking, memory, and cognitive abilities. Although many studies have shown success by analyzing hand movements [4], limb movement patterns [5], and facial expressions [6], speech is especially important because approximately 90% of patients with PD exhibit vocal impairment [7,8], which is often one of the earliest indicators of PD [9].

For speech analysis, researchers have looked into phonations (pronouncing "ahhh") from audio recordings [10] to quantify rhythm, stress, and intonation [11]. Little et al [12] introduced pitch period entropy (PPE) as a measure of dysphonia to distinguish healthy people from people with PD with 91% accuracy. Later, Tsanas [13] expanded on this by calculating 132 dysphonia measures to classify PD versus control with almost 99% accuracy. In addition, Peker et al [14] used a novel feature selection technique with a complex-valued artificial neural network. Rueda and Krishnan [15] identified a set of mel-frequency cepstral coefficients (MFCCs) and intrinsic mode functions to represent the characteristics of PD. In the domain of analyzing real-life audio data, Wroge et al [16] analyzed verbal phonation data collected from smartphones; Vaiciukynas et al [17] used a convolutional neural network to detect PD from speech; Vásquez-Correa et al [18] collected speech samples with a handheld device in uncontrolled noise conditions; and Dubey et al [19] designed a smartwatch-based voice and speech monitoring system for people with PD receiving speech therapies from speech-language pathologists. Although the current state-of-the-art method has shown promising results, it has limitations such as small sample size [12,19,20], oversampling from the same participants [14], noise-controlled data collection [12,15], and age discrepancy between PD and control [21].

In this paper, we present our analysis of 726 audio recordings of speech from 36.1% (262/726) individuals with PD and 63.9% (464/726) without PD. The speech recordings were collected using a web-based tool called *Parkinson's Analysis with Remote Kinetic-tasks* (PARK) [22]. The PARK tool instructed the participants to utter a popular pangram containing all the letters in the English alphabet, "The quick brown fox jumps over the lazy dog," and recorded it. This allowed us to rapidly collect a data set that is more likely to contain real-world variability associated with geographical boundaries, socioeconomic status, age groups, and a wide variety of heterogeneous recording devices. The findings in this study build on this unique real-world data set; thus, we believe it could potentially be generalized for real-world deployments.

Collecting audio data from individuals often requires in-person visits to the clinic, limiting the number of data points and the diversity within the data. Recent advancements have allowed the collection of tremor data from wearable sensors [23] and sleep data from radio frequency signals [24]. The existing work with speech and audio analysis uses sophisticated equipment for collecting data that are often noise-free [12,25] and do not contain real-world variability. As a significant portion of the population has access to a mobile device with recording capability (eg, 81% of Americans own a smartphone) [26], we opted to use a framework that allows participants to record data from their homes. From the recorded audio files, we extracted acoustic features including MFCCs, which represent the short-term power spectrum of a sound, jitter or shimmer variants (representing pathological voice quality), pitch-related features, spectral power, and dysphonia-related features designed to capture PD-induced vocal impairment [12].

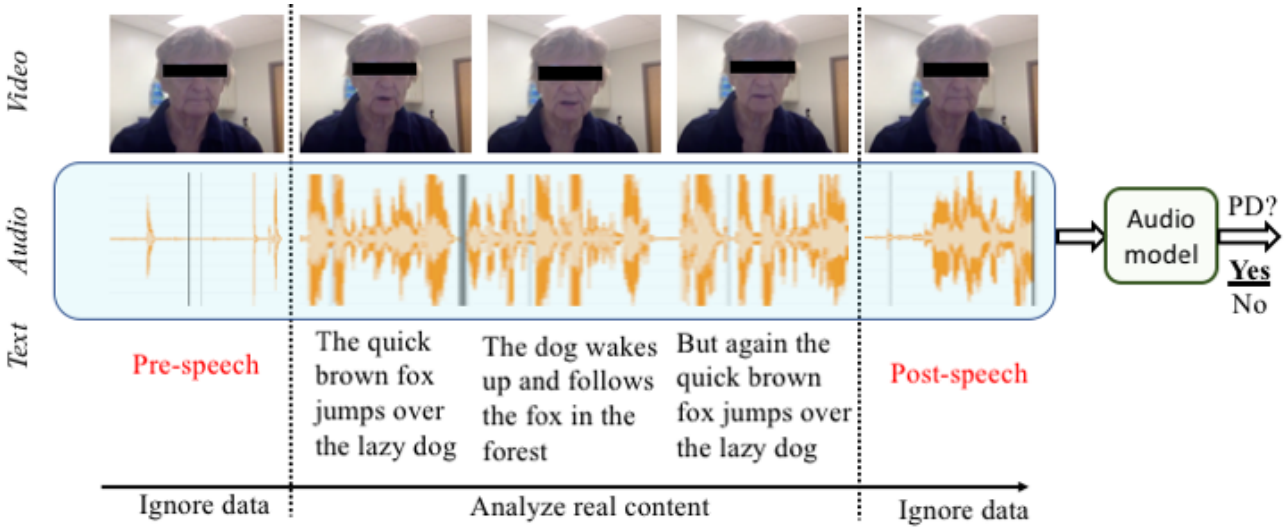
In addition, we extracted features from a deep-learning–based encoder—problem agnostic speech encoder (PASE) [27], which represents the information contained in a raw audio instance through a list of encoded vectors. These features are modeled with four different machine learning models—support vector machine (SVM), random forest, LightGBM, and XGBoost—to classify individuals with and without PD.

Figure 1 provides an outline of the data analysis system. Our contributions can be summarized as follows:

- We report findings from one of the largest data sets with real-world variability, containing 726 unique participants mostly from their homes.
- We analyzed the audio features of speech to predict PD versus non-PD with an area under the curve (AUC) score of 0.753.
- We provide evidence that our model prioritizes MFCC features and a subset of dysphonia features [12,28], which is consistent with previous literature.

- Our model performs consistently well when tested on gender- and age-stratified data collected in a controlled laboratory environment and in the wild.

Figure 1. An outline of our approach for solving the speech task of uttering "The quick brown fox...".



Methods

Recruitment and Data Collection

We collected data from 726 *unique* participants uttering the sentences, "The quick brown fox jumps over the lazy dog. The dog wakes up and follows the fox into the forest, but again the quick brown fox jumps over the lazy dog," using PARK [29] website. Figure 2 provides a brief overview of the data collection, storage, transfer, and analysis mechanisms. The users are recorded via a webcam and a microphone connected to the PC or laptop, and the recordings are uploaded to a server. Figure 3 shows images of some of the study participants, and Figure 4 shows the age distribution of the participants. The number of participants without PD is 1.8 times the number of participants with PD. Most of the participants with PD are concentrated in the age range of 40 to 80 years. However, participants without PD outnumber those with PD in the age group 20 to 40 years. Similarly, participants with PD significantly outnumber those without PD in the age group of 80 to 90 years. Table 1 provides the demographic information of the study participants.

Figure 2. An overview of our data collection, storage, and analysis pipeline.

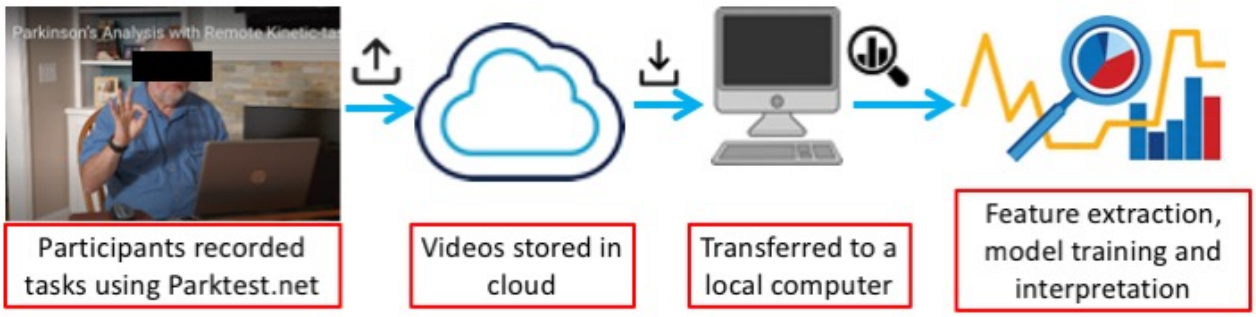


Figure 3. Some screenshots of our subjects while providing the data. All the subjects except B provided data without any supervision. B, D, E, and F have been diagnosed with Parkinson disease. Electronic informed consent was taken from the participants to use their photos for publication.

Figure 4. A bar plot showing the age distribution of participants with PD and those without PD in our data set. PD: Parkinson disease.

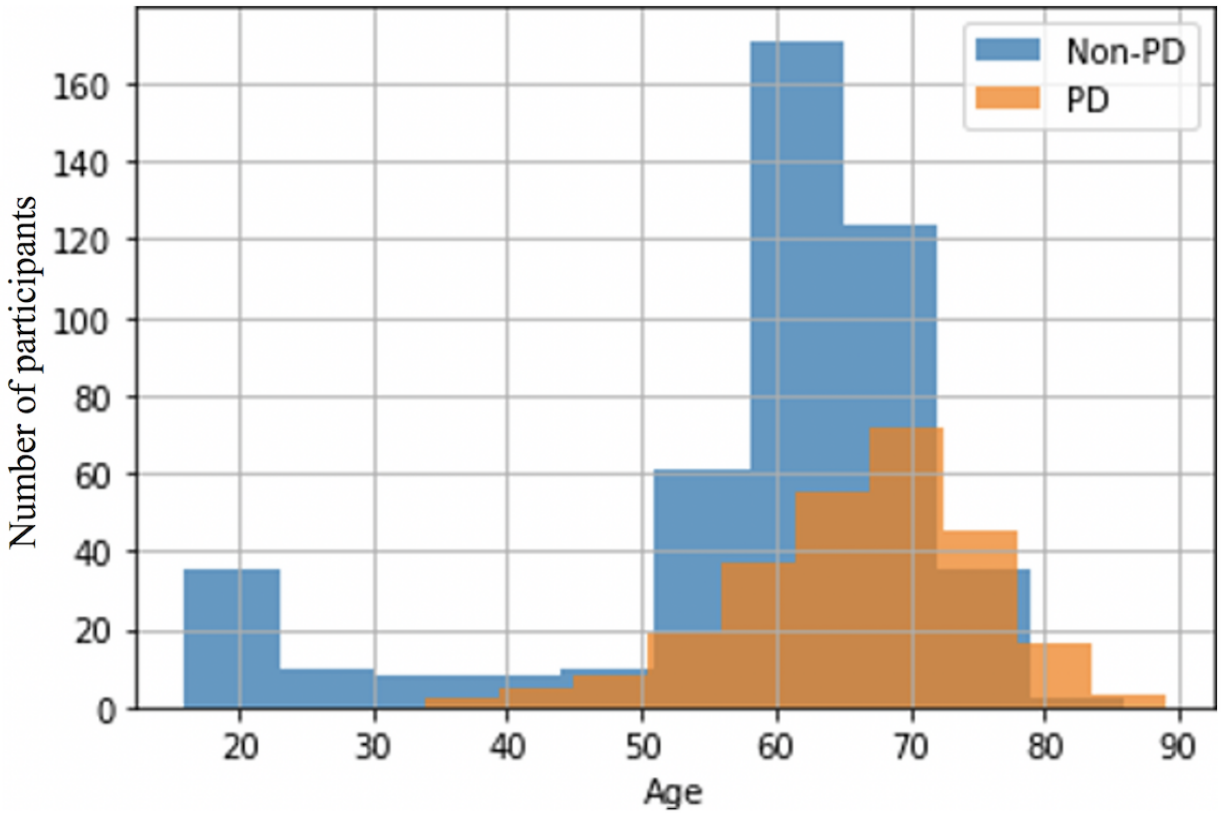

Table 1. Demographic composition of our data set (N=726).

Characteristics	Participants with PD[a]	Participants without PD
Total, n (%)	262 (36.1)	464 (63.9)
Gender, n (%)		
Female	101 (38.5)	300 (64.6)
Male	161 (61.4)	164 (22.5)
Age (years), mean (SD)	65.92 (9.2)	57.98 (14.2)
Country, n (%)		
United States	199 (75.9)	419 (90.3)
Other	63 (24)	45 (9.7)
Years since diagnosed, mean (SD)	7.88 (5.41)	N/A[b]

[a]PD: Parkinson disease.

[b]N/A: not applicable.

Among our 726 unique participants, 262 (36.1%) had received the diagnosis of PD, whereas the others were participants without PD. We obtained contact information of patients with PD from local clinics and various PD support groups. Participants without PD were recruited from Amazon Mechanical Turk. During data collection, informed consent of all participants was obtained in accordance with the protocol agreed upon between the researchers and the institutional review board of the University of Rochester. Among the 726 unique participants, only 54 (7.4%) provided data in the laboratory under the guidance of a study coordinator using the PARK tool; the rest of the 672 (92.6%) participants used the PARK system from their homes to provide data. Having participants perform the tasks at home and in the laboratory allowed us to compare the results across both conditions. No participant appeared in either set, and *all* of our participants used the identical PARK protocol.

The gender distribution in the data set was skewed, especially for female participants. Among all participants, 55.2% (401/726) were women, and 44.8% (325/726) were men. However, among participants with PD, only 38.5% (101/262) were women, and for participants without PD, 64.6% (300/464) were women. Most of the participants with PD were in the age range of 40 to 80 years, but most of the younger (20-40 years) and older (80-90 years) participants were from the group without PD and the group with PD, respectively.

As our data were collected through a web-based framework, we do not have the MDS-UPDRS scores for our participants because collecting them requires additional input from doctors. Among all the participants in our PD group, only 3 participants replied in affirmative that they had taken medication 2 hours before taking the test; others replied in the negative. Therefore, we assumed that medication effects were negligible for the purposes of this study.

Data Preprocessing

During data collection, participants often took some additional time to start to utter the task sentences and stop the recording once the sentences were uttered. Hence, we had a substantial amount of noisy and irrelevant data at the beginning and end of most data instances (Figure 1). To remove irrelevant data, we used the Penn Phonetics Lab Forced Aligner Toolkit (P2FA) [30]. Given an audio file and transcript, it attempts to predict the time boundaries in which each of the words in the transcript was pronounced. P2FA applies a combination of hidden Markov models [31] to predict the most likely sequence of phonemes for a given audio and Gaussian mixture models to combine those phonemes into words and obtain their time boundary using a predefined dictionary [32]. From the output of this system, we can obtain the starting time of the first word recognized by the P2FA and the ending time of the last word recognized by the P2FA. We used the audio segments between them for further analysis.

Acoustic Features Extraction

We extracted features by combining outputs of multiple sources: Praat features [33] obtained through the Parselmouth Python interface [34] and the previously used dysphonia features relevant for PD analysis [12,35,36]. After calculating all the features, we constructed a correlation matrix of the feature values to calculate the degree of correlation between them. Then, we iterated over each pair of features in an unordered fashion, and if the correlation coefficient between them was above 0.9, we dropped one of those features from further analysis [37]. Table 2 contains a short overview of the features used in our analysis; the feature names in italicized text are those used for building the models. We provide a more comprehensive description of the features in Multimedia Appendix 1 [12,14,36,38]. Some of our definitions were adapted from the official Praat documentation [33].

Table 2. Names of all the features, code source used for collecting them, and a short description[a].

Feature	Code source	Short description
Pitch		
MedianPitch [b]	Little et al [36]	Median principal frequency
MeanPitch	Boersma and Weenink [33]	Mean principal frequency
StdDevPitch	Little et al [36]	SD in principal frequency
Jitter		
MeanJitter	Little et al [36]	Perturbation in principal frequency (mean variation)
MedianJitter	Little et al [36]	Perturbation in principal frequency (median variation)
LocalJitter	Boersma and Weenink [33]	Average absolute difference between consecutive periods, divided by the average period
LocalAbsoluteJitter	Boersma and Weenink [33]	Average absolute difference between consecutive periods measured in seconds
RapJitter	Boersma and Weenink [33]	Average absolute difference between a period and the average of it and its two neighbors
Ppq5Jitter	Boersma and Weenink [33]	5-point period perturbation quotient
DdpJitter	Boersma and Weenink [33]	Difference of differences of periods of principal frequency
Shimmer		
MeanShimmer	Little et al [36]	Amplitude perturbation (using mean)
MedianShimmer	Little et al [36]	Amplitude perturbation (using median)
LocalShimmer	Boersma and Weenink [33]	Average absolute difference between amplitudes of consecutive period
LocaldbShimmer	Boersma and Weenink [33]	Average absolute base-10 logarithm of the difference between amplitudes of consecutive period
Apq3Shimmer	Boersma and Weenink [33]	3-point amplitude perturbation quotient
Apq5Shimmer	Boersma and Weenink [33]	5-point amplitude perturbation quotient
Apq11Shimmer	Boersma and Weenink [33]	11-point amplitude perturbation quotient
DdaShimmer	Boersma and Weenink [33]	Shimmer calculated by difference in differences of amplitude
MFCC[c]		
MeanMFCC (0-12)	Little et al [36]	13 features of mean MFCC
VariationMFCC (0-12)	Little et al [36]	13 features of mean variation of MFCC
RelBandPower (0-3)	Tsanas et al [39]	4 features capturing relative band power in 4 spectrum ranges
HNR [d]	Boersma and Weenink [33]	Signal-to-noise ratio
RPDE [e]	Little et al [36]	Pitch estimation uncertainty
DFA [f]	Little et al [36]	Measure of stochastic self-similarity in turbulent noise
PPE [g]	Little et al [36]	Measure of inability of maintaining constant pitch

[a]We collected the features using the code or methodology described in the corresponding code-source entry.

[b]The correlated features were removed, and features in italicized text were used to build the models. Feature names are preceded by the loosely defined umbrella category they belong to.

[c]MFCC: mel-frequency cepstral coefficient.

[d]HNR: harmonic-to-noise ratio.

[e]RPDE: recurrence period density entropy.

[f]DFA: detrended fluctuation analysis.

[g]PPE: pitch period entropy.

Embedding Features Extraction

We extracted deep learning–based PASE embeddings [27] for our audio files. PASE represents the information contained in a raw audio instance through a list of encoded vectors. To ensure that the encoded vectors contain the same information as the input audio file, it decodes various properties of the audio file, including the audio waveform, log power spectrum, MFCCs,

four prosody features (interpolated logarithm of the fundamental frequency, voiced or unvoiced probability, zero-crossing rate, and energy), and local InfoMax, from the encoded vectors. The encoded vectors must retain relevant information about the input audio file to decode all these properties successfully.

As these properties represent the inherent characteristics of the input audio file rather than any task-specific features, they have been used to solve a host of downstream tasks, such as speech classification, speaker recognition, and emotion recognition. Therefore, we also used them for PD detection.

Experiments

For each feature set, we applied a standard set of machine learning algorithms, such as SVM [40], XGBoost [41], LightGBM [42], and random forest [43], to classify PD versus non-PD. SVM separates the data into several classes while maintaining the maximum possible margin among the classes. A random forest is built as an ensemble of decision trees; each decision tree builds a tree using a subset of features and learns if-else type decision rules to make a prediction. We also used XGBoost and LightGBM, algorithms based on gradient boosting where they build successively better models by refining the models at hand.

We used a leave-one-out cross-validation training strategy; using this strategy, one sample of data from the data set is left out, and the other n−1 samples are used to create a model and predict the remaining sample. We used metrics such as binary accuracy and AUC to evaluate our model's performance. AUC is the area under the receiver operating characteristics (ROC) curve. The ROC curve is constructed by calculating the AUC produced by taking the ratio of the true-positive rate and the false-positive rate while varying the decision threshold. AUC has the highest value of 1, which denotes that the two classes can be separated perfectly, whereas an AUC value of 0.5 indicates that the model cannot distinguish between the two classes. Because our data set was imbalanced, AUC is a much better metric for understanding the true performance of our model. To reduce the effects of data imbalance, we used data augmentation techniques such as the synthetic minority oversampling technique [44] and SVM synthetic minority oversampling technique [45].

Model Interpretation Technique

To interpret the models, we used the Shapley additive explanations (SHAP) technique based on the Shapley value. The Shapley value is a game-theoretic concept of distributing the payouts fairly among players [46]. In the machine learning context, each individual feature of an instance can be thought of as a player, and the payout is the difference between an instance's prediction and the average prediction. We choose SHAP for two reasons: (1) it is well suited for explaining the output of any machine learning model, and (2) it is the only feature attribution method that fulfills the mathematical definition of fairness.

To use SHAP to explain gradient boosting and tree-based models such as XGBoost, Lundberg et al [47] introduced methods to provide a polynomial time model to compute optimized explanations. Their method can generate local interpretations—how the features affect one particular prediction of a data instance—and then combine those local interpretations to make global interpretations about features present in the entire data set. By setting up a class of features to condition on, they traverse the tree in the following manner: if we are traversing on a node that was split based on a feature we are conditioning on, we simply follow the decision path; otherwise, the results from the left and right subtrees originating from the current node are computed recursively, and their results are added through a weighted summation strategy, thus computing the SHAP value for the feature in question.

Results

Overview

The data were preprocessed, and both standard acoustic features (eg, pitch, jitter, shimmer, and MFCC) and deep learning–based audio embedding features, representing an audio clip as a feature vector, were extracted; henceforth, we call these *standard features* and *embedding features*. In the rest of the *Results* section, we discuss the results from the models built on the entire data set, interpretations of the best model on the entire data set, and results and interpretation from specialized models on gender-stratified and age-trimmed data sets.

Detecting PD From the Entire Data Set

Table 3 contains the AUC and accuracy scores of the four machine learning models trained on the *standard features* and *embedding features* separately. Applying XGBoost on the standard features showed the best performance of 0.75 AUC and 0.74 accuracy. We also noticed that models trained on *standard features* work better than those trained on *embedding features.*

Table 3. Performance on the entire data set. The performance of various machine learning algorithms using the standard and embedding features on a data set combining data from both home and laboratory environments[a].

Algorithm	Standard features		Embedding features	
	AUC[b]	Accuracy	AUC	Accuracy
SVM[c]	0.751	0.735	0.738	0.692
Random forest	0.745	0.720	0.726	0.708
LightGBM	0.753	0.720	0.737	0.693
XGBoost	*0.750* [d]	*0.741*	0.722	0.689

[a]Models using standard features perform better than the models using embedding features in terms of both binary accuracy and area under the curve. Although the performance of the models is almost similar in terms of area under the curve metric, XGBoost outperforms others by considering both the area under the curve and accuracy metrics simultaneously.

[b]AUC: area under the curve.

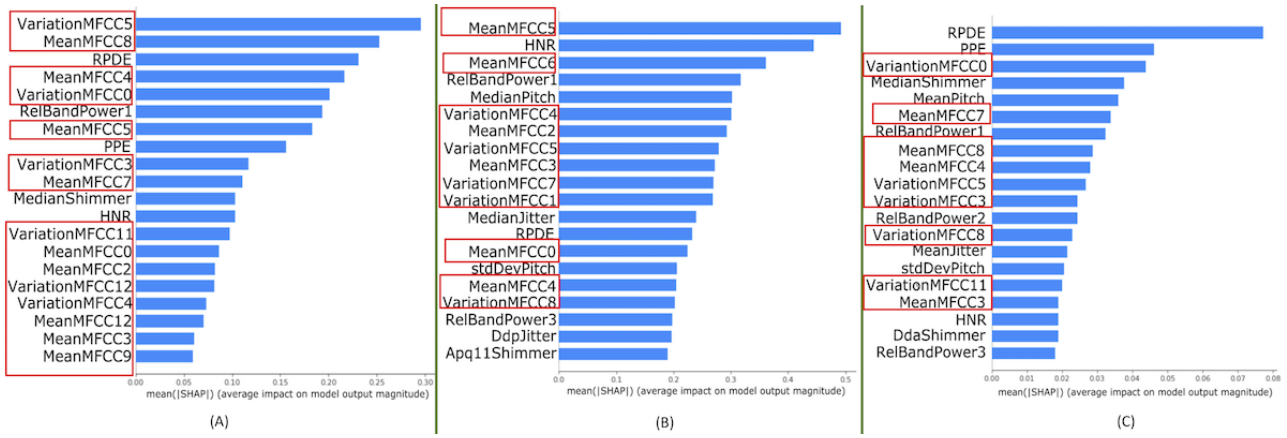
[c]SVM: support vector machine.

[d]Variable outperforms all others by taking both area under the curve and accuracy into account.

Model Interpretation

The goal of SHAP is to explain the model's prediction of any instance as a sum of contributions from its feature values; if a data instance can be thought of as $X_i=[f_1, f_2,...f_N]$, SHAP will assign a number to each of these f_j features, denoting the impact of that feature—both the magnitude and direction—on the model's prediction. Then, all these local explanations are aggregated to create a global interpretation for the entire data set. A global interpretation is presented in the first part of Figure 5; the top 10 most impactful features, ranked by having the most impact to the least, are presented. To calculate each feature's impact, all of its SHAP values across all the data instances are gathered, and then the mean of their absolute values is calculated.

Figure 5. Shapley additive explanations analysis of our best performing models on 3 data sets: (A) main model (ie, entire data set), (B) female model (ie, female only), and (C) age-trimmed model (all subjects are older than 50 years).

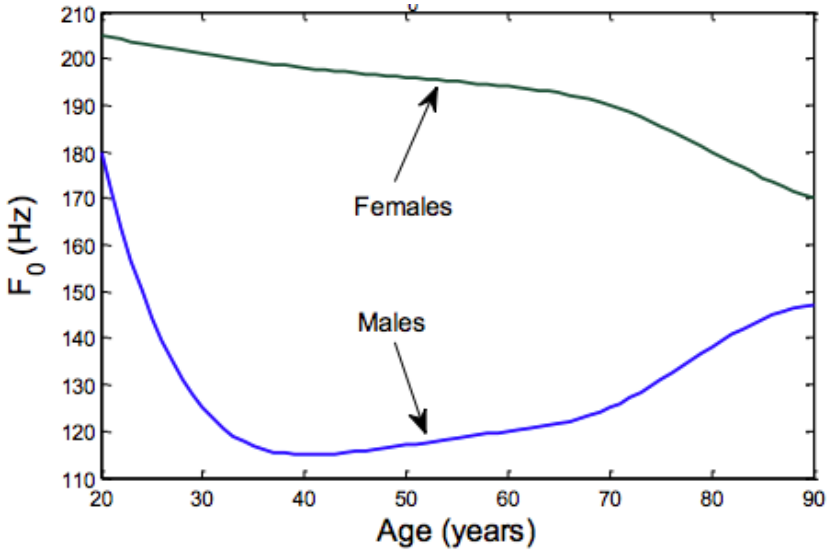


Features that have an impact on the model's performance are typically the spectral features: the mean values or the variation of MFCC in each spectrum range. Apart from that, some other complex features such as recurrence period density entropy (RPDE; a measure of uncertainty in F0 estimation), PPE (a measure of inability to maintain a constant F0), and harmonic-to-noise ratio (HNR) also affected the interpretation presented in the first part of Figure 5.

Gender- and Age-Stratified Analysis

The characteristics of a person's voice are greatly influenced by age and gender. In Figure 6, we see that men and women display a changing characteristic in their voices as they get older. Female voices have a higher F0 value, but it decreases with age. Males typically have a higher F0 value in their youth, which decreases with age and then increases roughly after the age of 45 years. Therefore, it can produce confounding effects when analyzing PD from audio, where the machine learning model uses audio features to detect PD. To minimize the effect of confounding factors, researchers trained separate models on data from male and female participants [28] or analyzed an age-trimmed data set by considering data from participants older than 50 years [4,29].

Figure 6. Changes in fundamental frequency F0 of voice as a function of gender and age (collected from Tsanas et al [13]).



Building Specialized Models for Each Gender- and Age-Trimmed Analysis

The performance metrics of the machine learning models trained on the male, female, and age-trimmed data sets are shown in Table 4. By comparing the performance with metrics presented in Table 3, we can see that the models that used male- or age-trimmed data sets performed at par or better than the models that used the whole data set to train. However, there was a performance drop in the models using the female data set. Table 1 shows that females are overrepresented in the non-PD group and underrepresented in the PD group, leading to data imbalance and possibly lowering performance for the female-only model.

Table 4. Gender- and age-stratified models. Three separate data sets were constructed: a male data set with male participants, a female data set with female participants, and age-trimmed data set by excluding the participants younger than 50 years. For each of these data sets, a separate model was constructed, and its performance is reported below (N=726).

Algorithm	Male (n=415)		Female (n=477)		Age-trimmed (male, n=366 and female, n=426)	
	AUC[a]	Accuracy	AUC	Accuracy	AUC	Accuracy
SVM[b]	0.795	0.717	0.659	0.763	0.755	0.723
Random Forest	0.758	0.702	0.699	0.788	0.739	0.713
LightGBM	0.725	0.665	0.717	0.768	0.749	0.712
XGBoost	0.762	0.717	0.682	0.771	0.742	0.704

[a]AUC: area under the curve.

[b]SVM: support vector machine.

We also analyzed the features that drive the performance of these specialized models through SHAP analysis. The second part of Figure 5 shows the most salient features ranked by their SHAP value and the distribution of the impact of each feature on the model's decision-making. The most important features are still dominated by the MFCC-related features or complex features such as the HNR, relative band power in different frequency ranges (RelBandPower1, RelBandPower3), RPDE (uncertainty in F0 estimation), perturbation in F0 (DdpJitter), or perturbation in amplitude (Apq11Shimmer). However, one noticeable fact is that three-pitch and jitter-related features—MedianPitch (median principal frequency, StdDevPitch (SD in principal frequency) and MedianJitter (median variation in F0)—also affected the model's prediction, which was not noticed in the SHAP analysis run on the all-data-model.

Similarly, we interpreted the salient features of the age-trimmed data set in the third part of Figure 5. We noticed that the most salient features usually come from the MFCC feature groups, complex features (RPDE, PPE, and HNR), relative band power (RelBandPower1, RelBandPower2, and RelBandPower3), and pitch-related features. In addition, the pitch-related features also drove the prediction of the model.

Discussion

Limitations

In all of our experiments, we chose leave-one-out cross-validation to maintain uniform experimental settings between different models, data augmentation, and data set combinations because K-fold cross-validation can show high variance in performance based on how stratified the folds are. However, we acknowledge that our choice introduces the problem of overfitting and increases the computational complexity manifold. Therefore, we could not run extensive hyperparameter tuning to improve the performance of our

models. By carefully stratifying the folds and maintaining the same fold settings for comparable experimental settings, K-fold cross-validation may enable us to achieve higher performance with lower computational complexity.

Moreover, our chosen metrics, accuracy and ROC AUC, can be overly optimistic because of the unbalanced nature of our data set. Metrics such as ROC–Precision-Recall balanced accuracy, and more information about sensitivity and specificity may shed more light on how we are performing in the minority class. In the future, we plan to apply other cross-validation techniques and better metrics to conduct our experiments and report our performance.

Detecting PD From Regular Conversation

Some of the most common voice disorders induced by PD are dysphonia (distortion or abnormality of voice), dysarthria (problems with speech articulation), and hypophonia (reduced voice volume). Two speech-related diagnostic tasks are commonly used to detect PD by exploiting the changing vocal pattern caused by these disorders: (1) sustained phonation (the participant is supposed to utter a single vowel for a long time with constant pitch) and (2) running speech (the participant speaks a standard sentence). Little et al [12] developed features for detecting dysphonia in patients with PD. Tsanas et al [25] focused on the telemonitoring of self-administered sustained vowel phonation task to predict the Unified Parkinson's Disease Rating Scale rating (on Rating Scales for Parkinson's Disease 2003), a commonly used indicator for quantifying PD symptoms. These studies trained their models with data captured by sophisticated devices (eg, wearable devices, high-resolution video recorder, and the Intel at-home–testing-device telemonitoring system) that are often not accessible to all and are difficult to scale. The performance of these models can be significantly reduced when classifying data collected in home acoustics. In addition, correctly completing the sustained phonation task requires following a specific set of guidelines, such as completing the task in one breath, which can be difficult for older individuals.

In contrast, we analyzed the running speech task from the data collected by using a web-based data collection platform that can be accessed by anyone anywhere in the world and requires only an internet-connected device with an integrated camera and microphone. In addition, the running speech task does not require conforming to specific instructions and is more similar to regular conversation; therefore, the model can be potentially augmented to predict PD from a regular conversation—a potential game-changer in PD assessment. In the future, user-consented plug-ins could be developed for apps such as Alexa, Google Home, or Zoom, where audio is transmitted between persons. Anyone who consents to download the plug-in and uses it while on the phone, over Zoom, or giving virtual or in-person presentations could benefit from receiving an informal referral to see a neurologist, when appropriate. The plug-in would not store the participants' data unless they opt to build a personalized profile to ensure privacy and ethical usage of our framework.

Validating Model Interpretation

The features that SHAP found to have an impact on modeling decisions are well supported by previous research. For example, MFCC features have already proven to be useful in a wide range of audio tasks such as speaker recognition [48], music information retrieval [38], voice activity detection [49], and most importantly, in voice quality assessment [50]. Similarly, the high impact of the HNR and the measures of uncertainty in F0 estimation (RPDE) and inability to maintain a constant F0 (PPE) on the model's output are in congruence with the findings from Little et al [12]. However, explaining the first part of Figure 5 in light of PD-induced vocal impairment is a difficult task. MFCC features are calculated by converting the audio signal into the frequency domain, and they denote how energy in the signal is distributed within various frequency ranges. Therefore, providing a physical interpretation of the SHAP values corresponding to the MFCC features is not straightforward. Similarly, Little et al [12] designed the RPDE and PPE features to model a sustained phonation task (uttering "ahh") with the assumption that healthy participants will be able to maintain a smooth and regular voice pattern. In contrast, uttering multiple sentences introduces considerable variation in the data, adding a wide set of heterogeneous patterns. Therefore, the underlying assumptions behind constructing these features do not hold for our task of uttering multiple sentences.

We conduct an empirical validation of the SHAP output shown in the first part of Figure 5. We incrementally add one feature at a time to build a dynamic feature set, train successive models on that feature set, and report the accuracy and AUC performances. We see that the performance of our model saturates after adding 7 to 8 features. Therefore, we can say that the SHAP analysis teases out the most important features driving the model's performance successfully.

Why Not Stratified Analysis Only?

We built models inclusive of all genders for several reasons. First, there are potential shared characteristics among vocal patterns of all genders that can be relevant for detecting PD. Second, dividing the data set into two portions reduces the available training data for each model, which may, in turn, reduce the generalization capability of each model. In addition, our model analyzes data from patients of all ages. Although most people diagnosed with PD are older than 60 years, approximately 10% to 20% of the population diagnosed with PD are younger than 50 years, and approximately half of them are younger than 40 years [51]. As anecdotal evidence, Michael J Fox was diagnosed with PD at the age of 29 years [52], and Muhammad Ali had PD by 42 years [53]. In our data set, there were also a minority of patients with PD who were younger than 50 years (Figure 4). On the basis of these observations, we believe that our system should provide access to all people, irrespective of age. PD does not discriminate by age while affecting a person, and an automated system should not discriminate based on age and provide equitable services to people of all ages. However, these factors can function as confounders in PD analysis. Therefore, we provided additional analysis to ensure that our model does not use the idiosyncrasies of group-specific information to make predictions.

Performance Excluding Laboratory Environment Data

When the data were collected in the laboratory, participants had access to a clinician providing support using a consistent recording setup and dedicated bandwidth. In contrast, the data collected in the home setting involved no assistance and included the real-world variability of heterogeneous recording setups and inconsistent internet speed. In theory, the data collected at the *laboratory* and *home* were very different from each other.

To ensure that our model works equally well without the *clean lab data*, we designed two experiments. In experiment 1, we removed clean lab data, which was approximately 7.4% (54/726) of the entire data set, retrained our model on the remaining 672 participants using the leave-one-out validation procedure, and calculated the performance metrics. In experiment 2, we randomly removed 7% (roughly 54 data points) of *home* data from the entire data set (while keeping the *lab* data intact), building a model with the remaining 93% data with the leave-one-out cross-validation method. Then, we conducted experiment 2 10 times and calculated the *average* performance from these 10 runs. We found that the AUC metric across these three experiments was fairly consistent, with a very small 0.015 decrease in AUC when removing lab data, demonstrating that our framework performs equally well across the *lab* and *home* data.

Label Inconsistency and Predicting Tremor Score

Using the PARK [29] protocol, we collected one of the largest data sets of participants conducting a series of motor, facial expression, and speech tasks following the MDS-UPDRS PD assessment protocol [3]. Although we analyzed only the speech task in this study, the data set can be potentially used to automate the assessment of a large set of MDS-UPDRS tasks and facilitate early-stage PD detection, thus improving the quality of life for millions of people worldwide. However, deploying the data collection protocol on the web and facilitating access to anyone anywhere around the world comes at a cost. To date, all of our participants with PD have been clinically verified to be diagnosed with PD. Therefore, the labels of the PD data points are reliable. However, the participants without PD did not undergo clinical verification. Our data collection protocol asked them appropriate questions to check whether they had been diagnosed with PD and collected data when they answered in the negative. However, we cannot discount the possibility that a small subset of our population without PD is in the very early stage of PD and is oblivious about it. At present, there are estimated to be around 1 million patients with PD in the United States, out of a population of 330 million [51], yielding a PD prevalence rate of 0.3%. However, as our non-PD data set was largely tilted toward people older than 50 years, the rate in our data set could be higher than 0.3%. Even if we consider a liberal 1% prevalence rate, the number of individuals with undiagnosed PD in our control population is likely low (at most 4.6 persons). Therefore, we believe that the non-PD data labels are generally reliable. In the future, we plan to model tremor score in (0-4 range for each task; 0 for no tremor, and 4 for severe tremor) instead of a binary label following the MDS-UPDRS protocol to address this problem more thoroughly.

Building a More Representative Data Set

The PARK protocol is web enabled, allowing anyone with access to the internet to contribute data. We plan to augment our data set by adding more non–native English speakers, females, and participants with PD. As our PD data are collected through contacts from local PD clinics and non-PD data through Amazon Mechanical Turk, most of our participants were from the United States or other English-speaking countries. To make our model more robust on data from non–native English speakers, we are in process of collecting both PD and non-PD data from non–native English-speaking countries. In addition, our current protocol can collect data from people with computer and internet access only, and therefore, it can potentially exclude underserved people. In the future, we plan to build desktop and mobile apps that can collect data offline to build a more inclusive framework.

Our best model for female data performed worse than its male counterparts, as shown in Table 4. We attribute this degraded performance PD or non-PD imbalance for female participants in our data set: the PD-to-non-PD ratio for females was 101 out of 300 (Table 1). Previous epidemiological studies have shown that both the incidence and prevalence of PD are 1.5 to 2 times higher in men than in women [54,55]. Therefore, any randomly sampled data set for PD will have a higher prevalence of males, contributing to models that are more biased toward males. Our immediate plan is to prioritize collecting balanced data from all genders, ages, and races across geographical boundaries, leading to a balanced data set.

Our data set also has the ubiquitous problem of data imbalance in diagnostic tests: the amount of data from participants without PD is 1.8 times more than their PD counterparts. Therefore, there is a risk that the model will be biased toward predicting the majority non-PD class as default and yield a high false-negative score. To address this, we plan to recruit more participants with PD in the future to make our data set more balanced. Another potential approach is to run the analysis on a subset of the data set produced by conducting proper age, gender, and matching of patients with and without PD.

As shown in Table 1, our participants with PD were diagnosed 7.88 (SD 5.41) years ago. Owing to limited data availability, we did not conduct an analysis on early-stage PD prediction. In the future, we plan to include more participants in the early stages of PD and build models that can detect them. We will especially focus on recruiting participants with PD in the age range of 20 to 40 years to analyze the very early-stage onset of PD among young adults. Furthermore, we plan to collect and analyze multiple speech instances from each person to reduce person-specific variability and obtain a more holistic view of their PD state.

Increasing Model Performance

Although we consider AUC to be a better metric for our data set, our model performs 10% better than always choosing non-PD as the prediction in terms of binary accuracy. To be practically deployable in clinical settings, the performance needs to be improved further. We will focus on four promising avenues: making the data set balanced, designing better features

capable of modeling the nuanced pattern in our data, making our model resilient to noise present in our data, and deconfounding the PD prediction from age and gender variables.

To remove noise, we plan to augment the techniques proposed in Poorjam et al [56] to automatically enhance our data quality by detecting the segments of data that conform to our experimental design. Moreover, as discussed above, gender and age can appear as confounding variables in the PD prediction task. In this paper, we have shown that our unified model and stratified sex-specific models have similar performance. However, we plan to build better models to systematically deconfound the effects of both age and gender variables while benefiting from them simultaneously. We can achieve this by incorporating the causal bootstrapping technique—a resampling method that considers the causal relationship between variables and negates the effect of spurious, indirect interactions, as outlined by Little and Badawy [57].

Acknowledgments

This research was funded by the National Institute of Neurological Disorders and Stroke of the National Institutes of Health under award number P50NS108676.

Authors' Contributions

WR, SL, MSI, and VNA worked in data analysis, feature extraction, model training, model interpretation, and manuscript preparation. HR, AAM, EW, and SJR helped build, maintain, and coordinate the data collection procedure. MRA, MAL, and RD helped improve the manuscript; suggested important experiments; and provided access to critical resources such as code and data. All the other authors helped in data collection. EH was the principal investigator of the project; he facilitated the entire project and helped shape the narrative of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The COVID-19 pandemic has increased the demand for youth mental health services in Canada as disruptions to clinical care continue to persist due to the risk of transmission and exposure to the virus. Digital mental health interventions, including web-based resources and mobile apps, have provided opportunities to support youth mental health remotely across Canada. There is a need to better understand how these digital interventions are being selected, recommended, and used in various regions across Canada.

Objective: A national jurisdictional scan was completed to (1) determine what web-based programs, apps, and websites are promoted and licensed in Canada for youth mental health; (2) identify criteria and decision-making processes that Canadian jurisdictions use to select web-based programs, apps, and websites for youth mental health; and (3) identify upcoming trends, innovations, and digital mental health possibilities that are emerging in the youth sector.

Methods: The aims of the jurisdictional scan were addressed through a review of related academic and grey literature; stakeholder interviews, including individuals involved in various areas of the youth mental health sector; and a social media review of pertinent Twitter content.

Results: A total of 66 web-based resources and apps were identified for use by youth in Canada. 16 stakeholder interviews were completed and included discussions with researchers, clinicians, youth organizations, and others involved in digital interventions for youth mental health. These discussions identified a limited use of frameworks used to guide decision-making processes when selecting digital interventions. Many clinicians agreed on a similar set of eligibility requirements for youth mental health apps and digital resources, such as the evidence base and cultural relevance of the intervention. Stakeholders also identified upcoming trends and innovations in the youth digital mental health space, including artificial intelligence, digital phenotyping, and personalized therapy. Over 4 weeks, 2184 tweets were reviewed to identify and compare global and national trends and innovations involving digital mental health and youth. Key trends included the promotion of regional chat services as well as the effects of the COVID-19 pandemic on youth mental health and access to care.

Conclusions: As organizations begin to plan for the delivery of mental health care following the pandemic, there are concerns about the sustainability of these digital mental health interventions as well as a need for services to be more informed by the experiences and preferences of youth.

(J Med Internet Res 2021;23(10):e30491) doi:10.2196/30491

KEYWORDS

youth mental health; digital mental health; COVID-19; digital mental health interventions; e-mental health

Introduction

Canadian jurisdictions have significantly altered their delivery of mental health care for youth over the past year, given the rising need for mental health services related to the COVID-19 pandemic [1]. A Canadian study indicated that 67% to 70% of children and adolescents aged 6-18 years have experienced a deterioration in one or more mental health domains because of changes such as stress and social isolation during the pandemic [1]. Organizations have broadened their use of virtual care and digital mental health interventions, including web-based programs, apps, and websites [2]. In consideration of the rapid shift to the use of digital mental health services and interventions, this review can support Canadian decision-makers and leaders in understanding these changes and how youth mental health is supported through digital interventions. To accomplish this, a jurisdictional scan was completed to address current needs and future directions in the youth mental health space.

To identify digital mental health resources, criteria, and decision-making processes used to select resources, and upcoming trends and innovations, the following aims were established:

1. Determine what web-based programs, apps, and websites are promoted and/or licensed by Canadian jurisdictions (eg, health authorities, national youth mental health organizations, provinces, and territories) for youth mental health.
2. Identify criteria and decision-making processes that Canadian jurisdictions use to select web-based programs, apps, and websites for youth mental health.
3. Identify upcoming trends, innovations, and digital mental health possibilities that are emerging in the youth sector.

Methods

A review of current academic and grey literature was completed, including searches of databases (eg, PubMed, University of Toronto Libraries), reports, working papers, and presentations from Canadian digital health organizations. Titles and abstracts were reviewed to determine if information about youth mental health and digital interventions was included. Sources that met this inclusion criterion were then subjected to rapid content analysis and were organized based on identified themes. App stores, including the Google Play Store and Apple App Store, were also reviewed to identify digital mental health apps currently available to youth in Canada.

A series of key stakeholder interviews were conducted with representatives across Canada. Single interviews were conducted by two members of the research team via videoconferencing or telephone and followed a semistructured design based on a set of six questions. Participants were asked to discuss the criteria their organization uses to select resources for youth or decision-making processes/appraisals that are used to evaluate digital resources such as websites and mobile apps. Trending and emerging innovations were also discussed, and all participants were able to provide additional information relevant to the topic. One research member took notes during each interview, and this information was later used for thematic analysis to identify key themes.

Data mining techniques and content analysis were used to retrieve and analyze information collected from the Twitter application programming interface over 4 weeks using a Twitter Archiving Google Sheet (TAGS). As Twitter is a platform commonly used by researchers, clinicians, youth organizations, health care leaders, and others involved in youth mental health care, Twitter data provided a snapshot of in-the-moment insights into trending topics and innovations related to digital mental health interventions for youth during the COVID-19 pandemic. These trends were identified to understand the similarities or disparities between the experiences of national and international stakeholders.

Further information about the methodology used for this research is available upon request from the corresponding author.

Results

Review of Web-Based Resources, Apps, and Related Literature

A total of 66 digital interventions were identified as promoted or licensed by Canadian jurisdictions and organized based on their delivery methods, including web-based resources or mobile apps. Information was recorded for each resource based on the American Psychiatric Associations App Evaluation Model [3]. A complete list of the digital interventions, including web-based resources, and associated criteria and tags are available in Multimedia Appendix 1, and the mobile apps are provided in Multimedia Appendix 2.

The review of related literature identified current trends in the youth digital mental health space. A common theme that was highlighted throughout the review of the literature was the limited availability of evidence-based apps. Numerous reviews revealed that formal evaluation methods were often not used to support the use of mobile apps for youth mental health, raising concerns about the efficacy of digital interventions used in clinical settings [4-8]. Researchers recommended that more

rigorous testing be done to provide high-quality evidence for the use of digital interventions for youth mental health [8].

Research studies also reviewed the use of evaluation methods for digital mental health interventions for youth and provided various metrics used to quantify effectiveness and improvements to mental health [9-11]. A systematic review included metrics such as mental health outcome data, health service outcome data, technology use, and feedback from children and youth [9]. Other evaluation methods included clinical outcomes of randomized control trials to determine the effectiveness of digital mental health interventions [10].

Co-design was identified as a powerful tool in the development of digital mental health interventions for children and youth. Researchers indicated that there is a need for co-design with youth, including "creative collaboration, varying stages of involvement, collaboration activities, user-engagement techniques, prototype development, and consideration for diversity within youth populations" [12].

Most of the articles focused on the development and use of mobile apps targeting child and youth experiences with anxiety and depression [13-16]. There was a paucity of research on other types of digital mental health interventions as well as any digital interventions for eating disorders and many complex mental illnesses, with only one article identified on youth experiences with psychosis [17].

Gamification was also identified as a prominent topic in the results of the review. Some considerations were discussed that can address the needs of specific youth groups who may benefit from the use of personalized game-based interventions [18-21]. Some considerations include the integration of video games with clinical care processes and programming, the use of gender-diverse characters in game-based digital mental health interventions, and a focus on the prevention of mental illness as opposed to treatment-based games [18].

Stakeholder Interviews

A total of 16 stakeholders, including clinicians, researchers, youth organizations, online therapists, business analysts, and others involved in the youth mental health space, took part in the interviews. Organizations included representation from numerous regions within Canada, including Ontario, British Columbia, Alberta, and Nova Scotia, as well as the US state of Massachusetts. Stakeholders discussed the digital mental health interventions they currently use, that their organization endorses, or that they are involved in for research purposes.

Additionally, the stakeholders discussed the need for improved guidance when selecting and appraising digital mental health interventions for youth. Overall, most respondents relied on individual selection criteria to inform their decision-making processes as opposed to standardized frameworks. Table 1 includes a list of specific appraisal tools referenced by participants as well as individual criteria cited by respondents as informing their decision-making processes.

Table 1. Decision-making processes and appraisal methods used for selecting digital mental health interventions for youth identified during stakeholder interviews.

Process or appraisal method	The rationale for process or appraisal
Frameworks	
Mental Health Commission of Canada Toolkit	The toolkit can reduce clinician workload, ensure resources are evidence-based, increase interoperability, and provide valuable information for those with limited experience with digital mental health.
Homewood Research Institute App Evaluation Framework	Used to evaluate the effectiveness of mental health apps and identifies the highest quality apps. Focuses on measuring outcomes, design and transparency, design methodology, and operational considerations of each application.
Selection criteria	
Evidence base	Resources that are evidence-based and have supporting literature are often more accepted for use in clinical settings.
Accessibility	Providers and researchers must consider the cost and technology requirements associated with recommending a digital intervention.
Visual appeal	Mobile apps and web-based resources should host bright and catchy graphics, including music and characters, to grab the attention of youth.
Feedback from youth	Recommendations should be developed based on feedback from youth about what they are looking for and the apps they are already using.
Cultural relevance	When serving youth, including BIPOC,[a] further considerations must be made to ensure that the digital resource/intervention considers specific needs of various cultural and racial minority groups.

[a]BIPOC: Black, Indigenous, and people of color.

The discussions with stakeholders also identified new trends and innovations these individuals and organizations have seen in the youth digital mental health space. Table 2 highlights the most frequently cited innovations considered in response to the COVID-19 pandemic and other trends currently being studied in Canada.

Table 2. Upcoming trends and innovations in digital youth mental health identified through stakeholder interviews.

Trend or innovation	Description
Artificial intelligence/ machine learning	Including mobile apps that use artificial intelligence–powered chatbots.
Digital phenotyping	Tracking the activities of users to determine how digital activity might indicate a change in behavior or mental state.
Personalized therapy	Interventions that consider culture, language, geography, and more.
Interoperability	Using data from mobile apps alongside clinical data from health information systems.
Online peer support groups	Online groups moderated by health professionals to create safer digital environments for youth.
Trauma-informed interventions	Emerging mobile apps that target specific experiences with trauma.
Increasing accessibility	Potential to reach a greater number of children and youth through digital means alongside traditional in-person care.
Gamification	Development of video and digital games used to provide support and education about mental health and wellness.
Social media	The use of platforms such as Instagram and Twitter to help organizations reach youth and promote the availability of digital health interventions and resources. Instagram was also used in specific cases by youth organizations to provide mental health support through the application's direct messaging feature.
TikTok	Includes TikTok accounts that provide short and accessible videos about mental health and wellness that can easily reach youth who are already using the app.

Social Media Review

A total of 2184 tweets containing content or hashtags relating to digital interventions for youth mental health were included. Of these tweets, themes included promotion of regional chat services, such as text and telephone lines available 24 hours per day, 7 days per week for youth mental health support. Effects of isolation due to COVID-19 on youth mental health were highlighted, primarily concerning families who have experienced suicide and self-harm in youth [22]. A greater need for access to mental health care and reduction of hospital beds available for youth mental health due to staff shortages in New Brunswick was also a prominent topic [23]. Web-based resource hubs, webinars, and virtual panel discussions provided by youth mental health organizations were frequently promoted. Advocacy for government funding due to an increasing national need for youth mental health care was also discussed. Lastly, resources specifically designed to meet the needs of lesbian, gay, bisexual, transgender, queer, and two-spirit (LGBTQ2S+) youth were also promoted on the platform through youth-friendly infographics.

Discussion

Future Directions

Although digital mental health interventions can provide great benefit during the COVID-19 pandemic, there is concern among some clinicians and researchers about the sustainability of these interventions once in-person care resumes across Canada. As digital mental health interventions are developed for youth, there needs to be increased awareness of how these interventions are being selected and the opportunities to better integrate these interventions with clinical care. One consideration includes improved transparency and quality considerations in how digital mental health interventions are selected, as shown in Table 1. Individuals involved in the development of digital resources for youth mental health must consider these selection criteria, such as cost, technology, privacy requirements, evidence base, visual appeal, and cultural relevance. Engagement with youth in planning and improving the integration of digital health with organizations across the mental health system continuum is vital to ensuring the longevity of these resources following the pandemic. Additionally, further research should be done to review content related to digital mental health on other social media platforms that are frequently used by youth, including Instagram and TikTok.

Conclusions

Current literature, key stakeholder interviews, and mining of a social networking platform all point to the need for a greater understanding of digital intervention use for youth mental health during and beyond the COVID-19 pandemic. The use of digital interventions such as web-based resources and apps can be driven using suitable frameworks and selection criteria. Upcoming trends and innovations indicate an opportunity to improve and expand the use of digital interventions for youth in Canada.

Abstract

Background: Clinic attendance, metabolic control, engagement in self-management, and psychological health are suboptimal in young-onset (age of onset <40 years) type 2 diabetes.

Objective: We examined the effectiveness of an enhanced SMS text message–based support and reminder program in improving clinic attendance, metabolic control, engagement in self-management, and psychological health in young-onset type 2 diabetes.

Methods: A 12-month, parallel-arm, randomized controlled trial comparing an enhanced, semipersonalized SMS text message–based intervention (incorporating 1-8 supportive and/or informative text messages per month) against standard care was conducted in a specialized clinic for young adult type 2 diabetes. The primary outcome was maintenance of 100% attendance at scheduled quarterly clinical appointments. Secondary outcomes included (1) metabolic indices, (2) pathology and self-monitored blood glucose (SMBG) data availability, and (3) psychosocial well-being.

Results: A total of 40 participants were randomized, and 32 completed their 12-month study visit. The average participant age was 32.7 (SD 5.1) years, 50% (20/40) were male, and baseline glycated hemoglobin A_{1c} (HbA_{1c}) was 7.3% (SD 1.9%) (56 mmol/mol, SD 20). A higher proportion of the intervention group achieved 100% attendance (12/21, 57%, vs 5/19, 26%, for the control group); Kaplan-Meier analysis demonstrated significantly greater cumulative attendance in the intervention group (*P*=.04). There were no between-group differences in HbA_{1c}, BMI, lipids, or availability of pathology and SMBG data. Odds of recording an improvement in the Diabetes Empowerment Scale–Short Form score were higher in the intervention group at 6 months (odds ratio [OR] 4.3, 95% CI 1.1-17), with attenuation of this effect at study end (OR 3.1, 95% CI 0.9-11). Program acceptability was high; >90% of participants would recommend the program to new patients.

Conclusions: An enhanced SMS text message–based support and reminder program doubled scheduled clinic attendance rates for patients with young-onset type 2 diabetes. The program was highly acceptable and provided early support for patient empowerment but had no significant effect on measures of metabolic control or self-management.

KEYWORDS

young-onset type 2 diabetes; SMS; clinic attendance; engagement; diabetes; digital health; mobile health; adolescents

Introduction

Over the past 20 years, young-onset type 2 diabetes (age of onset <40 years) has emerged as a significant clinical problem. The worldwide prevalence of young-onset type 2 diabetes more than doubled during the decade spanning 2003 to 2013, and today, well in excess of 60 million young people are living with type 2 diabetes [1,2]. This is particularly concerning given the aggressive nature of young-onset type 2 diabetes, with high rates of complications, established premature mortality, and the poorest comparative outcomes [3-6].

Suboptimal clinic attendance and poor engagement in self-management represent significant barriers to improving long-term outcomes [7,8]. There is specific evidence that clinic attendance associates with favorable outcomes in young-onset type 2 diabetes; during the landmark Treatment Options for Type 2 Diabetes in Adolescents and Youth (TODAY) study of adolescent type 2 diabetes, it was established that participants who attended ≥75% of scheduled lifestyle education sessions achieved significantly greater weight reductions than those who attended less often [9]. An audit of clinic attendance at a metropolitan, hospital-based diabetes center clearly demonstrated that young adults with type 2 diabetes were the subgroup that had the highest rate of nonattendance; median loss to follow-up time was approximately 4 months [10]. As each clinical encounter provides an excellent opportunity to review a patient's understanding of diabetes and its management, convey important messages relating to self-management, adjust pharmacotherapy, perform complications screening, and foster a therapeutic rapport, novel ideas are needed to motivate young adults with type 2 diabetes and encourage more reliable clinic attendance.

In recent years, innovative text messaging interventions have yielded promising results in high-risk groups. The landmark TEXTME study demonstrated that a structured, lifestyle-based SMS text messaging program could improve cardiovascular risk factor management after myocardial infarction [11]. In adolescent medicine, SMS text message interventions have been used to address important issues, including teenage pregnancy and binge drinking of alcohol [12,13]. In the field of diabetes, the SMS4BG study established that an SMS text messaging program could facilitate modest improvement in glycemic control [14]. However, the SMS4BG study did not specifically examine the impact of the program on clinic attendance, nor did it specifically target individuals with young-onset type 2 diabetes. A study from Hong Kong did identify a benefit of an SMS text message reminder for the attendance rate within a type 2 diabetes population at a primary care clinic [15]. However, participants in the Hong Kong study had a mean age of 63 years; as a result, the benefit of SMS text message reminders in the young-onset type 2 diabetes setting remains to be established. Overall, young adults with type 2 diabetes have been underrepresented in most clinical studies to date [16]. Consequently, high-quality evidence to guide management of young-onset type 2 diabetes remains scarce.

It is widely understood that young people are frequent users of information and communications technology. In 2012 and 2017, young adult respondents to our diabetes and technology survey reported the highest rates of mobile phone ownership and a high degree of comfort with the use of technology in diabetes management [17]. Familiarity with SMS text messaging technology as well as its low cost and ready scalability provide a great impetus for an exploration of the utility of SMS text message interventions in the young adult demographic. We hypothesized that an enhanced SMS text message–based support and reminder program would improve clinic attendance, metabolic health, and engagement in diabetes self-management and psychosocial well-being within our young-onset type 2 diabetes cohort. We set out to test this hypothesis in the TEXT2U randomized controlled trial (RCT).

Methods

Study Design

TEXT2U was a parallel group, investigator-blinded, 12-month RCT involving participants with young-onset type 2 diabetes (age of onset 18-40 years). The primary aim was to assess the effect of an enhanced SMS text message–based support and reminder program on clinic attendance. Secondary aims were to assess (1) metabolic outcomes, (2) diabetes self-management practices as evidenced by availability of self-monitoring of blood glucose (SMBG) data and pathology results, and (3) the psychosocial impact of the intervention as measured by change in validated diabetes-specific questionnaire scores (Problem Areas in Diabetes 5-item Short Form (PAID-5) [18], Diabetes Empowerment Scale–Short Form (DES-SF) [19], and Type 2 Diabetes Stigma Assessment Scale (DSAS-2) [20]). The study was approved by the Sydney Local Health District Ethics Review Committee and registered with the Australian and New Zealand Clinical Trials Registry (ACTRN12618000479202).

Study Setting and Participant Recruitment

The Royal Prince Alfred Hospital (RPAH) Diabetes Centre is a secondary and tertiary referral center that services an ethnically diverse population in metropolitan Sydney, Australia. Individuals were eligible to enter the study if they had an established type 2 diabetes diagnosis, had access to a mobile phone, and were aged 18-40 years at time of enrolment. Individuals with insufficient proficiency in English to read the text messages in the study were excluded. All participants

provided written informed consent prior to study entry. Recruitment was performed between March and August 2018.

Randomization

Block randomization was employed with a standard block size of 4 using a customized, computer-based program. Participants were allocated 1:1 to either the standard care control group or the standard care plus enhanced SMS text message–based support and reminder intervention group. Medical staff delivering patient care were blinded to study group allocation.

Interventions

Control: Clinic Standard of Care

The control group received our young-onset type 2 diabetes clinic standard of care, which is aligned with and realizes current recommendations for youth and young adults with type 2 diabetes [21]. It includes quarterly follow-up appointments with a diabetes educator and endocrinologist. Glycemic control was assessed via glycated hemoglobin A_{1c} (HbA_{1c}) and capillary-based SMBG results, weight and blood pressure (BP) were measured, and treatment adjustments were made at the discretion of the treating endocrinologist. Dietary review with an accredited dietitian was provided as required. All participants were given a personal blood glucose meter with a starter pack of glucose monitoring strips and a personal lancing device for SMBG. All individuals in the young adult type 2 diabetes clinic are enrolled in the Australian National Diabetes Services Scheme, which provides ongoing access to subsidized glucose testing strips and lancets.

After each clinic visit, participants were provided with details of their next follow-up appointment. A generic SMS text message reminder was sent prior to scheduled appointments via the hospital's outpatient management system. In the event of a missed clinic appointment, clinic staff made attempts to contact the relevant individual (via telephone and email) to reschedule a makeup appointment.

Intervention: Enhanced SMS Text Message–Based Support and Reminder Program

The enhanced SMS text message–based support and reminder program involved receipt of clinic standard of care as outlined above, plus a structured program of semipersonalized text messages. Message content was individualized on the basis of key baseline characteristics, including gender and smoking status. Message delivery was managed by an automated system developed and programmed by coauthor AT (TextQStream, Python 3.6, using the Pycap 1.02 library). This system was developed previously [22], and customization was performed in-house for the TEXT2U trial. Computer software was run through the University of Sydney Research Electronic Data Capture (REDCap) system [23]. Messages to the study participants were sent through a gateway interface over Australian telephone networks at no cost to individual participants. All SMS text messages sent during the study were logged by the system; the study log included the date and time that each message was delivered. All participants received an introductory message in the week following their baseline visit and then two messages per week for the first 2 months of the study. Text message frequency decreased to one message per week during the third month and then one text message per month thereafter. All study messages were sent at random times during standard business hours: Monday to Friday, 9 AM to 5 PM. Instructions on how to opt out of the messaging program were provided.

The SMS text messaging program was developed by a focus group of 10 diabetes specialists associated with the Royal Prince Alfred Hospital Diabetes Centre; adjustments were made following consumer review by young adults with diabetes. In particular, 15 young adults with diabetes (aged 18-40 years), who did not form part of the young adult type 2 diabetes clinic, were asked to complete a brief survey and each provide feedback on different subsets of messages that were to be featured in the study. Program messages were designed to contain a mix of supportive and informative content. Messages were entirely text-based; emojis and multimedia messaging were not incorporated into the program. A personalized appointment reminder was sent to participants in the enhanced SMS group in the week before each follow-up appointment. Examples of program text messages are included in Multimedia Appendix 1 (Table S1).

An option was provided for enhanced SMS group participants to engage with the study team via the study-specific SMS portal. Questions relating to diabetes and its management could be sent directly to the study team at a participant's convenience. The SMS portal was actively monitored by a research assistant, and all text messages received from participants were reviewed and replied to within 1 business day.

Trial Procedures

All participants underwent baseline assessment and were asked to attend quarterly follow-up visits for 12 months. Weight, BP, SMBG records, and routine pathology test results were assessed at each study visit. At baseline, all participants completed the Health Literacy Questionnaire [24]. Validated measures of psychosocial status, including the PAID-5 [18], DES-SF [19], and DSAS-2 [20], were self-completed by participants at baseline, 6 months, and 12 months. Participants assigned to the enhanced SMS intervention group were invited to complete an evaluation of the program via a standardized, study-specific questionnaire at the end of the study.

Statistical Analysis

From prior analyses [10], the median time to clinic dropout associated with our standard care approach in the young-onset type 2 diabetes clinic was 4 months. Previous studies comparing attendance rates in SMS text message reminder vs control interventions have demonstrated odds ratios (ORs) of 1.7-4.3 in favor of text messaging [25]. Given this information, we estimated that an enhanced SMS text message–based support and reminder system would increase the median time to clinic dropout in our young-onset type 2 diabetes cohort from 4 to 12 months. We determined that a 12-month study with quarterly clinic follow-up for 40 individuals (randomized 1:1 to the intervention and control groups) would have 80% power (α=.05) to enable us to reject the null hypothesis of no difference in loss to follow-up.

The primary outcome was evaluated using the principles of time to event analysis. For secondary outcomes, data collected at each follow-up visit (regardless of whether the visit was attended as scheduled or as a make-up appointment) were considered in the analyses. For those participants who failed to attend a follow-up appointment and did not attend a makeup appointment, missing data were not imputed. Participants were analyzed by original group assignment. Data from descriptive analyses are reported as mean (SD) or n (%) values. Comparisons between groups were made using analysis of variance for continuous variables and Pearson chi-squared tests for categorical variables.

The primary outcome of attendance at all scheduled follow-up appointments was analyzed using a Kaplan-Meier approach. Difference in scheduled follow-up attendance between the intervention and control groups was compared using the log-rank test. In addition to our primary attendance outcome, overall attendance (ie, attendance at scheduled appointments and rescheduled makeup appointments) was assessed.

With respect to secondary outcomes, metabolic indices at 12 months in the control and intervention groups were compared using the independent samples *t* test. Mean changes (from baseline) for metabolic indices in both the control and intervention groups were evaluated using the paired samples *t* test. Binary logistic regression analyses were performed to explore differences between the intervention and control groups in the log odds of observing the other secondary outcomes of interest. For the PAID-5, DES-SF, and DSAS-2 analyses, the outcome of interest was positive change in questionnaire score (ie, a score change that would indicate less diabetes distress and stigma or greater self-efficacy). The dependent variable for each model was the outcome of interest, and the independent variables included group assignment, follow-up time, and the interaction between group assignment and follow-up time. A general estimating equations framework was employed to allow within-participant correlations (in the context of repeated measures) to be taken into account. Data collected from participants who attended make-up appointments were considered in secondary outcome analyses. These data were ascribed to the nearest scheduled follow-up appointment.

Statistical analyses were performed using SPSS, version 24.0 (IBM Corporation). All statistical tests were two-tailed and were conducted at the .05 significance level.

Results

Between March and August 2018, 41 patients of the RPAH Diabetes Centre young-onset type 2 diabetes clinic were approached regarding study participation; 40 were enrolled and randomized, and 32 participants completed a 12-month follow-up appointment (Multimedia Appendix 2, Figure S1). The mean age of the study cohort was 32.7 years, 50% (20/40) of participants were male, mean HbA_{1c} was 7.3% (56 mmol/mol) and mean duration of diabetes at the time of study entry was 6.4 years. Baseline characteristics were similar in the enhanced SMS and standard of care groups (Table 1). Notably, there were no between-group differences in glycemic control, diabetic pharmacotherapy use, or health literacy measures.

Table 1. Baseline characteristics of the study cohort (N=40).

Triglycerides (mmol/L), mean (SD)	2.1 (1.6)	2.7 (2.1)	.32
Lipid-lowering medication, n (%)	6 (29)	7 (37)	.58
eGFR[c] (mL/min/1.73 m^2), mean (SD)	111 (19)	112 (13)	.88
Abnormal UACR[d], n (%)	8 (38)	6 (32)	.67
HLQ[e] Scale 2 score[f], mean (SD)	3.1 (0.3)	3.3 (0.5)	.14
HLQ Scale 6 score[g], mean (SD)	4.0 (0.7)	4.1 (0.6)	.40

[a]TAFE: Technical and Further Education.

[b]HbA_{1c}: glycated hemoglobin A_{1c}.

[c]eGFR: estimated glomerular filtration rate.

[d]UACR: urine albumin to creatinine ratio.

[e]HLQ: Health Literacy Questionnaire.

[f]HLQ Scale 2 score reflects an individual's confidence in their knowledge to manage their health. Higher scores equate to higher confidence levels.

[g]HLQ Scale 6 score reflects an individual's confidence in their ability to actively engage with health care providers. Higher scores equate to higher confidence levels.

Primary Endpoint: 100% Attendance at Scheduled Follow-up Appointments

The proportion of participants who maintained 100% attendance at scheduled clinic appointments for successive follow-up appointments is presented in Figure 1. At 12 months, more participants in the enhanced SMS intervention group achieved 100% attendance at scheduled clinic appointments (12/21, 57%, vs 5/19, 26%). A statistically significant difference between the intervention and control groups was observed with respect to 100% attendance (Figure 1, Table 2; log-rank *P*=.04).

Figure 1. Kaplan-Meier curve illustrating the proportion of participants who maintained 100% attendance as scheduled throughout the study.

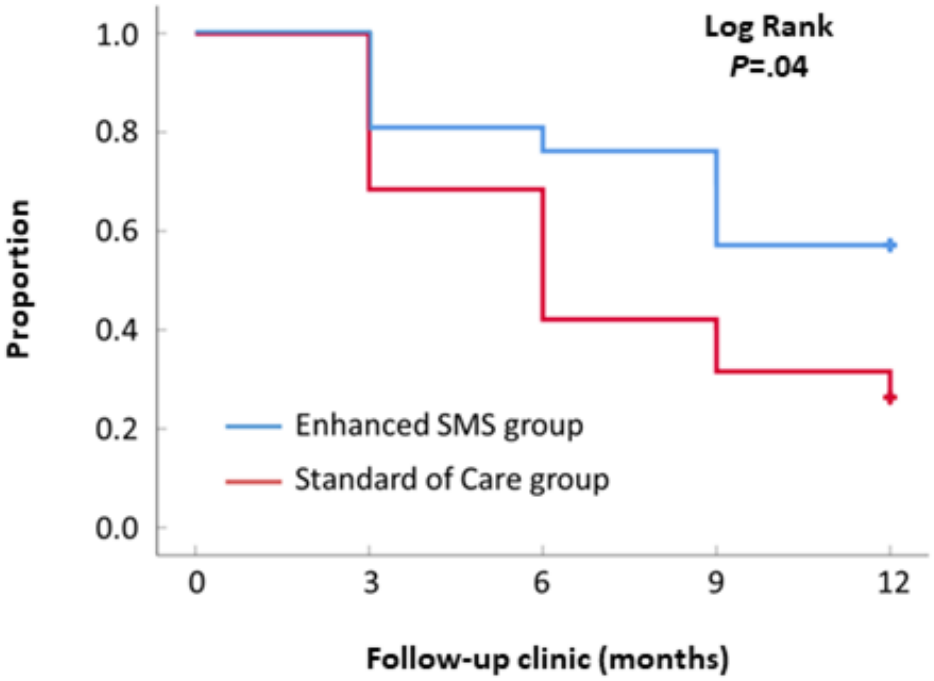

Table 2. Participants in the enhanced SMS and control groups who maintained 100% attendance in the TEXT2U study (N=40).

Group	Value, n (%)				
	Baseline	3 months	6 months	9 months	12 months
Intervention (n=21)	21 (100)	17 (81)	16 (76)	12 (57)	12 (57)
Control (n=19)	19 (100)	13 (68)	8 (42)	6 (32)	5 (26)

Secondary Endpoints

Overall Clinic Attendance

The proportion of clinic appointments that were attended as scheduled was greater in the intervention group than in the control group (64/84, 76%, vs 44/76, 58%; Multimedia Appendix 3, Table S2). It was possible to boost clinic attendance to 80% in both the intervention and control groups, but only after proactive contact by administrative staff and rescheduling of missed appointments (Multimedia Appendix 3, Table S2). The requirement for this extra administrative burden was lower in the intervention group; 18% fewer rescheduling interventions were necessary in this group.

Clinical Metabolic Outcomes

Key end-of-study metabolic indices for the intervention and control groups are presented in Table 3. For those with 12-month follow-up data (20/21 intervention and 15/19 control, respectively), there was no difference in mean HbA_{1c} between groups (mean 7.1%, SD 1.1%, for the intervention group vs mean 6.6%, SD 1.7%, for the control group; *P*=.37). For both groups, clinic attendance was associated with glycemic stability; there was no statistically significant change in mean 12-month HbA_{1c} (relative to baseline) for either the intervention or control group (Multimedia Appendix 4, Table S3). If the analysis was restricted to those with 100% attendance, the change in HbA_{1c} from baseline to study end was –0.58% (95% CI –1.70 to 0.59) (intervention) and –0.18% (95% CI –0.46 to 0.10) (control). Although the physicians working in the young adult type 2 diabetes clinic ensure that all patients have access to valid prescriptions for their diabetic pharmacotherapy at each clinic visit, absolute adherence to pharmacotherapy was not actively assessed during this study. Analogously to HbA_{1c}, there were no statistically significant between-group differences with respect to BMI, total cholesterol, or triglycerides.

Table 3. Mean (SD) values of selected metabolic indices after 12 months for the intervention and control groups.

Metabolic index	Values, mean (SD)			*P* value
	Intervention group	Control group	Mean difference (95% CI)	
HbA_{1c}[a] (%)	7.1 (1.1)	6.6 (1.7)	0.4 (–0.5 to +1.4)	.37
BMI[b] (kg/m^2)	30.4 (8.4)	31.8 (5.8)	–1.5 (–6.7 to +3.8)	.57
Total cholesterol[c] (mmol/L)	4.6 (1.4)	4.7 (0.9)	–0.1 (–1.0 to +0.7)	.75
Triglycerides[c] (mmol/L)	2.1 (1.7)	2.9 (4.1)	–0.8 (–3.3 to +1.6)	.50

[a]HbA_{1c}: glycated hemoglobin A_{1c}. 12-month HbA_{1c} data were available for 20/21 intervention group participants and 15/19 control group participants.

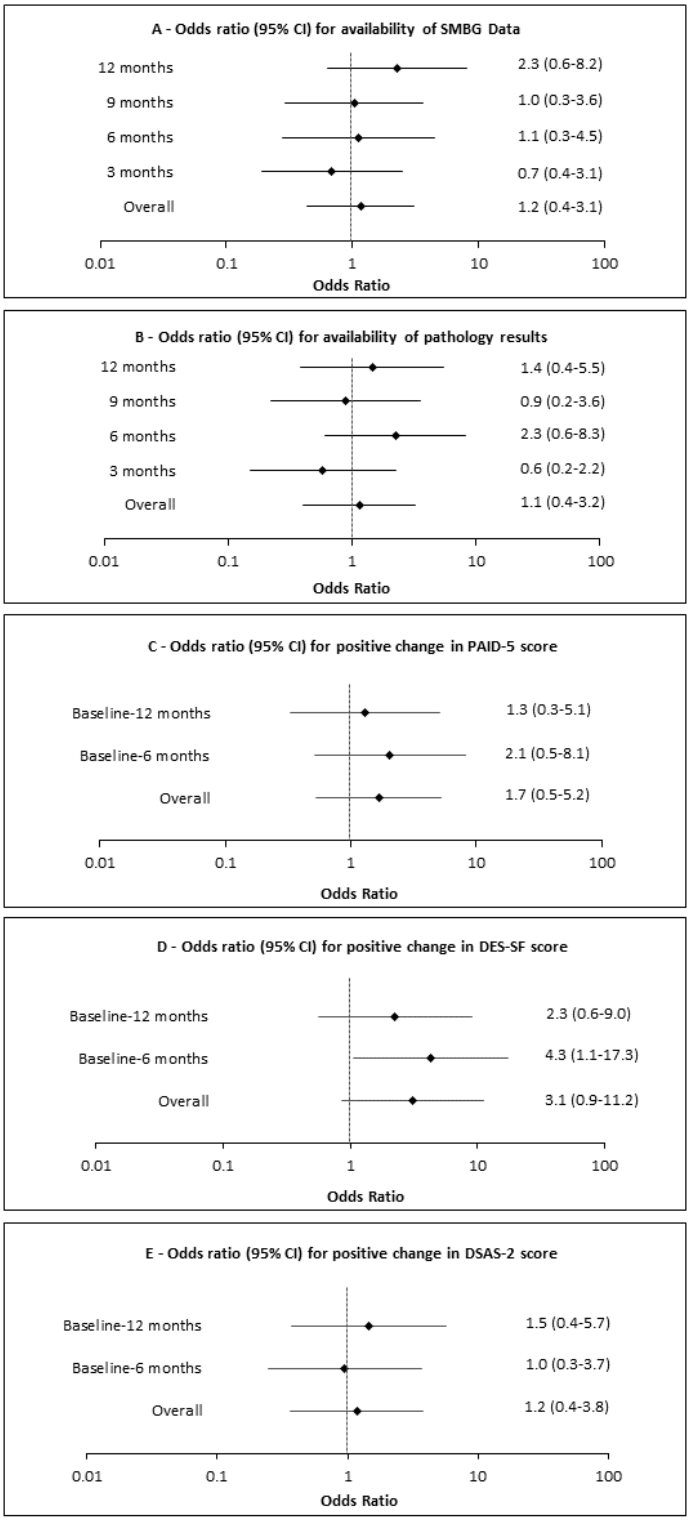
[b]12-month BMI data were available for 18/21 intervention group participants and 15/19 control group participants.

[c]12-month total cholesterol and triglyceride data were available for 20/21 intervention group participants and 14/19 control group participants.

Diabetes Self-management Practices

Overall, SMBG data were available at 40% of the intervention group's appointments, versus 37% of the control group's appointments (Multimedia Appendix 5, Figure S2). The corresponding figures for the pathology results were 69% and 66%, respectively (Multimedia Appendix 6, Figure S3). Binary logistic regression modeling revealed no between-group differences with respect to availability of SMBG or pathology results at follow-up. The ORs for availability of SMBG data and pathology results in the intervention group were 1.2 (95% CI 0.4-3.1) and 1.1 (95% CI 0.4-3.2), respectively (Figure 2, Panels A and B).

Figure 2. Forest plots illustrating the odds ratios and 95% confidence intervals for positive changes in selected secondary outcomes (A, SMBG; B, pathology results; C, PAID-5 score; D, DES-SF score; E, DSAS-2 score) for the TEXT2U intervention. DES-SF: Diabetes Empowerment Scale-Short Form; DSAS-2: Type 2 Diabetes Stigma Assessment Scale; PAID-5: Problem Areas in Diabetes 5-item Short Form; SMBG: self-monitored blood glucose.



Psychosocial Impact (Baseline Versus 6 Months and 12 Months)

An overview of the PAID-5, DES-SF, and DSAS-2 scores for the study cohort is presented in Multimedia Appendix 7 (Table S4). Analysis of the changes in DES-SF score at 6 months revealed a significant between-group difference favoring the intervention (Multimedia Appendix 7, Table S4); 68% (13/19) of members of the intervention group recorded a favorable change in DES-SF score at 6 months, versus 31% (5/16) in the control group (P=.03). At 12 months, this difference was no longer statistically significant. In the analyses of the changes in PAID-5 and DSAS-2 scores, there were no significant

between-group differences for either of the scores at 6 or 12 months (Multimedia Appendix 7, Table S4).

Binary logistic regression modeling revealed no evidence of a difference in the odds of recording a positive change in PAID-5 or DSAS-2 scores for the intervention and control groups (Figure 2, panels C and E). Although not statistically significant at 12 months, the OR for positive change in DES-SF score at 6 months (4.3, 95% CI 1.1-17.3) was significantly higher for those who participated in the enhanced SMS text messaging program (Figure 2, panel D).

Evaluation of the Enhanced SMS Text Message–Based Support and Reminder Program

Of the 21 participants randomized to the enhanced SMS text messaging intervention group, 20 received all study text messages; 1 participant asked to stop receiving text messages midstudy. Of the 21 participants randomized to the enhanced SMS group, 11 chose to use the study-specific SMS portal (Multimedia Appendix 8, Table S5). The median number of messages sent by participants was 3 (range 1-29). Analysis of message content revealed that 28% (21/74) of the messages sent by participants expressed gratitude (for a message received or a service provided by the clinic), 25% (19/74) of messages directed a diabetes-specific question to the study team or sought clarification regarding some aspect of diabetes management, and 24% (18/74) of messages were concerned with rescheduling a clinic appointment. With respect to diabetes-related questions, participants inquired about a variety of different issues, including management of hypoglycemia, dietary recommendations for people with type 2 diabetes, guidelines for dental follow-up, diabetic foot care, and the effects of stress and alcohol on blood glucose.

Following study completion, 16/21 (76%) of the SMS group participants provided feedback on their experience (Multimedia Appendix 9, Table S6). Of the 21 SMS group participants, 5 did not attend their scheduled 12-month follow-up clinic visit (or a makeup appointment for their missed clinic visit); therefore, these study participants did not provide feedback on the program. Those who did not provide feedback on the program were slightly younger (age 29.2 years, SD 6.1 years, vs 34.2 years, SD 5.4 years) and heavier (40.4 kg/m^2, SD 11.3 kg/m^2, vs 29.1 kg/m^2, SD 5.7 kg/m^2) with slightly lower baseline HbA_{1c} (6.8%, SD 0.9%, vs 7.4%, SD 1.8%).

All respondents to the end-of-study survey found that the study messages were easy to understand, supportive in nature, and delivered at appropriate times. In addition, 94% (15/16) of respondents reported that the messages contained practical information for people with diabetes and motivated them to think about their diabetes management. Overall, 94% (15/16) of respondents indicated that they would recommend the program to all new patients of the clinic.

Discussion

Principal Results

The TEXT2U study established that an enhanced SMS text message–based support and reminder program was effective at improving scheduled clinic attendance rates. Relative to the control group, the enhanced SMS text messaging intervention more than doubled the number of participants who attended all follow-up appointments. For those who attended all scheduled clinic appointments, the overall finding was stability of HbA_{1c}, weight, and lipid profiles during the 12-month study period. With respect to the psychological impact of the intervention, we observed an improvement in psychosocial self-efficacy; a statistically significant favorable change in DES-SF score was observed at 6 months. However, we did not observe any between-group differences in measures of diabetes-specific distress nor in measures of perceived and experienced stigma related to living with type 2 diabetes. Overall, the enhanced SMS text message–based support and reminder program was well received and facilitated between-visit engagement with the health care team; >90% of respondents to the end-of-study survey said they would recommend the program to new patients. Although the completion rate of the end-of-study survey was 76% (5 participants did not attend a 12-month study visit), it remains reassuring that >70% of all SMS program recipients found utility in the SMS text messaging program employed in this study. In this setting, one anticipates that the majority of future consumers of TEXT2U will derive benefit from participation in the program.

Research in Context

Our findings align with existing evidence that indicates text messaging interventions are an effective method to aid in the modification of health behaviors [11,13]. In a diabetes-specific context, the Sweet Talk RCT [26] identified that a text messaging system to support young people with type 1 diabetes was successful in improving measures of diabetes self-efficacy but not glycemic control. It is well recognized that the needs of youth with type 1 diabetes differ from those with type 2 diabetes [27]. Consequently, it is informative that this is the first study to show clear benefit of an enhanced SMS text message–based intervention over and above simple SMS reminder text messaging on clinic attendance in young-onset type 2 diabetes.

The issues of suboptimal clinic attendance and loss to follow-up are important problems in clinical practice. Maintaining clinic attendance is particularly important during young adulthood given the increased risk of diabetes complications [6] and the competing demands of family, work, study, and socializing, which interfere with maintenance of optimal care. Recurrent nonattendance prevents timely identification of changes in an individual's health status and eliminates the opportunity for diabetes complications screening, early intervention, and ongoing education; moreover, it hinders the development of a therapeutic relationship [28]. Various strategies, ranging from written, verbal, and electronic reminders to expensive case management approaches, have been used by health service providers in an attempt to improve clinic attendance and patient outcomes [29,30]. This study adds to the literature by demonstrating that a low-cost, enhanced SMS text message–based intervention is effective at improving clinic attendance over and above a standard SMS appointment reminder system for those with young-onset type 2 diabetes, a cohort that is arguably at greatest risk for poor diabetes outcomes.

Nevertheless, maintenance of optimal clinic attendance remained a significant challenge, with just over one half of the enhanced SMS group and one-quarter of the control group recording a 100% attendance record. The factors that influence clinic nonattendance in youth with type 2 diabetes are poorly understood, likely to be complex, and an important area for further study.

In addition to adverse effects for the individual, nonattendance reduces clinic efficiency and places a significant burden on administrative staff, who are required to contact nonattenders and reschedule make-up appointments [31]. Notably, the enhanced SMS text messaging intervention resulted in improved clinic attendance rate without additional administrative burden. Overall clinic attendance rates were boosted to 80% in both groups; however, with additional administrative intervention to contact patients after missed appointments and then reschedule makeup appointments, this requirement was much higher for the control group. In a resource-constrained setting, it is highly likely that youth who miss clinic appointments will be lost to follow-up and therefore at increased risk of poor long-term outcomes. Moving forward, in-built automation of this program will allow the intervention to be scaled with minimal demand on clinic resources. Although a formal cost-benefit analysis was not undertaken, the relatively low cost of SMS text messaging ensures that this program is not prohibitively expensive.

It is well accepted that improving engagement of patients with their own health care can improve outcomes, and the concept of an informed and empowered patient is now central to many models of care [32-34]. The DES-SF measures diabetes self-efficacy across three main domains: (1) managing psychosocial aspects of diabetes care, (2) assessing dissatisfaction and readiness to change, and (3) setting and achieving goals [19]. For those who attended follow-up appointments in our study, we observed a more favorable pattern of response with respect to serial DES-SF scores in the intervention group. Conceivably, delivery of supportive text messages and the opportunity to clarify queries by SMS text messaging between clinic visits in our study facilitated an increased sense of empowerment. Furthermore, incorporation of knowledge-based messages allowed important clinical information (including dietary and lifestyle recommendations) to be reinforced outside the clinic setting. This is particularly relevant given that postconsultation retention of medical information is poor [35].

The lack of a statistically significant improvement in DES-SF score at 12 months may indicate that the support provided by the enhanced SMS text messaging intervention has limited durability or that there may be a threshold to any improvement seen. Furthermore, we did not demonstrate improvement in measures of distress or stigma; plausibly, these more negative psychological elements respond best to in-person encounters and are not amenable to a text-based intervention. Although diabetes empowerment was supported by the enhanced SMS text message–based intervention, we did not see improvement in objective measures of self-care as evidenced by the availability of the SMBG/pathology results.

Although the intervention increased scheduled clinic attendance, we did not observe a difference in mean HbA_{1c}, weight, or lipids between the intervention and control groups at study completion. For the most part, this is unsurprising given that the overall attendance (ie, scheduled attendance plus attendance at makeup appointments) was equal in both study arms. Irrespective of whether a participant attended a scheduled or makeup appointment, those who attended were afforded the same opportunity to have their management adjusted by the treating clinician. Nonetheless, stability of glycemia, close to target HbA_{1c}, over 12 months of follow-up is not an insignificant achievement. The TODAY study clearly demonstrated that many adolescents with type 2 diabetes struggle to maintain glycemic control despite comprehensive care in a well-supervised setting [36].

Study Strengths

The age of the study cohort and their familiarity with text messaging allowed for immediate engagement with the SMS text messaging program; individuals were not hampered by a learning curve in deriving benefit from study participation. In designing this study, we were mindful of the need to avoid overwhelming participants with too many messages; prevention of participant withdrawal due to message fatigue was an important consideration. In previous studies of SMS interventions, investigators regularly sent participants multiple text messages every week. The length of most previous studies has been comparatively short (usually <6 months), and participant attrition due to message fatigue in the short term is less likely. Given our 12-month study duration, a conscious decision was made to taper message frequency over the course of the study. Certainly, there is evidence to suggest that text messaging interventions with a tapering frequency have higher efficacy [37]. Personalization of the text messages ensured that the messages received by each participant were relevant to their personal circumstances, and the intervention had high acceptability. Feedback revealed that 88% of participants felt they had received an appropriate number of messages and 100% felt they received messages at appropriate times. Of the 21 enhanced SMS text messaging program participants, 20 opted to receive all study text messages; study message fatigue was not a significant issue.

Limitations

There are several limitations of this study. First, it should be noted that our study was powered to detect a difference in clinic attendance but not to detect small differences in secondary outcomes. Secondly, our study was conducted at a secondary and tertiary referral center with a modest number of participants; testing in other settings will be required to confirm generalizability. In addition, our study population comprised a well-educated cohort (80% had attended, or were attending, Technical and Further Education [TAFE] or university). Although the message program employed plain language, it would be worthwhile to consider further testing in groups with lower literacy levels to establish better generalizability of the results. Furthermore, we specifically focused on the younger demographic; therefore, applicability in older age groups remains uncertain. Although all study participants had sufficient

English proficiency, given our multicultural population, provision of the program in a participant's native language may well have resulted in greater engagement. By design, it was not possible to blind both participants and treating clinicians in this study. However, blinding of treating clinicians and the use of an objectively measured primary endpoint were important aspects of the study design that help to mitigate observer bias.

Conclusions

In young-onset type 2 diabetes, a low-cost, automated, enhanced SMS text message–based support and reminder system improved scheduled clinic attendance and diabetes self-efficacy over 12 months of follow-up. These achievements were made with high acceptability and low administrative burden. This text-based intervention has the potential to have substantial impact on the care of youth with type 2 diabetes at an especially vulnerable time of life.

Acknowledgments

Abstract

Background: College campuses in the United States have begun implementing smoke and tobacco–free policies to discourage the use of tobacco. Smoke and tobacco–free policies, however, are contingent upon effective policy enforcement.

Objective: This study aimed to develop an empirically derived web-based tracking tool (Tracker) for crowdsourcing campus environmental reports of tobacco use and waste to support smoke and tobacco–free college policies.

Methods: An exploratory sequential mixed methods approach was utilized to inform the development and evaluation of Tracker. In October 2018, three focus groups across 2 California universities were conducted and themes were analyzed, guiding Tracker development. After 1 year of implementation, users were asked in April 2020 to complete a survey about their experience.

Results: In the focus groups, two major themes emerged: barriers and facilitators to tool utilization. Further Tracker development was guided by focus group input to address these barriers (eg, information, policing, and logistical concerns) and facilitators (eg, environmental motivators and positive reinforcement). Amongst 1163 Tracker reports, those who completed the user survey (n=316) reported that the top motivations for using the tool had been having a cleaner environment (212/316, 79%) and health concerns (185/316, 69%).

Conclusions: Environmental concerns, a motivator that emerged in focus groups, shaped Tracker's development and was cited by the majority of users surveyed as a top motivator for utilization.

KEYWORDS

tobacco cessation; college smoke and tobacco–free policies; crowdsourcing; environmental reporting; public health; smoke and tobacco research

Introduction

Smoke and tobacco–free (STF) policies among college and university campuses have become a high priority nationally to denormalize the use of tobacco [1,2]. The average smoker begins before the age of 26 years, making the transition into university life a significant period during which young people can either begin or avoid tobacco use [3]. Benefits of STF policies include decreased tobacco use and exposure to second-hand smoke, reduced tobacco litter, and greater well-being [4-6]. However, the benefits are contingent upon effective policy implementation and enforcement. Only 15% of US colleges detail methods for

reporting an STF policy violation and over a third do not formally reprimand individuals who smoke on campus [7].

Low STF policy compliance is widespread at universities and poses a critical barrier to reducing tobacco use and related disease risk for the estimated 19.9 million college students in the United States [8-10]. The majority (62%) of colleges rely on social enforcement of the policy, with typical methods including education and outreach [7]. Given the responsibility placed with campus community members for enforcement, innovative approaches to engage them with the STF policy are needed [11]. One innovative approach, crowdsourcing, is a method of involving a large group of people on a collective mission and is being used to address a number of environmental and public health problems [12,13]. A crowdsourcing tool for tobacco activity surveillance can help address a major barrier to social enforcement: discomfort confronting tobacco users [7,14,15]. Further, it provides a sustainable solution to an infrastructure issue faced by most campuses lacking resources to collect data on campus tobacco use and related litter.

The goal of this study is to develop and implement a web-based tracking tool (Tobacco Tracker hereafter "Tracker") to engage users with STF policies. This study aims to (1) describe the empirically driven process of developing and implementing Tracker using feedback from focus groups and (2) evaluate survey feedback from Tracker users about their motivations and experience using the tool.

Methods

Methods Overview

An exploratory sequential mixed methods approach was utilized to develop Tracker with guidance from campus focus groups and to evaluate Tracker with a user survey.

Study Setting

The 2 universities in the study are located in northern and southern California. University 1, in northern California, has been STF since 2014. Its campus has over 39,000 students, 21,000 staff, and 2000 faculty, and its campus encompass 5300 acres including a separate health campus. University 2, located in southern California, has been STF since 2017, has over 14,000 students, over 300 administrative staff, and 600 academic staff, and its campus encompasses 304 acres. Approval from human subjects was obtained through the institutional review board at each university.

Exploratory Focus Groups for Tracker Development

Focus groups aimed to explore ideas for prototype refinement were conducted in October 2018. A focus group comprising students was conducted at each university (n=7 at University 1 and n=10 at University 2). An additional focus group comprising employees was conducted at University 1 given its larger campus and staff size (n=6). Participants at University 1 were recruited from student or staff health and wellness listservs and a general staff electronic newsletter. Participants were selected in the order they responded to the recruitment advertisements and were offered a US $40 gift card. Participants at University 2 opted into the study from a web-based research portal and received credit toward their course requirement for participation. Eligibility included being at least 18 years old and a current university student or employee. Written informed consent was obtained from each participant prior to study participation. Each focus group lasted approximately 90 minutes.

To explore ideas for the Tracker prototype's content and design, guiding questions for the focus groups explored the (1) appearance and functionality of the tool prototype, (2) communication channels and strategies for promoting the tool, and (3) images and messages that may raise awareness or increase motivation to use the tool. Educational information was presented from the California Tobacco Control Program's public advertisements about how cigarette butts are the top litter problem and are not biodegradable with their plastic filters. All focus groups were conducted by the same moderator, a psychologist and tobacco control researcher (KP), audio recorded, and transcribed verbatim.

Two independent researchers, one of whom is a sociologist and qualitative researcher (MMG), conducted a thematic analysis [16]. Emergent codes were developed from the data inductively in addition to deductive priori codes. After the initial analysis, a codebook was constructed to create categories and develop themes. Two themes and 5 subthemes were developed collaboratively between the 2 independent researchers. No software programs were used to aid the focus group qualitative data analysis.

Tracker Development

The Tracker prototype's content, design, and promotion was refined on the basis of focus group findings, and themes linked to refined Tracker components are described below. Prototype components such as real-time web-based reporting and using visual maps to geographically locate environmental incidents were based on an existing crowdsourcing tool to measure energy overconsumption at University 1, TherMOOstat [17]. Tracker development in regard to content and design began in November 2018 and was promoted at both universities beginning in February 2019.

Survey of Tracker Users

Individuals who used Tracker at either university between February 2019 and February 2020 and provided contact information for entry into an opportunity drawing were invited by email to participate in a survey in April 2020. A 2-week period was provided for a response and 1 reminder email was sent. An opportunity drawing for 4 US $25 gift cards at each university was offered. Survey questions developed by the study team assessed user experience: (1) how participants accessed the tool, (2) motivation for using the tool, (3) barriers to tool use and for future study directions, and (4) ideal actions following a report. Survey questions allowed for multiple responses and data were coded as a selection, no selection, or as missing. Data were reported as n (%) values in total and by university.

Results

Focus Group Discussions

Focus group analysis yielded 2 distinct themes: (1) barriers and (2) facilitators to tool utilization (Table 1). Barriers to tool utilization contained 3 subthemes: logistical barriers limit tool use, information barriers, and framing as a policing tool. Facilitators for tool use contained 2 subthemes: environmental motivators and positive reinforcement to further engage with the tool. Minimal differences in responses were noted among the student participants, and differences between staff and student responses were minor (eg, less familiar with technology and less preference for a mascot or gamifying the tool). The results of thematic analysis are presented as an aggregate, given the goal of creating a tool for students and staff at both universities.

Table 1. Themes, subthemes, and representative quotes.

Themes, subthemes, and context	Representative quotes
Theme: Barriers to tool utilization	
Subtheme: Logistical barriers limit tool use	
Access to Tracker with QR[a] codes	• "What is it?" (University 1) • "I'm in IT and we mock them" (University 1) • "That's kind of scary. I don't know, that's crazy. I've never done that." (University 1)
Access to Tracker with campus app	• "I think the campus app would just be the best solution, because a lot of [inaudible] have it installed already, but I think a lot of people have it installed. Rather than going and getting a whole new account or having to go find it somewhere else, it's just an update and it's easy" (University 2) • "I really prefer the app a lot more… It seems more accessible in a sense. Like the online survey, you sometimes can't access it or it doesn't work. Obviously, that happens with apps too. It's just more reliable." (University 2)
Identifying location with automated GIS[b] location services	• "Yeah, it's really useful, because you can find yourself. At least to me, it seems kind of like a combination of the dropdown and the map, because it's just our campus and it has all the names of the buildings" (University 2) • "Sometimes you're like not at a building, you're in between. But I do think sometimes people feel weird about sharing their locations." (University 1)
Identifying location with a dropdown menu and a campus map	• "It would be best to have both options available in the tool" (University 1) • "I can see what you mean about the challenge of having it as a dropdown menu just from this example where you're like 'where's my place', it would be easier to type" (University 1)
Internet connection	• "I feel like this might be going too out of the scope of this. The internet connection on campus is awful, and if it's really slow, then I would just give up and not do it. That many reloading of pages would be really agonizing." (University 1)
Subtheme: Informational barriers	
Tobacco products	• "What's vaping?" (University 1) • "I don't know what Juul or blunts means" (University 1)
Tobacco Waste	• "Are vaping things becoming garbage?" (University 1) • "What is litter from vaping?" (University 2)
Image preference	• "Just because it's more identifiable because I'm on the go and I'm reporting this, I need to just see an actual picture." (University 1) • "It would be more helpful to have the different images of what you're actually saying" (University 1)
Subtheme: Framing as a policing tool	
	• "It also avoids the policing idea" (University 1) • "It just likes a very, it's an activity that's very much in a specific location, especially since it's forbidden to do it on campus, though. Again, I don't feel it's threatening, I don't feel like it's about policing people but rather about seeing signs of this activity. I can relate it to fire, but it could also be a consequence of smoking" (University 1) • "I just think maybe a title that plays along with being environmentally conscious, instead of 'Oh, I'm reporting somebody doing something bad and illegal,' it's more like, 'I'm taking care of the environment.' So it's less of like a whistle-blower thing" (University 1) • "Yeah. Because it almost seems like a tattling" (University 1)
Theme: Facilitators to tool utilization	

Themes, subthemes, and context	Representative quotes
Subtheme: Environmental motivators	
Design	• "I think you should have a blue theme… That kind of ties in the blue sky" (University 1) • "Well you don't necessarily think of the trees, so I think that, and making the art with it, I think that was very effective. Because I never thought about trees before" (University 1) • "You could have a bird with like a cigarette butt in its beak, like a cartoony bird. And maybe there could be like a friend bird with a fish in its beak, or something, next to it. I don't know. But make sure they're really cute" (University 1) • "I said the squirrel with the [University 1] shirt and binoculars, because I think it directly ties into the community on campus, and squirrels are really [University 1]. And I think it's good to have a cute little icon like the Thermoostat has because I think people want to use things that are cute, so I think it's just good to have a main character" (University 1) • "I said [University 1 mascot] Clean just because I think there's the school pride, and then the clean is, I don't know. Even with the air, I feel like that all goes back to like… I like that it's hinting at the environment, but it's still hinting at the smoking aspect versus the littering" (University 1)
Environmental concerns	• "Yeah, simple, but I also learned something. I did not know it took up to a decade to decompose. That would make me want to report that" (University 1)
Subtheme: Positive reinforcement	
Incentives	• "I think if you provide incentives, people would definitely be up for that" (University 2) • "Because I think it goes beyond this, and it's more like why we recycle right, because it makes us feel good. Right I kind of see this tool as the same thing" (University 1)
Gamification	• "Gamification is the way you're going to win this" (University 1) • "I think like also with stuff like this that's so widespread, it can be hard to see any impact and nobody wants to do something, but it's kind of hard to like want to be super engaged and do something all the time if you can't really tell what you're doing. I don't know. Like making kind of like mini games or something where it's like you've reported five times, and every time you report, you're cleaning up lungs or something" (University 2)

[a]QR: quick response.

[b]GIS: geographic information system.

Barriers to Tracker utilization

Logistical Barriers

Participants identified logistical barriers to tool utilization, such as technical and access barriers. Participants cited the utilization of a dropdown menu and geographic information system (GIS) location–enabling services as potential technical barriers to tool utilization. Participants had mixed feelings about the utility of an automated GIS location–enabling service compared to the utilization of a dropdown menu of buildings from a campus map. Some individuals were reluctant to share their location with Tracker, while others felt it was more efficient and convenient. Participants concluded they would like both choices.

Participants also discussed various access barriers such as quick response (QR) codes, mobile apps, and internet connectivity. Some participant concerns about QR codes, a barcode that can be photographed with a phone to redirect a user to a webpage, included how to use them or negative attitudes about their utility (Table 1). Furthermore, participants discussed the use of mobile apps instead of accessing the tool through a website. However, some participants believed students would be less inclined to download another app that would take up storage space. Therefore, one recommendation was to integrate Tracker with an existing campus tool. Lastly, 1 participant expressed concerns that slow internet connectivity for devices or phones themselves could discourage the use of Tracker.

Informational Barriers

To identify tobacco use and waste, many participants expressed concern that they were unaware of what vaping products or vaping waste looked like. Participants recommended presenting visual examples of such tobacco products and waste (Table 1).

Furthermore, participants preferred that these images look realistic rather than being a cartoon drawing.

Framing as a Policing Tool

Participants preferred the name and branding strategies to portray a neutral crowdsourcing tool. Specifically, participants were concerned about whether Tracker's name would be viewed as public surveillance by the campus community's smokers and nonsmokers. One participant suggested the use of an environmentally themed name to avoid portraying Tracker as one for policing fellow students and staff (Table 1). The participants preferred to de-emphasize the idea of policing smokers on campus.

Facilitators for Tracker Utilization

Environmental Motivators

When participants were asked about Tracker's design, environmentally themed color schemes such as blue or green and a name that suggested "clean" were preferred. Branding Tracker with an animal mascot, such as a dog or squirrel, was also recommended. Moreover, when presented with the California Tobacco Control Program's public advertisements, participants found information about tobacco waste's impact on the environment as a highly motivational reason to use Tracker.

Positive Reinforcement

To encourage continued use of Tracker, participants were asked about possible incentives. Participants agreed that incentives such as gift cards would encourage Tracker utilization. Some participants remarked that simply submitting a report would be rewarding enough for them to stay engaged. One user compared submitting a report to recycling and explained that the 2 actions made the individual feel motivated enough to continue.

To increase engagement with Tracker, student participants recommended that it be gamified to provide positive affirmation for Tracker reports on campus. Participants recommended that Tracker show a mascot dancing or interacting with the user for increased gratification and utilization. Other suggestions included using a reward system for reports to allow dressing the mascots.

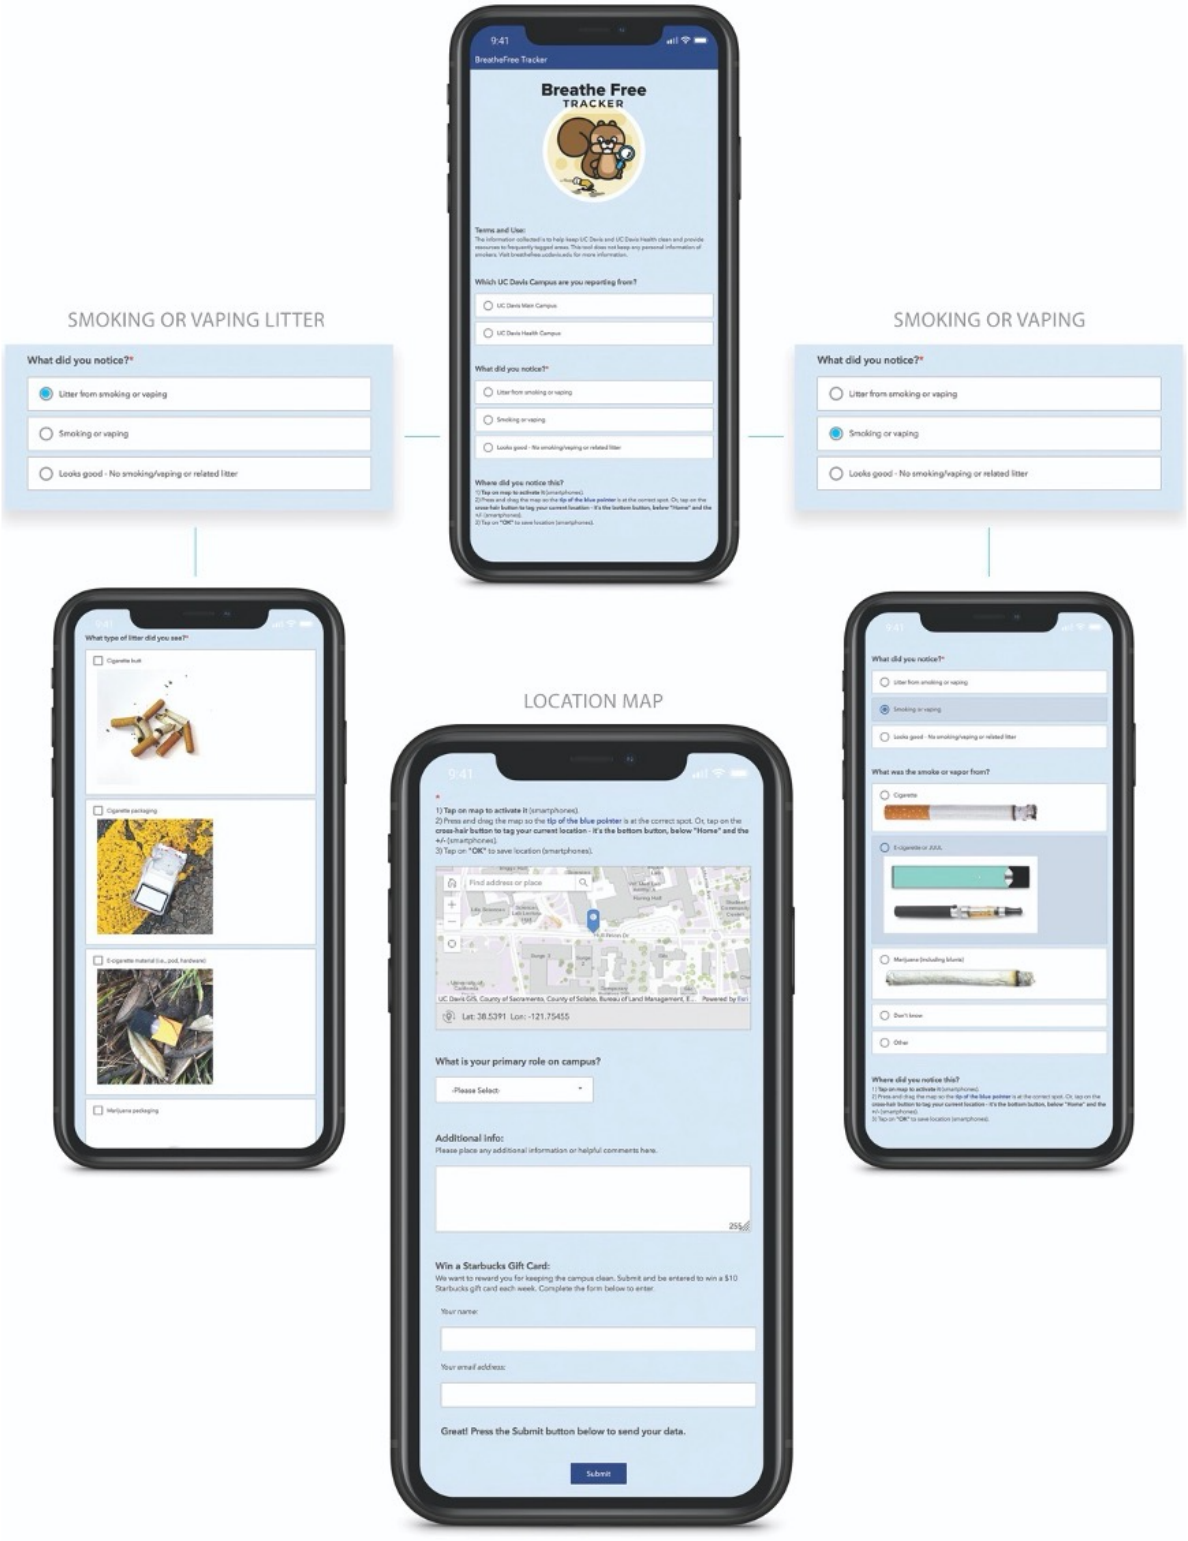
Empirically Driven Tracker Development

Based on focus group discussions, Tracker was designed for users to document tobacco use (smoking and vaping) or waste. Additionally, "no smoking or vaping" and "looks good" options were added for Tracker to have the capacity to reflect environmental improvements (Figure 1). Realistic images of tobacco products and waste were provided, in response to subtheme *Information Barriers*. Tracker instructions were framed to document observations of tobacco products and waste, not people, and the word "report" was purposefully avoided; instead, users were asked "what do you notice" and "where did you notice this" in response to subtheme *Framing as Policing Tool* as a barrier. Tracker was branded with environmentally themed names affiliated with the STF programs on each campus in response to subtheme *Environmental Motivator*. A squirrel mascot was adopted at University 1 and a hawk mascot at University 2, keeping with the environmental design theme.

The study team created a Tracker website for each university with features responsive to subtheme *Logistical Barriers*. The website-based platform Esri Survey 123 supported accessibility and subsequent integration with existing campus technological infrastructure, such as the campus app and websites. While both universities have a personal campus website account, mostly used by students, only University 1 allowed integration with Tracker. Multiple options for location tracking were provided to users: automatic GIS-enabled mobile location services, manual designation on the campus map, or manual selection of a building location from a drop-down menu. Additionally, graphic designers helped design images or promotional messages. Promotion consisted of flyers or advertisements and items (eg, stickers and bags) distributed at campus events.

Incentives for positive reinforcement, in response to subtheme *Positive Reinforcement* were also incorporated in Tracker. A positive affirmation message after the user pushed the submit button states, "Great! Your data was sent successfully. Thanks." To provide a reinforcing feedback loop, the message further stated, "Feedback is used to identify areas of concern and inform future policy efforts" where users may click on a link to a live map of submitted reports. The "Looks good. No smoking/vaping or related litter" option to report problem-free areas created an additional opportunity to build positive reinforcement in messages emphasizing a clean campus. Additionally, a weekly gift card raffle incentive was offered. The study team decided that gamification would need further development for future efforts.

Figure 1. Images of the final Tracker tool and key components.



Survey of Tracker Users

In total, 1163 discreet responses were documented in total from both universities' Tracker, and 717 individuals who provided an email ID were invited to participate in the user survey (n=605 users at University 1 and n=112 users at University 2). Tracker user survey responses by university are shown below (Table 2). The response rate for University 1 was 40% (242/605 invitations) and that for University 2 was 70% (78/112 invitations). Four duplicate surveys were omitted (University 2), yielding a total of 316 survey responses. Over half of the survey participants at both universities reported accessing Tracker through a website. Approximately a quarter of respondents at University 2 also reported using a QR code or campus app; however, few participants (10 of 242 participants, <5%) at University 1 reported using these methods.

Table 2. Tracker user survey results (N=316).

	Total, n (%)[a]	University 1 (n=242), n (%)	University 2 (n=74), n (%)
How did you access the Tracker?			
Personal campus website portal	N/A[b]	102[c] (45.9)	N/A
STF[d] or Tracker-specific website	148 (54.4)	114 (51.4)	34 (68.0)
Campus app	21 (7.7)	7 (3.2)	14 (28.0)
QR[e] code	18 (6.6)	5 (2.3)	13 (26.0)
Other	11 (4.0)	10 (4.5)	1 (2.0)
What motivates you to use the Tracker?			
A clean environment is important to me	212 (78.8)	172 (78.2)	40 (81.6)
Exposure to smoke or vapor is harmful to health	185 (68.8)	152 (69.1)	33 (67.3)
Smoking/vaping on campus encourages others to smoke/vape	110 (40.9)	87 (39.5)	23 (46.9)
I support the campus smoke and tobacco free policy	181 (67.3)	148 (67.3)	33 (67.3)
I believe campus policies should be followed	137 (50.9)	108 (49.1)	29 (59.2)
Smoking/vaping does not fit the campus image	87 (32.3)	72 (32.7)	15 (30.6)
Using the Tracker gives me an opportunity to win a gift card	98 (36.4)	82 (37.3)	16 (32.7)
Which of the following might discourage you from using the Tracker?			
I intend to use the Tracker, but forget	131 (50.6)	111 (51.9)	20 (44.4)
It takes too long to access the tool	108 (41.7)	87 (40.7)	21 (46.7)
There are too many questions	46 (17.8)	36 (16.8)	10 (22.2)
The instructions are not clear	23 (8.9)	19 (8.9)	4 (8.9)
The smoking/vaping or litter does not bother me very much	2 (0.8)	2 (0.9)	0
I am concerned people would know I reported	31 (12.0)	25 (11.7)	6 (13.3)
I do not want people to get in trouble	20 (7.7)	18 (8.4)	2 (4.4)
I feel uncomfortable using the Tracker	8 (3.1)	7 (3.3)	1 (2.2)
Other	34 (13.1)	31 (14.5)	3 (6.7)
Ideally, what would you like to happen after you report smoking/vaping or related litter?			
The litter will be cleaned up	205 (77.9)	171 (78.8)	34 (73.9)
The violator will be assigned community service	117 (44.5)	98 (45.2)	19 (41.3)
The violator will be fined	109 (41.4)	94 (43.3)	15 (32.6)
The violator will be assigned a diversion training	70 (26.6)	58 (26.7)	12 (26.1)
A new sign will be installed	69 (26.2)	61 (28.1)	8 (17.4)
The violator will be sanctioned	49 (18.6)	42 (19.4)	7 (15.2)
Other	24 (9.1)	19 (8.8)	5 (10.9)

[a]Total number of responses differed between questions and universities. In response to “How did you access the Tracker”, a total of 272 responses were recorded (222 at University 1; 50 at University 2); “What motivates you to use the Tracker”, a total of 269 responses (220 at University 1; 49 at University 2); “Which of the following might discourage you from using the Tracker” a total of 259 responses (214 at University 1; 45 at University 2); and “Ideally, what would you like to happen after you report smoking/ vaping or related litter?” a total of 263 responses (217 at University 1; 46 at University 2).

[b]N/A: not applicable.

[c]Percent sums over 100% are due to select-all type responses.

[d]STF: smoke and tobacco–free.

[e]QR: quick response.

The top motivations to use Tracker included environmental concerns, health concerns, and policy support. The majority (212/269, 78.8%) cited the importance of a clean environment, 185 (69%) participants were concerned about health hazards of exposure to smoke or vapor, and 181 (67%) voiced personal support for the campus STF policy.Approximately half (137/269, 50.9%) of the participants also expressed personal support that campus policies should be followed, and less than half (110/269, 40.9%) reported concerns that tobacco use encouraged others to smoke. Approximately one-third of participants (98/269, 36.4%) reported being motivated by campus images or the opportunity to win a gift card.

In regard to utilization barriers to Tracker, logistical issues were the leading barriers at both universities: of 259 participants, 131 (50.6%) intended but forgot to use Tracker, 108 (41.7%) were discouraged because it took too long to access Tracker, and 46 (17.8%) thought that Tracker had too many questions.Information barriers were infrequently cited, and few reported that the instructions were unclear or that they were unbothered by the tobacco use or waste. Other infrequently cited responses included concerns about a policing tool, concerns that others would know about their reporting, not wanting others to get in trouble, and being uncomfortable using Tracker.

When asked about users' ideal outcome following a Tracker report, the majority (205/263, 77.9%) of participants across both universities voiced environmental concerns with having the litter cleaned up. There was also interest in the consequences for policy violators including community service (117/263, 44.5%) and fines (109/263, 41.4%), followed by diversion trainings (70/263, 26.6%). Additional signage installation was selected by one-fourth (69/263) of respondents.

Discussion

Principal Findings

To our knowledge, this is the first reported study to describe the development of an empirically derived web-based Tracker for crowdsourcing campus environmental reports of tobacco use and waste to support STF college policy compliance. Campus focus group discussions identified barriers and facilitators for Tracker utilization, which informed Tracker development. Over 1 year, Tracker at both universities had been used by over 1000 people. In response to the survey, Tracker users cited environmental concerns as the leading motivator for utilization, complementary to focus group findings, followed by health concerns and STF policy support. Tracker users also cited having litter cleaned up as the ideal outcome, further highlighting their environmental concerns. Most potential barriers identified in the focus groups were not cited by Tracker users, although refinements should still be considered.

Health concerns from environmental and second-hand smoke/vapor, cited by Tracker users as top motivators for using Tracker, is consistent with broader population concerns, which may be due in part to existing public health educational campaigns. Environmental motives are consistent with a national study of 8000 students, which revealed that the majority (66%) reported that a college's commitment to environmental issues contributed to their decision to apply or attend a school [18]. Instead of focusing on individual smokers' behaviors and beliefs, which can create defensiveness, focusing on extrinsic issues, such as environmental concerns and second-hand smoke, has been recommended to promote a more receptive audience [19]. Public health education campaigns about the hazards of tobacco waste and second-hand smoke/vapor exposure are already found in the national Truth Campaign and state campaigns through the California Department of Public Health's Tobacco Free California [20,21] Future efforts incorporating environmentally focused public health campaign messages on campus could activate and reinforce crowdsourcing participation with Tracker.

Tracker was designed to minimize accessibility issues. The use of a web-based platform appears to have been a good choice, as accessing Tracker though campus websites was more common than through the Campus App or from QR codes. However, users cited the leading barrier as the time it took to access Tracker. Further study is needed to understand and resolve this issue. For example, it could be a convenience issue, such that users may be too focused on their commute to stop and access Tracker. This could also be related to Tracker users' second most frequently reported barrier: "intended to use the Tracker but forgot." Additional user research could inform modifications to make accessing Tracker faster and more efficient.

Positive reinforcers were built into the Tracker design to drive activation, crowdsourcing participation, and STF policy engagement. In response to focus group suggestions to provide a positive affirmation message, the Tracker message after a report submission stated its intended goal: to identify areas of concern and inform policy efforts. However, the user survey finding that the top desired action following the submission of a report was to "clean up litter." The positive affirmation messaging could be refined for greater specificity. For example, the message could provide more tangible feedback, such as "Your report has contributed to the clean-up of x number of tobacco litter items on campus." Interestingly, the opportunity to win a gift card was one of the least common reasons for using Tracker, suggesting that this incentive was not a strong reinforcement and could be scaled back or removed.

Our findings show mixed support for formal enforcement of Tracker. Focus group participants expressed concerns about policing, whereas Tracker users reported some preference for consequences for policy violators with community service or fines. Although punitive approaches such as fines may be perceived as a solution, they could decrease perceptions of university support among those who smoke [22]. A combined approach, including social and formal enforcement, may be warranted [9]. For example, the information gathered through crowdsourcing can be used to complement existing campus outreach programs, such as peer-led Ambassador programs, to target outreach or clean-up efforts in areas of concentrated tobacco activity [23]. For colleges without the resources for an ambassador or comparable enforcement program, the Tobacco Tracker provides a surveillance mechanism to monitor tobacco activity on campus and demonstrate to campus stakeholders the need for intervention [24].

There is growing interest in using crowdsourcing tools to effect change for the environment, including tracking tobacco use and litter. Ohio State's "Cleaner U" app focuses on all types of litter on their college campus [25] instead of just smoke and tobacco litter, similar to Tracker. Meanwhile, the World Health Organization's "Tobacco Spotter" app focuses on reporting compliance or noncompliance with a broad array of tobacco control policies in different countries, spanning tobacco retail, advertisement, and nonsmoking public policies [26]. Lastly, "Litterati," a smartphone app aimed at encouraging users to pick up litter in their respective communities, maps litter reports, including smoke and tobacco litter. Litterati's user community cleaned up approximately 50,000 pieces of litter within 1 week [27]. While these tools have effectively used crowdsourcing to report environmental issues, Tobacco Tracker uses crowdsourcing to record environmental reports of STF policies, namely tobacco use and waste, on college campuses.

Limitations

Our results must be interpreted with caution, owing to certain limitations. While both universities studied herein represent public systems with 100% STF policies, only 1 university per system was included, and the results may not be generalizable to those of other universities or outside of California. Furthermore, focus group sizes were small and participant-level characteristics were not assessed in the focus groups or user surveys. Therefore, it is not known how representative the respondents are of the university populations. Furthermore, Tracker user experience is limited to those who provided an email and responded to the survey and may not represent others, including those who decided not to use Tracker.

Conclusions

Environmental concerns successfully shaped Tracker's development and were commonly cited as the top motivators of use. Educating the campus community about the environmental hazards of tobacco waste may increase support for STF policies, especially among young adults [28]. Tracker is a promising tool that addresses environmental and health concerns to help support STF college policy compliance. Using Tracker, the campus community can be engaged to uphold STF policies by crowdsourcing data to help monitor campus areas in need of improvement. Future efforts may include refining Tracker for increased user accessibility or engagement and to target outreach and clean-up efforts. Additional research is needed to measure Tracker's effect on improving compliance with STF campus policies.

Acknowledgments

This study was funded by the California Tobacco Related Disease Research Program (#27IP-0041). No financial disclosures were reported by the authors of this paper. Abstract

Background: Although disclosing the predictors of different behavioral and psychological symptoms of dementia (BPSD) is the first step in developing person-centered interventions, current understanding is limited, as it considers BPSD as a homogenous construct. This fails to account for their heterogeneity and hinders development of interventions that address the underlying causes of the target BPSD subsyndromes. Moreover, understanding the influence of proximal factors—circadian rhythm–related factors (ie, sleep and activity levels) and physical and psychosocial unmet needs states—on BPSD subsyndromes is limited, due to the challenges of obtaining objective and/or continuous time-varying measures.

Objective: The aim of this study was to explore factors associated with BPSD subsyndromes among community-dwelling older adults with dementia, considering sets of background and proximal factors (ie, actigraphy-measured sleep and physical activity levels and diary-based caregiver-perceived symptom triggers), guided by the need-driven dementia-compromised behavior model.

Methods: A prospective observational study design was employed. Study participants included 145 older adults with dementia living at home. The mean age at baseline was 81.2 (SD 6.01) years and the sample consisted of 86 (59.3%) women. BPSD were measured with a BPSD diary kept by caregivers and were categorized into seven subsyndromes. Independent variables consisted of background characteristics and proximal factors (ie, sleep and physical activity levels measured using actigraphy and caregiver-reported contributing factors assessed using a BPSD diary). Generalized linear mixed models (GLMMs) were used to examine the factors that predicted the occurrence of BPSD subsyndromes. We compared the models based on the Akaike information criterion, the Bayesian information criterion, and likelihood ratio testing.

Results: Compared to the GLMMs with only background factors, the addition of actigraphy and diary-based data improved model fit for every BPSD subsyndrome. The number of hours of nighttime sleep was a predictor of the next day's sleep and nighttime behaviors (odds ratio [OR] 0.9, 95% CI 0.8-1.0; *P*=.005), and the amount of energy expenditure was a predictor for euphoria or elation (OR 0.02, 95% CI 0.0-0.5; *P*=.02). All subsyndromes, except for euphoria or elation, were significantly associated with hunger or thirst and urination or bowel movements, and all BPSD subsyndromes showed an association with environmental change. Age, marital status, premorbid personality, and taking sedatives were predictors of specific BPSD subsyndromes.

Conclusions: BPSD are clinically heterogeneous, and their occurrence can be predicted by different contributing factors. Our results for various BPSD suggest a critical window for timely intervention and care planning. Findings from this study will help devise symptom-targeted and individualized interventions to prevent and manage BPSD and facilitate personalized dementia care.

behavioral and psychological symptoms; dementia; older adults; actigraphy; sleep; activity; risk factors

Introduction

Behavioral and psychological symptoms of dementia (BPSD) constitute a core and prevalent feature of Alzheimer disease and related dementia [1], with most patients experiencing one or more types of symptoms over the course of the disease [2]. BPSD refer to frequently occurring symptoms of disturbed perception through content, mood, or behavior [3], which manifest into a wide range of forms, such as agitation, aggression, depression, apathy, wandering, and socially inappropriate behaviors [1]. Increasingly recognized as the most challenging aspect of dementia, BPSD present adverse outcomes, including decreased functioning and accelerated disease progression [4], and, if poorly managed, an increased risk of nursing home placement [5] and hospitalization [4,6,7]. BPSD are also associated with an increased burden on, and decreased quality of life of, caregivers [8-10].

Although BPSD are associated with neurological mechanisms of neurocognitive disease to some extent, previous studies have revealed that the actual occurrence of symptoms can be attributed to diverse personal factors (eg, medical conditions, premorbid personality, and physical and psychological unmet needs), social factors (eg, communication with caregivers, caregivers' stress and depression, and lack of social activities), and environmental factors (eg, overstimulation and lack of established routines), rather than to neurocognitive impairment alone [11,12]. While a few studies have provided evidence that supports frequent co-occurrence of individual BPSD, others have contended that BPSD are distinct and heterogeneous and have different determinants and consequences [13-15]. Determining key factors that predict the different types of BPSD is the first step, since it would guide the determination of which strategies should be chosen to target the underlying causes and ultimately prevent or manage the symptoms [12,16,17].

We based this study on the need-driven dementia-compromised behavior (NDB) model [18]. In the NDB model, BPSD arise from the interaction of two types of factors: (1) relatively stable background factors, including sociodemographic characteristics; neurological, cognitive, and functional status; underlying health; and personality traits, and (2) proximal factors, which are fluctuating and changing states of physical and psychological unmet needs and immediate environmental conditions. To further explain stress-related proximal factors, we incorporated the progressively lowered stress threshold (PLST) model [19], which posits that individuals with dementia are increasingly unable to manage stress, as the threshold for stress tolerance lowers as the disease progresses. If heightened perceived stressors accumulate, then exceed the stress threshold, the person with dementia starts to exhibit BPSD [19-21]. The PLST model recognizes circadian rhythms as a factor that influences the stress threshold level and accordingly postulates that impaired sleep and inadequate physical activity level are among the stressors that consequently trigger BPSD [22,23].

Previous studies have recommended person-centered nonpharmacological interventions as the first-line treatment modality for managing BPSD given the limited efficacy and undesired adverse effects of antipsychotics [24-26]. However, the effect size of the existing nonpharmacological interventions for BPSD has been small [27]. Thus, caregivers and providers continue to struggle to implement the most effective interventions targeting the underlying cause of certain types of BPSD due to limited evidence for target symptoms [28]. Moreover, current knowledge of BPSD is limited, since most existing studies considered BPSD imprecisely as a unitary construct by using measures that aggregated symptoms, which failed to account for the heterogeneity of different types of BPSD [12,14,29]. Although a range of factors have been associated with BPSD occurrence in the literature, most studies focused on only one aspect by testing the effect of a single intervention, such as music therapy, environmental modification, or structured recreational activities [30,31]. A recent scoping review highlighted a gap in the research, namely that diverse factors, including personal, social, and environmental, have been studied only for depression [12]. Surprisingly, few predictive models in existing studies accounted conjointly for the diverse factors [32,33].

A few studies found that sleep problems are associated with depression [34,35], apathy [35,36], agitation [37,38], and aggression [39]; however, efforts have been limited by the use of proxy-rated instruments for disturbed sleep [34,35,39]. Since caregiver-reported sleep measures require systemic and continuous observation of sleep behaviors, such a resource-intensive and time-consuming assessment may be infeasible in real-time care settings [40]. Further, as Blytt et al found significant discrepancies between proxy-rated sleep and actigraphy measures, proxy raters may underreport and fail to recognize sleep disturbances as compared with those measured by actigraphy [41].

Although physical activity has increasingly gained attention as a nonpharmacological approach to managing BPSD [42], few studies have examined the influence of physical activity on BPSD using observational rating instruments to measure activity level [43,44]. A study reported that physical activity objectively measured using actigraphy was significantly correlated with agitation and aggression but did not account for other potential factors [45]. In summary, surprisingly little is known about the

influence of circadian rhythms, including sleep and physical activity levels, on BPSD among community-dwelling older adults with dementia. This is due to the limited number of methodologically rigorous studies using objective measures, such as actigraphy, and accounting for personal, social, and environmental factors within a single study.

Understanding factors that predict BPSD subsyndromes is important not only for establishing early care planning for symptom prevention and management but for selecting the most effective person-centered interventions. Thus, this study explored factors associated with BPSD subsyndromes among community-dwelling older adults with dementia, considering background and proximal factors (ie, actigraphy-measured sleep and physical activity levels and diary-based caregiver-perceived symptom triggers), guided by the NDB model.

Methods

Design

This exploratory study employed a prospective observational design with two waves of data collection. Within each wave, background factors were collected at baseline, and repeated measures were collected for proximal factors over approximately 14 days. Reporting of this study adheres to the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statement [46].

Participants and Setting

Older adults with dementia living at home were recruited from outpatient neurology clinics at two tertiary hospitals and daycare centers in Seoul and the Gyeonggi region in Korea. Inclusion criteria for older adults with dementia were as follows: aged at least 65 years, a diagnosis of dementia by a physician, a Mini–Mental State Examination (MMSE) score of less than 24, and exhibition of BPSD at least once a week, as screened using the Korean version of the Neuropsychiatric Inventory at baseline [47]. The primary caregivers who provided the majority of care for the recruited older adults with dementia, lived in the same home, and were able to read and write in Korean were also included.

Procedure

The Institutional Review Board of the affiliated institutions approved this study. Participants were recruited via on-site visits between June 2018 and June 2019. We conducted the second-wave data collection for participants who agreed to continue in the study between July 2019 and June 2020. The assessment and data collection were conducted by research staff that included registered nurses with a master's degree and registered nurse research assistants with a bachelor's degree. The research staff with a master's degree taught the data collection protocol and trained the research assistants in on-site data collection. The research staff then contacted potential participants and explained the study purpose and procedures. All data collection was conducted at the participants' homes. After obtaining written informed consent at baseline from caregivers who were screened for eligibility, family caregivers completed a structured questionnaire consisting of sociodemographic information and standardized scales for physical and neuropsychological assessments, with assistance from the research staff. Following the baseline assessments, we placed an actigraphy device on the participants' wrists, and primary caregivers logged the BPSD manifestations into the BPSD diary on a daily basis for 14 consecutive days.

Measures

Outcome Measure: BPSD

Although the Neuropsychiatric Inventory [48] is a widely used tool to measure BPSD, its 2-week retrospective rating likely results in recall bias, since its rating reliability is dependent on caregiver training [49]. Therefore, we developed a BPSD diary, adapted from the Neuropsychiatric Inventory, to detect 12 behavioral and psychological symptoms commonly observed in patients with dementia on a daily basis: delusions, hallucinations, agitation or aggression, depression or dysphoria, anxiety, elation or euphoria, apathy or indifference, disinhibition, irritability or lability, aberrant motor behavior, sleep and nighttime behavior, and appetite or eating disorders. The BPSD diary is a structured, easy-to-use checklist that allows a caregiver to record the presence and severity (ie, mild, moderate, and severe) of individual symptoms.

Although BPSD encompass heterogeneous symptoms, clustering a number of individual symptoms that are highly correlated and contingently co-occur allows for a more meaningful interpretation of the study findings [17,50]. Moreover, use of subsyndromes rather than 12 individual symptoms can increase power, as the number of participants who endorse the symptom cluster will increase [51]. Since euphoria or elation, aberrant motor behavior, sleep and nighttime behavior, and appetite or eating disorders did not load on any clusters in previous studies [50-54], we included them as individual symptoms. The remaining eight symptoms were clustered as follows, based on results from factor analyses reported in the literature: (1) psychotic symptoms (hallucination and delusion), (2) affective symptoms (depression, anxiety, and apathy), and (3) hyperactivity (agitation or aggression, disinhibition, and irritability) [51,53-55].

Proximal Factors

Sleep and Physical Activity

Sleep and physical activity were objectively measured using actigraphy (the wGT3X-BT activity monitor; ActiGraph, LLC). Wrist actigraphy has been shown to be a reliable method by which to objectively measure sleep-wake cycles and is suitable for older adults with dementia [56,57]. Participants were asked to wear actigraphy devices on their nondominant wrist for 14 consecutive days starting on the day of the first visit. ActiLife software (version 6.13.3; ActiGraph, LLC) was used to evaluate actigraphy data and provide standard indices of sleep duration and fragmentation using vector magnitude counts in 60-second epoch data. We applied the Cole-Kripke algorithm to score a 1-minute epoch as asleep or awake [58]. We defined nighttime sleep as the time between 8 PM and 8 AM. We used total sleep time (TST) at night and wake time after sleep onset (WASO) at night as sleep parameters. The previous night's sleep parameters were used as potential predictors of BPSD occurring the following day. We also used actigraphy-derived energy

expenditure (kcal burned × 100/hour) as a parameter of activity level. Energy expenditure measured for 24 hours was used as a potential predictor of BPSD occurring on the same day, which reflected the physical conditions during the day when BPSD were exhibited.

Physiological Unmet Needs States and Interpersonal and Environmental Triggers

We used a checklist, embedded within the BPSD diary, to assess contributing factors that family caregivers considered to be immediate triggers for symptoms that encompassed physiological unmet needs states and interpersonal and environmental triggers. On the checklist, the triggers were specifically listed as follows: hunger or thirst, urination or bowel movement, pain or discomfort, sleep disturbance, noise, light, temperature, interpersonal trigger related to a person or persons who were present when the symptom occurred, environmental change, and other. Caregivers were asked to check all contributing factors that were present on the same day when the BPSD were present on this daily-basis symptom checklist. When caregivers checked the "other" option, they were asked to provide a brief description of the triggers. Diary-based caregiver-reported contributing factors that were observed immediately prior to BPSD occurrence were used as potential predictors of BPSD occurring on the same day.

Background Factors

Sociodemographic and Health Information

Participants provided demographic data, including age, gender, marital status, and education level. Dementia diagnosis and neurological and psychiatric medications were obtained via medical chart review or interviews with family caregivers and staff at the recruitment sites.

Cognitive and Functional Status

The Korean version of the MMSE (K-MMSE) was administered to evaluate cognitive functioning at baseline. The highest total score is 30 points, with a higher score indicating better cognitive function [59]. The Cronbach α score for Korean older adults with dementia was .91 [60]. The Korean version of the Activities of Daily Living scale (K-ADL) was administered to measure baseline functional status. This measure consists of seven items that are rated on a 3-point Likert scale, with higher scores indicating more severe dependency. The K-ADL has been validated for Korean older adults with dementia, exhibiting good psychometric properties (eg, Cronbach α score of .94) [61].

Personality Type

A family caregiver informant was asked to rate his or her family member's premorbid personality using the Korean version of the Big Five Inventory (BFI-K) [62]. The BFI-K consists of 15 items that are rated on a 5-point Likert scale, which assess five domains of personality features, namely openness, conscientiousness, neuroticism, extroversion, and agreeableness. The instrument is known to be reliable, with Cronbach α scores ranging from .67 to .82 in a Korean sample [62].

Statistical Analysis

For descriptive statistics, categorical variables were expressed as the number of dementia patients by percentage, while continuous variables were presented as means and SDs. We used two-sample independent *t* tests and Fisher exact tests to compare the difference between data from waves 1 and 2 (Tables S1-S3 in Multimedia Appendix 1). We used generalized linear mixed models (GLMMs) to explore factors predictive of BPSD subsyndromes, with estimation of odds ratios (ORs) and 95% CIs. The GLMM, a commonly used random-effects model, was well suited to this analysis because the approach permits random effects and is suitable for nonnormal or discrete outcomes that are repeatedly measured for each subject [63,64]. All models included a random effect of participant with a random intercept to account for heterogeneity among individuals; all other factors were modeled as fixed effects [65]. Once we decided on the variables to be included in the final model based on clinical and theoretical relevance, we then calculated variance inflation factors to assess multicollinearity among variables. We found that the data were suitable for regression analyses, given that all variance inflation factors were <5, which indicated that no multicollinearity could be detected (Multimedia Appendix 2). The GLMMs to predict each BPSD subsyndrome (ie, psychotic symptoms, affective symptoms, hyperactivity, euphoria or elation, aberrant motor behavior, sleep and nighttime behaviors, and appetite or eating disorders) were tested and compared. Predictors were included in the models in a block-wise manner: (1) background factors (age, gender, marital status, education, K-ADL score, K-MMSE score, premorbid personality type, taking sedative, and dementia type) and (2) proximal factors (TST at night, WASO at night, and caregiver-reported symptom triggers). The order in which the blocks entered the model was determined based on clinical and theoretical considerations: background factors entered first (Model 1), followed by proximal factors (Model 2) for each BPSD subsyndrome. Given that all available data from each participant in the data sets from waves 1 and 2 were used to fit the GLMM, a time variable that indicated the wave (wave 1 vs wave 2) was also present in the models. Fit of the models was assessed and compared using the Akaike information criterion (AIC), the Bayes information criterion (BIC), and the likelihood ratio test. Results were statistically significant if $P<.05$. All analyses were performed using R (version 3.6.3; The R Foundation).

Results

Background Characteristics

During the first wave of data collection, we initially recruited 166 eligible participants. Out of these participants, 18 (10.8%) were lost to follow-up due to refusal to wear the actigraphy devices (n=10), hospitalization or emergency room visits (n=6), death (n=1), and absence of family caregivers at home during the study period (n=1). A total of 3 (1.8%) participants were excluded from the analysis due to no available actigraphy data. During the second wave of data collection, out of 64 eligible participants, 5 (8%) were excluded from the analysis due to no available actigraphy data (n=3) and no available BPSD diary data (n=2). Consequently, this study included a total of 145 older adults with dementia who participated in the first wave.

Of the 145 participants, 59 (40.7%) older adults with dementia continued to participate in the second wave.

At baseline for the first wave, the participants' mean age was 81.23 (SD 6.01) years, with a female to male ratio of approximately 3:2 (86/145, 59.3% female). Education level for most participants was elementary school or below. Participants had moderate cognitive impairment, as indicated by the K-MMSE mean score of 17.28 (SD 5.5); the mean score of the K-ADL was 10.57 (SD 3.6). Background characteristics of the 145 participants in the first wave at baseline are illustrated in Table 1; these characteristics are presented separately for the first and second waves in Table S1 in Multimedia Appendix 1.

Table 1. Background characteristics of older adults with dementia in the first wave at baseline.

Variable	Value (N=145)
Age (years), mean (SD)	81.23 (6.01)
Gender, n (%)	
Male	59 (40.7)
Female	86 (59.3)
Marital status, n (%)	
Married	86 (59.3)
Bereaved or divorced	59 (40.7)
Education level, n (%)	
Elementary school or below	73 (50.3)
Middle school	14 (9.7)
High school	34 (23.4)
College or above	24 (16.6)
Total K-ADL[a] score, mean (SD)	10.57 (3.63)
Total K-MMSE[b] score, mean (SD)	17.28 (5.51)
Big Five Inventory score, mean (SD)	
Openness	8.60 (2.96)
Conscientiousness	11.66 (2.73)
Neuroticism	7.74 (2.87)
Extroversion	8.49 (1.87)
Agreeableness	10.92 (2.96)
Sedative (yes), n (%)	51 (35.2)
Dementia type, n (%)	
Alzheimer disease	71 (49.0)
Lewy body dementia	60 (41.4)
Vascular dementia	23 (15.9)
Other dementia	31 (21.4)

Descriptive Statistics for BPSD Occurrence and Proximal Factors

Summary statistics of BPSD and proximal factors for the 2354 days that encompassed the first and second waves are presented in Table 2; these factors are presented separately for the first and second waves in Table S2 in Multimedia Appendix 1. Caregivers completed the BPSD diaries and participants wore actigraphy devices for a mean of 11.5 (SD 3.5) days. Of the 2354 days during which the symptoms were measured, the most frequently occurring BPSD subsyndrome was affective symptoms (n=548, 23.3%), followed by hyperactivity symptoms (n=350, 14.9%) and sleep and nighttime behaviors (n=275, 11.7%). Euphoria or elation (n=108, 4.6%) and aberrant motor behaviors (n=103, 4.4%) were relatively infrequent. The prevalence of BPSD across participants is also presented in Table S3 in Multimedia Appendix 1. The prevalence of affective symptoms was the highest (82/145, 56.6%), followed by hyperactivity (70/145, 48.3%).

The mean TST at night was 6.4 (SD 2.5) hours, and the mean WASO at night was 0.4 (SD 0.4) hours. The mean energy

expenditure (100 kcal/hour) was 0.21 (SD 0.14). Among the diverse set of caregiver-reported contributing factors, the most frequently reported factor was sleep disturbance (276/2354, 11.7%). Urination or bowel movement (220/2354, 9.3%), pain or discomfort (190/2354, 8.1%), and interpersonal triggers (171/2354, 7.3%) were also relatively frequent.

Table 2. Summary statistics of BPSD subsyndromes and proximal factors.

BPSD[a] subsyndromes and proximal factors	Value (N=2354 days)
Days of recording BPSD and actigraphy per person, mean (SD)	11.54 (3.50)
BPSD subsyndromes, n (%)	
Psychotic symptoms	234 (9.9)
Affective symptoms	548 (23.3)
Hyperactivity symptoms	350 (14.9)
Euphoria or elation	108 (4.6)
Aberrant motor behavior	103 (4.4)
Sleep and nighttime behavior	275 (11.7)
Appetite or eating disorders	193 (8.2)
Proximal factors	
Sleep- and energy-related factors, mean (SD)	
Total sleep time (hours at night)	6.44 (2.52)
Wake time after sleep onset (hours at night)	0.43 (0.36)
Energy expenditure (100 kcal/hour)	0.21 (0.14)
Caregiver-reported contributing factors, n (%)	
Hunger or thirst	149 (6.3)
Urination or bowel movement	220 (9.3)
Pain or discomfort	190 (8.1)
Sleep disturbance	276 (11.7)
Noise	76 (3.2)
Light	69 (2.9)
Temperature	103 (4.4)
Interpersonal trigger	171 (7.3)
Environmental change	87 (3.7)
Other	238 (10.1)

[a]BPSD: behavioral and psychological symptoms of dementia.

GLMMs Predicting BPSD Subsyndromes From Background and Proximal Factors

In the first step, the GLMMs for each BPSD subsyndrome were assessed with only background factors included in the models (Model 1; see results in Tables S1 and S2 in Multimedia Appendix 3). Based on Model 1, proximal factors—actigraphy-measured sleep and activity levels and diary-based caregiver-reported symptom triggers—were entered into Model 2. Table 3 presents *P* values of the likelihood ratio tests as well as the respective AIC and BIC scores for Models 1 and 2 for each BPSD subsyndrome. Likelihood ratio testing comparing Model 1, which consisted of only background factors, with Model 2 (ie, the full model), which included both background and proximal factors, showed that the full model had superior fit for every subsyndrome ($P<.001$). Goodness-of-fit statistics (ie, lower AIC and BIC values) indicated that models for every subsyndrome improved with the addition of proximal factors.

Table 3. Comparisons of generalized linear mixed models.

Outcomes (BPSD[a] subsyndromes)	Background factors (Model 1)		Background factors + proximal factors (Model 2)		*P* value[b]
	AIC[c]	BIC[d]	AIC	BIC	
Psychotic symptoms	872.94	993.98	756.84	952.81	<.001
Affective symptoms	1683.85	1804.89	1379.99	1575.96	<.001
Hyperactivity symptoms	1278.41	1399.46	1064.87	1260.84	<.001
Euphoria or elation	689.12	810.17	587.68	783.65	<.001
Aberrant motor behaviors	525.33	646.37	442.19	638.16	<.001
Sleep and nighttime behaviors	1215.43	1336.47	957.22	1153.20	<.001
Appetite or eating disorders	882.84	1003.88	792.87	988.84	<.001

[b]*P* values were calculated by the likelihood ratio test.

[c]AIC: Akaike information criterion.

[d]BIC: Bayesian information criterion.

Factors Predictive of BPSD Subsyndromes

The results of the GLMMs of background and proximal factors as predictors of BPSD subsyndromes are depicted in forest plots of ORs in Figures 1 and 2 and displayed in Tables S1 and S2 in Multimedia Appendix 4. The results are also summarized below for each subsyndrome.

Figure 1. Forest plots of odds ratios (with 95% CIs shown as whiskers) for the influence of background and proximal factors on psychotic symptoms, affective symptoms, hyperactivity symptoms, and euphoria or elation. ADL: Activities of Daily Living scale; MMSE: Mini–Mental State Examination; BFI: Big Five Inventory; ref.: reference; WASO: wake time after sleep onset.

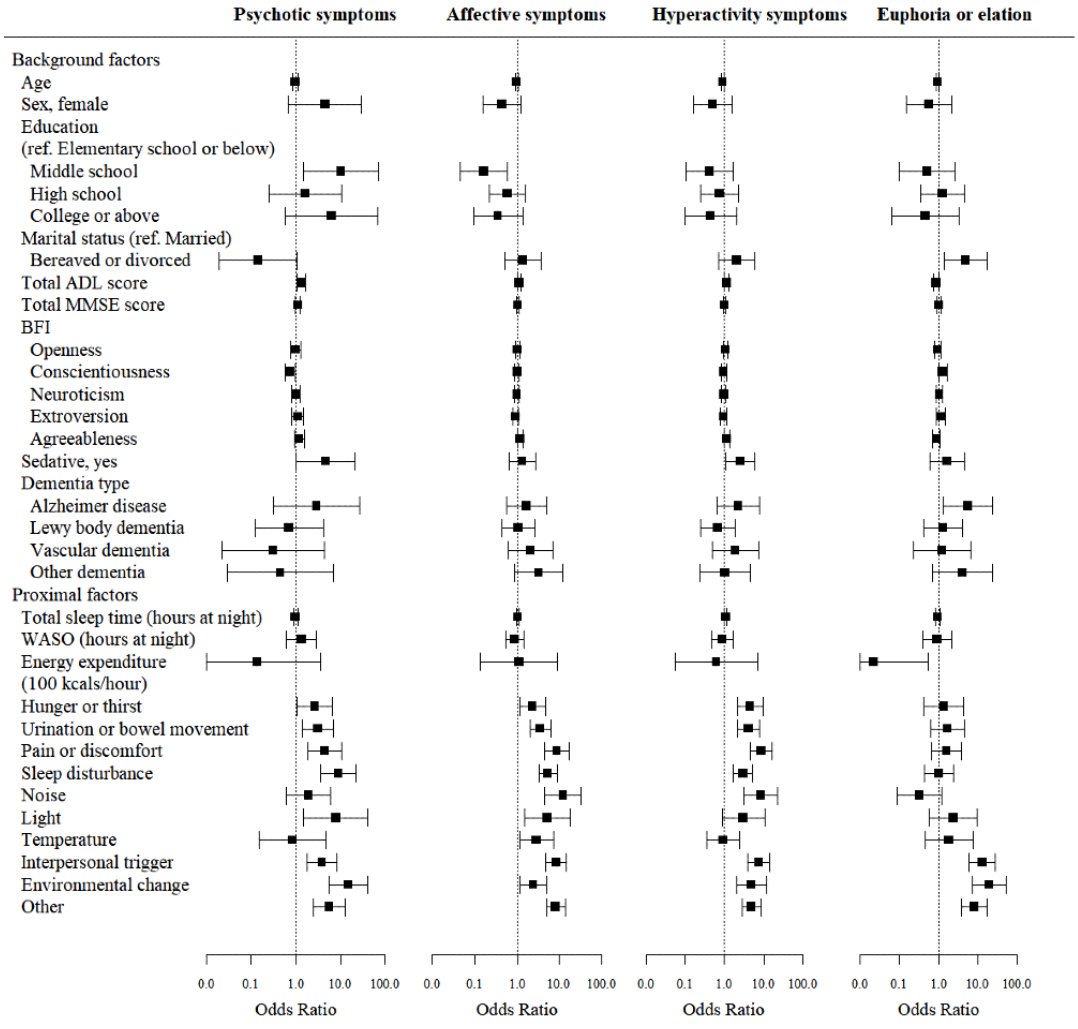

Figure 2. Forest plots of odds ratios (with 95% CIs shown as whiskers) for the influence of background and proximal factors on aberrant motor behavior, sleep and nighttime behaviors, and appetite or eating disorders. ADL: Activities of Daily Living scale; MMSE: Mini–Mental State Examination; BFI: Big Five Inventory; ref.: reference; WASO: wake time after sleep onset.

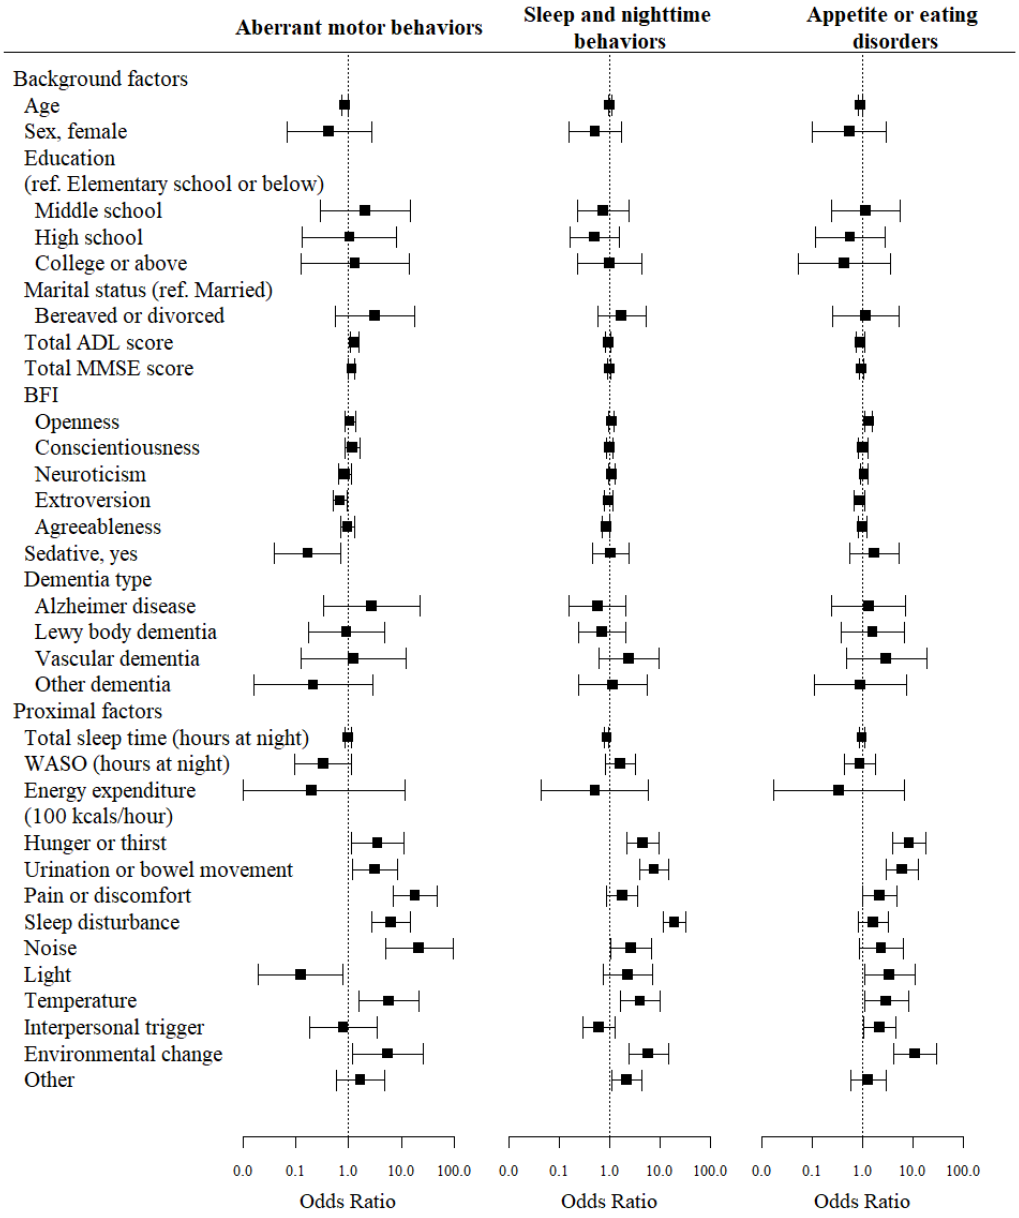

Psychotic Symptoms

Regarding proximal factors, patients were more likely to exhibit psychotic symptoms on the same day if they were exposed to environmental change (OR 14.7, 95% CI 5.3-40.8; *P*<.001) or inadequate light (OR 7.8, 95% CI 1.5-40.7; *P*=.02). Patients were more likely to exhibit psychotic symptoms (OR 8.8, 95% CI 3.6-21.7; *P*<.001) if they had sleep disturbance observed and reported by caregivers as well as pain or discomfort (OR 4.4, 95% CI 1.9-10.3; *P*<.001), urination or bowel movement–related problems (OR 3.1, 95% CI 1.4-6.9; *P*=.005), or hunger or thirst (OR 2.6, 95% CI 1.1-6.4; *P*=.03).

Background factors significantly associated with psychotic symptoms were educational attainment at the middle school level (OR 10.2, 95% CI 1.5-70.1; *P*=.02), greater impairment in activities of daily living (ADLs) (OR 1.3, 95% CI 1.1-1.7; *P*=.01), taking sedatives (OR 4.6, 95% CI 1.0-21.1; *P*=.049), and high conscientiousness traits (OR 0.8, 95% CI 0.6-1.0; *P*=.02).

Affective Symptoms

Of environmental condition–related proximal factors, increased likelihood of affective symptoms was significantly associated with noise (OR 12.1, 95% CI 4.5-32.4; *P*<.001), inadequate light (OR 5.1, 95% CI 1.5-17.4; *P*=.01), inadequate temperature (OR 2.9, 95% CI 1.2-7.1; *P*=.02), and being exposed to environmental change (OR 2.4, 95% CI 1.2-4.9; *P*=.02). Of proximal factors associated with physical unmet needs states, affective symptoms were more likely to be exhibited by patients with pain or discomfort (OR 8.6, 95% CI 4.6-16.4; *P*<.001), sleep disturbance (OR 5.3, 95% CI 3.3-8.7; *P*<.001), urination or bowel movement problems (OR 3.5, 95% CI 2.0-6.1; *P*<.001), or hunger or thirst (OR 2.3, 95% CI 1.2-4.6; *P*=.02). Interpersonal triggers related to a person or persons who were

present with the patients with dementia were also significantly associated with an increased likelihood of affective symptoms (OR 8.4, 95% CI 4.8-14.6; *P*<.001).

Background factors significantly associated with affective symptoms included agreeable personality traits (OR 1.2, 95% CI 1.0-1.3; *P*=.03), greater impairment in ADLs (OR 1.1, 95% CI 1.0-1.3; *P*=.03), and educational attainment at the middle school level (OR 0.2, 95% CI 0.0-0.6; *P*=.005).

Hyperactivity Symptoms

With respect to proximal factors, patients were more likely to exhibit hyperactivity symptoms if they experienced pain or discomfort (OR 8.8, 95% CI 4.6-16.9; *P*<.001), hunger or thirst (OR 4.5, 95% CI 2.1-9.5; *P*<.001), urination or bowel movement problems (OR 4.2, 95% CI 2.2-8.0; *P*<.001), or sleep disturbance (OR 3.0, 95% CI 1.7-5.2; *P*<.001). Increased likelihood of hyperactivity symptoms was also predicted by being exposed to noise (OR 8.5, 95% CI 3.2-22.6; *P*<.001) and environmental change (OR 4.9, 95% CI 2.1-11.8; *P*<.001). Interpersonal triggers also increased the predicted odds of hyperactivity symptoms (OR 7.6, 95% CI 4.0-14.4; *P*<.001).

Background factors that increased the predicted odds of hyperactivity symptoms were greater impairment in ADLs (OR 1.1, 95% CI 1.0-1.3; *P*=.04) and taking sedatives (OR 2.5, 95% CI 1.1-5.9; *P*=.03).

Euphoria or Elation

Regarding proximal factors, patients with greater levels of energy expenditure (100 kcal/hour) measured by actigraphy were less likely to exhibit euphoria or elation on the same day (OR 0.02, 95% CI 0.0-0.5; *P*=.02). In contrast, patients who were exposed to environmental change (OR 19.7, 95% CI 7.5-51.7; *P*<.001) or interpersonal triggers (OR 13.0, 95% CI 6.0-28.4; *P*<.001) were more likely to show symptoms of euphoria or elation.

Background factors significantly associated with euphoria or elation included diagnosis of Alzheimer disease (OR 5.7, 95% CI 1.4-23.6; *P*=.02), bereavement or divorced status (OR 4.9, 95% CI 1.4-17.1; *P*=.01), and high conscientiousness traits (OR 1.3, 95% CI 1.0-1.6; *P*=.046).

Aberrant Motor Behaviors

Of proximal factors, environmental condition–related factors that increased the likelihood of aberrant motor behaviors were being exposed to noise (OR 21.6, 95% CI 5.0-93.5; *P*<.001), inadequate temperature (OR 5.8, 95% CI 1.6-21.3; *P*=.008), and environmental change (OR 5.6, 95% CI 1.2-26.0; *P*=.03). In contrast, light was significantly associated with decreased likelihood of such behaviors (OR 0.1, 95% CI 0.0-0.8; *P*=.03). Patients were more likely to exhibit BPSD behaviors if they had pain or discomfort (OR 18.0, 95% CI 6.9-47.1; *P*<.001), sleep disturbance (OR 6.4, 95% CI 2.7-14.9; *P*<.001), hunger or thirst (OR 3.6, 95% CI 1.1-11.2; *P*=.03), or urination or bowel movement problems (OR 3.2, 95% CI 1.2-8.3; *P*=.02).

Background factors significantly associated with aberrant motor behaviors were greater impairment in ADLs (OR 1.3, 95% CI 1.1-1.6; *P*=.01), higher K-MMSE score (OR 1.2, 95% CI 1.0-1.3; *P*=.048), older age (OR 0.9, 95% CI 0.8-1.0; *P*=.02), high extroversion traits (OR 0.7, 95% CI 0.5-0.9; *P*=.01), and taking sedatives (OR 0.2, 95% CI 0.0-0.7; *P*=.02).

Sleep and Nighttime Behaviors

Among proximal factors, greater numbers of total nighttime sleep hours measured by actigraphy were significantly associated with decreased likelihood of sleep and nighttime behaviors occurring the next day (OR 0.9, 95% CI 0.8-1.0; *P*=.005). In contrast, patients were more likely to exhibit sleep and nighttime behaviors given sleep disturbance observed and reported by caregivers (OR 19.4, 95% CI 11.6-32.7; *P*<.001), urination or bowel movement problems (OR 7.7, 95% CI 4.0-14.7; *P*<.001), or hunger or thirst (OR 4.6, 95% CI 2.2-9.6; *P*<.001). Increased odds of sleep and nighttime behaviors were also associated with environmental change (OR 5.9, 95% CI 2.4-14.6; *P*<.001), inadequate temperature (OR 4.0, 95% CI 1.6-10.2; *P*=.003), and noise (OR 2.7, 95% CI 1.0-6.8; *P*=.04). None of the background factors were significantly associated with the likelihood of sleep and nighttime behaviors.

Appetite or Eating Disorders

Of proximal factors, increased likelihood of appetite or eating disorders was associated with exposure to environmental change (OR 11.1, 95% CI 4.2-29.3; *P*<.001), inadequate lighting (OR 3.4, 95% CI 1.1-10.8; *P*=.03), and inadequate temperature (OR 2.9, 95% CI 1.1-8.0; *P*=.04). Patients were also more likely to exhibit appetite or eating disorders on the same day if they experienced hunger or thirst (OR 8.5, 95% CI 4.0-18.1; *P*<.001) or urination or bowel movement problems (OR 6.0, 95% CI 2.9-12.6; *P*<.001). Interpersonal triggers also predicted an increased likelihood of appetite or eating disorders (OR 2.2, 95% CI 1.0-4.6; *P*=.04). The openness trait was the only background factor that significantly predicted appetite or eating disorders (OR 1.3, 95% CI 1.1-1.6; *P*=.003).

Discussion

Principal Findings

Although BPSD are recognized to arise from background and proximal factors, it is unclear exactly how the different BPSD subsyndromes are influenced by specific proximal factors, such as sleep and physical activity levels and physical and psychosocial unmet needs states. This study explored factors associated with BPSD subsyndromes among community-dwelling older adults with dementia, including sets of background and proximal factors (ie, actigraphy-measured sleep and physical activity levels and diary-based caregiver-perceived symptom triggers) guided by the NDB model. This research expanded upon the limited previous research by using actigraphy and diary-based assessments, thereby enabling the collection of objective and/or continuous time-varying proximal data.

The Effects of Proximal Factors on the Occurrence of BPSD Subsyndromes

Our results demonstrated that BPSD subsyndromes were predictable based on proximal factors, including actigraphy-measured sleep and activity levels and diary-based

caregiver-reported symptom triggers. The models to predict BPSD subsyndromes demonstrated better predictive ability when both background and proximal factors served as predictors in the models compared to those with only background factors. While BPSD have been largely considered unpredictable [17] and few previous studies have considered the impact of preventative approaches to BPSD [11], our results support a paradigm shift to an individualized approach to BPSD subsyndromes through prediction and early prevention. In particular, caregiver-reported physical, psychosocial, and environmental triggers largely influenced most subsyndromes, except for euphoria or elation. This suggests that, despite the unmodifiable nature of background factors, most BPSD can be prevented through early identification of at-risk individuals and timely assessment of targeted physical and psychosocial unmet needs.

However, it remains unclear as to which BPSD subsyndromes are under circadian control (ie, influenced by sleep and activity levels). In this study, greater nighttime sleep hours were associated with a lower likelihood of sleep and nighttime behaviors, manifested as nighttime awakening or excessive daytime napping, occurring the next day. This finding is consistent with previous studies, in that sleep problems are both a risk factor and a symptom outcome [66,67]. In previous studies, the association between sleep disturbance and BPSD has been inconsistent and variable among different BPSD. For example, a previous study of a Korean sample found that more severe sleep impairment, measured by the Korean version of the Pittsburgh Sleep Quality Index (PSQI) [68], was significantly associated with apathy or indifference, but not with other types of symptoms [69]. In another study conducted in China, the total scores of the PSQI and its subscales were significantly correlated with depression, apathy, and sleep and nighttime behaviors [35]. Moreover, one study of a hospitalized sample noted that the average number of sleep minutes significantly predicted agitation and irritability [37]; another study of nursing home residents with severe dementia found that a greater number of nighttime sleep hours was a predictor of daytime aggressive behaviors [70]. One possible explanation for the nonsignificant relationship between sleep parameters and aggression in our study could lie in the differences in sample characteristics. Given that the mean K-MMSE score in our sample indicated moderate cognitive impairment, nighttime sleep perhaps affects aggression when cognitive impairment is severe. Regarding the activity level, euphoria or elation was associated with energy expenditure measured by actigraphy. A previous study showed that an increased physical activity level was associated with an increased likelihood of agitation and aggression in hospitalized patients with severe dementia [45]. This may be because increased physical activities could reflect heightened agitation and aggressive symptoms per se rather than physical exercise. To summarize, it still remains unclear as to which BPSD subsyndromes are under circadian control. The inconsistent results among prior studies call for further research to build on extant knowledge.

Implications for Different Approaches to Heterogeneous BPSD Subsyndromes

While the NDB model explains the effect of the interplay between background and proximal factors on the broad construct of BPSD [71], the findings from this study extend the NDB model by indicating which specific background and proximal factors exert their effects on which specific BPSD subsyndromes. For example, while a greater number of nighttime sleep hours was associated with attenuated likelihood of sleep and nighttime behaviors occurring the next day, nighttime sleep hours did not influence other BPSD subsyndromes. While physical unmet needs states (eg, pain or discomfort, sleep disturbance, and hunger or thirst) and physical environmental conditions (eg, noise and lighting) were significant factors associated with affective symptoms, they were not found to influence symptoms of euphoria or elation. Instead, actigraphy-measured energy expenditure was a proximal factor that predicted euphoria or elation, whereas it did not influence any other symptoms. Thus, the results underscore that etiological-based differentiated interventions are needed to focus on the factors underlying the target BPSD subsyndromes [17].

Accordingly, our study provides empirical evidence regarding the heterogeneity of BPSD [13-15] by revealing the distinct underlying predictors for the seven BPSD subsyndromes. Results showed that there were multiple predictors of all BPSD; however, the mechanisms underlying how a set of neurobiological, psychosocial, and environmental factors interplay and subsequently result in specific symptoms remain elusive [72]. Since the etiopathogenesis of BPSD is complex, multifactorial, and variable depending on the BPSD subsyndromes or individual symptoms [12,72], it is challenging for health care providers and caregivers to decide which interventions should be used to manage certain types of symptoms. Several interventional algorithms have been proposed to simplify complex information on the relationships among multifactorial factors and make it usable, such as the Describe, Investigate, Create, and Evaluate (DICE) approach [11,73] and the BPSD–Describe and Measure, Analyze, Treat, and Evaluate (DATE) algorithm [72]. Although the algorithms have been helpful for caregivers to simplify the complex nature of heterogeneous BPSD trajectories, further research is needed to develop predictive models that will guide health care providers and caregivers to move toward personalized BPSD care. Our study represents a starting point for developing more data-driven predictive algorithms tailored to BPSD subsyndromes to advance more precise BPSD care.

Advancing BPSD Research and Practice by Leveraging Digital Health Technologies

The results also facilitate the use of technological advances to achieve personalized BPSD care. Assessment of BPSD has largely relied on information reported by informal or formal caregivers, which has resulted in information bias and caregiver burden [74]. While the traditional nomothetic approach to assessment of BPSD has limitations in terms of capturing the unique trajectories of BPSD manifestations and their contexts, human behavior and psychology research has considered idiographic approaches to capture prospective and

time-dependent variation within individuals [75]. Our study demonstrates the potential of using real-world data to measure fluctuating contextual information by leveraging digital health technologies to advance BPSD research and practice using an idiographic and personalized approach. Although concerns may exist regarding applying actigraphy to patients with dementia, our results demonstrated the feasibility of assessing sleep and activity levels using actigraphy in individuals with dementia, as evidenced by relatively low attrition rates and low amounts of missing data.

Along with the objectively measured actigraphy data, the results of the GLMMs revealed the large magnitude of the associations between diary-based caregiver-perceived symptom triggers and BPSD subsyndromes, which indicates the importance of collateral information from caregivers for predicting BPSD subsyndromes. Information and communications technologies (ICTs) can be a solution to complement paper-based symptom diaries by allowing the collection of high-frequency contextual information on BPSD that is episodic and evolves over time [76]. Future studies could adopt mobile app–based symptom diaries, which would facilitate the tracking and monitoring of BPSD by using push notifications to ensure measurements are not missed and to assist caregivers in easily checking symptoms anywhere and anytime with their mobile phones. Ecological momentary assessment (EMA) [77] is a promising tool that could be incorporated into mobile app–based symptom diaries. EMA data collected using electronic diaries could capture the momentary aspects of BPSD occurrence, rather than relying on recall over time and how BPSD manifestations vary over time and situations through repeated assessments [77]. Moreover, integrating prediction models into digital devices, such as smartphones, or connecting them to electronic health records could further improve the clinical utility of prediction models.

Limitations

Several limitations should be noted. First, we used a proxy measure of BPSD based on caregivers' reporting, rather than direct observation of symptoms, which may have introduced observer and recall bias. Second, because BPSD and caregiver-reported contributing factors were checked on a daily rather than episodic basis, caregivers could check multiple types of symptoms and related triggers if different types of symptoms were observed within a day. This may have made it difficult to identify the caregiver-reported factors that contributed to specific types of BPSD that occurred during the day. Future mobile app–based symptom diaries that collect episodic data would make it possible to disentangle aggregated proximal factors and symptoms that occur within a day. Finally, although it was not within the scope of this study, the bidirectionality of the relationships between proximal factors and BPSD is unclear in the current literature. A more thorough understanding of the reciprocal effects of sleep and physical activity levels with BPSD is needed to understand the mechanisms that underly the associations.

Conclusions

In conclusion, this prospective study demonstrated that BPSD are clinically heterogeneous, and their occurrence can be predicted by different contributing factors. Our results for various BPSD suggest a critical window for timely intervention and care planning. These findings represent the starting point for the establishment of a prediction model tailored to specific symptoms. However, further studies with larger samples are needed to confirm these findings. Nonetheless, these findings will assist in devising symptom-targeted and individualized interventions to prevent and manage different types of BPSD and to ultimately facilitate personalized dementia care.

Acknowledgments

This work was supported by a National Research Foundation of Korea (NRF) grant funded by the Korea government (Ministry of Science and ICT) (grant NRF-2018R1A2B6003506) and supported by the Basic Science Research Program through the NRF funded by the Ministry of Education (grant NRF-2020R1A6A1A03041989). The funders had no role in the study design, data collection and interpretation, or preparation of the manuscript.

Authors' Contributions

EC contributed to the study concept and design. SK, SH, EK, JHL, and BSY were responsible for acquisition of the data. EC, BK, and S-JH analyzed and interpreted the data and drafted the manuscript. All authors participated in the interpretation of the results and revision of the manuscript. All authors have read and approved the final manuscript.

Abstract

Background: Multisensor fitness trackers offer the ability to longitudinally estimate sleep quality in a home environment with the potential to outperform traditional actigraphy. To benefit from these new tools for objectively assessing sleep for clinical and research purposes, multisensor wearable devices require careful validation against the gold standard of sleep polysomnography (PSG). Naturalistic studies favor validation.

Objective: This study aims to validate the Fitbit Charge 2 against portable home PSG in a shift-work population composed of 59 first responder police officers and paramedics undergoing shift work.

Methods: A reliable comparison between the two measurements was ensured through the data-driven alignment of a PSG and Fitbit time series that was recorded at night. Epoch-by-epoch analyses and Bland-Altman plots were used to assess sensitivity, specificity, accuracy, the Matthews correlation coefficient, bias, and limits of agreement.

Results: Sleep onset and offset, total sleep time, and the durations of rapid eye movement (REM) sleep and non–rapid-eye movement sleep stages N1+N2 and N3 displayed unbiased estimates with nonnegligible limits of agreement. In contrast, the proprietary Fitbit algorithm overestimated REM sleep latency by 29.4 minutes and wakefulness after sleep onset (WASO) by 37.1 minutes. Epoch-by-epoch analyses indicated better specificity than sensitivity, with higher accuracies for WASO (0.82) and REM sleep (0.86) than those for N1+N2 (0.55) and N3 (0.78) sleep. Fitbit heart rate (HR) displayed a small underestimation of 0.9 beats per minute (bpm) and a limited capability to capture sudden HR changes because of the lower time resolution compared to that of PSG. The underestimation was smaller in N2, N3, and REM sleep (0.6-0.7 bpm) than in N1 sleep (1.2 bpm) and wakefulness (1.9 bpm), indicating a state-specific bias. Finally, Fitbit suggested a distribution of all sleep episode durations that was different from that derived from PSG and showed nonbiological discontinuities, indicating the potential limitations of the staging algorithm.

Conclusions: We conclude that by following careful data processing processes, the Fitbit Charge 2 can provide reasonably accurate mean values of sleep and HR estimates in shift workers under naturalistic conditions. Nevertheless, the generally wide

limits of agreement hamper the precision of quantifying individual sleep episodes. The value of this consumer-grade multisensor wearable in terms of tackling clinical and research questions could be enhanced with open-source algorithms, raw data access, and the ability to blind participants to their own sleep data.

Introduction

Highly sensitive and precise instruments are necessary for the accurate measurement of sleep in healthy and clinical populations. Polysomnography (PSG), the prevailing gold standard in clinical and research settings [1], reliably reflects the physiological processes underlying sleep with high temporal resolution [2]. The PSG recordings are conducted to capture sleep macrostructure (eg, stages and cycles) and microstructure (eg, K-complexes, spindles, and arousals), and to quantify different variables such as power density spectra of the electroencephalogram and heart rate (HR) variability, to estimate an individual's sleep quality and health. Despite the many strengths of PSG, attendant disadvantages include high cost, the need for personnel trained in technical aspects and interpretation of data, and the highly technical recording system itself, which usually necessitates a dedicated sleep laboratory, although ambulatory systems also exist [3]. Inexpensive, practical, and portable alternatives that are equally accurate and reliable as PSG in measuring sleep would be welcome for clinicians and researchers.

Currently, the only validated and United States Food and Drug Administration–approved alternative to PSG in ambulatory settings is actigraphy [4]. Actigraphy measures movement using a multiaxis accelerometer in a device resembling a wristwatch, sometimes accompanied by an embedded light sensor. Actigraphy captures rest-activity behaviors such as sleep habits, bedrest, rise times, and light exposure [5,6]. The basic assumption of actigraphy is that motion implies wakefulness, whereas no motion implies sleep. Fully disclosed algorithms [7,8] are used to compute sleep variables with some precision, but performance compared with PSG varies because of the inherent limitation in discriminating sleep from waking that is not accompanied by movement [3,4]. Actigraphy is a dedicated scientific instrument in clinical and research contexts and depends on specialists for setting up and interpreting data [9].

Recently, there has been greater acceptance, but also controversy, among the scientific community about using commercially available wearable devices such as fitness trackers in research [10]. Fitness trackers are multisensor, consumer-grade devices that represent a cost-efficient, practical, and convenient means of objectively collecting rest-activity data longitudinally under ambulatory conditions [4]. Fitbit is a market leader [11], and efforts have been made to validate its devices, such as the Fitbit Charge 2, against PSG [4,12-15] and the portable single-channel electroencephalogram sleep scope device [16]. Such devices not only rely on movement but also measure HR via photoplethysmography. Changes in the activity of the autonomic nervous system regulating HR are coupled to changes in electroencephalogram patterns [17,18], and various HR measures are correlated with electroencephalogram-defined sleep states [19]. These relationships potentially permit a multisensor fitness tracker to estimate an array of sleep variables above and beyond that of conventional actigraphy [20-22].

A recent laboratory-based validation study suggested that the proprietary algorithm of Fitbit Charge 2 (Fitbit Inc) to estimate different sleep variables performed reasonably well [3]. More specifically, the device displayed a 9-minute overestimation of total sleep time (TST), whereas sleep onset (S_{on}) latency was underestimated by 4 minutes. Furthermore, Fitbit's *light* stage was overestimated by 34 minutes, and Fitbit's *deep* sleep stage, assumed to be equivalent to the N3 sleep stage, was underestimated by 24 minutes compared with the PSG-derived sleep stages N1+N2 and N3, respectively. No bias was observed in wakefulness after S_{on} (WASO) or the duration of rapid eye movement (REM) sleep stage. Findings in patients with periodic limb movements during sleep revealed comparable results [3]. In contrast, a study in patients with obstructive sleep apnea contradicted the unbiasedness of WASO for 2 Fitbit devices, Fitbit Charge 2 and Fitbit Alta HR. Both devices underestimated WASO, possibly indicating variable performance in different clinical populations [23]. Other work performed at participants' homes compared Fitbit Charge 2 with a portable single-channel electroencephalogram sleep monitor [16]. This study showed 86.9% agreement; however, there was an underestimation of TST by 12.3 minutes, of *light* sleep by 42.4 minutes, and of REM sleep by 11.6 minutes. Conversely, WASO was overestimated by 24.5 minutes and deep sleep by 39.8 minutes. These estimates also showed a large SD.

Regarding HR, a study found a moderate underestimation of 5.9 beats per minute (bpm) with Fitbit Charge 2 compared with the electrocardiogram, whereas precision for individual measurements was poor as reflected by wide limits of agreement (LoA) [24]. Another study found that this device tended to slightly overestimate HR in ranges <50 bpm (bias=0.51 bpm) and underestimate HR in ranges >80 bpm (bias=0.63 bpm) compared with the electrocardiogram [13]. The Fitbit Charge HR model displayed a general underestimation (bias=0.88 bpm) in a similar range [25].

Therefore, the findings of previous sleep and HR validation studies of Fitbit Charge 2 are rather inconsistent and warrant further research. It was previously concluded that apart from the sample population studied, inaccurate temporal synchronization between Fitbit wearables and PSG is an important challenge in some validation studies [26]. In addition, consumer-grade wearables need to be validated under naturalistic conditions and in diverse populations, as such factors

may affect their performance. We attempted to validate Fitbit Charge 2 against gold-standard PSG in a healthy study sample, but one that regularly performed shift work and exhibited an elevated risk of occupational stressors, which likely interfered with and attenuated the quality of sleep. With these objectives in mind, we seek to validate the usefulness of Fitbit Charge 2 to evaluate sleep quality in first responder shift workers under naturalistic conditions, with a special focus on rigorous data preprocessing and time alignment of the data recordings.

Methods

Study Sample

The participants of this study were recruited from July 2017 to November 2019 by various informational media, emails, and presentations at shift change as part of a larger study investigating sleep and resilience to psychological stress and trauma. They completed 1 month of monitoring of wrist-derived rest-activity behavior with a Fitbit Charge 2 that was worn continuously by all individuals on their nondominant wrist.

The Ethics Commission of the Canton of Zurich approved (2016-01357) all study protocols and experimental procedures, and written informed consent was obtained before participation. Participants invited to participate fulfilled all inclusion criteria: aged between 18 and 65 years, BMI ≤26 (or if exceeding a BMI of 26, which is typical of very athletic participants, an absence of sleep problems, such as sleep breathing disorders, was reported), current employment in 1 of 2 participating emergency rescue stations and a police station in the greater Zurich area of Switzerland, possession of a smartphone, and German language fluency. Exclusion criteria included the presence of a neurological disorder diagnosis or head injury with the potential to affect electroencephalogram variables, reported intake of >5 alcoholic beverages per week, or if a urine drug screen (Drug Screen Multi 12-AE; Nal von Minden GmbH) revealed drug abuse. All participants were shift workers, although specific shift schedules varied among individuals by occupation, such that emergency medical rescue workers and emergency doctors worked cycles of two 12-hour days followed by two 12-hour nights, terminating in 4 free days. Police officers worked four contiguous shifts with varying individual activities and bedrest times. Data on individual shifts were not collected or analyzed. Individuals received monetary compensation for participating in the study. Participants additionally received a report on their sleep derived from their own sleep data derived from Fitbit Charge 2 and PSG. This report was explained to them by a study staff member.

Validated German translations of questionnaires administered at meetings at the start and upon completion of 1 month of monitoring were used to assess lifestyle and psychological and sleep variables. The Pittsburgh Sleep Quality Index (PSQI) [27], Posttraumatic Stress Disorder Checklist for Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [28], and the Perceived Stress Scale 10 (PSS-10) [29] were used to assess subjective sleep quality, posttraumatic stress symptoms, and stress in the past month. Cutoff scores of ≥5 on the PSQI, >31 on the Posttraumatic Stress Disorder Checklist for Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, and substantial deviations from the normative values—12.1 (SD 5.9) for men and 13.7 (SD 6.6) for women—indicate poor sleep quality [27], a probable posttraumatic stress disorder diagnosis [28], and elevated perceived stress [29], respectively. The Horne-Östberg Morningness-Eveningness Questionnaire-A Reduced Scale (rMEQ) was used to assess the participants' preferred rest-activity behavior or *chronotype*, with higher scores indicating increased morning activity preference. Scores on the rMEQ have a range of 4-25. A previous study found that most individuals (60%; scores: 12-17) show neither a pronounced evening (20% of individuals; scores: 4-11) nor morning (20% of individuals; scores: 18-25) activity preference [30].

Polysomnographic Recordings

A total of 62 individuals (43 emergency medical rescue workers, 16 police officers, and 3 emergency doctors), of whom 56% (35/62) were women, completed 2 nights of ambulatory PSG recordings in their homes. The PSG recordings were always made of nocturnal sleep following a day work shift and consisted of an adaptation night and then a baseline night the following evening. Individuals were free to determine their bedtime and sleep duration. The adaptation night served as a combined adaptation and screening night, whereas the baseline night provided the data analyzed in this report, with the exception of 8 individuals, whose data originated from the adaptation night because the PSG data of the baseline nights were of poor quality. The PSG data from one individual were excluded from the analyses because the data were of poor quality on both nights. Therefore, the total PSG sample consisted of 61 individuals. On 2 nights, the Fitbit Charge 2 data sets for 2 individuals were not obtained, reducing the sample to 59 individuals who had both PSG and Fitbit Charge 2 data for comparison. All PSG data were acquired using dedicated ambulatory polysomnographic amplifiers (SOMNOscreen Plus, SOMNOmedics GmbH). All electrodes and sensors for PSG recordings were applied by trained members of the research team. The overall PSG montage consisted of scalp electrode sites Fz, Cz, Pz, Oz, C3, C4, A1, and A2 applied according to the International 10-20 System [31] and electrooculogram, submental electromyogram, and electrocardiogram and grounding electrode according to the American Academy of Sleep Medicine standards [32]. The Cz electrode served as the reference during recording, and the opposite mastoid was used for the rereferenced display. The sampling rate for all the sites was 256 Hz. For recording, high-pass (0.2 Hz) and low-pass filters (128.0 Hz) were used. High-pass (0.3 Hz) and low-pass (35.0 Hz) filters in addition to a powerline filter were applied for visual sleep scoring. Sleep stages were scored visually by an experienced individual in 20-second epochs according to the American Academy of Sleep Medicine (2007) criteria.

The electrocardiogram trace in the PSG recordings was examined visually for one epoch at a time for all wake epochs before S_{on} and all epochs of sleep and wake stages after S_{on} (performed by an experienced individual). Artifacts and ectopic beats present in the electrocardiogram trace that had the potential to interfere with the quantification of interbeat intervals (IBIs), defined as the time interval between the normal R peaks of the QRS complex, were manually marked and removed before data processing and analysis.

Fitbit Charge 2 Recordings

All participants wore the Fitbit Charge 2 continuously during the PSG recorded nights. The device records wrist activity using accelerometry and pulses via photoplethysmography. It produces two types of sleep data depending on whether certain criteria are fulfilled during data collection. These criteria are sufficient battery charge, a sleep episode >3 hours in duration, and sufficient skin contact with the photoplethysmography sensor. If these criteria are not fulfilled, then *classic* sleep data are generated, comprising *asleep*, *awake*, and *restless* variables at a 1-minute data granularity. If these criteria are fulfilled, then *stages* data are produced, comprising *wake*, *light*, *REM*, and *deep* sleep at a 30-second data granularity. If *stages* data are obtained for a given sleep episode, then users receive two data sets, that is, (1) sleep data, which is composed of stages, and (2) wake data, which is composed exclusively of wake episodes <30 seconds. Both data sets are present in a single JSON file for a given data collection date. However, there were also wake episodes contained within the sleep data set. This data structure is especially relevant for researchers who wish to extract entire hypnogram data and information not provided by Fitbit, such as REM sleep latency (REML). The variable WASO was created in this study by merging these two data sets contained within the *stages* data type output. The Fitbit sleep staging algorithm occasionally scores the first stage after S_{on} and the last stage before sleep offset (S_{off}) as *wake*. This runs counter to the intuitive definition of S_{on} and S_{off} as the first occurrence of sleep and the last occurrence of sleep, respectively.

We manually omitted such bordering wake epochs and adjusted the S_{on}, S_{off}, TST (ie, $S_{off} - S_{on}$), and WASO values accordingly. S_{on}, S_{off}, and REML are variables that are not provided directly by Fitbit; hence, we calculated them from the sleep staging information provided by Fitbit. All other variables were standard Fitbit variables. Adjustments only affected the Bland-Altman analyses. The results of the analyses without adjustment for the standard Fitbit variables can be found in Figure S1 and Table S1 in Multimedia Appendix 1. A sleep sensitivity setting is needed to be set for Fitbit's sleep recordings, with options *sensitive* and *normal*. When set to *normal*, only major body movements, such as rolling over, will register as *wake*, whereas when set to *sensitive*, more subtle movements will additionally be registered as *wake*. We set the setting to *sensitive* throughout the data collection.

Statistical Analyses

All analyses and data processing steps were performed in the programming language *R* (version 4.0.0; R Foundation for Statistical Computing) [33]. Fitbit intraday HR measures were used. For electrocardiogram R peak detection, the Pan-Tompkins algorithm [34] was used as implemented in the *rsleep* package (version 1.0.3) [35]. However, the algorithm could not distinguish sharp T waves from R peaks on various occasions. Thus, a modification of the algorithm had to be made. The signal can sometimes be inverted in the sign, and for this reason, we changed the signal to have positive R peaks (which was revealed by the mean of the detected peak values by the Pan-Tompkins algorithm). Sometimes, the peak can be slightly misaligned with the actual R peak maximum. Therefore, after running the Pan-Tompkins algorithm, the detected peak was aligned with the actual maximum ±200 ms around the detected peak. Furthermore, in cases where two peaks were observed within less than 360 ms, we checked if the subsequent peak was a mistakenly detected T wave or an actual R peak. This was done by examining the signal in a small window of ±28 ms around the detected and maximally aligned peak and taking its second derivative. T waves generally display slower changes in the tangents of the electrocardiogram signal as compared to faster tangent changes found in R peaks. The 60% quantile of the absolute value of the second derivative ($QAVSD_{60}$) was then compared with a cutoff point specific to an individual participant derived from the density function of the $QAVSD_{60}$ values from all the detected peaks. The cutoff point was defined as the first local minimum of the density within the hard limits of 35/256 $\mu V/s^2$ and 120/256 $\mu V/s^2$. If no local minimum was present, 35/256 $\mu V/s^2$ was used instead. The density of $QAVSD_{60}$ revealed a multimodal distribution of nearly no overlap between the T wave characteristic $QAVSD_{60}$ values compared with those originating from R peaks. Erroneously detected T waves were omitted, thereby rescuing the affected segments of the electrocardiogram data sets for subsequent analyses. This small T wave check and alignment of the peak to the local maximum significantly improved the algorithm performance on visual inspection. From PSG IBIs, a transformation into bpm was made with 60 seconds divided by the IBI duration in seconds.

The internal clock times of the Fitbit and PSG systems were misaligned. This is a common problem in studies involving multiple measurement instruments, as they often do not share the same clock and thus require temporal alignment [36,37]. Hence, we estimated a time shift for each individual to ensure good time alignment. For this, linear interpolation was used to estimate values between two data points in either the PSG beat-per-beat data or the lower-resolution Fitbit data. We resampled both the Fitbit and PSG interpolated time series of a given night at 0.2-second intervals. The cross-correlation function was used to extract the lag with the maximal correlation between the time series.

Bland-Altman plots were constructed with the *blandr* package (version 0.5.1) [38] for all the sleep variables, two tailed *t* tests, and LoA defined as b (SD 1.96), where b denotes the bias and SD is the standard deviation of the bias. A variable is termed as *unbiased* if bias b is not significantly different from 0 from the corresponding *t* test. The differences in the Bland-Altman analyses were set to denote PSG *minus* Fitbit. Thus, a positive difference corresponds to an underestimation of Fitbit compared with PSG, and a negative difference corresponds to an overestimation. Concerning the repeated measurements of the 10%-trimmed HR average (HR_{10}) and 10%-trimmed HR variance average ($HRvar_{10}$) as measured at 1-minute intervals, a linear mixed effects regression with the *nlme* package (version 3.1-147) was estimated [39]. The dependent variable was set to be the PSG-Fitbit value, and just a single intercept without a slope was considered the independent variable. For the random effect, a random intercept per subject was included. Owing to the consecutive 1-minute HR_{10} and $HRvar_{10}$ measurements with potential time correlations, an autocorrelation structure of order

one was added. The *t* tests and LoAs were estimated using a mixed model.

Epoch-by-epoch (EBE) analyses were performed through the following statistical measures:

Sensitivity = TP/P **(1)**

Specificity = TN/N **(2)**

Accuracy = (TP + TN)/(P + N) **(3)**

Matthews correlation coefficient (MCC) = (TP * TN - FP * FN)/ **(4)**

Positive predictive value (PPV) = TP/(TP + FP) **(5)**

Negative predictive value (NPV) = TN/(TN + FN) **(6)**

In these equations, TP represents true positives (number of Fitbit epochs that share a given PSG stage), TN represents true negatives (the number of Fitbit epochs that are not in a given stage and where the according PSG epoch is also not labeled as that stage), FP represents false positives (number of Fitbit epochs that do not share a given PSG stage), and FN represents false negatives (number of Fitbit epochs that did detect a given stage, whereas PSG did not detect it). Sensitivity measures the proportion of epochs of a given PSG-derived sleep state that was correctly identified by Fitbit (eg, for REM sleep, it is the percentage of Fitbit *REM* sleep stages among all PSG REM sleep stages). Specificity, however, describes the percentage of Fitbit correctly identifying the nonoccurrence of a given sleep state. Accuracy is a combined measure of the true discoveries and true negatives of Fitbit divided by all positives and negatives in the PSG sample. MCC is more informative than the measure accuracy, because it considers all true positive, true negative, false positive, and false negative. This can be interpreted as a correlation coefficient, that is, the more positive, the better Fitbit predicts the PSG epochs, such that 0 would be random guessing, and negative values indicate disagreement. PPV, often called precision, describes the proportion of Fitbit correctly identifying a given stage among the number of times Fitbit assigned that stage, and NPV describes the equivalent for correctly identifying an epoch that is not a given stage. In our sample, the epoch length was defined as 20 seconds, but Fitbit's algorithm has an epoch length of 30 seconds. Thus, a direct EBE analysis was not possible. Therefore, we looked at all PSG-derived epochs and compared them with the dominating Fitbit stage (>50%) in the same interval. In cases where one PSG epoch contained two different Fitbit stages of equal length, we chose the first stage.

Results

Demographic Characteristics of the Study Sample

The demographics of the 59 individuals studied as well as their mean PSG- and Fitbit-derived sleep and HR measures are summarized in Tables 1 and 2. The mean values on the PSQI and PSS-10 indicated slightly impaired subjective sleep quality and a slightly elevated perceived stress level [27]; however, no diagnostic criteria for possible posttraumatic stress disorder have been met [28].

Table 1. Demographics of study sample (N=59).

	Value
Female, n (%)	33 (56)
Police, n (%)	15 (25)
Age (years), mean (SD)	33.5 (8.1)
BMI, mean (SD)	23.9 (2.9)
PSQI[a], mean (SD)	5.8 (2.7)
PCL-5[b], mean (SD)	6.2 (7.9)
PSS-10[c], mean (SD)	12.2 (4.9)
rMEQ[d], mean (SD)	14.4 (3.5)

[a]$N1_{so}$: sleep onset with non–rapid eye movement (NREM) sleep stages 1 criteria.

[b]TST: total sleep time.

[c]REM_d: rapid eye movement sleep duration.

[d]$light_d$: light sleep or NREM sleep stages 1+NREM sleep stages 2 duration, respectively.

[e]$deep_d$: deep sleep or NREM sleep stages 3 duration, respectively.

[f]WASO: wakefulness after sleep onset.

[g]REML: rapid eye movement sleep latency.

[h]REM: rapid eye movement.

[i]HR_{10}: 10%-trimmed heart rate average.

[j]bpm: beats per minute.

[k]N1: NREM sleep stages 1.

[l]N2: NREM sleep stages 2.

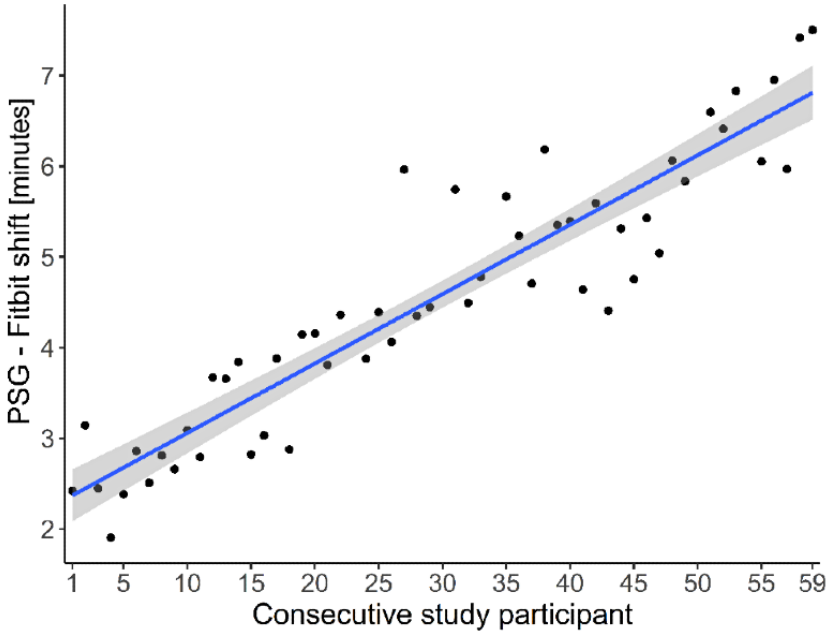
[m]N3: NREM sleep stages 3.

[n]$HRvar_{10}$: 10%-trimmed heart rate variability.

Time Alignment

Accurate temporal synchronization between the PSG system and the wearable Fitbit device often poses a methodological challenge in validation studies [4]. This was also the case in this study. When scrutinizing our data, we noticed that the time discrepancies between the PSG system's and the Fitbit app's clocks increased as the study progressed. In other words, the later the participant entered the study, the higher the time difference between PSG and Fitbit recordings. This relationship can be seen in Figure 1 as a linear association between the individual participant identifier number and the estimated time shift between the two measurement instruments.

Figure 1. The consecutive study participant numbers (higher numbers indicate chronologically later entry into the study) from the entire study sample are shown on the x-axis; the data-driven timeshift between polysomnography and Fitbit is shown on the y-axis. There was a significant linear relationship between the identifier and the shift (P<.001; adjusted R^2=0.85). Thus, the times drifted apart as the study went on, with a minimum time misalignment of 1.9 minutes and a maximum of 7.5 minutes. PSG: polysomnography.



To align the time series, we computed the cross-correlation function for each participant and corrected the time shift by the emergent maximum. Our time alignment efforts produced good correspondence in our data between the two instruments, as evident in the simultaneous occurrences of HR bursts in the two time series (Figure 2). Nevertheless, the variability and amplitude of the Fitbit curve were reduced compared with PSG because only between 4 and 12 measurements per minute were made available by Fitbit. The analysis of the entire Fitbit sample revealed that an average of 7.48 HR counts per minute was available (Figure 3). In contrast, PSG HR data were sampled at a frequency of 1/256 Hz.

Figure 2. Data on the validation night of the first participant in the study with identifying number 004 (left column) and the last participant in the study with number 104 (right column) are shown. Row A displays the cross-correlation function, which displays a large visible maximum at the orange vertical line representing the best alignment between the two devices (PSG and Fitbit). The dashed vertical reference line shows a lag of 0 minutes. Rows B-D share the same x-axis, which denotes hours after PSG-derived sleep onset with criteria. For each hour in the recording, a vertical dashed gray line was added. Row B shows the HR in bpm derived from PSG (red) and Fitbit (black) that were seen before any time alignment was applied, whereas row C presents the HR data after the data-driven shift from panel A was applied. The time-aligned time series visually shows good agreement after correcting for the time difference. Fitbit shows reduced variability in the signal but fairly good average correspondence. In panel D, the top row shows PSG-derived hypnograms for both participants, whereas in the bottom row, the Fitbit-derived hypnograms are displayed. All hypnograms have been time-corrected according to panel A. The overall sleep structure is captured reasonably well by Fitbit, but Fitbit detects more wake and REM episodes compared with PSG, and the distinction of light (N1+N2) and deep (N3) sleep often seems to be particularly challenging for Fitbit. bpm: beats per minute; HR: heart rate; PSG: polysomnography; REM: rapid eye movement; W: wake.

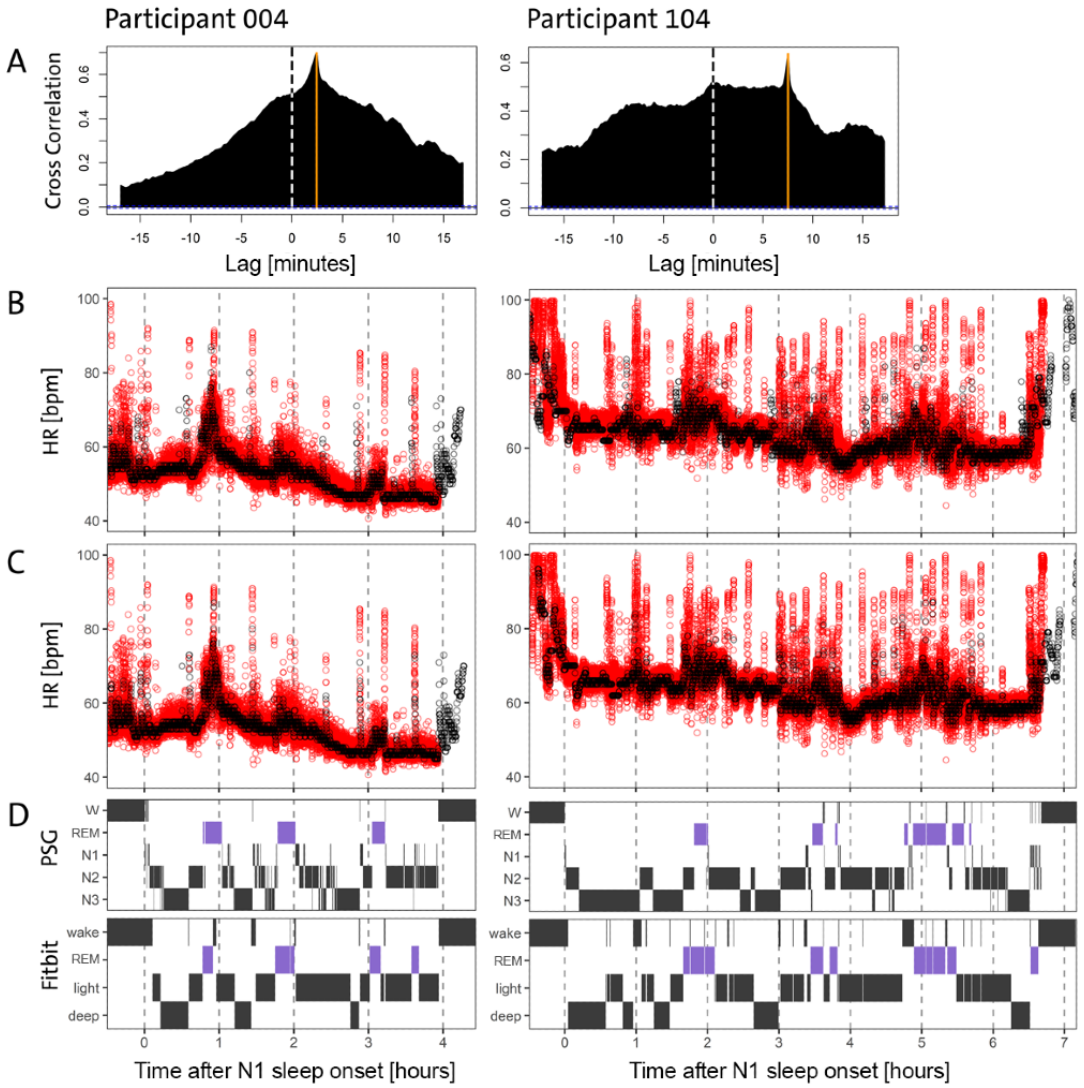


Figure 3. The available data of all nights (n=59) were extracted and counted for the number of heart rate measures contained. A total of roughly 28,320 minutes (corresponding to 59 study participants who, on average, spent 8×60 minutes asleep) were expected. In fact, 28,601 individual minutes of data were recorded; this figure displays the distribution of all heart rate measures, yielding an average of 7.48 measures per minute. Count data for >12 measures per minute and <4 measures per minute are not displayed because their occurrences were so small that they are not visible on the plot.

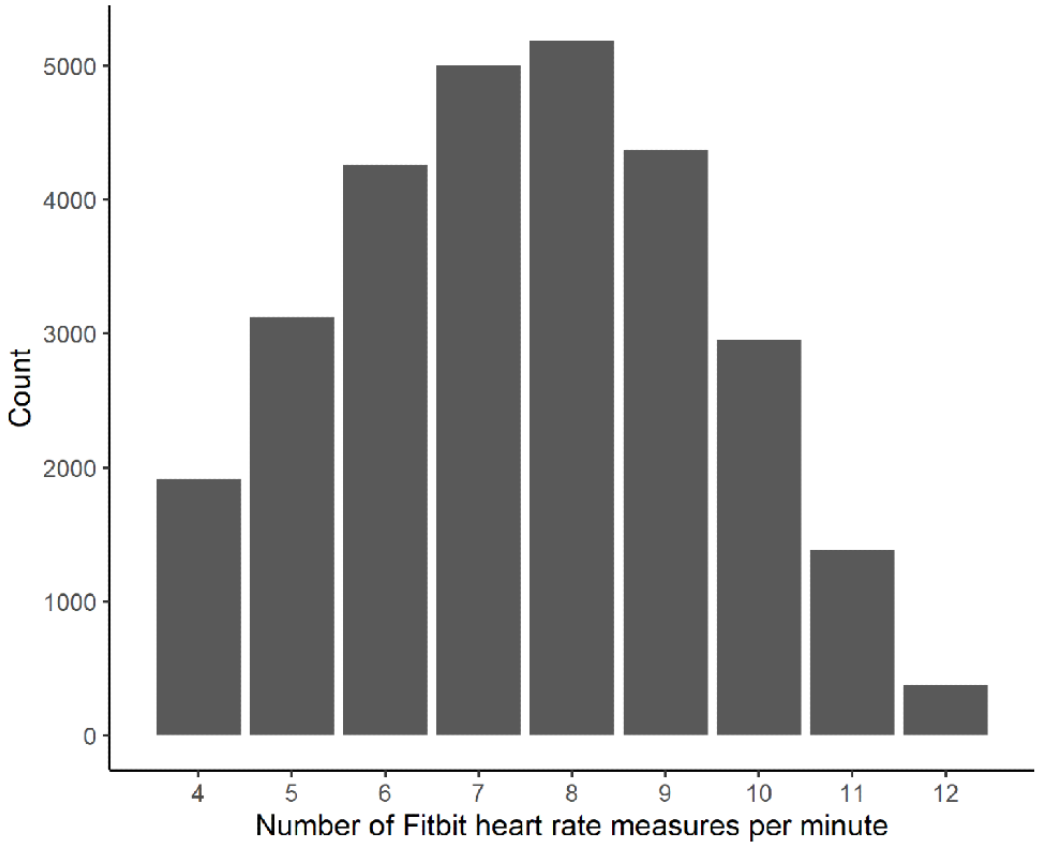
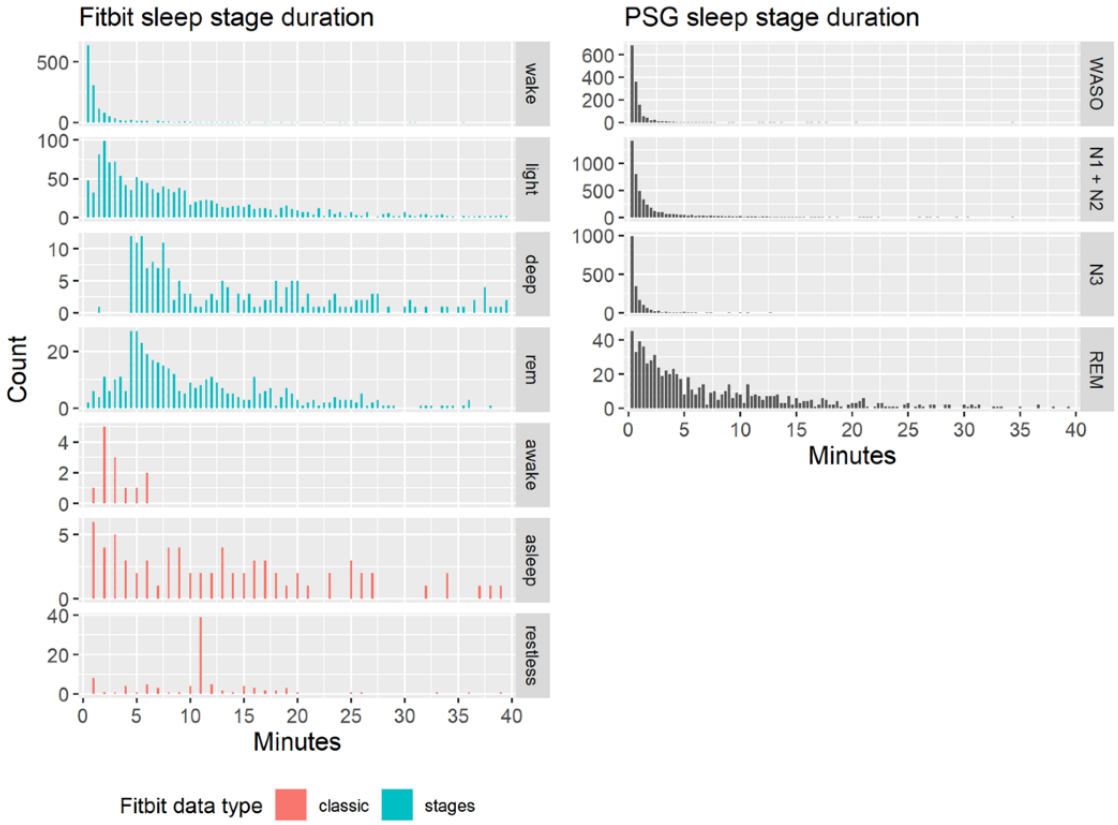


Distribution of Sleep Stage Durations

Next, we compared the distribution of sleep stage durations between the Fitbit and PSG data (Figure 4). Duration was defined as the duration of consecutive epochs with the same sleep stage until interrupted by any other stage, independent of its duration. We observed that Fitbit uses 30-second intervals to classify the *stages* data, whereas the *classic* data are presented with less time-resolved, 1-minute resolutions. With respect to wake episodes, the Fitbit data resembled the PSG distribution, with mostly short uninterrupted wake episodes and much rarer longer episodes. The *awake* category in the *classic* datatype had higher tails, possibly owing to having a resolution of 1 minute instead of 30 seconds, thus potentially missing certain stage changes that occur faster. On the basis of the inspection of the data distributions, we assumed that Fitbit's *light* sleep stage in the *stages* datatype might capture PSG-defined N1+N2 sleep stages, whereas *deep* sleep might capture PSG-defined N3 sleep. However, these assumptions need to be treated with caution because no information is provided by Fitbit. In general, *light* and *deep* sleep showed longer tails than the PSG-defined non–rapid eye movement (NREM) sleep stages, possibly owing to different temporal resolutions or slower changes in HR and HR variability compared with the more sudden changes in brain states. Furthermore, the *deep* sleep distribution showed a pronounced discontinuity at around 4 minutes and 30 seconds, which could also be observed in the Fitbit *REM* sleep stage duration. The distributions of *light*, *deep*, and *REM* sleep showed discrepancies to the PSG-derived durations, indicating that the algorithm does not fully reflect PSG-derived data and may miss brief stage changes and stage interruptions. Furthermore, the *restless* stage in the *classic* datatype is unknown. This stage displayed a peak at approximately 11 minutes, with an unknown origin.

Figure 4. The distribution of sleep stage durations for Fitbit (left panel) and PSG (right panel). Both were computed on the sample of the nights used for validation. Here, the plot has been cut off at 40 minutes for visual purposes; the tails continue to decrease as one would expect. The Fitbit sleep staging data types "classic" (red) and "stages" (blue) show large deviations compared with PSG sleep stages (black). Of note, deep and REM sleep show nonbiological discontinuity at around 4.5 minutes, and all Fitbit stages have larger tails. The stage "restless" has a peak at 11 minutes with unknown meaning. PSG: polysomnography. REM: rapid eye movement; WASO: wakefulness after sleep onset.



Bland-Altman Analyses of Sleep Variables

We split our validation into two analyses, one with the PSG-determined first occurrence of N1 sleep as the criterion for S_{on} (N1 S_{on} [$N1_{on}$]) and the other with the first occurrence of N2 sleep as the criterion for S_{on} (N2 S_{on} [$N2_{on}$]). This was done because it is unknown how Fitbit estimates S_{on}. In Figure 5, we plotted the variables computed with $N1_{on}$, and Table 3 provides the associated statistics. The $N2_{on}$ analyses revealed systematically higher biases. These data are presented in Figure S2 and Table S2 in Multimedia Appendix 1. S_{on}, defined as $N1_{on}$, was unbiased (–1.6 minutes; P=.73). S_{off}, TST, REM sleep duration (REM_d), the duration of Fitbit's *light* sleep duration ($light_d$) in minutes (as recorded by the Fitbit; interpreted as N1+N2), and the *deep* sleep duration ($deep_d$) in minutes (as recorded by the Fitbit) did not display significant bias. Nevertheless, $deep_d$ showed a trend toward a bias of 11.2 minutes with $N1_{on}$ (P=.08), likely pointing to a slight underestimation with Fitbit of N3 sleep. REML and WASO both exhibited a significant overestimation with Fitbit—REML was overestimated by 29.4 minutes and WASO by 37.1 minutes (P_{all}<.001). Although the marginal densities of the differences for S_{on}, S_{off}, and TST were quite narrow, indicating a good estimator in general, some occasional sleep episodes disagreed strongly between the Fitbit and PSG instruments, as reflected in the large LoA (Table 3). The marginal distributions of REM_d, $light_d$, and $deep_d$ showed higher variance, even if outliers were neglected. This observation may indicate that the estimation of stages of sleep is challenging for Fitbit's algorithm and a source of variability, although being unbiased. The data on the standard Fitbit variables without the bordering wake epoch adjustment revealed very similar results, however, with slightly larger biases for TST and WASO, as shown in Figure S1 and Table S1 in Multimedia Appendix 1.

Figure 5. Bland-Altman plots for various sleep variables are shown with sleep onset defined as the first occurrence of N1. The dashed lines denote lower limits of agreement, bias, and upper limits of agreement. The dotted lines are the respective 95% CI of limits of agreement. On the top and right of each panel, the marginal densities are plotted. The x-axis displays the PSG variables, and the y-axis denotes the differences between the two devices (PSG-Fitbit). N1-derived sleep onset is unbiased. Sleep offset, total sleep time, light sleep or N1+N2 sleep duration, deep sleep or N3 sleep duration, and REMd do not have significant bias. WASO and REML display a significant deviation of the difference between the devices from 0. $deep_d$: deep sleep duration; $light_d$: light sleep duration; PSG: polysomnography; REM_d: rapid eye movement sleep duration; REML: rapid eye movement sleep latency; S_{off}: sleep offset; S_{on}: sleep onset; TST: total sleep time; WASO: wake after sleep onset.

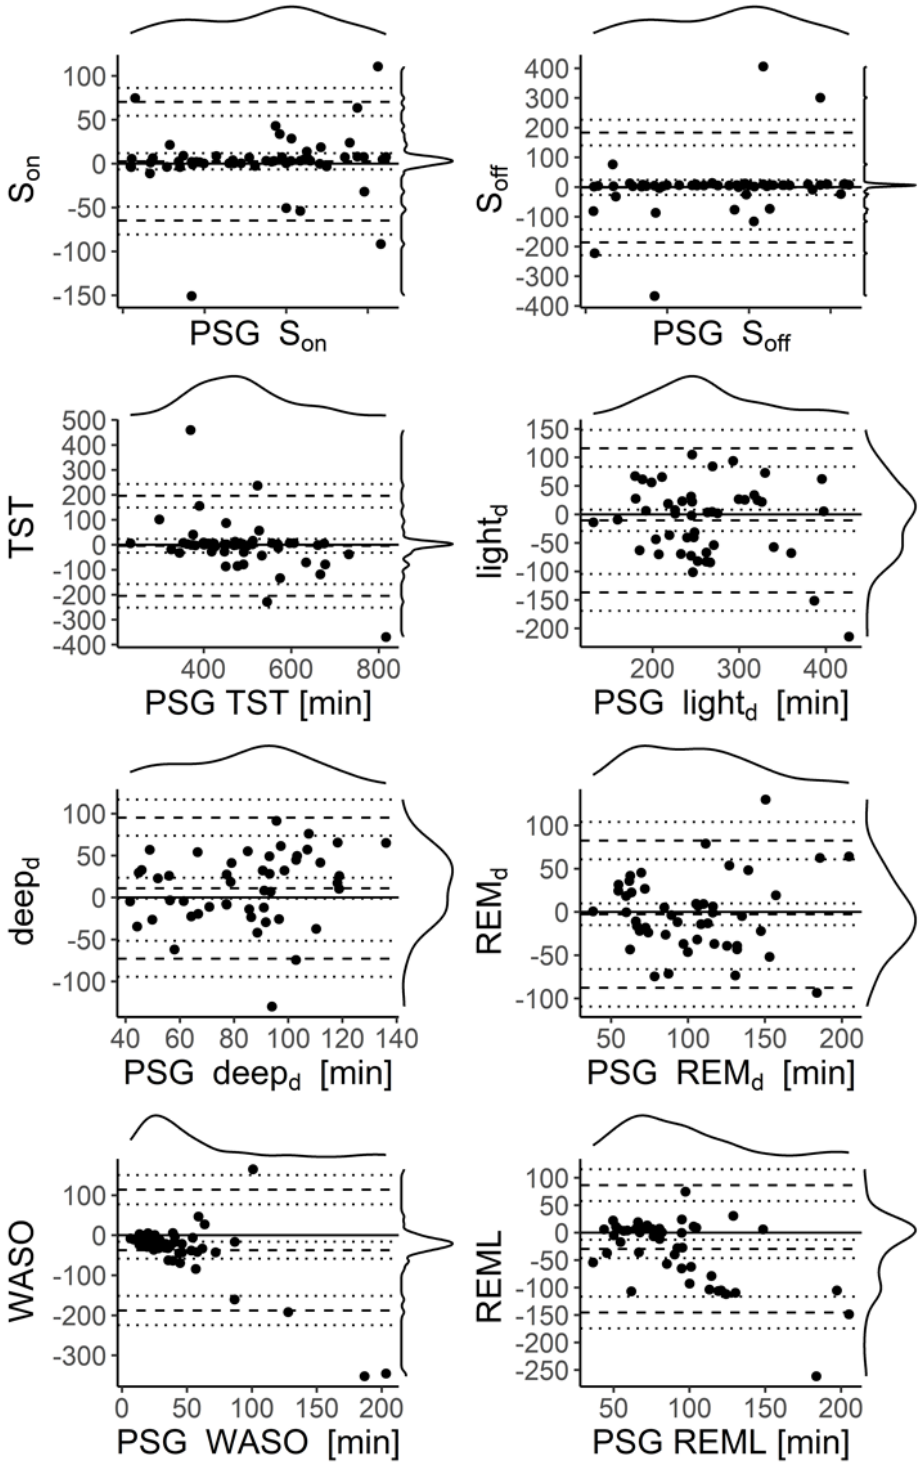


Table 3. Bland-Altman statistics[a].

Variable	PSG[b]-Fitbit	Lower LoA[c]	Upper LoA	*P* value
S_{on}[d] (minutes)	–1.6	–68.8	65.6	.73
S_{off}[e] (minutes)	–5.6	–189.3	178.2	.66
TST[f] (minutes)	–4.0	–204.3	196.3	.77
REM_d[g] (minutes)	–2.7	–87.8	82.4	.67
$light_d$[h] (minutes)	–10.4	–136.8	116.0	.27
$deep_d$[i] (minutes)	11.2	–72.9	95.2	.08
WASO[j] (minutes)	–37.1	188.1	113.8	.001
REML[k] (minutes)	–29.4	–145.4	86.6	.001
HR_{10}[l] (bpm[m])				
Overall	0.9	–6.9	8.6	<.001
WASO	1.9	–5.4	9.2	.03
N1[n]	1.2	–8.9	11.3	.14
N2[o]	0.6	–4.7	6.0	.001
N3[p]	0.6	–6.4	7.6	.008
REM[q]	0.7	–4.7	6.0	<.001

[a]Statistics accompanying the Bland-Altman plots (Figure 5). Sleep onset and rapid eye movement (REM) sleep latency were calculated using the non–rapid eye movement (NREM) sleep stages 1 sleep onset criteria. The average 10%-trimmed heart rate and 10%-trimmed heart rate variance values in various sleep states are presented in the columns below the sleep variables. The average difference between polysomnography and Fitbit measures bias can be found in the first column. The lower and upper limits of agreement describe 1.96 times the SD around the bias and can be found in the subsequent columns. In the last column, the *P* values for the paired *t* test are reported; we tested whether the bias was significantly different from 0.

[b]PSG: polysomnography.

[c]LoA: limit of agreement.

[g]REM_d: REM sleep duration.

[h]$light_d$: light sleep duration.

[i]$deep_d$: deep sleep duration.

[j]WASO: wakefulness after sleep onset.

[k]REML: REM sleep latency.

[l]HR_{10}: 10%-trimmed heart rate average.

[m]bpm: beats per minute.

[n]N1: NREM stage 1 sleep.

[o]N2: NREM stage 2 sleep.

[p]N3: NREM stage 3 sleep.

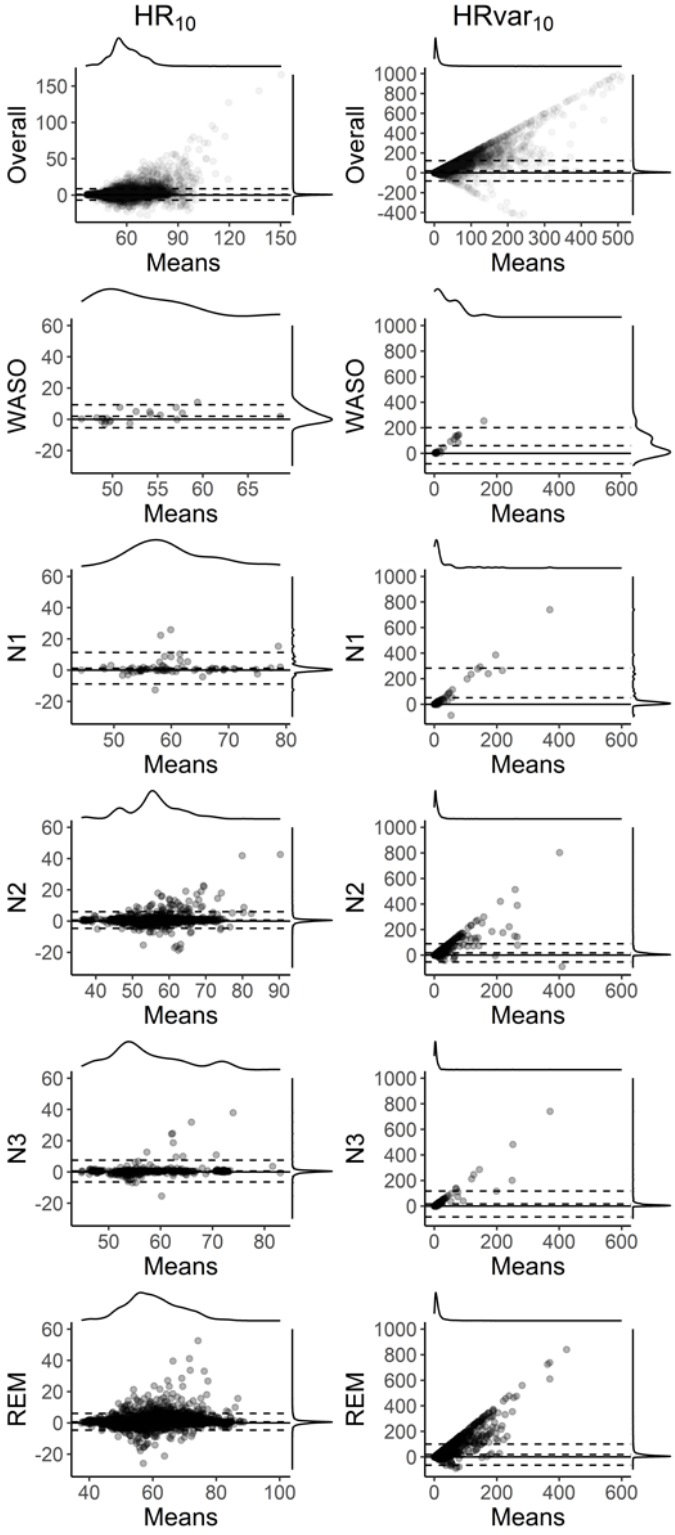
[q]REM: rapid eye movement.

Bland-Altman Analyses of HR Variables

The Bland-Altman plots for the HR variables are shown in Figure 6. When computing the interval between 30 minutes before $N1_{on}$ until S_{off} without considering the different wakefulness and sleep states, HR_{10} and $HRvar_{10}$ measures both appeared biased. More specifically, Fitbit underestimated HR_{10} overall by 0.9 bpm and displayed LoA of –6.9 and 8.6 bpm (Table 3). This underestimation was rather small, with a relatively narrow marginal distribution of the differences. When focusing on 1-minute HR_{10} values restricted to the time interval between S_{on} and S_{off} and dividing among the PSG-derived states N1, N2, N3, REM sleep, and wake, HR_{10} displayed a higher bias in the wake (1.9 bpm; *P*=.03) and N1 (1.2 bpm; *P*=.14) stages compared with the sleep stages N2 (0.6 bpm; *P*=.001), N3 (0.6 bpm; *P*=.008), and REM sleep (0.7 bpm; *P*<.001).

When analyzing overall HR variance, Fitbit strongly underestimated $HRvar_{10}$ with a bias of 20.3 bpm (P<.001), which was associated with higher LoA –82.1 and 122.7. When $HRvar_{10}$ was divided among the different sleep stages, we observed behavior similar to HR_{10}, such that $HRvar_{10}$ wake and N1 had a higher bias (60.2 and 51.1 bpm) than N2, N3, and REM sleep (17.6, 16.3, and 18.5 bpm), all with low P values and considerably large LoA.

Figure 6. Bland-Altman plots for heart rate–derived variables. The dashed lines denote lower limits of agreement, bias, and upper limits of agreement for a mixed model dealing with the repeated measures. On the top and right of each panel are the marginal densities. The x-axis displays the means of both devices (ie, [polysomnography + Fitbit]/2), and the y-axis denotes the differences between the two devices (polysomnography-Fitbit). Overall average 10%-trimmed heart rate and 10%-trimmed heart rate variance values are calculated for 1-minute intervals between 30 minutes before sleep onset with N1 criteria and 30 minutes after sleep offset. All other variables are calculated between sleep onset and sleep offset, only extracting the designated variable, in 1-minute intervals. HR_{10}: 10%-trimmed heart rate average; $HRvar_{10}$: 10%-trimmed heart rate variance average; REM: rapid eye movement; WASO: wake after sleep onset.



EBE Analysis

The EBE analysis results are displayed in Table 4. The EBE comparison between Fitbit and PSG revealed that Fitbit displayed better specificity (WASO: 0.898; light sleep as N1+N2: 0.574; deep sleep as N3: 0.92; REM sleep: 0.889) than sensitivity (WASO: 0.428; light sleep as N1+N2: 0.534; deep sleep as N3: 0.279; REM sleep: 0.548). The sensitivity for REM

sleep was worse during the initial 120 minutes of sleep (0.432) when compared with REM episodes beginning 120 minutes or more after S_{on} (0.57). In contrast, for specificity, this relationship was reversed (REM<120 minutes: 0.963; REM>120 minutes: 0.864). Accuracy was best for WASO (0.898) and REM sleep (0.880) and worse for deep sleep N3 (0.776) and light sleep N1+N2 (0.553). A similar relationship was reflected in the MCC, ranging from weak to moderate correlation (REM sleep: 0.339; WASO: 0.329; deep sleep as N3: 0.25; light sleep as N1+N2: 0.108). The MCC measure is preferable to accuracy as it only leads to higher scores if the prediction is simultaneously accurate in all confusion matrix categories (true positive, false positive, true negative, and false negative) [40]. PPV, the probability that an episode with a given Fitbit stage will also have the same PSG stage, was generally lower (WASO: 0.438; light sleep as N1+N2: 0.592; deep sleep as N3: 0.501; REM sleep 0.306) compared with NPV, the probability that an episode that does not have a certain Fitbit stage will also not have that PSG stage (WASO: 0.894; light sleep as N1+N2: 0.516; deep sleep as N3: 0.815; REM sleep: 0.956).

Table 4. Epoch-by-epoch analysis[a].

State	Sensitivity	Specificity	Accuracy	MCC[b]	PPV[c]	NPV[d]
WASO[e]	0.428	0.898	0.824	0.329	0.438	0.894
Light sleep	0.534	0.574	0.553	0.108	0.592	0.516
Deep sleep	0.279	0.920	0.776	0.250	0.501	0.815
REM[f] sleep	0.548	0.889	0.861	0.339	0.306	0.956
REM sleep <120 minute	0.432	0.963	0.934	0.383	0.403	0.967
REM sleep >120 minute	0.570	0.864	0.837	0.329	0.296	0.953

[a]Epoch-by-epoch comparison of Fitbit and polysomnography stages.Each stage—wakefulness after sleep onset, light sleep (non–rapid eye movement [REM] stage 1 [N1] sleep+NREM stage 2 sleep), deep sleep (NREM stage 3 sleep), and REM sleep—was analyzed. REM sleep was divided into analyses with REM sleep episodes occurring during the first 120 minutes after sleep onset with N1 sleep criteria (N1 sleep onset) and REM sleep episodes occurring later than 120 minutes after N1 sleep onset. Various performance measures were used, including sensitivity, specificity, accuracy, the Matthews correlation coefficient, the positive predictive value, and the negative predictive value. More information on these measures can be found in the *Methods* section. Fitbit showed mostly good specificity but poor sensitivity. The accuracy was relatively high except for the light sleep stage. The Matthews correlation coefficient displayed a moderately positive relationship, with light and deep sleep being considerably less good. The negative predictive value was usually higher than the positive predictive value.

[b]MCC: Matthews correlation coefficient.

[c]PPV: positive predictive value.

[d]NPV: negative predictive value.

[e]WASO: wakefulness after sleep onset.

[f]REM: rapid eye movement.

Discussion

Principal Findings

We evaluated the performance of the multisensor wearable Fitbit Charge 2 against PSG of the sleep macrostructure and HR in a sample of first responder shift workers under naturalistic conditions. We observed that S_{on}, S_{off}, TST, REM_d, N1+N2 sleep duration, and N3 sleep duration showed unbiased estimates but nonnegligible LoA. Fitbit overestimated REML by –29.4 minutes, possibly because the proprietary algorithm failed to detect very short first REM sleep episodes. This hypothesis is supported by the right shift in the maximum duration of stages and larger tails (Figure 4) and a cluster of REML data points occurring at approximately –100 minutes (Figure 5), indicating that Fitbit cannot capture short-lasting stage durations well. Not only REML but also other sleep variables often exhibited a wide LoA. In addition, despite performing a careful, data-driven time alignment between the Fitbit and PSG time series, which differed from 1.9 minutes to 7.5 minutes depending on the participants' entrance into the study, Fitbit overestimated WASO by as much as 37.1 minutes. We concluded that the unbiased sleep variables allow average estimations of important sleep quality characteristics in ecological conditions. However, the wide LoA in most variables and the large biases in REML and WASO limited the meaningfulness of quantifying individual sleep episodes. These findings highlight the considerable challenges still present when relying on consumer-grade technology to address clinical and research questions.

One of our most striking and novel findings is that the distribution of all sleep episode durations differs between the Fitbit Charge 2 and PSG. Fitbit's sleep staging algorithm probably treats *REM* and *deep* sleep states of less than 4.5 minutes differently than sleep stages exceeding this duration. This introduces a nonbiological discontinuity, indicating the potential limitations of the tracker's staging algorithm. Furthermore, it is not clear what PSG measurement corresponds to the Fitbit stage *restless*, which renders meaningful comparisons impossible. Our findings in the sleep episode duration distribution are consistent with recent work [41], which also revealed an underestimation of sleep stage transition dynamics.

The S_{on} measures from Fitbit were unbiased concerning the $N1_{on}$ criteria, whereas there was a higher but nonsignificant underestimation for $N2_{on}$. Thus, it is likely that Fitbit's definition

of S_{on} time roughly corresponds to PSG-derived $N1_{on}$. S_{on} criteria should be reported in future validation studies because whatever criterion one selects (eg, $N1_{on}$, $N2_{on,}$ or alternatively any stage of sleep) will impact many sleep variables, such as TST, REML, and WASO, whose operational definition and calculation depend upon the criterion of S_{on}. This may be one of the reasons for discrepancies reported in the validation literature. A peculiarity of the staging information provided by Fitbit is that the first stage after the S_{on} time and the last stage before S_{off} time is sometimes staged as *awake* or *wake*. We manually adjusted the S_{on} and S_{off} times to be delineated by the first and last occurring stages of sleep rather than including stages of wake at the border of sleep. In a large Fitbit data set collected in 89 individuals for 1 month capturing roughly 3000 sleep episodes [42], 69.8% of all sleep episodes in the first stage after S_{on} and in 50% of all cases, the last stage before S_{off} was not coded as a sleep stage. In other words, an appreciable proportion of Fitbit sleep episodes are *bookended* by a stage of wake. This is an inconspicuous but important caveat. Our adjustment of these data could be a reason why we found $N1_{on}$, S_{off}, and TST to be unbiased when comparing Fitbit data with PSG data, whereas Liang et al [16], de Zambotti et al [43], and Morena-Pino et al [23] found TST biases in different directions. More specifically, a previous study [43] found unbiasedness; another reported an overestimation of WASO [16], whereas Moreno-Pino [23] found an underestimation of WASO when validating Fitbit Charge 2 against PSG. The study by Liang et al [16] with a WASO bias of 24.5 minutes is closest to our results of 37.1 minutes.

Overall, EBE analyses revealed better specificity than sensitivity for all sleep states. This might have been expected. For example, there are much fewer *deep* sleep epochs than epochs labeled as any other sleep stage, which is why a single misclassification carries more weight for sensitivity than specificity. We found *light* sleep to have 0.55 accuracy, whereas de Zambotti et al [43] found an accuracy of 0.81. However, the same study found an accuracy of 0.49 for *deep* sleep, whereas we found a higher respective value of 0.78. Furthermore, REM sleep showed an accuracy of 0.86, similar to that of 0.74 found by de Zambotti et al [43]. A recent systematic review (Haghayegh [14] on various Fitbit devices including Alta, Alta HR, Charge 2, Charge HR, Classic, Flex, One, Surge, Ultra and Versa models) found accuracy values in the range of 0.69-0.81 for *light* sleep, 0.36-0.89 for *deep* sleep, and 0.62-0.89 for REM sleep. Thus, our results for *light* sleep are slightly lower than the range suggested previously, whereas, for *deep* sleep and REM sleep, the accuracy in our study was in the upper range reported. The MCC value, which can be interpreted as a usual correlation coefficient, ranged from 0.11 in *light* sleep to 0.34 in REM sleep. These numbers indicate low to medium strength of correlation, pointing toward room for improvement in the estimation of sleep stages by Fitbit.

The information Fitbit provides on the sleep sensitivity setting, with options *sensitive* and *normal*, may have an influence on the amount of stages that are scored as wake [44]. We set the setting to *sensitive* when data were collected, which might have led to an overestimation of WASO, as seen in Figure 2. However, Fitbit states that this setting has no impact on devices utilizing HR to track sleep [45]. Consistent with our results, REM_d was also found to be unbiased by [3]. In addition, we found $light_d$ and $deep_d$ to be unbiased. As the algorithm is not open source, we do not know with certainty whether our study was running on an updated version of the algorithm compared with other validation studies. This limitation makes it difficult to compare the validation study outcomes of consumer fitness trackers in general [4] and could contribute to the discrepancies with the previous literature. Another reason might stem from the different populations sampled or recording conditions. For example, the algorithm might be better suited to assess sleep in healthy individuals than in patients or shift workers or may perform better in a sleep laboratory than in a naturalistic environment. The discrepancies among studies underscore the necessity to define standardized procedures to test consumer sleep technology to benefit from their potential to collect large-scale sleep data in ecological conditions [21,22,26].

Regarding the HR data, Fitbit slightly underestimated overall HR_{10} by 0.9 bpm with a limited capability to capture sudden HR changes. This underestimation was smaller in N2, N3, and REM sleep stages (0.6, 0.6, and 0.7 bpm, respectively) compared with N1 sleep and wake (1.2 and 1.9 bpm), thus indicating a sleep stage–specific bias. The bias was low and probably not biologically relevant. The low *P* values of biases in differences in the HR measures between the devices arise from the repeated measure design as a vast number of 1-minute values during the whole night for each subject was calculated, thereby increasing the statistical power to detect small biases as significant. The evident HR bias of 0.9 bpm is strikingly similar to the HR bias of 0.88 bpm found in de Zambotti et al [25] in the related Fitbit Charge HR device. As mentioned in the report by Haghayegh et al [13], Fitbit Charge HR and Fitbit Charge 2 share the same hardware and software, thus making a comparison feasible, software updates notwithstanding. We found a stage-dependent bias with lower underestimation in deeper sleep stages sharing lower HR on average and a larger underestimation in wake state and a more transitory sleep stage N1, which share higher HR values on average, a finding compatible with the HR-dependent bias reported by Haghayegh et al [13]. For an HR during sleep of <50 bpm, these authors found an overestimation of 0.51 bpm, and for an HR during sleep >80 bpm, an underestimation of 0.63 bpm. These values are comparable with our findings. On the other hand, Benedetto et al [24] found an HR underestimation of 5.9 bpm during wake state. We also found a larger underestimation during wake episodes of 1.2 bpm, but not as high as 5.9 bpm. In the study by Benedetto et al [24], no time alignment between the two instruments was reported. The method of capturing HR via video recording of live values displayed on the Fitbit app was innovative but could be a source of error. Hence, the results could potentially be influenced by a timing misalignment between the instruments and data collection methods.

Fitbit HR variance was reduced owing to the inaccessibility of raw data and showed higher LoA than the LoA for HR. The differences between the assessments are not surprising, as Fitbit only provided 7.4 measurements per minute on average (Figure 3). This is probably owing to their algorithm providing some

averaged values in preferably 5 seconds, 10 seconds, and 15 seconds measurement intervals (but other interval lengths, eg, 2-second or 7-second intervals, can also be found in the data). For comparison, a PSG-derived HR value can be computed for each IBI. Thus, receiving preprocessed data from Fitbit instead of raw data naturally leads to a considerably higher variance in PSG recordings. Moreover, all HR values from Fitbit are integers, whereas the values from the PSG are real values. This difference in the nature of the values (rounded to integers) additionally leads to slightly different behaviors of the HR_{10} and $HRvar_{10}$ measures. The Fitbit photoplethysmography would be able to capture brief bursts in HR, as evidenced by a study on exercising awake individuals [24]. Data with approximately 1-second time resolutions are only made available in the device's *exercise* mode, which prevents sleep tracking. Nevertheless, Fitbit may still be able to detect variability changes for longer periods during sleep with a reasonable degree of accuracy even without providing users with high resolution or raw HR data (as seen in Table 1, where the ordering of the variance per sleep stage remains nearly intact between Fitbit and PSG).

Limitations

The missing information regarding an objective marker of *lights out* is a limitation of our study, which prevented us from estimating sleep latency. In addition, the number of measurements per minute provided by Fitbit varied, potentially owing to variable signal quality and other internal decision-making processes in Fitbit's proprietary data preprocessing algorithms. Updates to software or firmware could have occurred without notice, harboring a great potential to confound research or clinical undertaking, particularly in longitudinal scenarios. Individual sleep episodes can vary appreciably even within an individual, and caution should be exercised when interpreting results from a Fitbit device. Not being able to blind participants to their own sleep data after collection could influence their behavior in subsequent sleep episodes. This concern is particularly pressing when clinical or otherwise vulnerable populations are involved, and device output is interpreted, which may impact treatment options or health outcomes. For this reason, it is crucial that these devices be validated in more clinically diverse populations.

Conclusions

In a study conducted at home in a relatively large sample validating Fitbit Charge 2 against PSG, compared with most previous validation studies (n=15 [24]; n=25 [16]; n=35 [43]; n=35 [14]; and n=65 [23]), we found unbiased mean estimates of various sleep and HR variables, although the data generally exhibited wide LoA. In addition, we noticed problems in capturing the first REM sleep episodes. The naturalistic design of the study in a heterogeneous sample in terms of age and sex and regularly performing shift work increased the external validity and benefited our understanding of the Fitbit Charge 2's performance in a minimally controlled home environment. Nevertheless, for the reliable use of consumer-grade sleep technology for clinical and research purposes, access to raw data, the use of open-source data analysis algorithms, more control of the data flow to blind users, and compliance with all regulatory aspects are indispensable. Furthermore, future validation studies should also be conducted in populations with sleep disorders, such as narcolepsy, who often present with S_{on} REM sleep episodes that appear particularly difficult to detect. Such studies can help identify the factors that determine the accuracy of Fitbit's sleep and HR measures.

Acknowledgments

The authors thank all participants and staff members of Schutz & Rettung Zürich, Rettungsdienst Winterthur and Stadtpolizei Winterthur. The authors also thank Maria Dimitriu, Giulia Haller, Zilla Huber, Zora Kaiser, Nora Krucker, Josefine Meier, Gioia Peterhans, Daniel Prossnitz, Sinja Rosemann-Niedrig, Nora Werner, Rafael Wespi, Laura van Bommel, and Chantal Wey for assisting with data collection and data processing. This study was supported by the Clinical Research Priority Program Sleep and Health of the University of Zurich, the University of Zurich, and the Swiss National Science Foundation (grant 320030_163439 to HPL).

Authors' Contributions

HPL, BK, YA, and IC conceived the study. YA and IC contributed to implementation and data acquisition. BS, HPL, IC, PA, and WK contributed to data acquisition, analysis, and interpretation. BS, IC, and HPL wrote the manuscript. All authors contributed to manuscript revisions. All authors approved the submitted version.

Abstract

Background: Mutual support groups are an important source of long-term help for people impacted by addictive behaviors. Routine outcome monitoring (ROM) and feedback are yet to be implemented in these settings. SMART Recovery mutual support groups focus on self-empowerment and use evidence-based techniques (eg, motivational and behavioral strategies). Trained facilitators lead all SMART Recovery groups, providing an opportunity to implement ROM.

Objective: The aim of this stage 1 pilot study is to explore the feasibility, acceptability, and preliminary outcomes of a novel, purpose-built mobile health ROM and feedback app (*SMART Track*) in mutual support groups coordinated by SMART Recovery Australia (SRAU) over 8 weeks.

Methods: *SMART Track* was developed during phase 1 of this study using participatory design methods and an iterative development process. During phase 2, 72 SRAU group participants were recruited to a nonrandomized, prospective, single-arm trial of the *SMART Track* app. Four modes of data collection were used: ROM data directly entered by participants into the app; app data analytics captured by Amplitude Analytics (number of visits, number of unique users, visit duration, time of visit, and

user retention); baseline, 2-, and 8-week follow-up assessments conducted through telephone; and qualitative telephone interviews with a convenience sample of study participants (20/72, 28%) and facilitators (n=8).

Results: Of the 72 study participants, 68 (94%) created a *SMART Track* account, 64 (88%) used *SMART Track* at least once, and 42 (58%) used the app for more than 5 weeks. During week 1, 83% (60/72) of participants entered ROM data for one or more outcomes, decreasing to 31% (22/72) by the end of 8 weeks. The two main screens designed to provide personal feedback data (*Urges* screen and *Overall Progress* screen) were the most frequently visited sections of the app. Qualitative feedback from participants and facilitators supported the acceptability of *SMART Track* and the need for improved integration into the SRAU groups. Participants reported significant reductions between the baseline and 8- week scores on the Severity of Dependence Scale (mean difference 1.93, SD 3.02; 95% CI 1.12-2.73) and the Kessler Psychological Distress Scale-10 (mean difference 3.96, SD 8.31; 95% CI 1.75-6.17), but no change on the Substance Use Recovery Evaluator (mean difference 0.11, SD 7.97; 95% CI –2.02 to 2.24) was reported.

Conclusions: Findings support the feasibility, acceptability, and utility of *SMART Track*. Given that sustained engagement with mobile health apps is notoriously difficult to achieve, our findings are promising. *SMART Track* offers a potential solution for ROM and personal feedback, particularly for people with substance use disorders who attend mutual support groups.

Introduction

Background

Routine outcome monitoring (ROM) is central to evidence-based health care for a range of chronic conditions [1], including addictive behaviors [2,3]. ROM is central to understanding, evaluating, and improving service delivery [4-6]. A range of clinical benefits have been identified [7-9], particularly for those people identified as *not on track* early in the course of treatment [10,11]. Emerging evidence suggests that providing clients with tailored feedback may be central to demonstrated improvements in client outcomes [12].

To date, ROM and feedback have been implemented in a range of mental health [13] and addiction [14,15] treatment settings but not in mutual support groups. Mutual support groups offer an important source of fee-free, accessible support to people experiencing a range of addictive behaviors. Mutual support is particularly important for people experiencing addictive behaviors, given the often long-term and nonlinear process of recovery [16]. Mutual support groups may be attended before, during, after, or in lieu of engagement with formal treatment services, providing the potential for continuity across the recovery process. Although accumulating evidence highlights the importance and benefits of participating in mutual support [17-21], a major limitation is the lack of systematically collected data evaluating the outcomes. Unlike other clinically endorsed [2,3] models of mutual support for addictive behaviors (eg, 12-step approaches), SMART Recovery groups use a trained facilitator. This provides a unique opportunity to work with group facilitators to embed ROM and personal feedback as a standard component of the groups.

Integrating ROM and tailored feedback into routine service provision is not without challenges [22,23]. Common barriers include the *time burden* associated with completing, scoring, interpreting, or discussing outcome assessments [22,24], as well as skepticism regarding the perceived relevance of the outcomes assessed and feedback generated [25,26]. Additional limitations include the traditionally clinician-centric nature of ROM (see studies by Carlier and van Eden [7] and Thompson et al [13] for a discussion and studies by Lambert et al [8], Goodman et al [12], and Burgess et al [27] for common instruments) and accompanying feedback [28,29]. Improved acknowledgment of the client perspective during assessment [30] and greater client involvement in the feedback process [31] are both important clinical and research priorities.

The idea of using technology to track progress within health care settings is not new, but current approaches are limited [32]. Unlike other health information technology approaches (eg, web-based platforms), mobile health (mHealth [33]) apps offer a quick, easy, interactive, and engaging platform for tracking and accessing information about health and health-related behaviors [34]. A key benefit of mHealth apps is their ability to provide timely, individualized feedback [35]. Given the ubiquity of smartphone ownership [36,37], smartphone apps can engage individuals in real time and in their natural environment and by offering moment-to-moment support as needed [38]. Indeed, a recent systematic review of digital support services highlighted that their *on-demand* nature is a key benefit [39].

Although not specifically designed for the purposes of ROM and feedback, mHealth apps with the capability to track a variety of health behaviors, conditions, or outcomes [40-45], including alcohol consumption, substance use, and other addictive behaviors [39,44-52], have been developed. However, a key limitation is the ever-increasing gap between the availability of mHealth apps and their scientific validation [40,52-55].

Moreover, the level of end-user involvement throughout the development process is often unclear. This is important because inadequate consideration of the needs and preferences of the end user has been implicated in mHealth attrition [56-58]. Accordingly, we worked alongside end users to develop a purpose-built mHealth app for ROM and feedback in SMART Recovery Australia (SRAU) mutual support groups (*SMART Track*), which was then evaluated in this study.

Objective

The aim of this stage 1 nonrandomized, single-arm pilot study is to explore the feasibility, acceptability, and preliminary outcomes of a novel mHealth ROM and feedback app (*SMART Track*) in mutual support groups coordinated by SRAU.

Methods

Overview

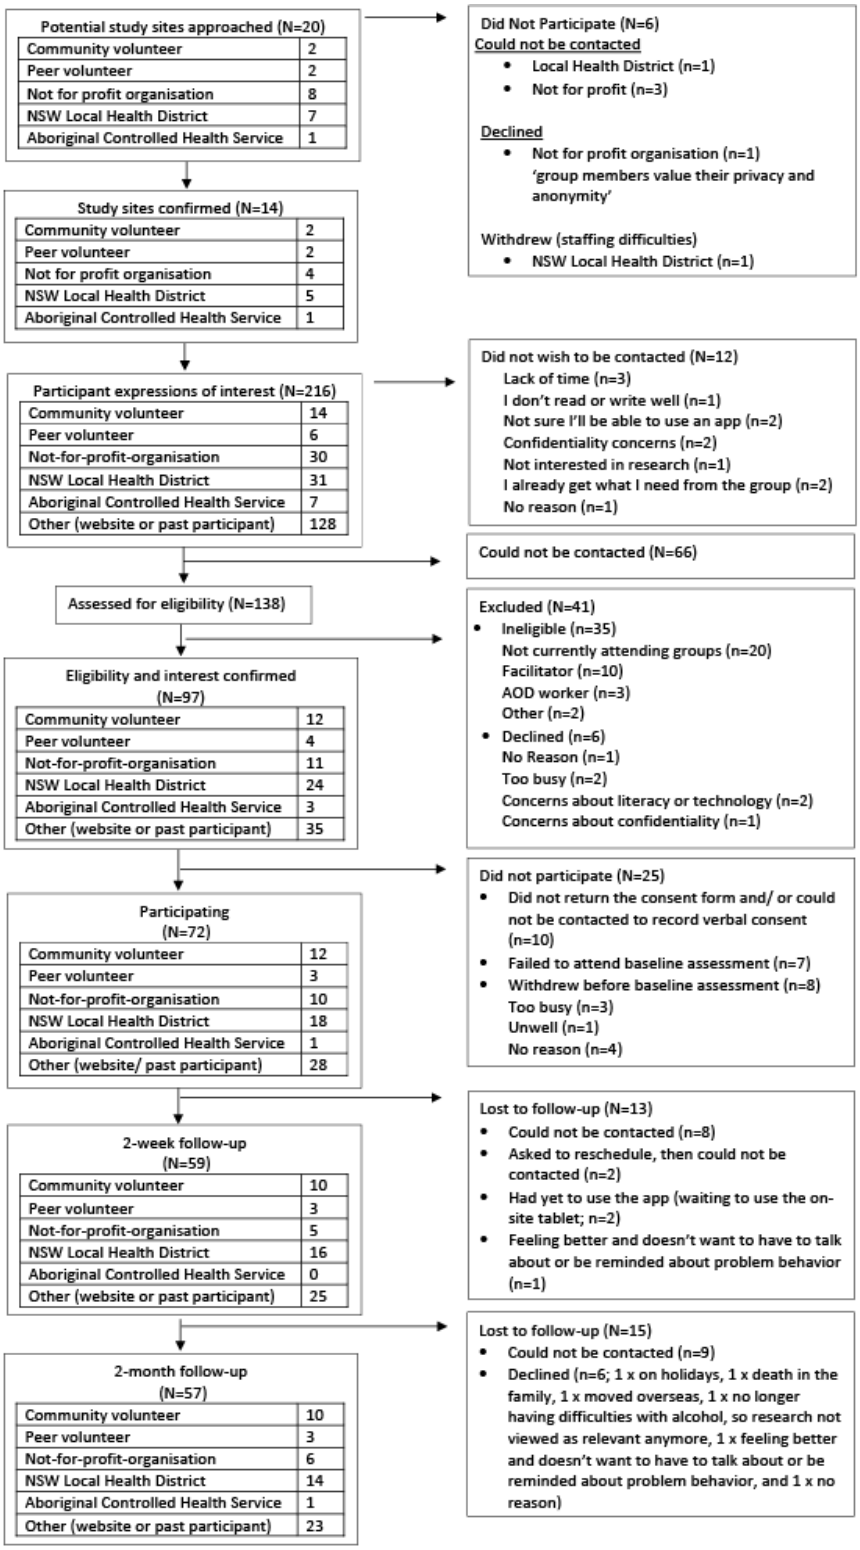
Approval was granted by the University of Wollongong and Illawarra Shoalhaven Local Health District Health and Medical Human Research Ethics Committee (2018/099; HREC/18/WGONG/34). The study was registered with the Australian New Zealand Clinical Trials Registry (ACTRN12619000686101), and a protocol was published [59]. The reporting of this study follows the CONSORT (Consolidated Standards of Reporting Trials)-EHEALTH checklist [60].

Setting

Participants were recruited from the SMART Recovery groups registered with SRAU. Detailed accounts of SMART Recovery groups have been published [61]. Briefly, SMART Recovery groups originated in the United States and are now available across 23 countries. They offer support for people experiencing a range of addictive behaviors, including substance- and non–substance-related behaviors. SMART Recovery groups focus on self-empowerment and use evidence-based techniques (eg, cognitive behavioral therapy and motivational interviewing) [62]. These groups are held in a variety of community, inpatient, outpatient, residential rehabilitation, and clinical health settings. Online support groups are also available.

We invited 20 sites in New South Wales, Australia, to participate in this study, and 14 (70%) agreed (Figure 1). To enhance generalizability, the invited sites were selected to reflect a range of geographical locations and service providers. We sought to recruit 100 study participants. A sample of this size was selected to allow estimation of the recruitment rate and 95% CI with a margin of error of no more than 7%.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram depicting the number of participants referred, lost, and retained according to the referral source. AOD: alcohol and other drugs; NSW: New South Wales.



Participants

Participants were eligible if they were aged at least 18 years, were currently participating in SRAU groups (either face-to-face or online), had (or were willing to obtain) an email address, and comprehended English at a level sufficient to complete the study requirements. Participants were eligible irrespective of self-reported computer or smartphone literacy, and they did not have to own a smartphone. The study sites were provided with an Android (Samsung Galaxy Tab A) tablet for on-site participant use. No restrictions were placed on concomitant care or the frequency or duration of SMART Recovery group participation. The only exclusion criterion was inability or unwillingness to provide informed consent.

Recruitment

A group facilitator or member of the research team provided potential participants with standardized written and verbal information at the beginning of the SMART Recovery group session. Potential participants were asked to provide their preferred contact details, and they were contacted directly by a member of the research team. To avoid any potential coercion or desirability bias arising from the working relationship between facilitators and participants, the researcher (not the facilitator) was responsible for confirming participant interest and seeking informed consent. To boost accrual, during the final month of recruitment, a web-based expression-of-interest form (displayed prominently on the SRAU website) was introduced. Potential participants could contact the research team directly through email, phone, or the web-based expression-of-interest form. All participants provided verbal or written informed consent. The participants were reimbursed (Aus $30 [US $22.02] supermarket voucher) for their time, travel, and effort associated with each interview: baseline and 8-week assessments, as well as qualitative interviews (up to a total of Aus $90 [US $66.06]).

SMART Track: ROM and Feedback mHealth App

Development

Overview

The preparatory qualitative work [63] and development process [64] have been reported separately, and further details are available in the published protocol [59]. Briefly, three frameworks [56,65,66] informed the design, development, and content of *SMART Track*. Although each framework can be used in isolation, we chose to combine these approaches to ensure that app development was informed by a more comprehensive set of guidelines that included foci related to the end user (ie, *person*; *person-based* [56]); best practice recommendations for mHealth development (Behavioral Intervention Technology Model [65]); and a collaborative, iterative development process involving the research team, app developers, and participants (Integrate, Design, Assess, and Share Framework [66]). *SMART Track* is grounded in behavioral theory (Self-Determination Theory [67] and Social Control Theory [68]) and the guiding principles of SMART Recovery (self-management, mutual aid, and choice [69]). Behavioral strategies are drawn from the Behavior Change Taxonomy (self-monitoring, feedback, action planning, prompts or cues, and nonspecific reward [70]) and process motivators (choice or control, competence, context, curiosity, personalization, and reframing [66]). The agency contracted for app development and design was GHO, Sydney [71].

Beta-Testing

The initial beta version of the app was submitted to the Apple App Store and Google Play Store for approval in March 2019. The functionality of the app was initially tested with 3 members of the research team (beginning April 5, 2019). Several bugs were identified and fixed before the emended beta version was released (June 4, 2019) for further testing to a convenience sample comprising 40 members of the SRAU Research Advisory Committee, SRAU steering committee, and SMART Recovery board, as well as SMART Recovery facilitators. Further refinements were made in line with the feedback (bug fixes and minor amendments to functionality and content). The participant version of *SMART Track* was available in the Google Play Store (version 0.0.7) and Apple App Store (version 0.7) on July 15, 2019. *SMART Track* is freely available for Android [72] and Apple [73] devices.

Revisions and Updating

The time frame of the weekly period of ROM data collection was emended in July 2019 (from closing 24 hours after the nominated meeting began to closing 30 minutes after the nominated meeting began). This was to enable the next week of data collection to begin during the meeting such that the participants could set a new 7-day plan at the end of the meeting (rather than having to wait 24 hours). Cloud functions were updated in September 2019 to fix to participant reports (4/72, 6%) that they had not received the expected prompt from *SMART Track* to complete the ROM items.

Overview

Summary

The *SMART Track* app is designed for participants attending SMART Recovery groups (either face-to-face or online). *SMART Track* comprises core ROM and feedback functionality and several additional features to enhance engagement (resources, customizable supports, personal motivations, interactive urge log, and pop-up motivations and self-management strategies, as described below). The content is distributed across five main screens (Figure S1 of Multimedia Appendix 1).

ROM Domains and Items

Consistent with clinical guidelines [2,3] and published recommendations [7,31], *SMART Track* provides multidimensional assessment and feedback. The items included in the app are detailed in Table S1 of Multimedia Appendix 2 [74-83] as a function of target domain and assessment frequency. Further details are available in the published protocol [59]. Briefly, the participants were prompted each week to answer a set of questions, and their responses were used to provide tailored progress feedback.

Progress Feedback

Feedback consists of tailored visual and written feedback across eight domains (7-day plan, behavior of concern, effect of substance use, self-care, relationships, outlook on life, resources, and mental health; see Tables S2 and S3 of Multimedia Appendix 2 for the scoring algorithms).

Resources

The *Resources* screen is able to deliver a maximum of 10 pieces of content. This was distributed across seven self-management resources (including SMART Recovery resources) and three motivational stories (extracted with permission from the *Lives of Substance* website [84]). Content upload was managed by the research team using *WordPress* according to the schedule outlined in Table S4 of Multimedia Appendix 2.

Customizable Supports and Personal Motivations

Participants have the option of tailoring app content by uploading one or more contact numbers, support services or personal motivations for change (photo, audio, video, or text) into the *Me* section of the app.

Interactive Urge Log

In addition to tracking the number, frequency, and strength of urges, when the participant reports an urge, this interactive tool prompts them to manage their urges, log triggers, and reflect on how to maintain or improve effective urge self-management. The interactive urge log contains a range of urge management strategies or motivational content (Table S5 of Multimedia Appendix 2). The content was derived from SMART Recovery manuals [85,86] and transcripts of participants' qualitative interviews [63] and presented to the participants in random order. The participants could also use the *Me* section of the app to enter their own personal strategies and motivations. Participant-entered content is always shown before prespecified content, and it is not accessible to other participants.

Pop-up Motivations and Self-management Strategies

The participants received *pop*-up messages when they opened the app for the first time each day (Table S6 of Multimedia Appendix 2). This content is derived from transcripts of qualitative interviews [63]. A combination of direct excerpts and emended content (modified for clarity) was used.

Implementation

Orientation

After completion of the baseline assessment, the researcher asked the participants to use *SMART Track* at least once a week to complete the ROM questions and enter their 7-day plan and use the other app functions *as needed*. This was reinforced in an introductory email, which also contained the Google Play Store and Apple App Store links to download the app. SMART Recovery facilitators were asked to prompt the participants at the beginning and end of each group session. No additional training or support was provided (outside of what may have been naturally provided by facilitators and peers as part of the group session). A *walk-through* is included in the app to orient participants to the app (Figure S1 of Multimedia Appendix 1).

Prompts and Reminders

The 7-day plan and ROM questions were linked to the day and time that the participant used *SMART Track* in their regular SMART Recovery group session. Tasks were set for 7 days after the meeting. The 7-day plan notifications were customizable. For each task, the participants elected whether and when to receive a reminder notification. A notification to complete the ROM questions was automatically sent 24 hours before the nominated group session. If the questions were not answered, additional reminders were sent 12 hours and again 30 minutes before the group session. The ROM notifications could not be *switched off* by the participant.

Privacy and Confidentiality

To allow participants to reset their password, *SMART Track* captures the email addresses of all end users. However, it is up to the participant to decide whether the email address they choose to use contains any element of personal information (eg, their name). Given the potential impact of privacy- and confidentiality-related concerns on participant engagement with *SMART Track*, a comprehensive privacy and confidentiality policy is available.

Data Collection Procedures

Overview

The study activities are outlined in Figure 2. The four modes of data collection included (1) participant-completed ROM data collected through *SMART Track* (Table S1 of Multimedia Appendix 2); (2) app data analytics captured using Amplitude Analytics (Amplitude, Inc; number of visits, number of unique users, visit duration, time of visit, and user retention) [87]; (3) baseline, 2-week, and 8-week follow-up assessments conducted over the telephone by AKB; and (4) qualitative interviews with the study participants and group facilitators (conducted over the telephone by RMG). The primary and secondary objectives, measures, and indicator variables are summarized in Table 1.

Figure 2. Flowchart of study activities.

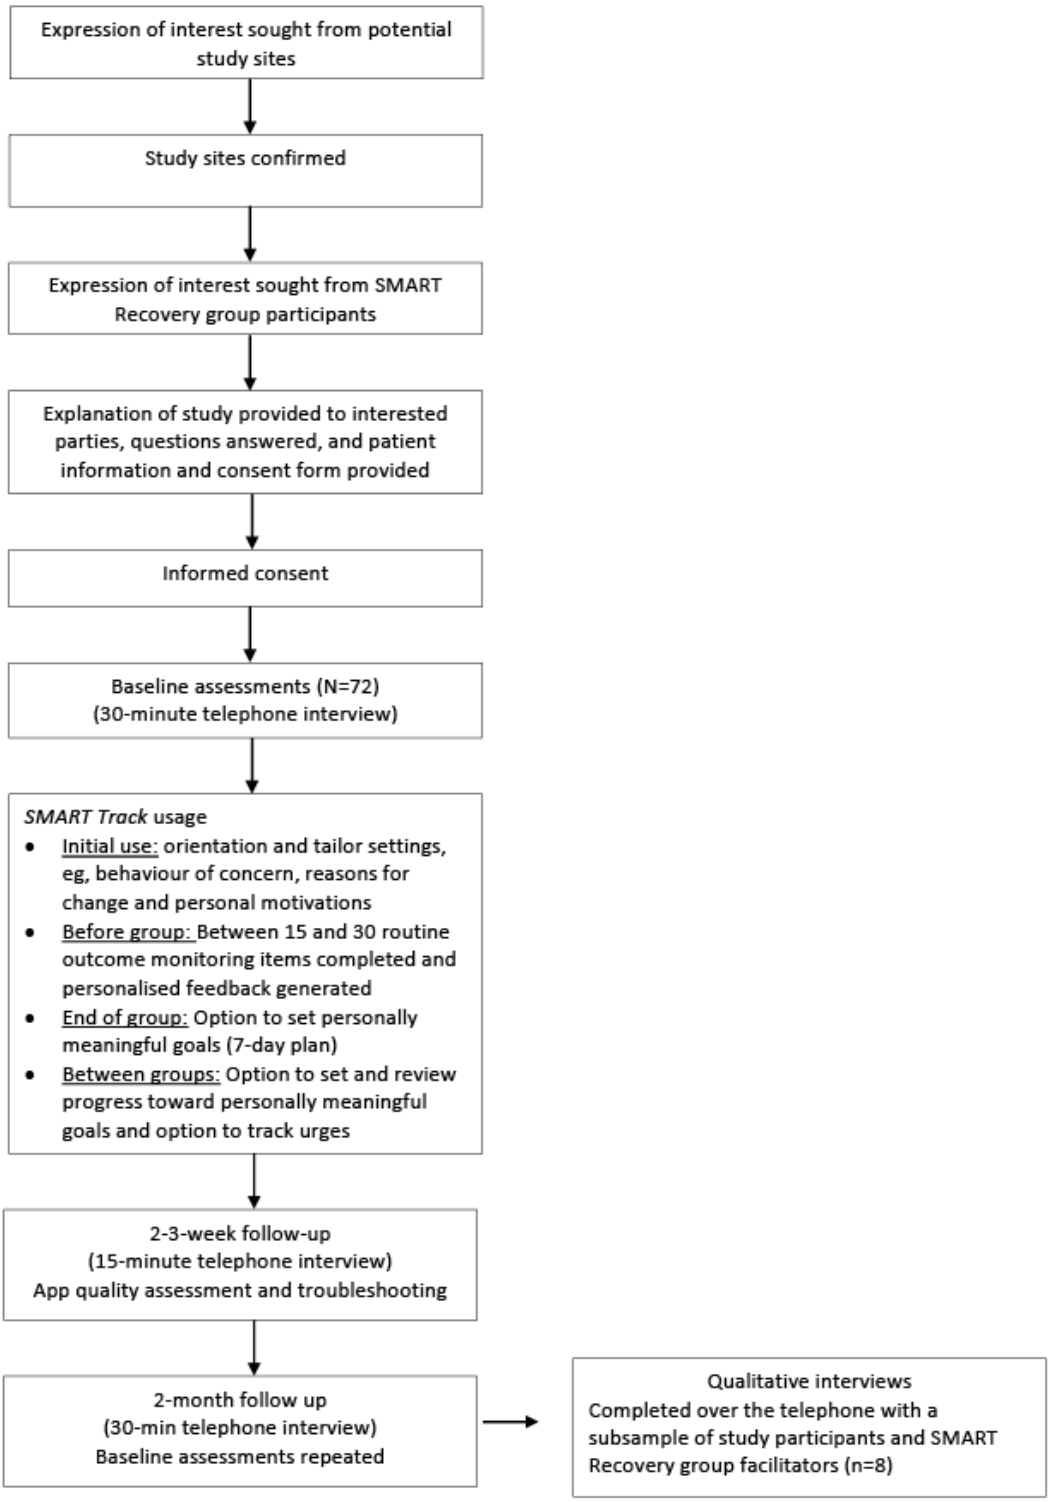


Table 1. Primary and secondary objectives, measures, and indicators.

Objectives	Variables
Primary objectives (measures and indicators)	
To explore the feasibility of using *SMART Track* as part of SMART Recovery groups	• Proportion of eligible participants who consent to the study, create an account, and use SMART Track • Proportion of missing data for each of the routine outcome monitoring items and instruments at each week of administration across the 8-week period of SMART Track use • Engagement and use patterns indexed through data analytics captured daily across the data collection period • Costs associated with developing SMART Track and maintaining the app until the completion of data collection
To explore the acceptability of using *SMART Track* as part of SMART Recovery groups	• Detailed qualitative feedback from SMART Recovery group members and facilitators to explore their experience of, and satisfaction with, SMART Track (8-week follow-up) • Quality ratings as assessed by participant ratings of the end-user version [87] of the Mobile App Rating Scale [88] at 8-week follow-up • Digital therapeutic alliance ratings as assessed by participant ratings of the Digital Working Alliance Inventory at 8-week follow-up
Secondary objective (secondary end points)	
To provide preliminary evidence for participant-reported outcomes	• Participant-reported progress across the 8-week period of app use in (1) substance dependence (Severity of Dependence Scale [89]), (2) addiction recovery (Substance Use Recovery Evaluator [74]), and (3) mental health (Kessler Psychological Distress Scale [75,90])

Key Measures and Assessment Instruments

Overview

The study measures and assessment instruments are detailed in the published protocol [59] and summarized in Table 2. Feasibility and acceptability were informed by data analytics captured using Amplitude Analytics (number of visits, number of unique users, visit duration, time of visit, and user retention) [87]; qualitative interviews; quality assessment conducted using the simplified, end-user version [88] of the Mobile App Rating Scale (MARS) [89] and the Digital Working Alliance Inventory (DWAI) [92]; and a cost analysis informed by a *cost capture template* [93-95] and an adapted version of the Client Service Receipt Inventory—*Generic* UK Mental Health [96]. Preliminary evidence for participant-reported outcomes after the use of *SMART Track* in conjunction with SMART Recovery groups was captured using the Severity of Dependence Scale (SDS) [90], Kessler Psychological Distress Scale-10 (K-10) [97], and the Substance Use Recovery Evaluator (SURE) [74].

[g]BTOM-C: Brief Treatment Outcome Measure—Concise.

Nested Qualitative Evaluation

Qualitative interviews were conducted by RMG after the 8-week period of app use to explore the experiences and opinions of participants with diverse engagement with *SMART Track*. The participants were sampled to reflect the diversity of their characteristics (gender and primary behavior of concern), referral source, and pattern of *SMART Track* use. An independent qualitative researcher (RMG) used a topic guide (Table S7 of Multimedia Appendix 2) to ask additional open-ended questions of a selection of participants (n=20) and facilitators (n=8). The participants and facilitators were sampled to reflect diversity in gender, geographical location, and (for participants only) behavior of concern. For the app users, this included the pathway to SMART Recovery groups (opening and warm-up), perceptions and experiences of app use, initiation circumstances for the app, motivation to join the trial and use the app, and suggestions for improvements. The facilitators were asked similar questions, but the focus was on their professional capacity rather than on their personal experience with apps. The interview started by eliciting information about how they came to be a facilitator, how the app was initiated with their group, their perceptions and experiences in implementing the app with the service users, their motivation levels related to the implementation of the app, and suggestions for improvements. All interviews were audio recorded and transcribed by a professional transcriber working under a confidentiality agreement.

Analysis

Feasibility Indicators

Enrollment and Engagement

Data analytics were captured daily from the time the app was launched until the last participant completed their 8-week follow-up interview. The first participant was given the download details on July 15, 2019, and follow-up data collection was completed on December 2, 2019. Weekly summaries for the total number of unique users and the average number of visits per user were downloaded from Amplitude Analytics. Unique user codes were linked, and the number of weeks that each study participant used the app was calculated.

Use Patterns

To explore how the participants engaged with the various features of *SMART Track*, weekly analytics (total number of visits, total number of unique users, and total duration) for each of the *SMART Track* features (*Urge button*, *Urges* screen, *Resources* screen, *Me* screen, and *Overall Progress* screen) and the time of day that the app was used were downloaded from Amplitude Analytics and descriptive statistics calculated. Retention was characterized using weekly summaries from the *User Lifecycle* feature of Amplitude Analytics. This feature categorizes participants into the following mutually exclusive categories:

1. New users (used the app for the first time that week).
2. Current users (used the app at least once that week and at least once during the preceding week).
3. Resurrected users (used the app at least once during the week after being dormant during at least the previous week).
4. Dormant users (did not use the app that week but did use the app at least once during the preceding week).

Proportion of Missing ROM Data

ROM use (yes or no) for each week of the 8-week follow-up period was defined as participant entry of *SMART Track* data for at least one outcome domain (7-day plan, ROM questionnaire, and Urges). This was used to calculate the weekly proportion of participants who entered the data.

Research and Development Costs

An economic costing analysis was conducted to assess the research and development (R&D) costs related to the creation of the *SMART Track* app. This included both the costs of developing the technology and the research costs (mainly time) that were integral to the development of the app, such as workshops to assess development and testing. Furthermore, an estimate of the total time spent in meetings across the R&D process was estimated, from steering group meetings to the conduct of focus groups. The number of hours were estimated to provide additional context of the time invested in the R&D process in developing a comprehensive and user-friendly app.

Acceptability Indicators

Nested Qualitative Evaluation

The qualitative analysis component of the study was undertaken through two processes: first, as a thematic study to provide insights into the acceptability of the app and the meetings more broadly, which was described in detail in a previous paper [63], and second, as part of the nested evaluation process [98], where the qualitative data were used to support app development and contribute to the experimental nature of the study. Unlike strictly triangulated studies, nested research studies use a combination of data to enrich insights and provide points of comparison to generate new hypotheses [98]. Research questions and interview topics informed the first more deductive coding frame. Categories were summarized and presented with pertinent quotes to the broader team for discussion, which continued until consensus was reached. The analysis sought to shed light on specific questions about the feasibility and acceptability of the app from the perspective of end users. We also explored accounts of the experience of submitting ROMs. Although thematic saturation was not the aim of this part of the analysis, we noticed recurring themes in 12 interviews.

Quality Ratings and Digital Therapeutic Alliance

The MARS–User Version (uMARS) [88] and DWAI [92] domain as well as overall mean scores were calculated at the 2-week follow-up.

Preliminary Outcomes

Paired sample two-tailed *t* tests were used to compare participant-reported outcomes on the SDS, K-10, and SURE between baseline and the 8-week follow-up.

Results

Sample Characteristics

A total of 72 participants were enrolled in this study (Figure 1). The participant characteristics were comparable with prior accounts of SRAU group characteristics [99]; the average age of the participants was 44 years (SD 11), with more men (44/72, 61%) than women (28/72, 39%; Table 3). Most of the participants were born in Australia (59/72, 81%), and 6% (4/72) reported being of Aboriginal, Torres Strait Islander, or both Aboriginal and Torres Strait Islander descent. Employment was the main source of income for almost half of the participants (35/72, 48%).

At baseline, the participants reported attending an average of 6.63 (SD 5.44) SMART Recovery meetings in the preceding 12 weeks (range 0-24). Excessive alcohol consumption was the most common primary behavior of concern, endorsed by 68% (49/72) of participants over the preceding 4 weeks. Injecting drug use (ever) was reported by 25% (18/72), and 11% (8/72) of the sample reported a recent arrest (past 3 months).

[a]Missing data for 1 participant.

[b]Missing data for 2 participants.

[c]Three new SMART Recovery participants reported that their first meeting (scheduled for the week before baseline assessment) had been canceled. These participants were due to participate in their first group the week of the baseline assessment.

Feasibility Indicators

Enrollment and Engagement

In total, 216 people expressed interest in participating in the study. Of these 216, 97 (44.9%) were deemed eligible, and 72 (33.3%) went on to enroll. Of the 72 participants enrolled in the study, 68 (94%) created an account, 64 (88%) subsequently used *SMART Track* at least once, and 57 (79%) used *SMART Track* multiple times (mean 16.39, SD 16.10; range 2-83 visits). More than half of the participants (42/72, 58%) used *SMART Track* for ≥5 weeks across the study period (Table 4). *SMART Track* was accessed on 74 unique devices (ie, some participants used the app across multiple devices). Apple iPhone (n=33) and Samsung Galaxy (n=21) smartphones were the primary devices used.

Table 4. Frequency of SMART Track use expressed as the proportion of study participants per time interval across the 20-week study period (n=72).

	Participants, n (%)
Never	8 (11)
1 week	7 (10)
2-4 weeks	15 (21)
5-8 weeks	25 (35)
>8 weeks	17 (24)

Use Patterns

The number of participants using *SMART Track* each week gradually increased across the recruitment period (ie, until the week beginning September 16, 2019), with a gradual decline thereafter (Figure 3). In any one week, the maximum number of study participants using the app was 49% (35/72), and the number of visits to the app ranged from 2.47 to 5.27 (mean 3.39, SD 0.75; Figure 3).

The changes in the number of new, current, resurrected, and dormant users each week (Figure 4) suggest that the participants typically used *SMART Track* intermittently rather than on a regular (weekly) basis.

Figure 3. Total number of study participants using SMART Track each week and the corresponding average number of visits per user.

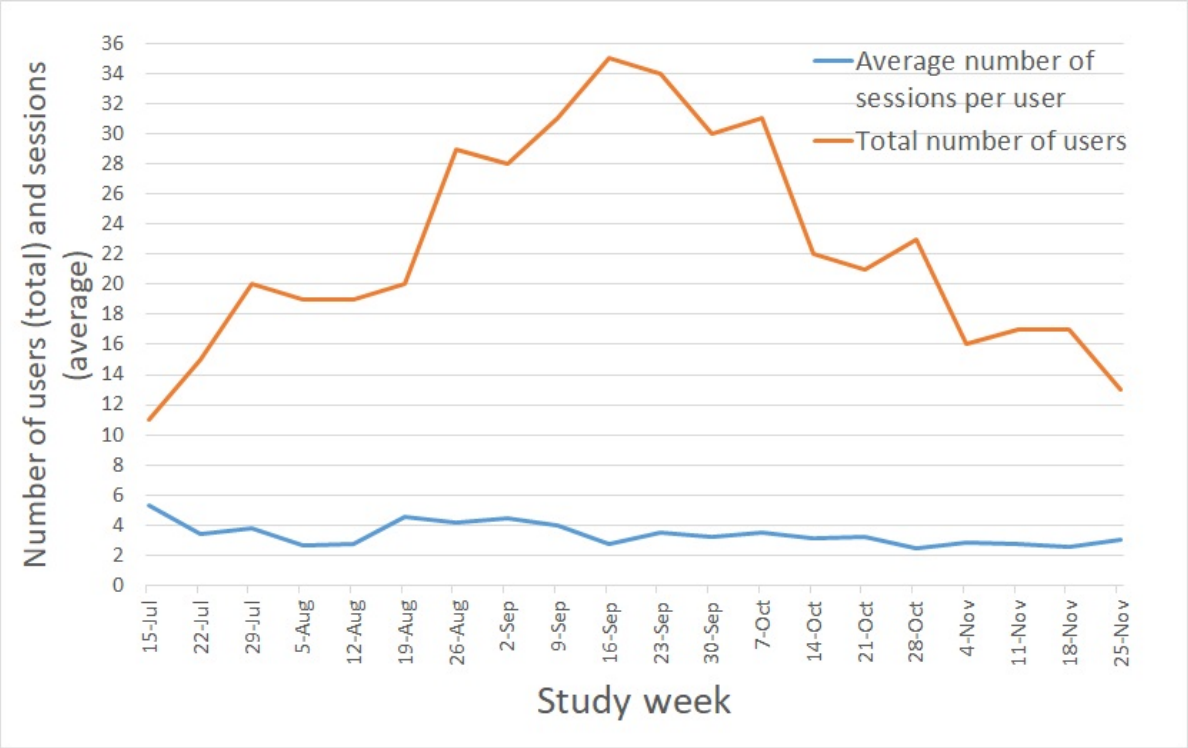

Figure 4. Incoming and outgoing users each week expressed as current versus new versus resurrected versus dormant users.

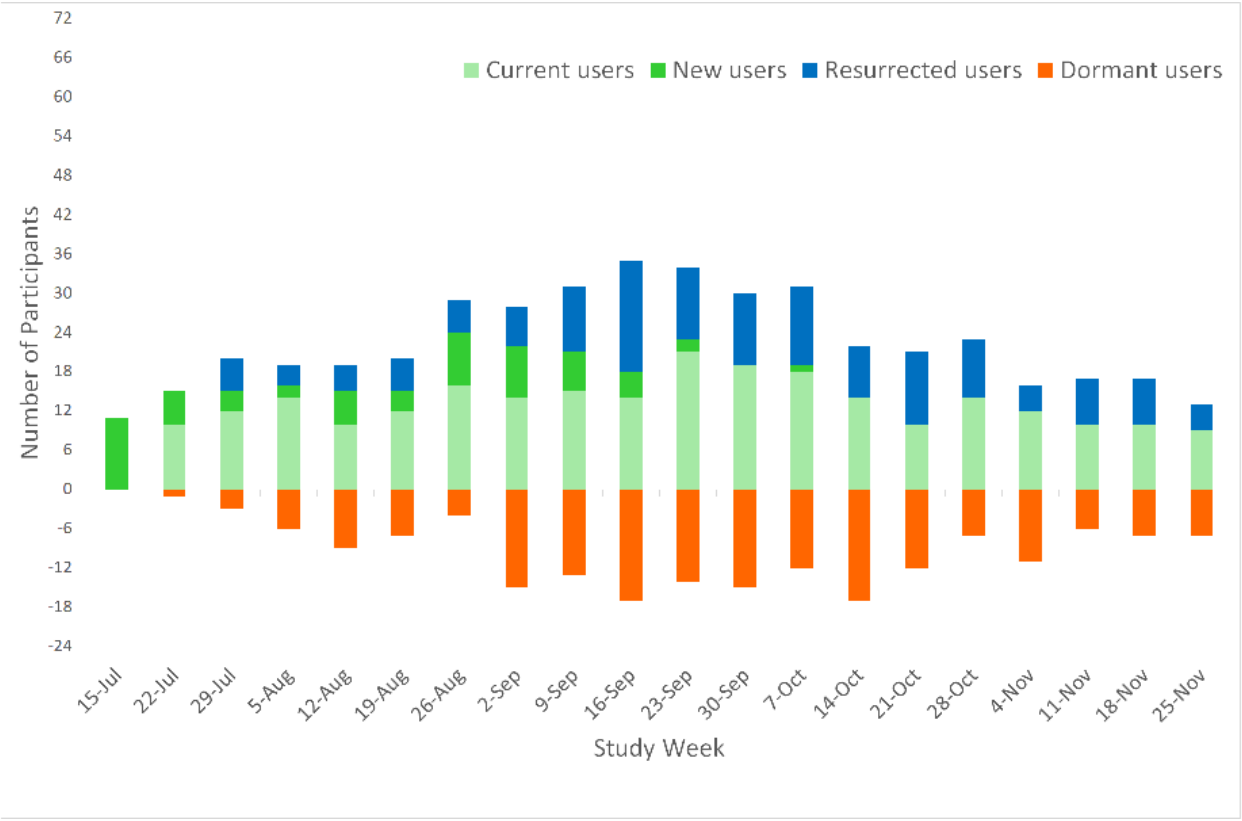


The two main *SMART Track* screens designed to provide feedback data (*Urges* screen and *Overall Progress* screen) were the most frequently visited sections of the app (Table 5). The participants spent the most time (minutes) using the *Me* screen and the least time viewing the *Overall Progress* screen (Table 5).

Table 5. Use of SMART Track features, expressed as the total number of visits to each of the main screens and the total time spent using each of the main screens.

	Total visits	Total duration (minutes)
Urge button	361	—[a]
Track urges	913	2468.4
Resources	587	443.62
Me	467	3915.94
Overall progress	789	321.33

[a]Duration is not provided for the urge button as use requires a single brief click and is therefore not captured.

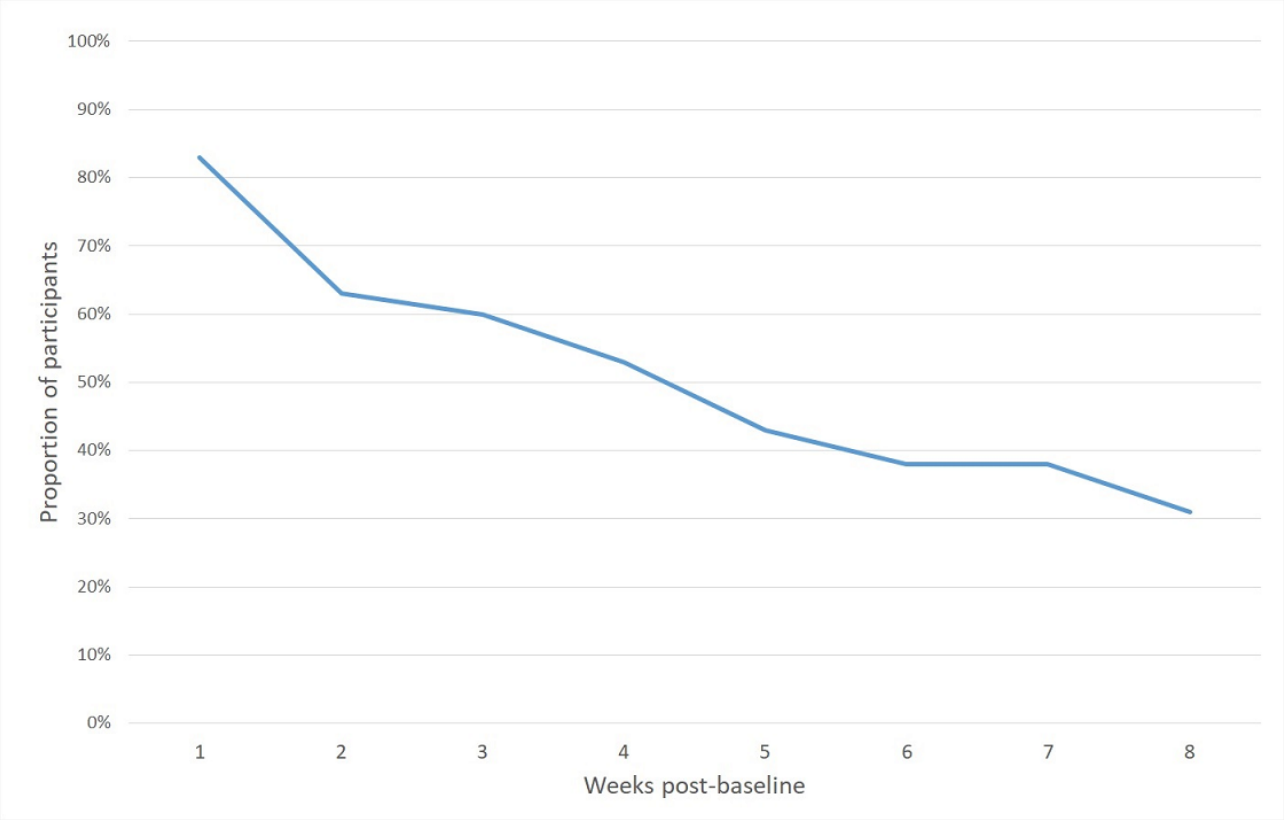
Considerably fewer visits were documented for each of the individual progress screens. These sections of the app were visited, on average, only once or twice per week across the duration of the study by a maximum of 8% (6/72) of the participants (Figure S2 of Multimedia Appendix 1).

The study participants most frequently used the app between 6 PM and 9 PM, with almost a quarter of all visits (500/2166, 23.08%) occurring during this time frame. In the morning, use was greatest between 9 AM and midday (Figure S3 of Multimedia Appendix 1).

Proportion of Missing ROM Data

During the first week of app use, 83% (60/72) of the participants had used *SMART Track* to enter data for at least one ROM instrument (7-day plan, ROM questionnaire, or urge log). There was a reduction across time in the number of participants completing the ROM items. At the end of 8 weeks, almost a third (22/72, 31%) of the participants had provided ROM data, reflecting a 50% reduction compared with week 1 (Figure 5).

Figure 5. Proportion of study participants using SMART Track to enter routine outcome monitoring data.



R&D Costs

To develop the *SMART Track* app, the developer (GHO) received Aus $76,500. However, the true cost to GHO was more than double (Aus $154,034) when the actual time invested by GHO staff (8 staff members; 876 hours) was fully accounted for (Table 4). Furthermore, the research costs to support the development of the app, such as workshops to assess feasibility and usability testing, were estimated at Aus $127,023 (Table 6). This also includes staff time spent by the trial coordinator

and qualitative researcher on development activities. These costs exclude the academic research and evaluation costs that were conducted alongside app development (eg, ethics, recruitment, and economic evaluation; Table 7).

In total, the R&D cost incurred was Aus $203,523. If the true costs to GHO Sydney were included, then the total R&D cost would have been Aus $281,058. Finally, an estimate of the total number of hours invested in the R&D process was estimated at 1485 hours (Table 7). More than three-quarters were in-kind costs and goodwill.

Table 6. Cost of SMART Track development and research costs to support development.

Variable	Hours	Rate	Cost (Aus $)
Development costs			
App developer	452	160	72,320
Account director	48	180	8640

[a]Over three-quarters of time was *in-kind*.

Acceptability Indicators

Qualitative Findings

In total, 28 in-depth qualitative interviews were conducted with 20 app users (group members) and 8 facilitators. The participants tended to perceive and describe their use of *SMART Track* within their broader experiences and competencies related to information and communication technology. Of the 20 app users interviewed, the level of knowledge and prior experience of mHealth apps and other digital resources varied widely and were not related to their age or education level. Moreover, the participants' prior knowledge and experience of apps did not seem to be connected to their use of *SMART Track*. For example, those who demonstrated *high* use of *SMART Track* often described themselves as *new* to apps. Participants with "lots of experience" with apps often described ceasing use after a short time (Alec, group member, low app use).

Compared with another sample of SRAU participants who provided input to inform the development of *SMART Track* [63], the participants in this study expressed less concern about digital support tools replacing face-to-face meetings. These group members tended to perceive the app as complementary to their mutual aid group and described using the resources within it to "stay on track between meetings" (Jasmine, group member, high app use). For these participants, "logging urges and tracking progress" were more desirable than completing routine outcome measures (Campbell, group member, low app use), except when the outcomes data were available to them in "more detail" (Harold, group member, high app use). It is therefore possible that increasing the usability of outcome data tracking activities would increase app users' engagement with outcome measurements. Consistent with other research, end users seem to be more open to completing repeated and routine outcome measures when their understanding of their outcomes is aligned with the outcome measures selected by the program designers [30,74].

The group facilitator seemed to play a key role in implementing the app and collecting routine outcome data. Facilitators who were knowledgeable about the app and purposefully integrated its use in meetings were more likely to report higher app use among the participants. This is consistent with feedback received from client-participants, who described the facilitators' efforts, or lack of efforts, when "inspiring" group members to use the app (Mitchell, group member, high app use). Given the lack of experience that some facilitators have with app use and other information and communication technology, it is possible that basic training would have improved their engagement with implementation. In summary, the posttrial interview findings suggest that *SMART Track* is an engaging platform for collecting routine outcome data, and participant concerns expressed at the pretrial time point were not described after the trial.

Quality Ratings

The uMARS ratings (Table 8) confirmed the acceptability of *SMART Track*. The overall app quality score was *good*, and every domain was rated as either acceptable or good (ie, uMARS rating >3).

Table 8. Quality assessment as indexed by participant responses to the uMARS[a] and DWAI[b].

Variable	Values, mean (SD)	Value, median (range)
uMARS[c]		
Engagement	3.6 (0.5)	3.6 (2.0-5.0)
Functionality	4.1 (0.7)	4.0 (2.5-5.0)
Aesthetics	4.2 (0.6)	4.3 (3.0-5.0)
Information	4.3 (0.5)	4.5 (2.5-5.0)
Overall quality	4.0 (0.5)	4.1 (3.0-4.9)
Subjective quality	3.8 (0.8)	4.0 (1.0-5.0)
Perceived impact	3.7 (0.9)	3.7 (1.7-5.0)
DWAI[d]		
Goals	3.5 (1.0)	3.5 (1.0-5.0)
Tasks	3.7 (1.0)	3.5 (2.0-5.0)
Bond	3.4 (1.1)	3.5 (1.5-5.0)
Overall	3.5 (0.9)	3.7 (1.7-5.0)

[a]uMARS: Mobile App Rating Scale–User Version.

[b]DWAI: Digital Working Alliance Inventory.

[c]All items are rated on a 5-point scale from 1 (inadequate) to 5 (excellent).

[d]All items are rated on a 5-point scale from 1 (seldom) to 5 (always).

Digital Therapeutic Alliance

The DWAI ratings (Table 8) also support the acceptability of the app with the domain scores indicating that, on average, the participants rated the key elements of therapeutic alliance (goals, tasks, and bonds) as being present between *fairly* often and *very* often.

Preliminary Evidence on Outcomes

There was a significant reduction between baseline and 8-week follow-up for the SDS (mean difference 1.93, SD 3.02; 95% CI 1.12 to 2.73) and K-10 scores (mean difference 3.96, SD 8.31; 95% CI 1.75 to 6.17), but there was no change in the SURE scores (mean difference 0.11, SD 7.97; 95% CI –2.02 to 2.24).

ROM Reliability

There was a strong relationship between the clinician-administered SURE [74] (at baseline) and the app-administered SURE (week 1; r=0.89; P<.001). For the quality-of-life item, there was a moderate relationship between baseline clinician administration as part of the EUROHIS-QOL 8-item index [76] and as part of the app-administered measures 2 weeks later (r=0.61; P=.005). For the Kessler Psychological Distress Scale-6 (K-6) [75], there was a moderate relationship between baseline clinician administration as part of the K-10 [97] and app administration as part of the K-6 2 weeks later (r=0.51; P=.02). The internal consistency (Cronbach α) for the SURE and K-6 was high across time points and when collected through clinician-interviewed telephone assessments or within the app (SURE: .86 to .94; K-6: .86 to .90).

Discussion

Principal Findings

This study was designed to assess the feasibility, acceptability, and preliminary outcomes of *SMART Track* for ROM and feedback in SRAU. The qualitative and quantitative findings support the feasibility, acceptability, and utility of *SMART Track* for ROM and feedback in SRAU. The findings also provide insight into avenues for enhancing sustained engagement. SMART Recovery participants were willing to use *SMART Track*, demonstrated sustained use across the 8-week follow-up interval, engaged most with the two main progress screens (*Urges* and *Overall Progress*), and experienced *SMART Track* as useful and consistent with SMART Recovery principles and strategies. Although it is difficult to attribute it directly to the use of *SMART Track* or SMART Recovery, the participants also showed clinical improvement over the 8-week follow-up, specifically reductions in the severity of dependence and psychological distress. Varied rates of ROM completion, minimal use of domain-specific feedback screens, and qualitative feedback suggest that the utility of *SMART Track* would be improved by making minor changes to app functionality and improving attention to implementation strategies.

Engagement With SMART Track

To put engagement with *SMART Track* in perspective, it is helpful to consider the rates of engagement with other mHealth apps. One of the challenges with such comparisons is the considerable variation in the metric used to capture mHealth use (eg, mean number of log-ins, sessions, modules, activities completed [100]) and the degree to which these variables are reported [101,102]. Although several systematic reviews of digital recovery support services [39], digital measurement feedback systems [32], and addiction-related mHealth apps are available [54,103-105], the focus tends to be on content, experience, or outcomes, with little to no data examining participant engagement or use. However, the use of mHealth apps by people in recovery from substance use has been shown to vary from as high as 90% in the first few weeks to as low as 18% after 6 weeks [105]. For people with mental health conditions, engagement varied according to the target mental health condition. The number of *nonusers* (individuals who fail to download or use the intervention) has been calculated as 41% (range 25%-58%) for apps targeting depression and 8% (range 0%-16%) for apps targeting anxiety [100]. Reduced engagement over time was common [100]. Compared with these data, participant engagement with, and sustained use of, *SMART Track* is at least comparable, if not higher than the available evidence.

Another useful point of comparison comes from use trends within the global app marketplace. In 2019, data derived from more than 12,000 apps demonstrated that a quarter of the users will abandon an app after one-time use [106]. In comparison, of the 94% (68/72) of the participants in this study who created a *SMART Track* account, more than one occasion of use was documented for 79% (57/72) of the participants. Benchmarks pertaining specifically to lifestyle-related apps (which include fitness-, health-, and travel-related apps) indicate that the average 2-month retention rate is 36% [107]. In comparison, more than half of the participants in this study used *SMART Track* for between 5 and 8 weeks (25/72, 35%) or longer (17/72, 23%), and week 8 ROM data were provided by 31% (22/72) of the study participants.

Uncertainty exists around what is considered a *good* level of mHealth use. Some addiction-related apps (eg, *In My First Year of Recovery* and *A-CHESS* mHealth interventions) have documented high levels of sustained participant engagement (78% program completion and 4-month retention, respectively [105]). In contrast, *SMART Track* use was intermittent, with a proportion of the participants using the app weekly, whereas others disengaged and re-engaged every few weeks. Emerging evidence suggests that engagement with digital recovery support tools may be influenced by recovery duration [39]. Accordingly, engagement with *SMART Track* is likely to vary widely, given that SRAU caters to people across the spectrum of recovery experiences. It is also possible that users may perceive apps as a *short-term commitment* [108]. Therefore, compared with the use of other digital platforms (eg, the web), app use may be shorter and more sporadic [109]. Moreover, training in *SMART Track* was not extensive. The researchers met with the facilitators at each site to orient them to the features of the app. The participants received an email with brief instructions and an in-app onboarding process, although analytics showed that this was used by less than 45.2% (105/232) of users who downloaded *SMART Track* during the study period. The exemplary use rates documented by *In My First Year of*

Recovery and *A-CHESS* may have been due to the more active role of counselors in encouraging mHealth use [105] and point to the importance of improved integration of *SMART Track* into SMART Recovery groups. Identifying participant and contextual factors that influence engagement represents an important challenge for future research.

Routine Outcome Monitoring

A few studies have examined ROM implementation report data on engagement and attrition rates [8,25,28,110,111]. Compared with recent data from the Netherlands, however, the proportion of participants using *SMART Track* to input ROM data is largely comparable, and in some cases, greater than traditional clinician-completed methods [112]. A 50% response rate has been recently suggested as an acceptable benchmark for ROM data and is likely sufficient to protect against bias and yield valid information about patient progress (see study by de Beurs et al [112] for a discussion). In this study, this benchmark was achieved each week across the first month of data collection, with 83% (60/72), 63% (45/72), 60% (43/72), and 53% (38/72) of the study participants completing at least one of the ROM instruments across the first 4 weeks of app use. ROM completion continued to decline during the second month of data collection, with 31% (22/72) of the sample providing ROM data during week 8. Ongoing efforts are needed to improve ROM completion and understand the participant characteristics associated with drop-off (eg, through attrition analyses). For example, given the voluntary, open-enrolling format of SMART Recovery groups and individual variation in group attendance (0-24 in this study), it would be interesting to examine whether app use varies according to group engagement.

Cost Analysis

The R&D costs of *SMART Track* were estimated at Aus $203,523. However, the developer offered considerable in-kind support, and the overall true cost was Aus $281,058. It is important to reiterate that these are essentially *sunk costs*. If *SMART Track* had been rolled out routinely in SMART Recovery groups, the cost of implementation would have consisted of costs related to app hosting, infrastructure, maintenance, and training. The dynamic nature of the industry makes it difficult to estimate these costs and points to the need for ongoing data collection to understand the long-term real-world feasibility of *SMART Track*.

Opportunities

To maximize participant engagement in ROM, a clear rationale for why the data are being collected and what they will be used for is essential [25]. The measures must be experienced as *relevant* [110] and the process deemed *worthwhile* [113]. Analytics revealed that few people accessed the detailed, personalized feedback provided within each of the domains listed on the summary page. Qualitative feedback highlighted a mismatch between the effort expended and satisfaction with the feedback provided. Given that the participants were asking for feedback that was already provided in the app (but not accessed), we expect that modifications to improve the visibility of these sections of the app will further enhance ROM completion. Importantly, the regular and frequent use of app self-monitoring features has been linked to a longer period of use and reduced likelihood of abandoning apps [114]. Additional features that have been linked to mHealth engagement include an esthetically pleasing interface, ease of use, degree of personalization, reinforcement (eg, rewards and reminders), communication (with peers or professionals), message presentation (including language, tone, and design), and credibility (encompassing trustworthiness and confidentiality [115]). Although these features were considered throughout the design of *SMART Track* (and positively evaluated as part of the quality assessment), an opportunity exists to further enhance the user experience (eg, through improved personalization, greater use of rewards, and the addition of information-sharing or communication capabilities).

Organizational resources are essential for ensuring the sustained implementation of digital interventions to reduce substance use [105], for example, ensuring leadership support; providing adequate training and resources to both staff and service users; leveraging the expertise of service users to contribute to training; and having a process in place to monitor, evaluate, provide feedback, and respond to uptake rates [116]. Training is a particularly important consideration and provides a forum to (1) build clinician knowledge and confidence in app use and features, (2) practice introducing it to participants, and (3) identify and overcome any concerns or perceived barriers to implementation of mHealth to support routine care [117]. The next steps for *SMART Track* include improved facilitator training and support and leveraging of participant and facilitator *champions* (ie, individuals who actively support the use of *SMART Track*).

Strengths

The development of *SMART Track* was grounded in theory [40,57] and user-centered design [57]. Consistent with recommendations for enhancing measurement-based care, *SMART Track* includes both standardized and idiographic outcome assessment and harnesses technology to overcome traditional barriers to ROM (eg, scoring and providing tailored feedback [110]). Quality assessment was conducted using a psychometrically valid tool [88], and *SMART Track* surpassed the minimum acceptable quality benchmark (≥3 [88]) on each of the domains assessed by the uMARS, with an overall quality rating of *good*. This is superior to several published accounts [50]. The observed quality of *SMART Track* likely reflects the user-centric approach to development. However, because the ratings were collected as part of a telephone interview with the researcher, the contribution of response bias cannot be ruled out.

Evidence from mental health settings suggests that mHealth apps that have a clear purpose and simple user interface and are easy and time efficient to navigate and demonstrate were more likely to be used as part of routine practice [117]. Quantitative and qualitative data indicate that *SMART Track* possesses these attributes. Pending minor upgrades and improved training and support, this finding further bolsters our confidence in the routine uptake of *SMART Track* within SMART Recovery groups.

Limitations

This study includes several limitations. In its current format, *SMART Track* is not suitable for people who cannot adequately read and comprehend English. The reliance on written and visual information may also compromise the suitability of *SMART Track* for people with vision impairment. The use of cloud functions for collecting and storing data means that *SMART Track* needs a reliable internet connection to function. The study's approach to assessing engagement is consistent with recommendations for a multidimensional approach using mobile app data analytics (index of *microengagement*), indices of behavior change (macro level of engagement), and participant subjective experience [102]. However, differences in how various studies define engagement and use make it hard to position *SMART Track* within the context of existing studies. Recent guidelines for the measurement and reporting of engagement data in digital interventions may be beneficial in the future [118].

The current findings are derived from a small sample of participants who attended a limited sample of SRAU groups. We did not collect data on the number of participants attending SRAU groups across the study period; therefore, although participant characteristics are comparable with published accounts [99], generalizability is unclear. Furthermore, the short-term nature of the study makes it challenging to position the findings within the often long-term, nonlinear experience of recovery [16]. Finally, because this is a stage 1 feasibility study, our finding that participants reported reduced severity of dependence and psychological distress from baseline to 8 weeks needs to be interpreted cautiously.

Conclusions

The qualitative and quantitative findings support the feasibility and acceptability of *SMART Track* and lend insight into avenues for enhancing sustained engagement. Low rates of engagement and high rates of attrition are known challenges for services working with participants who experience substance use and mental health–related difficulties [119]. Sustained engagement with mHealth apps is notoriously difficult to achieve. In light of these challenges, our findings are promising. *SMART Track* offers a potential solution for ROM and feedback, particularly for people with substance use disorders who attend mutual support groups. Future research should focus on identifying relevant demographic, clinical, and contextual factors that may influence the engagement, attrition, and perceived utility of this promising mHealth app.

Acknowledgments

The authors gratefully acknowledge the creative and technical expertise of the customer experience agency (GHO Sydney). Ryan Chao (executive creative director) provided overall creative direction and led the user experience design process. James Legge (executive strategy director) led the strategy and facilitated the workshops. Marcos Martini (technical lead) was responsible for the overall development of the app across the iOS and Android platforms, Sharon Peng (user experience or user interface designer) designed the user experience and user interface and conducted usability tests, and Phoebe Calcutt (project manager) managed the overall delivery of the app. The authors also gratefully acknowledge the time of, and expert insights from, the members of our steering committee and the valuable support and contributions made by SMART Recovery participants and facilitators to the development of *SMART Track* and the conduct of this research.

Funding for this research was provided by the New South Wales Ministry of Health under the New South Wales Health Alcohol and Other Drugs Early Intervention Innovation Grant Scheme. The funding body did not directly contribute to the design, conduct, analysis, write-up, and submission of this research for publication and does not have the ultimate authority over any of these activities.

Conflicts of Interest

RM is the executive director of SRAU. AA is employed by SMART Recovery as the National Program Manager and Trainer. PJK, FPD, ALB, AS, LH, VM, BL, AKB, JFK, and AA all volunteer as members of the SRAU Research Advisory Committee. The potential perceived conflicts of interest are negligible. The role of study investigators on the research advisory committee or as an employee of SMART Recovery is freely available on the SRAU website (and study participants can be directed to this information as required). Furthermore, the team responsible for informing the study design and overseeing the conduct of the study and data analysis also consists of researchers, clinicians, and statisticians independent of SMART Recovery.

Abstract

Background: GPS alarms aim to support users in independent activities. Previous systematic reviews have reported a lack of clear evidence of the effectiveness of GPS alarms for the health and welfare of users and their families and for social care provision. As GPS devices are currently being implemented in social care, it is important to investigate whether the evidence of their clinical effectiveness remains insufficient. Standardized evidence frameworks have been developed to ensure that new technologies are clinically effective and offer economic value. The frameworks for analyzing existing evidence of the clinical effectiveness of GPS devices can be used to identify the risks associated with their implementation and demonstrate key aspects of successful piloting or implementation.

Objective: The principal aim of this study is to provide an up-to-date systematic review of evidence based on existing studies of the effects of GPS alarms on health, welfare, and social provision in the care of older adults compared with non–GPS-based standard care. In addition, the study findings were assessed by using the evidence standards framework for digital health technologies (DHTs) established by the National Institute for Health and Care Excellence (NICE) in the United Kingdom.

Methods: This review was conducted according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. Primary studies published in peer-reviewed journals and gray literature from January 2005 to August 2020 were identified through searches in 13 databases and several sources of gray literature. Included studies had individuals (aged ≥50 years) who were receiving social care for older adults or for persons with dementia; used GPS devices as an intervention; were performed in Canada, the United States, European Union, Singapore, Australia, New Zealand, Hong Kong, South Korea, or Japan; and addressed quantitative outcomes related to health, welfare, and social care. The study findings were analyzed by using the NICE framework requirements for *active monitoring* DHTs.

Results: Of the screened records, 1.6% (16/986) were included. Following the standards of the NICE framework, practice evidence was identified for the tier 1 categories *Relevance to current pathways in health/social care system* and *Acceptability with users*, and minimum evidence was identified for the tier 1 category *Credibility with health, social care professionals*. However, several evidence categories for tiers 1 and 2 could not be assessed, and no clear evidence demonstrating effectiveness could be identified. Thus, the evidence required for using DHTs to track patient location according to the NICE framework was insufficient.

Conclusions: Evidence of the beneficial effects of GPS alarms on the health and welfare of older adults and social care provision remains insufficient. This review illustrated the application of the NICE framework in analyses of evidence, demonstrated successful piloting and acceptability with users of GPS devices, and identified implications for future research.

Introduction

Background

Health and welfare technologies (HWTs) are "technology-based interventions that aim at maintaining or promoting health, well-being, quality of life (QoL) and/or increasing efficiency in the service delivery system of welfare, social and health care services, while improving working conditions of the staff" [1]. This definition can be regarded as an integration of the Scandinavian term *welfare technology* [2] and the global concept *digital health* [3], including a broader definition of health according to the World Health Organization: "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." GPS alarms are examples of HWTs that aim to support users in independent activities of daily living, both indoors and outdoors, something that is needed by large groups of older adults who want to maintain independent living in spite of cognitive impairments, for example, persons with dementia in the early or middle stage. Globally, approximately 50 million people have dementia, and nearly 10 million new persons develop dementia every year [4]. The global population of persons with dementia is estimated to increase to 82 million in 2030 and to 152 million in 2050 [4].

GPS solutions enable the user to send an alarm to home care, family members, or both, either at home or outdoors. The user's position can be localized through GPS coordinates when an alarm is sent. GPS alarms may also include a geofencing function that automatically generates an alarm if the user leaves a predefined geographical area. A European overview has identified ongoing implementation of GPS alarms in the municipal care of older adults in Sweden and Norway [5].

Research on the implementation of welfare technology in Swedish municipalities has identified several barriers to its use, including lack of supporting evidence of the benefits and positive outcomes [6]. Hence, evidence of positive outcomes of GPS alarms can justify large-scale implementation and confidence in their use.

When making implementation decisions, it is important to consider what kind of evidence is needed to make an informed decision. To date, there is no national Swedish evidence-based framework to support decision-making processes related to HWTs [7]. However, the National Institute for Health and Care Excellence (NICE) in the United Kingdom, together with relevant stakeholders, has produced an evidence standards framework for digital health technologies (DHTs) to ensure that new technologies can demonstrate clinically effective and economic value in a structured and transparent manner [8]. The framework classifies DHTs by function and thereby allows them to be stratified into evidence tiers based on the potential risk to users. For example, DHTs that track patient location can be classified as *active monitoring* and thereby stratified into evidence tier 3b in the framework. Good levels of evidence for tier 3 DHTs include evidence of credibility with health and social care professionals, relevance to current care pathways in health care systems, acceptability with users, equalities considerations in provision and use, accurate and reliable measurements and transmission of data, reliable information content, ongoing and planned continuous data collection to follow up on the use and value of the DHT, quality and safeguarding, and demonstration of its effectiveness according to intended outcomes. The framework has been applied in examples of case studies that demonstrate evidence of effectiveness and economic value of a number of DHTs [9]. These studies are based largely on information provided by the developers that has not been independently verified. Information from studies published in peer-reviewed journals and in gray literature can therefore strengthen the validity of evidence of DHTs.

Two previous scoping reviews of tracking technology in the care of older adults conducted by Røhne et al [10] and Neubauer et al [11] identified limited evidence in peer-reviewed scientific studies for the effects of GPS use on health, quality, and cost-efficiency among users and spouses and in the health and welfare sector [10] as well as pointed out that further research was needed to identify technologies with high levels of evidence for effectiveness and usability [11]. Moreover, a synthesizing review of empirical evidence on the broader use of GPS technologies by home-dwelling persons with dementia and their family caregivers (CGs), conducted by Bartlett et al [12], found only nontrial evidence and demonstrated the lack of large-scale studies. As GPS devices are currently being implemented in social care, it is important to investigate whether the evidence of their clinical effectiveness remains insufficient. By analyzing existing evidence of GPS devices using an established framework, the risks associated with their implementation and conclusions from successful piloting or implementations can be identified.

Objectives

The aims of this review are to (1) systematically update evidence from existing studies of the effects of GPS alarms on the health, welfare, and social provision in receivers of care for older adults compared with non–GPS-based standard care and (2) review the findings using an established evidence framework for DHTs. Studies from both peer-reviewed journals and gray literature were included, and the findings were compared with the NICE evidence standards framework for DHTs [8]. The goal is to assess the available evidence according to the desired evidence standards of an established framework to support decision-making in future implementations of GPS-based alarms.

Methods

Protocol and Registration

This systematic literature review was reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [13].

Eligibility Criteria

The elements of the review (aim, eligibility criteria, and outcomes) were defined as shown in Textbox 1.

Textbox 1. Review elements.

Aim

- To conduct a systematic review of existing evidence of the effects of GPS alarms on the health, welfare, and social provision in the care of older adults compared with standard non–GPS-based care

Inclusion criteria

- Original, peer-reviewed publications published between January 2005 and August 2020 in the English language
- Studies performed in Canada, the United States, European Union, Australia, New Zealand, Singapore, Hong Kong, South Korea, or Japan
- Population aged ≥50 years
- GPS-based alarm interventions enabled the users to initiate alarms, with or without localization and with or without geofencing functions

Exclusion criteria

- Qualitative studies, technical validations, proof-of-concept studies, system descriptions, reviews, and editorials

Outcomes

- Outcomes related to the health and welfare of users and their informal caregivers, and outcomes related to provision in the care of older adults

Search Strategy

A three-step search strategy was used: (1) an initial search of electronic peer-reviewed scientific publication databases; (2) a search of gray literature databases, trial registers, and Google Scholar; and (3) a search of gray literature from the Nordic countries in targeted websites set up by authorities and organizations, academic publication databases, and Google Scholar. All three steps used a snowballing approach [14,15] in which the articles that reached title-, abstract-, or full-text screening of an initial database search were used in iterations of both backward (reference search) and forward (citation search) snowballing.

Information Sources and Searches

Summary and Complete Strategies

A summary of information sources and retrieved records for all the search steps is presented in Multimedia Appendix 1 [10,16-19]. The complete database-specific search strategies for the initial searches of scientific and gray literature are presented in Multimedia Appendix 2.

Scientific Literature

The literature search was completed on August 20, 2020, in the following electronic databases: Academic Search Elite, APA PsycINFO, Applied Social Sciences Index & Abstracts, CINAHL Plus, Cochrane Library, International Bibliography of the Social Sciences, IEEE Xplore, PubMed, Scopus, SocINDEX, Social Services Abstracts, Sociological Abstracts, and Web of Science Core Collection. The search strategy included both free-text and controlled vocabulary. The search was limited to articles published in 2005 or later.

Gray Literature

A primary search in gray literature databases was conducted on September 8 and 9, 2020. The databases searched included Base, OpenGrey, OAIster, DART-Europe, ProQuest Dissertations & Theses Global, WHO ICTRP, ClinicalTrials.gov, International HTA Database, and Google Scholar. The search strategy was simplified and adapted to the search interface of gray literature databases. Finally, a larger search for gray literature from the Nordic countries was conducted by searching the websites of government agencies and organizations working with health and welfare issues. Publication databases from universities in the Nordic countries were also searched including the databases and websites of associations of local authorities and regions in the Nordic countries and Google Scholar. The searches were conducted from September 22, 2020, to September 29, 2020, and involved searching for terms in Swedish, Norwegian, Danish, Finnish, and Icelandic.

Study Selection

The relevant records were downloaded to the reference management software EndNote (Clarivate Analytics). In the search for Nordic gray literature, the retrieved records were screened to determine their relevance related to the aim of the review before downloading the publications to EndNote. In the other searches, all retrieved records were directly downloaded to EndNote. After the removal of duplicates, the records were transferred to the systematic review software Covidence (Veritas Health Innovation Ltd). All four steps were performed by an information science specialist or librarian. The Covidence software, which automatically detected and removed any remaining duplicates, was used for title and abstract screening, full-text review, and data extraction. The screening of titles or abstracts, eligibility assessment of full-text articles, and full-text

screening were performed independently by 2 reviewers; any conflicts were resolved by a third reviewer.

Data Extraction

Information on the included studies' aims, design, conduct, population, intervention, and outcomes as well as the results for relevant outcomes were extracted from the publications by 2 reviewers independently using a predefined template. Any conflicts in eligibility assessment were resolved through discussion between the reviewers. Information regarding the included studies is presented in Table 1.

Risk-of-Bias Assessment

Publications that aimed to demonstrate evidence of effectiveness (for tier 3a) were assessed for risk of bias at the study level by 2 researchers independently. The criteria assessed for the randomized study followed the Cochrane Risk-of-Bias Tool 2.0 guidelines [20] and included the method used for random sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, the completeness of outcome data, the possibility of selective outcome reporting, and other sources of bias. For nonrandomized studies, the Risk of Bias in Non-randomized Studies of Interventions tool [21] was used to assess bias due to confounding and missing data as well as selective reporting and in the selection of participants and classification of, and deviations from, interventions. Consensus resulted in inclusion of the risk assessment in this review's summary of findings. Any conflicts in risk assessment were discussed by the 2 researchers (ME and MR) and any conflicts remaining were resolved by the third reviewer (SLS).

Analysis of Findings From the Systematic Review via the Application of the Evidence Framework

The extracted data for relevant outcomes were categorized and summarized according to the tiers 1-3b evidence categories in the NICE evidence standards framework for DHTs described below. An overview of each study's contribution to the respective evidence categories is presented in Table 2, and a more extensive version of the table, including the criteria for minimum evidence and best practice standards in all evidence categories, is presented in Multimedia Appendix 3 [22-37]. The table was prepared by one of the researchers and reviewed by a second reviewer. For each evidence category, data extracted from all included studies were compared with the defined minimum evidence and best practice standards of evidence. The extracted data were summarized for each evidence category, and the extent to which the results met the requirements for minimum evidence and best practice standards in each category was assessed. The process was carried out by one of the researchers and reviewed by a second reviewer. Any assessment conflicts were resolved through discussion between the reviewers. The summarized data according to the evidence framework are presented in this review's summary of the findings (Table 2).

The Standard Evidence Framework for DHTs

The framework classifies DHTs by function and thereby allows them to be stratified into evidence tiers based on the potential risk to users [8]. Examples of effectiveness and economic value of digital health case studies have been provided to illustrate how the framework can be used [9]. DHTs that track patient location were classified as *active monitoring* and thereby stratified into evidence tier 3b. Moreover, the NICE guidelines state that "best practice evidence standards in each relevant evidence tier should be used for DHTs that present a potential high risk" [8]. GPS alarms can be identified as high-risk DHTs because the intended user group is a vulnerable group and GPS alarm failure could have serious consequences for the user, and in some countries GPS alarms might be used without regular support from social care professionals.

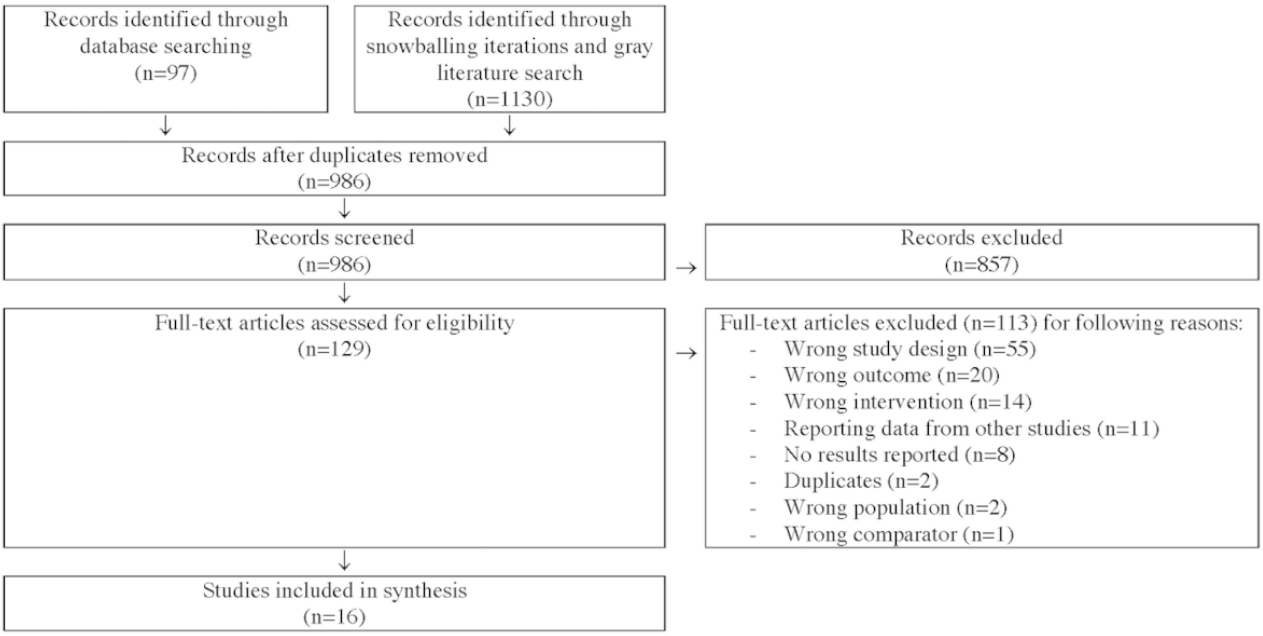
Good levels of evidence for tier 3 DHTs are presented in Multimedia Appendix 3 [22-37]. Evidence standards of the tier 1 and tier 2 categories require documentation that demonstrate that specific aspects have been considered and that the procedures have been completed with a certain level of quality control. Therefore, both the results and aims of the included studies were considered for tier 1 evidence categories. In contrast, tiers 3a and 3b require evidence demonstrating effectiveness.

Results

Study Selection

The literature searches identified 1227 records. After the removal of 240 (240/1227, 19.56%) duplicates, the titles or abstracts of 80.36% (986/1227) of the publications were screened for relevance; 69.85%, (857/1227) of articles were excluded in the screening, and 10.51% (129/1227) full-text publications were assessed for eligibility according to the inclusion and exclusion criteria presented in Textbox 1. Of the 129 full-text publications, 113 (87.6%) were excluded, and the remaining 16 (12.4%) articles were included in the final assessment. Figure 1 provides an overview of the publication selection process.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of publications assessed in each step of the review process.



Study Characteristics

The 16 included studies were published as original articles in scientific journals (n=6), conference papers (n=2), a master's thesis (n=1), and project reports (n=7). A summary of the characteristics of each publication is presented in Table 1.

Of the 6 peer-reviewed journal studies, 1 was a randomized controlled trial (RCT), and the others were nonrandomized studies with either an experimental (n=4) or an observational design (n=1). The other 10 studies had the following study designs: observational design (n=5, of which 3 used mixed methods and two used quantitative methods), pre- and postintervention design using mixed methods (n=2), economic evaluation (n=2), and within-subjects design using mixed methods (n=1). Of these 10 studies, 5 were part of larger innovation or pilot implementation projects.

The study populations were older adults in general (n=4), older adults with dementia and their family CGs (n=11), and municipal employees working with GPS trackers for persons with dementia (n=1).

Table 1. Characteristics of the included studies (N=16).

Study, country	Aim	Intervention	Duration	Design	Participants
Magnusson et al [22], Sweden[a,b]	To investigate views and experiences of persons with dementia living at home, their CGs[c], and the staff involved in use and implementation of advanced electronic tracking; to analyze results in relation to ethics; and to discuss methodological aspects of research involving persons with dementia	Extended safety and support system Posifon in mobile phone	9 months	Nonrandomized experimental study with pre- and postintervention measurements	Older persons with dementia living at home and their family CGs. Recruited: 76 persons with dementia and 76 CGs; final sample: 20 persons with dementia and 36 CGs
Megges et al [23], Germany[a,b]	To perform an in-depth comparison of the user experiences of persons with dementia and their informal CGs with 2 similar commercial GPS watches in home dementia care; to study the products' clinical effectiveness in persons with dementia and CGs	2 GPS watches for people with orientation impairment (products A and B)	4 weeks for each product	Nonrandomized experimental study, 2×2 crossover	Dyads: persons with dementia and CGs. Recruited: 12 persons with dementia and 12 CGs; final sample: 4 persons with dementia and 8 CGs
Milne et al [24], Scotland[a,b]	To determine the feasibility of a prospective randomized controlled trial	GPS in watch or pendant, some with a geofencing option. CGs track persons with dementia and are contacted by monitoring agency if persons with dementia report that they are lost or have reached the geofence	4 months (mean and median), range 1-7 months	Mixed methods observational design	20 dyads: persons with dementia with a history of wandering and CGs
Olsson et al [25], Sweden[a,b]	To investigate the effects of using tracking technology on independent outdoor activities and psychological well-being in 3 persons with dementia and their spouses	Passive positioning alarm (transmitter based on GPS, cell phone, and support person)	Intervention phase B1: 5-7 weeks; intervention phase B2: 4-5 weeks	Nonrandomized experimental study with crossover design	3 dyads: persons with dementia and CGs
Pot et al [26], The Netherlands[a,b]	To investigate feasibility, acceptability, and effectiveness of 3-month use of GPS by persons with dementia and CGs	Tracking device (GPS and general packet radio service) worn on belt, including track and trace function, telephone contact, and loudspeaker function	3 months	Nonrandomized experimental study	Dyads: persons with dementia and CGs; persons with dementia in early stage of dementia. Recruited: 33; included: 28
Scheffer et al [27], The Netherlands[a,b]	To investigate the effects of a mobile safety alarm on frequency of going outside and experiences regarding fear of falling, feelings of being unsafe, and quality of life in older adults	Mobile safety alarm with a built-in drop sensor using a positioning system over a mobile phone network	6 months	Randomized controlled trial	Older adults using indoor alarm. Included: 203 (100 in intervention and 103 in control); final sample: 135 (58 in intervention and 77 in control)

Study, country	Aim	Intervention	Duration	Design	Participants
Ribas Miquel et al [37], Spain[d]	To describe the perceptions and experiences of professionals and family members of users and nonusers of GPS tracking devices	GPS tracking device	N/A[e]	Mixed methods observational design	30 care professionals, 7 family members of care receivers who use a GPS tracking device, and 7 family members of care receivers not using a tracking device
Røhne et al [28], Norway[b,f]	To verify if or how mobile safety alarms make older adults more independent, increase their mobility and physical activity, engage relatives and lead to reduced need for care, and increase the ability of older adults to live longer at home	Global System for Mobile communication or GPS-based alarm unit (hanging around the user's neck) with geofencing, voice connection, and tracking ability	2-9 months	Mixed methods with pre- and postintervention design[f]	Populations of older adults in Bærum, Skien, and Stavanger municipalities. Included in pilot: 71; included in evaluation: 46
Sørli [29], Norway[g]	To investigate the effects and the experiences of municipal employees of GPS use among persons with dementia on the quality of the municipal services	GPS tracking device	8 months	Observational design	19 municipal employees working with GPS for persons with dementia
Ausen et al [30], Norway[h]	To establish knowledge about users' and employees' experience of piloted GPS; to establish knowledge of the effects of use of the technology on users, employees, and the service; to identify potential gains; to describe service models for the use of various security and coping technologies in the municipality	GPS unit (possible to attach to key chain) for localization with geofencing alarm	1 year (mean)	Observational design[f]	Older adults living at home or in nursing homes in Larvik. 47 care receivers; number of employees unclear
Boysen and Støle [31], Norway[h]	To establish knowledge of the users' and employees' experience of the technologies being piloted; to identify potential gains; and to propose measures to realize the benefits	Mobile safety alarm with GPS tracking and geofencing (Safemate)	6 months	Mixed methods with pre- and postintervention design[f]	9 persons with dementia and with affiliation with either housing associations, nursing homes, or activity centers; 13 home users with follow-up of relatives

Study, country	Aim	Intervention	Duration	Design	Participants
Dahlberg [32], Sweden[h]	To perform a socioeconomic analysis in the form of a cost-benefit assessment of a mobile security alarm	Mobile safety alarm with GPS tracking, geofencing, and voice communication (Posifon, same as [22])	9-10 months	Economic evaluation	Persons with mild and more advanced dementia; persons with more advanced dementia with municipal care; all living in a home setting with some form of care from relatives. Approximately 80 (same as [22])
Malmquist [33], Sweden[h]	To assess the costs and benefits of passive alarms for users, their relatives, the municipality, and society; to develop a decision-making basis for prescription of different passive alarms; to increase knowledge regarding passive alarms and their costs and benefits for stakeholders	GPS or Global System for Mobile communication passive position alarm (bracelet) with geofencing function	37-260 days	Economic evaluation	8 persons with dementia living in home settings in Östersund municipality and their relatives or informal CGs. Prescribers of alarms within the municipality
Øderud et al [34], Norway[h]	To investigate how location technology can be organized and integrated as part of the municipalities' operational health and care services and to develop service models for interaction among public, private, and volunteer service providers to help persons with dementia and their CGs	GPS devices (1 of 3) with alarm, tracking, and voice communication features	Up to 1 year (58% of the users); 1-2 years (35% of the users), more than 2 years (7% of the users)	Mixed methods observational design[i]	Oslo inhabitants with dementia or dementia-like conditions, 94% living in their own home. 109 users; 216 in total (users and their relatives, employees in care services and at alarm center, and localization technology providers)
Røhne et al [35], Norway[h]	To investigate how mobile safety alarms can contribute toward enabling older adults to reside at home for as long as possible and to establish knowledge of how today's mobile safety alarms can be developed	Mobile safety alarm with tracking and voice communication	8-10 months	Mixed methods observational design[j]	Older adults living independently Recruited: 12; final sample: 10

Study, country	Aim	Intervention	Duration	Design	Participants
Vidensförmidling and Syd [36], Denmark[h]	To investigate whether early allocation of GPS alarms can provide greater security and quality of life for persons with dementia and their relatives and thereby reduce the need for help from the municipality	A combined GPS or Global System for Mobile communication device carried in a pocket or worn on the belt, individually adapted to the individual. Unit equipped with a call button, with which the person with dementia can call for help in the event of a fall or similar incident	At least three months	Mixed methods, within-subjects design; economic evaluation[k]	180 persons with dementia and their informal CGs living in the home setting in 5 municipalities

Summary of Findings

Table 2 presents an overview of the study findings from individual studies assessed using the NICE evidence standards framework for DHTs [8]. A more extensive version of the table, including the definition of minimum evidence and best practice standards for each category, is presented in Multimedia Appendix 3 [22-37]. As can be seen in Table 2, the included studies provide best practice evidence according to the standards of two of the five tier 1 evidence categories, that is, *Relevance to current pathways in health/social care system* and *Acceptability with users*. In more than 60% of the included studies, GPS devices had been successfully piloted or implemented in social care systems. All these studies had been performed in Nordic countries as part of larger projects supporting the development of products, services, and decision-making processes. Most of these projects were part of national government programs that aimed to stimulate the use of welfare technology. Furthermore, best practice evidence showing that representatives from the intended user groups (older adults and persons with dementia) were involved in the testing of the GPS alarms and that the users were satisfied with them was identified in 38% (6/16) of the included studies. Table 2 also shows that minimum standard evidence was identified for the tier 1 category *Credibility with health, social care professionals* because relevant social care professionals had been involved in 75% (12/16) of the included studies.

However, the evidence according to the standards for tier 2 evidence categories could not be assessed from the included studies. For example, because the alarm systems do not provide general information or advice to users concerning health, healthy living, lifestyle, diseases, illnesses, or conditions, the minimum and best practice standards were not relevant for this assessment. Nevertheless, the information that the alarm systems provides to formal and informal CGs and security service providers about user position and emergency situations must be accurate. None of the evaluated studies investigated the reliability of this information. However, one study elaborated on alarm testing and the timeliness of the transmission of information in case of an alarm during the development of test routines, and two studies investigated the CGs' views on the accuracy of the information regarding the user position and the user-friendly aspects of the interfaces. The two latter studies identified that some situations (eg, when users reach places with poor mobile coverage) can limit the updating of user position and thereby reduce the reliability of the system's information content.

Furthermore, evidence of ongoing data collection to show use and value could not be identified from the included studies. Indeed, several studies demonstrated use and value on study follow-up occasions. Use was reported both for specific system functions and on a system level with varied levels of detail. Although some studies collected use data from system logs, reporting by CGs or users was more common. The measured values for users (persons with dementia or older adults) related to improved outdoor activity (increased independence, fewer worries, increased frequency with regard to visiting new places and making longer trips, and increased or maintained physical activity level); improved relationship with CGs (fewer conflicts with CGs and more freedom); increased security and safety (increased security in daily life and prolonged period living independently); and increased QoL. The measured values for CGs of persons with dementia related to improved well-being, QoL, enhanced possibility of giving more freedom to persons with dementia, and improved security and safety. Finally, examples of measures for safeguarding (service models, test routines, and role of relatives or alarm center) in the use of GPS

alarms were described in three of the included studies. However, evidence according to the standards could not be identified.

Moreover, the included studies provide clear evidence of effectiveness in outcomes or improvements in outcomes relevant to tiers 3a and 3b. Of the 16 included studies, 10 [22-27,32,33,36,37] investigated the outcomes that could be related to effectiveness. The findings of the included RCT [27] were compared with the framework's standards for best practice evidence to demonstrate effectiveness in outcomes or improvements in outcomes. However, no increase in the frequency of older adults going outside was found in the intervention group, and no significant differences in secondary outcomes, including fear of falling, feelings of unsafety, or QoL, were identified [27]. The other nine studies that used observational or quasi-experimental designs were assessed with regard to requirements for minimum evidence standards (ie, demonstrating effectiveness in outcomes or improvements in outcomes). Improvements were indicated with regard to an increase in the percentage of days that persons with dementia were engaged in independent outdoor activity (there were indications of an increase in three cases based on CG reports; no statistical data were available) [25] and to a decrease in role-overload and feelings of worry for CGs of persons with dementia ($P>.05$) [26]. Furthermore, GPS tracker use was associated with an important decrease in time spent searching for persons with dementia who were lost [24]. However, the data were based on CG recall and could not be objectively verified. In addition, this outcome is more related to efficiency than effectiveness. Interestingly, one study found decreased activity among persons with dementia because of disease progression [22], and another study identified no significant changes in burden or QoL for CGs of persons with dementia [23]. In contrast, economic evaluations indicated reduced costs for the care of persons with dementia because of prolonged periods living independently instead of special housing (up to 3 months) [32,33,36]. As a crossover design was used, the difference in the mean CG burden between relatives of persons with dementia using or not using GPS trackers was indicated in small samples [37].

Table 2. Summary of findings in relation to the evidence categories of the evidence standards framework for digital health technologies (N=16).

Tiers	Findings	Studies, n (%)	Risk of bias[a]
Tier 1			
Credibility with health and social care professionals	• Minimum evidence standards show that relevant social care professionals were involved in the design, development, or testing of the GPS devices • In 12 (75%) [22,24,25,28-36] of the included studies, social care professionals were involved in the testing of the GPS devices to a varied extent	• 12 (75)	—[b]
Relevance to current pathways in health or social care system	• Minimum and best practice evidence standards show that GPS devices have been successfully piloted or implemented in social care systems. This was described in 10 (63%) of the included studies. Of these 10, 3 were performed in Sweden [22,32,33], 6 in Norway [28-31,34,35], and 1 in Denmark [36]. All of them were part of larger projects supporting development of products, services, and decision-making processes to support OAsc and their families in their homes. Most of those projects were part of national government programs that aimed to stimulate the use of welfare technology	• 10 (63)	—
Acceptability with users	• Best practice evidence shows that representatives from the intended user groups (persons with dementia and OAs) were involved in the design, development, or testing of the DHTd and to show that users were satisfied with the DHT • Representatives from the intended user groups (OAs in general or persons with dementia) were involved in testing of the GPS alarms in 15 (94%) of the studies (ie, all the included studies except [29]) • Six (38%) of these studies showed that the users were satisfied with the alarms: 77% of the CGse of persons with dementia stated that they would recommend the use of GPS alarms in the Pot et al study [26]; 97% of the OAs who participated in the Røhne et al study [28] and 90% of the OAs in the Røhne et al study [35] stated that they were satisfied with the alarm • All older users in the Ausen et al study [30] would recommend others in similar situations to use the GPS alarm • User satisfaction was confirmed in the interviews in the Milne et al study [24] and in the values identified in the Boysen et al study [31]	• 6 (38)	—
Equalities considerations	• No information retrieved from included studies. Socioeconomic aspects were not addressed • However, persons with dementia and OAs may be considered vulnerable groups	• 0 (0)	—
Accurate and reliable measurements (if relevant)	• No information retrieved from included studies. Technical validations were not included in the review. All included studies used commercial products	• 0 (0)	—
Accurate and reliable transmission of data (if relevant)	• No information retrieved from included studies. Technical validations were not included in the review. All included studies used commercial products	• 0 (0)	—
Tier 2			
Reliable information content	• Minimum and best practice standards category is not relevant for GPS devices because they do not provide general information or advice to users concerning health, healthy living, lifestyle, diseases, illnesses, or conditions • However, for reliability of information on user position and emergency situations, data on user testing were provided by 1 study (6%) [28], and data on CGs' perceptions of the accuracy of the GPS information were provided by 2 (13%) studies. For example, relatives and staff in the Øderud et al study [34] had experienced slow or unreliable information on the user's position. Moreover, [30] reported cases of poor mobile coverage that had resulted in failures in updating user position	• 0 (0)	—

Tiers	Findings	Studies, n (%)	Risk of bias[a]
Ongoing data collection to show use	• Cannot be assessed from the included studies. Evidence of ongoing data collection (required according to evidence standards for the category) was not reported in the included studies • However, 10 (63%) of the included studies presented data on use on specific occasions related to the interventions • In all, 3 studies (19%) reported quantitative data on usage period: [30] and [34] presented the number of participants who had used GPS trackers for up to 1 year and between 1 and 2 years, respectively. [33] reported the number of days that each participant had used the GPS trackers (mean 158 days, median 210 days, and range 37-260 days) • A total of 3 (19%) studies [22,25,28] included system logs in the collection of data to investigate use. Interestingly, [22] saw that the extent to which persons with dementia used mobile phone–based GPS varied widely among the participants. Moreover, [28] described that the logs from the technical systems were thoroughly analyzed to understand the role and function of users, alarm units, response center, CGs, and relatives • In all, 4 (25%) studies [23,24,26,27] based the data collection of use on the recall of the users or their CGs, and 2 of these [26,27] reported that the persons with dementia did not always take along the GPS devices (mobile phone or tracker worn on the belt) when going out and that the devices were not always switched on	• 0 (0)	—
Ongoing data collection to show value	• Cannot be assessed from the included studies. Evidence of ongoing data collection to show value (required according to evidence standards for the category) was not reported • However, 11 (69%) of the included studies presented data on use for values related to the health and welfare outcomes of users (OAs, persons with dementia, and CGs of persons with dementia) on specific occasions related to the interventions; one (6%) study [22] identified that CGs experienced that the persons with dementia had become more independent in outdoor activity; 1 (6%) study [24] identified that CGs and staff saw that GPS trackers could give persons with dementia in milder stages of dementia and their CGs increased freedom and decreased stress and anxiety; and 1 (6%) study [26] identified values perceived by some of the CRsf, including increased freedom and decreased worries and fewer conflicts with CGs when going outside alone. Moreover, the CGs experienced that they gave more freedom to the CR and some experienced fewer conflicts with the CR • Another study (6%) [28] identified that more than 50% of the users thought that the GPS alarm helped to increase their freedom • One study (6%) [29] noted that more than 50% of the participating staff perceived that GPS trackers for persons with dementia could, to some degree, free up time for service providers by reducing the number of inspections they carried out to see if the person is well, driving to and from the user and following the user on walks; [30] identified that all persons with dementia thought that GPS trackers enabled them to increase or maintain physical activity, to increase freedom in outdoor activities, and that all relatives experienced that the GPS trackers increased their feelings of safety when leaving the person with dementia by themselves; and [31] identified positive values of GPS trackers both in shared housing for persons with dementia, including freedom for persons with dementia, decreased stress and anxiety for employees, time savings for staff and cost reduction, and for home users, including increased security, with, in some cases, increased outdoor activity and CG relief • Another study [32] identified that 5 of the 8 GPS tracker users experienced increased security and could continue to live at home for a longer periods. In addition, 5 of the 8 relatives experienced fewer concerns and worries; [34] noted that most of the users perceived that the GPS trackers provide security (for the user, CG, and staff), increase freedom for the user and sometimes also the CG, as well as help the user to be physically active and maintain their activity level; [35] identified that most of the GPS alarm users experienced that it increased their safety and freedom in daily life; and [36] identified that the GPS tracker increased the security and quality of life of persons with dementia and their CGs	• 0 (0)	—
Quality and safeguarding		• 0 (0)	—

Tiers	Findings	Studies, n (%)	Risk of bias[a]
	• Cannot be assessed from the included studies • However, 3 (19%) of the included studies had a study aim or presented data related to system-level quality and safeguarding: [30] and [34] presented the service model for implementation of GPS trackers in the homes of older adults, which included safeguarding measures taken by the municipality. Moreover, [34] presented data on the roles of different actors (users, relatives, and alarm centers) in charging and administration of the alarm as well as locating and retrieving the user, if necessary • One study (6%) [28] described the establishment of an initial test routine to encourage users to regularly trigger the alarm when out walking		
Tier 3a			

Demonstrating effectiveness in outcomes or improvements in outcomes	• Effectiveness is not demonstrated in outcomes or improvements in outcomes according to best practice standards: no increase in the frequency of OAs going outside; no significant differences in changes in fear of falling, feelings of unsafety, or quality of life [27]
	• Effectiveness is not demonstrated in outcomes or improvements in outcomes according to minimum evidence standards. Indications were identified for the following:
	  • Decrease in time searching for person with dementia (from a mean of 3-4 hours per event to 40 minutes) [24]
	  • Increase in the number of days that person with dementia was engaged in independent outdoor activity (three cases, no statistics available) [25]
	  • Decrease in role-overload of CGs of persons with dementia (P=.126; d=–0.25 for all CGs, and P=.119; d=–0.34 for CGs who could reach CR with the mobile alarm) and in feelings of worry (P=.08; d=–0.32 for all CGs, and P=.057; d=–0.46 for CGs who could reach CR with the alarm) [26]
	  • Reduction in costs for care of persons with dementia because of prolonged time that the person could live independently instead of in special housing (up to 3 months) [32,33,36]
	  • Difference in mean CG burden between relatives of persons with dementia using and not using GPS (P=.04) was indicated in small samples because a crossover design was used [37]
	• Outcomes investigated with negative results:
	  • Activity of person with dementia: reduced because of disease progression [22]
	  • Burden and quality of life for CGs of persons with dementia: no significant changes [23]
		• 1 (6)
		• 7 (44)
		• 2 (12)
			• High
			• High
			• High

Use of appropriate behavior change techniques (if relevant)	• Not relevant for GPS devices: no behavior change techniques used	• 0 (0)	—
Tier 3b			
Demonstrating effectiveness: improvements in outcomes	• Effectiveness is not demonstrated in improvements in outcomes according to minimum evidence or best practice standards (see above)	• 0 (0)	—

[a]Risk-of-bias assessment: a “high” risk of bias is equivalent to “high” for the Cochrane Risk-of-Bias Tool 2.0 (randomized studies) or “serious/critical” for the Risk of Bias in Non-randomized Studies of Interventions Tool (nonrandomized studies), and a “low” risk of bias is equivalent to “low” for the Cochrane Risk-of-Bias Tool 2.0 (randomized studies) or “low/moderate” for the Risk of Bias in Non-randomized Studies of Interventions Tool (nonrandomized studies).

[c]OA: older adult.

[d]DHT: digital health technology.

[e]CG: caregiver.

[f]CR: care receiver.

Risk of Bias

The summaries of the assessed risk of bias for individual studies that aimed to demonstrate evidence of effectiveness are presented in Table 3 (nonrandomized studies) and Table 4 (randomized study). The overall risk of bias was assessed to be serious or critical in all nonrandomized studies, particularly bias due to confounding and in measuring outcomes

[22-26,32,33,36,37]. The RCT was assessed as having a high risk of bias, in particular with regard to the blinding of patients or personnel and incomplete outcome data [27].

Table 3. Risk-of-bias assessments for individual studies investigating effectiveness according to standardized criteria for nonrandomized studies using the Risk of Bias in Non-randomized Studies of Interventions Tool. The tool's scale for ascending risk is low, moderate, serious, and critical.

Domains of bias	Study								
	Magnusson et al [22]	Megges et al [23]	Milne et al [24]	Olsson et al [25]	Pot et al [26]	Ribas Miquel et al [37]	Dahlberg [32]	Malmquist [33]	Vidensförmidling and Syd [36]
Bias due to confounding	Serious	Serious	Critical	Moderate	Serious	Serious	Critical	Critical	Critical
Bias in selection of participants	Low	Low	Critical	Serious	Low	Serious	No information	Serious	No information
Bias in classification of interventions	Low	Low	Low	Low	Low	Moderate	No information	Moderate	Moderate
Bias in deviations from intervention	Low	No information	Low	Low	Serious	No information	Serious	No information	No information
Bias due to missing data	Critical	Moderate	Serious	Low	Moderate	No information	No information	Low	No information
Bias in measurement of outcomes	Serious	Serious	Serious	Serious	Serious	Serious	Moderate	Critical	Serious
Bias in selective reporting	Low	Moderate	Serious	Low	Low	Low	Serious	Serious	Serious
Overall bias	Critical	Serious	Critical	Serious	Serious	Serious	Critical	Critical	Critical
Comments or direction of bias	Unpredictable	Unpredictable	Unpredictable	Unpredictable	Unpredictable	Unpredictable	Unpredictable	Unpredictable	Unpredictable

Table 4. Risk-of-bias assessments for individual studies investigating effectiveness according to standardized criteria for randomized studies using the Cochrane Risk-of-Bias Tool 2.0. Bias is assessed as low, high, or unsure (when sufficient information is not available to allow assessment).

Risk of bias domain	Study (Scheffer et al [27])
Random sequence generation	Low
Allocation concealment	Low
Blinding of participants or personnel	High
Blinding of outcome assessment	Unsure
Incomplete outcome data	High
Selective reporting	Low
Other bias	Unsure
Comments	High dropout, especially in the intervention group where the provided foremost reason was that the participants found the alarm too big and heavy

Discussion

Principal Findings

GPS alarms are implemented in social care with the aim of supporting users in independent activities of daily living, particularly outdoors. This systematic review included 16 studies investigating the effects of GPS alarms on health, welfare, and social provision in older adult care. The review demonstrates best practice evidence in peer-reviewed and gray literature for two of the tier 1 evidence categories (*Relevance to current pathways in health/social care system* and *Acceptability with users*) of the NICE evidence standards framework for DHTs [8]. The approach of using an existing framework to assess the quality of studies is relevant for all types of DHTs. This review also presents evidence of the minimum standard for the tier 1 category *Credibility with health, social care professionals*, although the minimum standard is insufficient for high-risk DHTs such as technologies that track patient location. More specifically, the studies in this review showed that social care professionals have been involved in the testing of alarm systems; that GPS trackers have been successfully piloted or implemented in the Swedish, Norwegian, and Danish social care systems; that representatives from the intended user groups (persons with dementia and older adults) have been involved in testing the alarm systems; and that users were satisfied with the alarm systems. Although a number of studies reported findings regarding use, value, and measures for safeguarding at specific time points, our review concluded that evidence categories for tier 2 could not be assessed from the included studies. Finally,

this review identified a lack of clear evidence for effectiveness according to the standards of evidence categories in tiers 3a and 3b in the NICE framework, which is required for DHTs that track patient location [8]. Moreover, the overall risk of bias of the included studies that evaluated effectiveness was assessed to be high. Therefore, the study findings should be interpreted with caution.

Some of the included studies demonstrated negative or absent effects on healthy behaviors and on the users' health and welfare. For example, the only RCT included in our review demonstrated no effect of GPS trackers on older adults' frequency of going out, feelings of unsafety, or fear of falling, and the authors stated that "some of the participants did not take the mobile alarm outside with them at all times. This might have been caused by perceived user - unfriendliness of the alarm [27].

Moreover, a nonrandomized intervention study demonstrated that activity among persons with dementia was reduced during the intervention and concluded that this was due most likely to disease progression [22]. The need to identify primary user groups has been addressed in previous research on GPS alarms for older adults [10]. Both examples illustrate the complexity of this type of intervention in populations of persons with dementia, which might increase the risk of bias due to deviations from the interventions and to missing data, respectively. Additional potential challenges for RCTs investigating the use of GPS alarms in persons with dementia were identified in a feasibility study [24] and included challenges in finding social care staff willing to recruit participants, randomizing the participants, and finding participants or CGs willing to participate as controls [24].

It should be pointed out that GPS trackers and the context of use varied among the studies included in this review; simply put, these studies evaluated different wearables, technical infrastructures, and supporting services. For example, some studies reported on insufficient usability of the trackers, which might have limited their use. However, the rapid development of mobile health systems has enabled the incorporation of GPS alarms in discrete wearables such as bracelets and pendants or consumer products that older adults are already using in daily life. These more sophisticated wearables might help to overcome the obstacles of poor usability and the potential stigma of older GPS devices such as mobile trackers attached to the belt or additional mobile phones. Hence, the usability, acceptability, and desirability of GPS wearables need to be addressed in future research [38]. Other aspects that are relevant to investigate in future studies of GPS use include the system's ease of use (including usability and learnability) and the users' readiness (including expectations [39] and eHealth literacy [40]). In addition, involving user groups in the design of user interfaces and supporting services can be effective in the development of new systems that meet the needs of user groups and the context of use [41,42].

The alarm systems studied have been implemented to varying degrees in the social care systems of different countries. User and CG support services also varied across the studies: in some cases, CGs were the sole alarm receivers, whereas in others, resources from a security company or the municipality have supported the CGs.

Interestingly, economic effects are likely to be affected by the value models and organization of national social care systems. In this review, the heterogeneity of the studies in terms of population, context, and systems was high; therefore, the generalizability of the results is uncertain.

Further research on service development, implementation of information and communication technologies in the public sector, profit realization, processes for change, contribution to political goals, business models, and health and welfare has been recommended to support the implementation of GPS alarms in older adult care [10]. Studies in this review that were found in gray literature have demonstrated progress in these areas (eg, usable and acceptable systems that were properly integrated in the social care services of Nordic countries). These studies were conducted as a part of larger projects—often within national programs to promote the use of HWTs among older adults—that aimed to study and develop products, services, and methods for implementation.

Notably, the studies included in this review identified outcomes that might be relevant for future studies investigating the effectiveness of GPS-based mobile alarms on the health and welfare of older adults and social care provision. Furthermore, outcomes related to the health and welfare of CGs of persons with dementia might be relevant for further investigation [23,26]. Other outcomes related more to efficiency, such as time spent searching for persons with dementia who were lost [24], may be less useful in assessing effectiveness and should therefore be considered as complementary or secondary.

This review identified a need to establish evidence in several evidence categories in all tiers of the NICE evidence framework. Evidence for tiers 1 and 2 might be identified from several sources, including product documentation from suppliers of HWT products; expert authorities; and initiatives for service development, piloting, and implementation of HWT products. However, for tiers 3a and 3b, further research on the effectiveness of GPS-based mobile alarms is still needed.

Limitations

A potential limitation of this review is the exclusion of studies with a qualitative design as well as technical validation studies. The findings from these types of studies might have been relevant for providing evidence for tiers 1 and 2. The study findings were assessed using the NICE evidence standards framework for DHTs [8], which includes evidence categories (especially in tiers 3a and 3b) that do not support qualitative studies. However, other evaluation strategies exist [43]. In addition, the searches were restricted to the English and Nordic languages, thus excluding studies published in other languages.

Comparison With Prior Work

The findings of this review are in line with previous reviews of GPS tracker use among older adults (including persons with dementia), which identified limited evidence on the effectiveness of GPS tracker use on health-related outcomes, for example [10-12]. The previous reviews provided a broader picture of

state-of-the-art research on GPS tracker use in older adult care [10] and for managing wandering behavior among persons with dementia [11]. For example, the study by Røhne et al [10] categorized findings in different research areas from 74 articles published from 1998 to 2016. The study by Røhne et al [10] concluded that research on GPS had increased significantly by 2014-2015, most likely because of the increased use of smartphones, wearables, and other health technologies, and had concentrated, up to that time, on identifying the primary user groups and their needs and experiences. Moreover, the study by Røhne et al [10] identified knowledge gaps related to service development, implementation of information and communication technologies in the public sector, profit realization, change processes, contributions to political objectives, business models, and health and well-being that need to be filled for location services to be used as ordinary services in Norwegian municipalities. This systematic review could not identify a large increase in published studies of the effectiveness of GPS alarms on health, welfare, and social care outcomes after 2014. On the contrary, the publication years of the studies included in this review are rather evenly distributed over the search period (two each in 2012 and in the years 2014-2017, one each in 2011 and 2018, and four in 2013). It is worth mentioning that the included economic evaluations were published in 2011 and 2013.

Moreover, the scoping review by Neubauer et al [11], which included studies that used any type of study design or methodology with positive or negative results, identified that the most commonly used wander management technology—from scholarly and gray literature—was GPS, followed by alarms and sensors, with only 22% of the devices clinically tested in home or institution settings. The review by Neubauer et al [11] concluded that further research is needed to identify technologies with high levels of evidence for effectiveness and usability. The seven studies on mobile locators included in the review by Neubauer et al [11] were published in the period 2000-2012. Interestingly, no overlap in the included studies was identified between the review by Neubauer et al [11] and this review. However, this review had a small overlap of four studies with a synthesizing review by Bartlett et al [12], which included empirical studies of persons with dementia or their family CGs or both using GPS. A total of 23 studies published in the period 2007-2016 were included, and data were synthesized across three identified themes: using GPS to prevent harm and promote well-being; taking control; and value of GPS data [12]. The review by Bartlett et al [12] found only nontrial evidence and identified a lack of large-scale studies. This review therefore complements the previous reviews in several aspects: first, by analyzing data from different studies, mainly because of the inclusion of only quantitative results; second, by contributing results published after 2016; and third, by reviewing the current evidence on GPS trackers according to the requirements of the NICE framework. So far, the NICE framework has been used for examples of case studies that demonstrate evidence of the effectiveness and economic value of a number of DHTs [9]. These studies are based largely on information provided by the developers that has not been independently verified. Study results published in peer-reviewed and gray literature can therefore strengthen the validity of evidence of DHTs. We have not been able to identify prior systematic reviews of evidence related to HWTs that have applied the NICE framework to the study findings. However, one study has used the framework for classifying medical mobile apps [44]. We envision that the number of studies that apply the NICE framework for various purposes will increase in the future and contribute to demonstrating evidence related to HWTs.

Implications for Clinical Practice and Future Research

This review has identified a need for further research to provide the required evidence for the effects of the use of GPS-based mobile alarms on the health and welfare of older adults and social care provision. On the basis of the NICE evidence standards framework, examples of successful piloting of GPS alarms in social care systems and of testing that involved older adults and CGs have been identified.

The results can be beneficial to the social care organizations that see the potential in GPS alarms to support older citizens' independence in daily living activities. First, we demonstrated that there is a lack of evidence of the clinical effectiveness of GPS trackers in the care of older adults. Hence, the ongoing implementations of GPS trackers have not been based on evidence of their clinical effectiveness. Second, we clarified the risks of implementing patient-locating systems such as GPS with insufficient evidence based on the NICE evidence framework. On the basis of the framework, the types of potential risks associated with the use of HWTs with insufficient evidence (eg, safety risks for the user and inefficient use of resources) can be identified. Social care organizations can use this knowledge to make informed decisions on whether they should wait for, or demand, more evidence before they start using new HWTs. Hence, increased awareness of what can be gained from better evidence is important. Third, we presented experiences from successful piloting of GPS trackers in social care systems, for example, with regard to suitable user groups, usable and acceptable GPS solutions, customization and development of products and services, processes for decision-making, and implementation. The level of evidence regarding effectiveness and economic value needs to be considered in decision-making processes on the implementation of HWTs when potential benefits and risks need to be balanced. After all, money spent on improving the health of older adults needs to be spent wisely and efficiently.

This review has identified critical knowledge gaps that need to be addressed in future research, most importantly with regard to clinical effectiveness. Open questions include the clinical effectiveness of specific GPS trackers for certain user groups with defined supporting services. The included studies can contribute with positive examples of implementation on which to base future research (eg, products, user groups, and service models) and with challenges that have been experienced in previous research. Potential evolutions of this review are future studies on the clinical effectiveness of already implemented or piloted GPS trackers in their *real-world* implementation environment. Thus, the interventions to be evaluated should include user groups and service models that have been identified and developed in the previous implementation or pilot projects.

In addition, generating real-world evidence during the implementation of GPS trackers in social care systems seems to be of great importance in addressing the evidence gaps.

Conclusions

There is insufficient evidence for the effects of the use of GPS-based mobile alarms on the health and welfare of older adults, as well as social care provision. Best practice evidence for two of the tier 1 evidence categories and evidence of minimum standard for the tier 1 category of the NICE evidence standards framework for DHTs [8] were identified. This review identified that social care professionals have been involved in the testing of GPS trackers, that GPS trackers have been successfully piloted or implemented in the Nordic social care systems, that representatives from the intended user groups (persons with dementia and older adults) have been involved in testing the devices, and that users were satisfied with them. Although a number of studies have contributed data demonstrating use, value, and measures for safeguarding at specific time points, our review concluded that the evidence categories for tier 2 could not be assessed from the included studies. Finally, this review demonstrated a lack of clear evidence of effectiveness according to the standards of evidence categories in tiers 3a and 3b in the NICE framework, which is required for DHTs that track patient location [8]. Future research needs to address clinical effectiveness broadly and incorporate aspects related to products, user groups, service models, and challenges in social care systems in the *real world*.

Acknowledgments

This research is funded by Mälardalen University and the Sörmlandskontraktet regional funding partnership.

Authors' Contributions

ME conducted the literature assessment, data extraction, and risk-of-bias analysis together with MR; summarized the results and assessed them by using the NICE framework; and wrote the manuscript with input from all coauthors. MR conducted the literature assessment, data extraction, and risk-of-bias analysis together with ME and reviewed the study findings and their application by using the NICE framework. SLS contributed search strategies, performed literature searches, documented the search results, prepared the references for screening, and resolved conflicts that arose during the screening. SWA conceptualized the research questions. KR made contributions related to the NICE framework. All authors contributed to the study conceptualization, scientific discussions, and the manuscript review, and all have accepted the final version of the manuscript.

Abstract

Background: Gait speed measurements are widely used in clinical practice, as slow gait is a major predictor of frailty and a diagnostic criterion for sarcopenia. With the development of wearable devices, it is possible to estimate the gait speed in daily life by simply wearing the device.

Objective: This study aims to accurately determine the characteristics of daily life gait speed and analyze their association with sarcopenia.

Methods: We invited community-dwelling men aged >50 years who had visited the outpatient clinic at a tertiary university hospital to participate in the study. Daily life gait speed was assessed using a wearable smart belt (WELT) for a period of 4 weeks. Data from participants who wore the smart belt for at least 10 days during this period were included. After 4 weeks, data from a survey about medical and social history, *usual gait speed* measurements, handgrip strength measurements, and dual-energy x-ray absorptiometry were analyzed.

Results: A total of 217,578 daily life gait speed measurements from 106 participants (mean age 71.1, SD 7.6 years) were analyzed. The mean daily life gait speed was 1.23 (SD 0.26) m/s. The daily life gait speed of the participants varied according to the time of the day and day of the week. Daily life gait speed significantly slowed down with age (P<.001). Participants with sarcopenia had significantly lower mean daily life gait speed (mean 1.12, SD 0.11 m/s) than participants without sarcopenia (mean 1.23, SD 0.08 m/s; P<.001). Analysis of factors related to mean daily life gait speed showed that age and skeletal muscle mass of the lower limbs were significantly associated characteristics.

Conclusions: More diverse and accurate information about gait speed can be obtained by measuring daily life gait speed using a wearable device over an appropriate period, compared with one-time measurements performed in a laboratory setting. Importantly, in addition to age, daily life gait speed is significantly associated with skeletal muscle mass of the lower limbs.

KEYWORDS

gait speed; sarcopenia; skeletal muscle mass; wearable device

Introduction

Background

Globally, populations are aging, including in Korea, where the population is aging rapidly because of extended life expectancy [1] and a low fertility rate. In 2017, more than 14% of the total population in Korea was aged ≥65 years.

Frailty, as a reflection of decreased physiological reserve, is closely associated with increased biological age [2], concurrent medical conditions, morbidity, and decreased survival in older individuals [3]. Frailty assessments are clinically useful for determining the heterogeneous health status of older individuals [4]. Sarcopenia, defined as low muscle mass and low muscle strength, is a key characteristic of frailty [5-7]. Recently, the treatment of sarcopenia has become a key strategy for preventing and overcoming frailty [8].

Slow gait speed is a major feature of frailty [9] and a diagnostic criterion for sarcopenia [6,7]; therefore, gait speed measurement is widely used to assess frailty. However, gait speed measurement methods are not completely standardized, and the term *usual gait speed* refers to a measure that has been commonly used as part of this fast, safe, and inexpensive assessment [10,11]. *Usual gait speed* is calculated by instructing the individual to walk a certain distance at their usual pace in the laboratory and then measuring the time it takes to cover that distance.

Currently, technology is advancing at a rapid pace in the area of wearable devices, which can be used to measure a variety of attributes. Wearable sensors allow frequent and continuous measurements of body functions, including various physical activities, such as walking, running, and biking [12]. With the availability of these wearable devices, it is possible to measure and track daily life gait speed in the real world without significant additional effort by asking the patient to wear the device [13,14]. Moreover, it is questionable whether the *usual gait speed* measured in the laboratory can represent daily gait speed in an individual's real world [15]. Few studies have compared *usual gait speed* and real-world gait speed in analyses of the associations between muscle mass or muscle strength and gait speed.

Objectives

The primary aim of this study was to identify the characteristics of daily life gait speed in community-dwelling older male adults and to analyze the association of these characteristics with sarcopenia. The secondary objective was to compare the results of daily life gait speed obtained using a wearable device with *usual gait speed* measured in the laboratory by analyzing the associations of muscle mass and muscle strength with gait speed.

Methods

Study Population

This observational study was conducted at Seoul National University Bundang Hospital. Men aged >50 years who could walk unassisted were recruited consecutively from November 16, 2018, to April 12, 2019.

Study Protocol

The WELT (WELT Corp, Ltd) is a belt-type wearable device that uses a triaxial accelerometer to continuously measure the wearer's gait speed while walking. The smart belt measures the walking speed using the step interval time and stride length. An algorithm for detecting and analyzing peaks is used to identify the steps. Two consecutive peaks are detected as steps occur, and the step interval time between the peaks is measured in 0.1-second increments. There are several ways to estimate stride length, and WELT adopts a method that uses a sex-based constant and height [16,17]. As a result, it is possible to continuously measure gait speed that changes with the step interval time.

Participants were asked to wear the WELT for 4 weeks as they went about their daily lives, and their daily life gait speed was recorded. After 4 weeks, a survey that included questions about social history and past medical history was administered, *usual gait speed* and handgrip strength measurements were obtained, and a dual-energy x-ray absorptiometry (DEXA) was performed.

Usual gait speed was calculated for each participant using distance in meters and time in seconds. A marked walkway and an automated laser-gated chronometer attached to the wall were used to calculate gait speed [18]. The walkway consisted of a 1-m acceleration phase, 4.5-m timed section, and a 1-m deceleration phase. The chronometer started and stopped automatically as each participant crossed into and out of the timed section. The participants were instructed to walk at their usual pace. Handgrip strength was measured using a Jamar Plus digital hand dynamometer (Patterson Medical). Participants were seated in a chair with their shoulder adducted and neutrally rotated, their elbow flexed to 90°, and their forearm and wrist neutrally positioned. A total of three consecutive measurements of the dominant hand were taken with a brief rest between measurements, and the average scores were obtained and recorded in kilograms. DEXA was used to measure the limb skeletal muscle mass of the participants. It is very useful for body composition analysis because fat mass, nonbone lean mass, and bone mineral content can be differentiated at both the regional and whole-body levels [19]. A Horizon W machine (Hologic Inc) was used to measure appendicular skeletal muscle mass [20]. Before the DEXA scan, participants were asked to remove all metal objects and change into hospital gowns. Scanning was performed by an imaging technician in the laboratory. The scan time was approximately 10 minutes. Appendicular skeletal muscle mass was calculated as the sum of the muscle mass of both arms and legs.

Sarcopenia was defined based on the diagnostic criteria of the Asian Working Group for Sarcopenia [6]. Low muscle strength was defined as a handgrip measurement of <28 kg. Low physical performance was defined as a *usual gait speed* of <1.0 m/s. Sarcopenia was diagnosed when the individual demonstrated a low appendicular skeletal muscle mass and low muscle strength or low physical performance.

Daily life gait speed was analyzed using data from participants who wore the wearable device for at least 10 days during the 4-week study period. The characteristics of daily life gait speed in the real world were identified, and the association between

daily life gait speed and sarcopenia was analyzed. In addition, *usual gait speed* and daily life gait speed were compared by an analysis of the association between muscle mass or muscle strength and gait speed.

Statistical Analysis

All statistical analyses were performed using SPSS version 21.0 (IBM Corporation). Continuous variables were expressed as mean (SD) and were compared using either a two-tailed unpaired *t* test or one-way analysis of variance. Discrete variables were expressed as counts and percentages, and the proportions were compared using the chi-square test or Fisher exact test. We used correlation analysis and linear regression analysis to identify factors related to daily life gait speed. All statistical analyses were two tailed, and $P<.05$ were considered statistically significant.

Ethical Standards

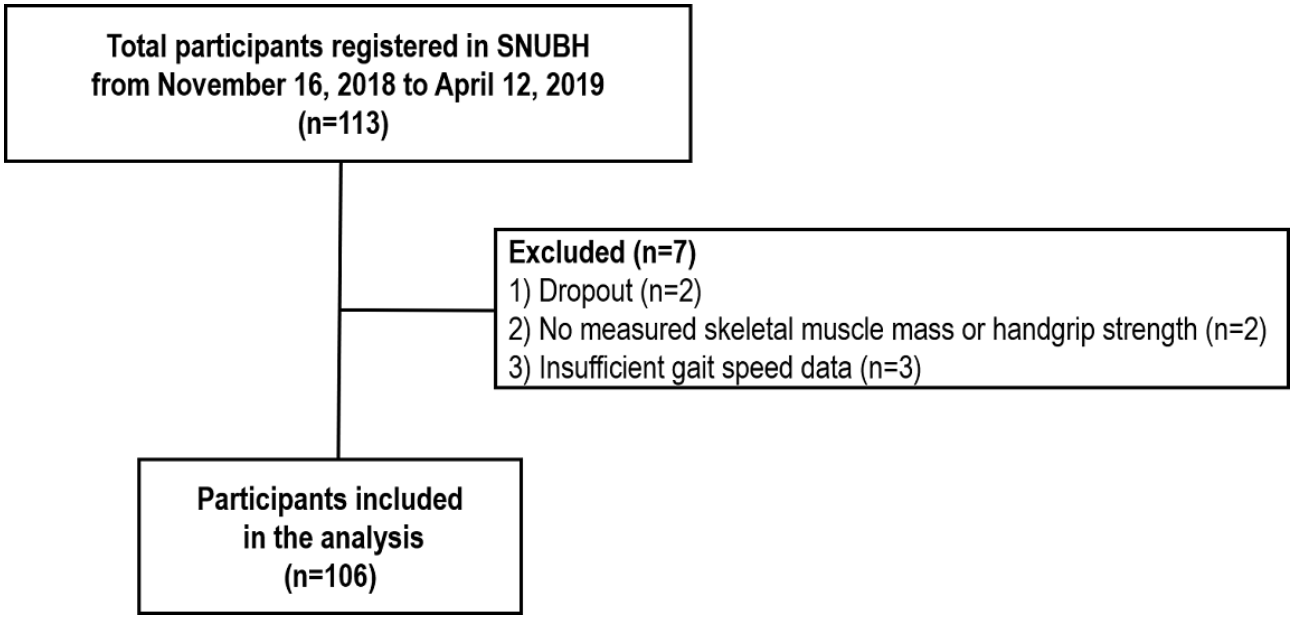
This study was approved by the institutional review board of Seoul National University Bundang Hospital (Institutional Review Board No. B-1808/486-002). All participants provided written informed consent before participation. The study was performed in accordance with the principles of the Declaration of Helsinki.

Results

Characteristics of Study Participants

A total of 217,578 daily life gait speed measurements were analyzed from 106 participants who completed the study (Figure 1). The average age of the participants was 71.1 (SD 7.6; range 52-90) years, and the average number of gait speed measurements per participant was 2052.6 (SD 1022.3; range 618-4783). The mean daily life gait speed of the participants was 1.23 (SD 0.26; range 0.94-1.39) m/s, and the average walking time per day was 88.0 (SD 40.2; range 30.5-176.5) minutes.

Figure 1. Flow diagram of the study population. SNUBH: Seoul National University Bundang Hospital.



Characteristics of Daily Life Gait Speed Measured Using a Wearable Device

The characteristics of daily life gait speed were presented in Figure 2. The daily life gait speed was significantly lower in older individuals ($P<.001$). Participants walked the fastest between 5 AM and 7 AM and the slowest at night ($P<.001$). There was a statistically significant difference in daily life gait speed according to the day of the week ($P<.001$), and weekday gait speed (mean 1.23, SD 0.26 m/s) was significantly faster than weekend gait speed (mean 1.22, SD 0.26 m/s; $P<.001$). Walking time per day differed significantly on weekdays (mean 93. 4, SD 47.0 minutes) and weekends (mean 74.5, SD 41.6 minutes; $P<.001$).

To compare daily life gait speed with *usual gait speed*, the daily life gait speed for each participant was calculated as a percentile compared with their own *usual gait speed*. The participants' daily life gait speed varied widely. The corresponding percentiles ranged from 30.3 percentile to 181.0 percentile, with a median value of 102.9 percentile. In their daily lives, a walking speed >25% faster than their own *usual gait speed* was observed in 13.46% (29,279/217,578) of the total number of measurements, and a walking speed >25% slower than their own *usual gait speed* was observed in 14.58% (31,728/217,578) of the total number of measurements. In the analysis of the correlation between daily life gait speed and *usual gait speed*, only a negligible correlation was confirmed (Pearson $r=0.155$; $P<.001$; Figure 3). However, in the analysis of the correlation between mean daily life gait speed and *usual gait speed*, a moderate positive correlation was confirmed (Pearson $r=0.504$; $P<.001$; Figure 3). In the analysis of the correlation between the SD of daily life gait speed and *usual gait speed*, only a negligible correlation was confirmed (Pearson $r=0.195$; $P=.046$; Figure 3). In addition, no significant correlation was found

between the coefficient of variation of daily life gait speed and *usual gait speed* (Pearson r=−0.139; P=.16; Figure 3).

Figure 2. The characteristics of daily life gait speed measured using a wearable device. Comparison of daily life gait speed (A) by age group; (B) by time of day; (C) by day of the week; (D) between weekdays and weekends.

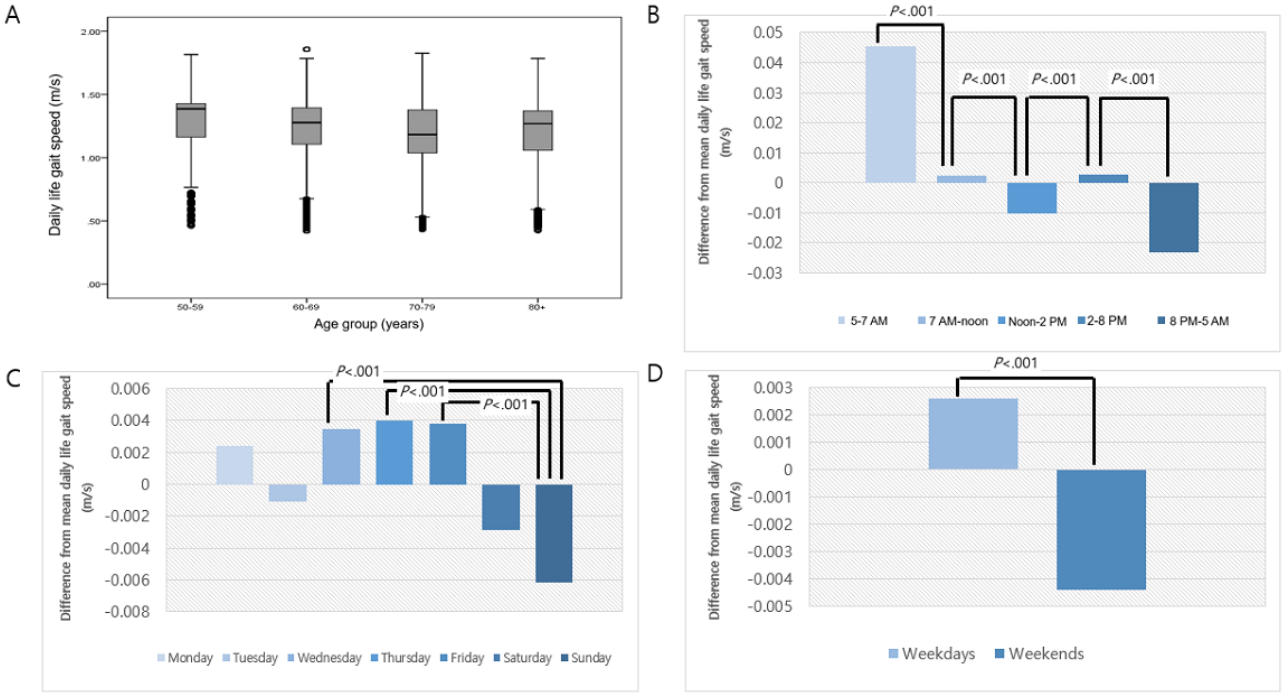


Figure 3. Scatterplot of daily life gait speed and usual gait speed. (A) Scatterplot of daily life gait speed and usual gait speed (Pearson correlation coefficient = 0.155; P<.001). (B) Scatterplot of mean daily life gait speed and usual gait speed (Pearson correlation coefficient = 0.504; P<.001). (C) Scatterplot of SD of daily life gait speed and usual gait speed (Pearson correlation coefficient = 0.195; P=.046). (D) Scatterplot of coefficient of variation of daily life gait speed and usual gait speed (Pearson correlation coefficient = −0.139; P=.16).

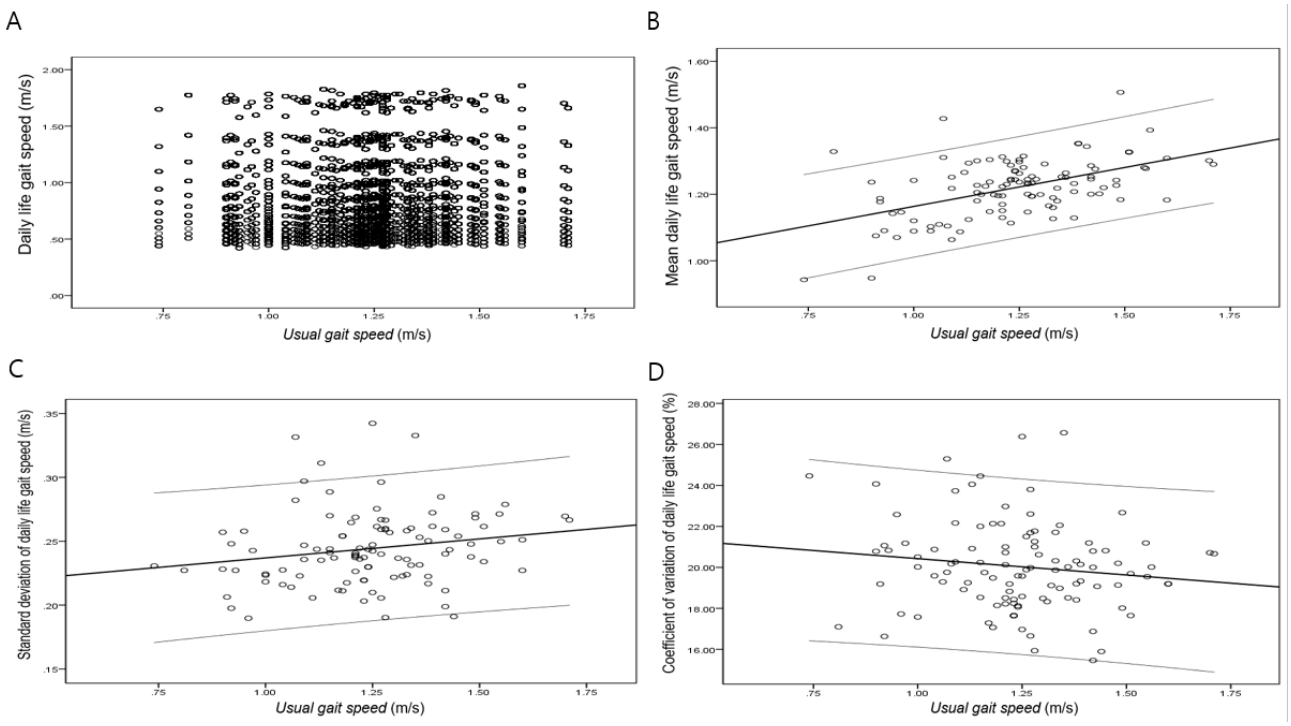

Comparison Between Study Participants With and Without Sarcopenia

Participants with low muscle strength (handgrip strength <28 kg) had significantly lower daily life gait speed than those with normal muscle strength (mean 1.15, SD 0.25 m/s vs mean 1.23, SD 0.26 m/s; P<.001). There were also significant differences in daily life gait speed between participants with low muscle mass (appendicular skeletal muscle mass <7.0 kg/m^2) and those

with normal muscle mass (mean 1.22, SD 0.26 m/s vs mean 1.25, SD 0.26 m/s; *P*<.001).

A total of 13 participants (13/106, 12.3%) were diagnosed with sarcopenia based on the diagnostic criteria of the Asian Working Group for Sarcopenia. Participants with sarcopenia (mean 76.0, SD 6.2 years) were older than participants without sarcopenia (mean 70.5, SD 7.6 years; *P*=.01) and had significantly lower mean daily life gait speed than normal participants (mean 1.12, SD 0.11 m/s vs mean 1.23, SD 0.08 m/s; *P*<.001). Sarcopenic participants had significantly lower handgrip strength and lower appendicular skeletal muscle mass. In addition, among participants with sarcopenia, the proportion of patients who had angina and were current smokers was significantly higher (Table 1).

Table 1. Comparison between study participants with and without sarcopenia.

Characteristics	Total (N=106)	Sarcopenia (n=13)	Normal (n=93)	*P* value
Age (years)				.01

Mean (SD)	6.74 (0.74)	6.39 (0.34)	6.79 (0.77)	
Range	5.21-8.87	5.68-6.97	5.21-8.87	

[a]Average grip strength measured three times in the dominant hand.

Participants with sarcopenia walked faster from 5 AM to 7 AM than at other times of the day (*P*<.001); however, there were no significant differences between weekday and weekend gait speeds (*P*=.64). Participants with sarcopenia (mean 78.2, SD 45.4 minutes) had significantly less walking time per day than participants without sarcopenia (mean 89.3, SD 46.3 minutes;

P=.03). In addition, there was no significant difference in walking time per day between weekdays (mean 82.4, SD 46.3 minutes) and weekends (mean 67.8, SD 42.1 minutes) in the participants with sarcopenia (*P*=.17). In the analysis of the correlation between daily walking time and sarcopenia-related factors, it was observed that grip strength, skeletal muscle mass of the lower limbs, and *usual gait speed* had a negligible correlation with walking time (walking time and grip strength: Pearson *r*=0.111; *P*=.003; walking time and skeletal muscle mass of the lower limbs: Pearson *r*= 0.152; *P*<.001; and walking time and *usual gait speed*: Pearson *r*=0.112; *P*=.002). Analysis of the correlation between daily walking time and mean daily life gait speed revealed a low positive correlation (Pearson *r*=0.315; *P*<.001).

There was no significant difference between the mean daily life gait speed (mean 1.12, SD 0.11 m/s) and the median value of daily life gait speed (mean 1.11, SD 0.12 m/s; *P*=.45) in participants with sarcopenia, but those without sarcopenia had median values (mean 1.27, SD 0.13 m/s) significantly higher than the mean values (mean 1.23, SD 0.08 m/s; *P*<.001). There was no significant difference in the SD of daily life gait speed in participants with sarcopenia (mean 0.23, SD 0.02 m/s) and those without sarcopenia (mean 0.25, SD 0.03 m/s; *P*=.06). There was also no significant difference in the coefficient of variation in daily life gait speed between participants with sarcopenia (mean 20.58%, SD 2.37%) and those without sarcopenia (mean 19.96%, SD 2.13%; *P*=.34).

Factors Associated With Mean Daily Life Gait Speed

The correlation analysis of the potential factors associated with mean daily life gait speed showed that age, height, and skeletal muscle mass of the lower limbs were significantly correlated with mean daily life gait speed (Table 2). In a linear regression analysis with correlated factors, age and lower skeletal muscle mass were significantly associated with mean daily life gait speed. Participants who were younger and had more skeletal muscle mass in their lower limbs walked faster (Table 3).

Table 2. Correlation analysis (Pearson *r* and one/two-tailed *P* values) with mean daily life gait speed.[a]

Variable	Mean daily life gait speed	Age	Height	Body weight	BMI	Skeletal muscle mass of the lower limbs
Mean daily life gait speed						
r	1	−0.357	0.333	0.108	−0.074	0.383

[a]Dependent variable is mean daily life gait speed.

[b]N/A: not applicable.

Comparison Between Daily Life Gait Speed and Usual Gait Speed in the Analysis of Associations With Muscle Mass and Muscle Strength

A correlation analysis of gait speed, handgrip strength, and appendicular skeletal muscle mass showed that mean daily life gait speed was significantly and positively correlated with handgrip strength (Pearson r=0.380; P<.001) and appendicular skeletal muscle mass (Pearson r=0.355; P<.001). *Usual gait speed* had a significant positive correlation with handgrip strength (Pearson r=0.501; P<.001) but was less correlated with muscle mass (Pearson r=0.227; P=.02).

Discussion

Principal Findings

In this study, we showed that daily life gait speeds varied depending on the time of day and day of the week. Daily life gait speed showed greater variability than *usual gait speed*. The mean daily life gait speed was lower in participants with sarcopenia. When analyzing factors related to daily life gait speed, age and skeletal muscle mass of the lower limbs were significantly associated with mean daily life gait speed. The mean daily life gait speed was significantly and positively correlated with handgrip strength and appendicular skeletal muscle mass.

Walking speed is a valid and reliable measure for assessing the functional status of older adults [21], and identification of a slow walking speed is a simple approach to the diagnosis of frailty [22]. Gait speed at an individual's usual pace is known to be associated with survival in older adults [23] and has been widely used as a tool to predict adverse outcomes in community-dwelling older individuals, including falls, disability, institutionalization, and mortality [9,24]. However, one study demonstrated that *usual gait speed* does not represent daily life gait speed because it is not strongly related to daily gait speed [15]. Assessment of daily life gait speed showed that the men in our study walked significantly faster in the morning than during the rest of the day, and men with sarcopenia also walked faster in the morning. People may walk faster in the early morning because they usually have to go to work or attend social activities at a specified time. Participants in our study also walked faster on weekdays than on weekends. However, this difference was not significant in individuals with sarcopenia. This may be related to a decrease in the daily life gait speed of participants with sarcopenia, especially a decrease in the use of a fast gait speed. This is supported by the fact that men without sarcopenia often walked faster than their mean daily life gait speed, whereas participants with sarcopenia did not. As gait speed varied depending on the time of day and day of the week and the distribution of gait speed was very diverse, it would be difficult to accurately reflect the actual gait speed of individuals using one or two *usual gait speed* measurements obtained in the clinical setting. In fact, we found that the Pearson correlation coefficient between daily life gait speed and *usual gait speed* was negligible [25]. In addition, although the direct correlation between walking time and sarcopenia-related factors is not clear, people who spend more time walking tend to walk faster in their daily lives. An increase in walking-related exercise may be associated with a decrease in sarcopenia [26].

In this study, the mean value was used to represent the daily life gait speed to identify factors related to gait speed and to analyze the associations between gait speed and sarcopenia. Age and skeletal muscle mass of the lower limbs were significantly associated with the mean daily life gait speed. Reduced walking speed is associated with increasing age [27,28]. A decrease in the muscle mass of the lower limbs is also associated with a decrease in gait speed [29].

The participants in our study who had sarcopenia walked significantly more slowly in their daily lives than those without sarcopenia. This result was expected considering that patients with sarcopenia demonstrate various deteriorations in their physical performance [30,31]. Gait speed is a representative indicator of physical performance and is included in the diagnostic criteria for sarcopenia [6,7]. Diagnostic criteria commonly use the results of a 4- or 6-m *usual gait speed* test. Analyzing associations between daily life gait speed, muscle strength, and muscle mass, daily life gait speed also accurately reflects the sarcopenic state.

Advances in wearable devices have made it possible to continuously measure daily gait speed in the real world. As men usually wear belts in their daily lives, belt-type wearable devices can be used to measure daily life gait speed as naturally as possible over a long period. In fact, smart belt wearers can check their average walking speed on a daily, weekly, or monthly basis using a specific application. Therefore, older people would be able to identify a decrease in their physical performance in real life and, if so, would be able to visit health care providers for active intervention.

Strengths and Limitations

This study had several strengths. First, the analysis was performed using gait speed data measured more than 200,000

times over a period of ≥10 days. Therefore, the results reflect the actual gait speed of the participants more accurately than the current common practice of *usual gait speed* measured in a laboratory at only one point in time. Second, the skeletal muscle mass of participants was accurately measured by the standard method using DEXA, and it was confirmed that the skeletal muscle mass of the lower limbs had a statistically significant association with gait speed. Third, we found that walking speed could be measured continuously over a long period using a belt-type wearable device. On the basis of these results, it is feasible to carry out more precise longitudinal studies in the future, including studies focused on the prediction of a negative prognosis related to a change in walking speed.

This study has some limitations. First, we could not determine a causal relationship between skeletal muscle mass and gait speed because of the limitations inherent to the cross-sectional study design. A second limitation was that the study included only male participants. We chose male participants as Korean women who met our age criterion of >50 years do not usually wear belts, and we wanted to be certain that the participants could wear the device with ease. Accordingly, the findings observed in this study cannot be applied to women who usually do not use belts. To overcome this problem, we considered two solutions to this limitation. One was to improve the esthetic look of the belt so that women could wear it as a fashion accessory. The other was to place a plastic case containing the sensor, circuit, and battery in the same position as the buckle of the belt in the form of a clip.

Finally, we developed an algorithm for detecting and analyzing gait speed, but this has not been fully validated. However, a previous study reported that a method based on the detection of heel-strike events using a triaxial accelerometer to confirm that each step is suitable for measuring gait speed [32]. In our unpublished data, when comparing the gait data measured using WELT with that measured using video readings in 10 healthy adults, the mean step count was 95.9% (SD 4.2%) consistent. The mean sensitivity of the WELT step detection algorithm was 87.9% (SD 2.8%), and the mean positive predictive value was 92.4% (SD 3.3%). However, there were no data regarding gait speed in patients with pathological gait patterns such as neurologic (Parkinson disease) or orthopedic conditions. Further studies are required to confirm the validity of wearable device–based gait speed measurements.

Conclusions

Diverse and accurate information can be obtained by measuring daily life gait speed using a wearable device. Daily life gait speed is significantly associated with age and skeletal muscle mass of the lower limbs. As gait speed is a representative indicator of physical performance, older individuals would be able to detect a decrease in physical performance in real life by checking their walking speed. In addition, as it is possible to measure daily gait speed continuously over a long period using a wearable device, daily life gait speed data will be available for use in future longitudinal studies. Further studies are needed, especially studies aimed at developing a method to accurately measure women's daily life gait speed as naturally as possible.

Abstract

Background: Mobile apps targeting women with breast cancer can facilitate access to information, improve well-being, and record reports of treatment-related symptoms. However, it is important to confirm the benefits of these apps before they are used as a tool in clinical care.

Objective: The aim of this study was to evaluate the functionality and the usability of a mobile app created to guide and monitor patients with breast cancer undergoing radiation therapy.

Methods: The evaluation process of the mobile app was performed in 2 steps with 8 professionals, including nurses, physician, medical physicists, and communication networks engineer. The first step was the focus group, which allowed obtaining suggestions proposed by the participants regarding the improvement of the mobile app. The second step was the individual filling in of an evaluation tool to obtain objective measures about the mobile app. A minimum concordance index of 80% was considered to ensure the adequacy of the material.

Results: After the mobile app was evaluated by 8 professionals, only 1 item of the evaluation tool, that is, concerning the potentiality of the app to be used by users of different educational levels, obtained a concordance index <80%.

Conclusions: The mobile app titled “AMOR Mama” was considered suitable, which suggests its contribution to an educational health technology to guide and monitor patients with breast cancer undergoing radiation therapy. More studies with this target population should be carried out to assess the performance and quality of the mobile app during its use.

Introduction

Cancer is a leading cause of disability and mortality worldwide, affecting more than 18 million people each year [1]. Breast cancer is the most frequent among women, with approximately 2.1 million new cases diagnosed in 2018 [2]. Radiation therapy is a treatment modality that uses ionizing radiation to prevent the multiplication of tumor cells and to determine their death by delivering radiation to the tumor with the least possible damage to the healthy surrounding tissues [3]. When the breast

region is exposed to radiation therapy, the most common side-effects are pain, radiation dermatitis, restricted mobility, local sensory alteration, and fatigue [4]. In addition to the physical factors related to the disease and treatment, it is worth mentioning the negative psychological impacts caused by breast cancer, mainly on the perception of body image, sexuality, and femininity [5]. Therefore, nurses need to perform their care role related to cancer and therapy effects as a facilitator in the coping process when providing comprehensive and individualized care to patients.

Mobile apps can help individuals in managing their own health and well-being as well as in promoting healthy lifestyles and obtaining quick access to important information. The use of mobile technologies has brought innovative possibilities for improving health care provision [6]. A study reported the development of a mobile app prototype to assist health care professionals in the prevention and classification of pressure ulcers. The app was evaluated for technical and functional quality by experts in the field of computing and nursing, and it was considered adequate with respect to reliability, usability, efficiency, functionality, and portability [7]. Another study described the development and evaluation of an app to support decision-making in the process of early mobilization of critical patients admitted to an intensive care unit. The app was evaluated by 58 physiotherapy undergraduate students, and it was considered practical and easy to understand and manipulate [8]. A separate study focused on the development and testing of a tablet app to collect computerized data on tobacco use among psychiatric patients and the general population, thereby replacing paper surveys. This app prevented human errors, allowed automatic tabulation, and made the interviews less tiring [9]. A recent systematic review suggests that apps for women with breast cancer can facilitate access to information and improve patients' well-being as well as improve the report of symptoms and adverse treatment-related effects. However, the real benefit of using apps is still uncertain since the apps are often introduced into clinical care before necessary research is carried out to confirm their benefits [10]. In this context, this study aimed to evaluate the functionality and the usability of a mobile app created to guide and monitor patients with breast cancer undergoing radiation therapy.

Methods

Study Design

This is a methodological research focusing on the evaluation of the functionality and usability of a mobile app prototype for patients with breast cancer undergoing radiation therapy. The app was entitled "AMOR Mama" and features content of an educational manual developed and validated in a previous study called as "Orientations Manual: breast radiation therapy" [11]. The manual contains 36 pages, divided into pretextual items (cover, back cover, cataloguing sheet, index, presentation, and registration card), textual items (chapters on radiation therapy, stages of treatment, adverse effects of radiation therapy, and how to prevent them), and posttextual items (latest information, weekly diary, and bibliographical references).

The features and functionality of the app were then defined and associated with the textual content of the validated manual. Among them, we can mention user registration; registration of events in calendar and medications in use, including the possibility of generating automatic reminders through notifications; calculation of the water intake target according to the user's weight; recording and monitoring of signs and symptoms related to breast radiation therapy, as well as recommendations and necessary care. The data registration was planned to be used in the preparation of reports that can be forwarded to the health team involved in the user's care, thus facilitating their monitoring.

We aimed to develop a prototype of an app with relevant information and useful resources to encourage interaction between the user and the app. It has 5 menus that list the main sections: Home Page, About Radiation Therapy, Diary, Schedule, and Settings. One of the features of "Settings" is the tutorial that was designed to be the user's initial experience during their first access.

Methodological Reference

We chose to use the standard published by the International Organization of Standardization and the International Electrotechnical Commission, revised and translated by the Brazilian Association of Technical Standards, named as NBR ISO/IEC 9126-1. This standard describes a quality model for software products, which is composed of 2 parts: internal and external quality and quality in use [12]. The internal and external quality of the software refer to a group of characteristics that the model must present to be able to meet the user's needs, such as functionality, usability, reliability, efficiency, maintainability, and portability [12]. Quality in use involves 4 characteristics: effectiveness, productivity, safety, and satisfaction. It is related to the evaluation of the final product from the user's point of view, which is measured according to the performance obtained by the target audience when using the software. It is necessary to guarantee the internal and external quality of software to obtain the quality in use [12].

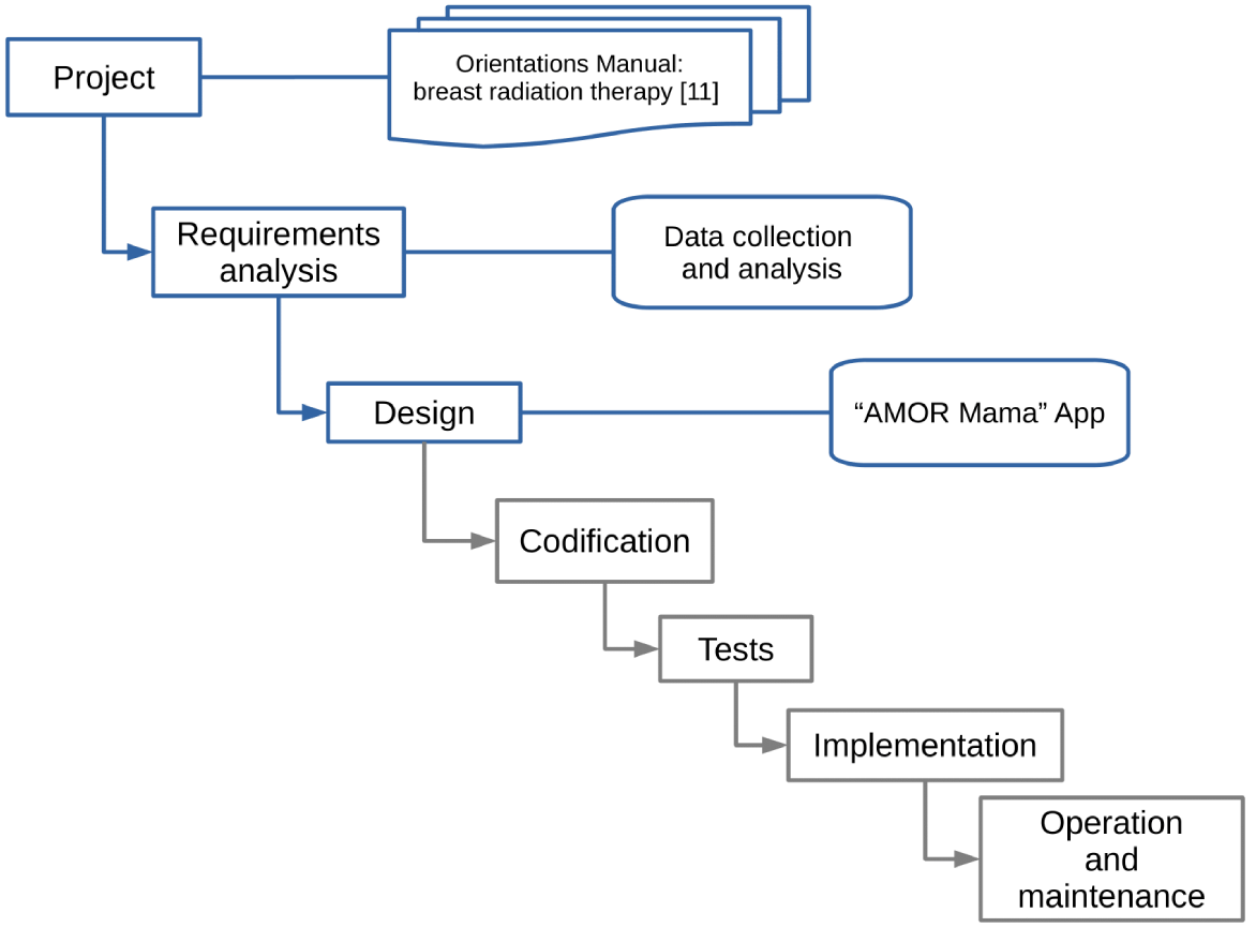
This study carried out the internal and external quality of the software, and the characteristics of functionality and usability were investigated since what is being evaluated is a prototype of an app, that is, a set of screens that present the interface and the proposed functions for the app and not the software that is already developed. The functionality is related to the potentiality of the app to offer the functions and resources that meet the needs of users, that is, the degree to which the software is able to provide functions that satisfy such needs [12,13]. Usability is achieved when the software has intelligibility, apprehensibility, and operability, that is, when it is easy to understand, to learn, and to operate [12]. Good usability is directly related to the success of the software in which the user is able to employ the functions and resources offered by the app with ease and efficiency [13].

Process of the Mobile App Design Assessment

This study carried out actions that involve the development of software up to the modeling phase, that is, the elaboration and analysis of a project. A project is the representation of the

aspects of software that are visible to the user such as the interface layout and the display formats on the screen [13]. Figure 1 shows the software development cycle: the blue boxes show the steps that were developed in this study while the gray boxes show the steps that will be developed in a future study.

Figure 1. Phases of software development. The blue boxes show the steps that were developed in this study while the gray boxes show the steps that will be developed in a future study.



The evaluation process of the app prototype was performed in 2 steps. The first one was the focus group, which allowed obtaining the suggestions proposed by the participants regarding the improvement of the app. The second step was the individual filling in of an evaluation tool to obtain objective measures about the mobile app. The researcher presented the display screens of the mobile app prototype during the meeting of the focus groups, with the aid of a multimedia projector. The interface was exhibited and its functionality demonstrated.

Research Participants

Intentional nonprobabilistic sampling was used, considering that the sample must be defined according to the study objectives. The factors used to choose these professionals were then determined according to their academic degree, specialization, scientific production, knowledge, and time of work, according to the adaptation of the evaluation system defined in the Fehring model (1987) [14]. The recommendation is that at least 8 participants perform the design assessment of the mobile app [15]. The invitation was sent by email to 20 professionals qualified to participate in the study. Six professionals expressed interest in participating; however, they were not available during the days and times foreseen for the focus group, while 6 other professionals did not respond to the invitation even after 3 attempts to contact them. Therefore, 8 professionals participated in this research who attended the focus group at an agreed date and time.

Data Collection and Analysis

The data were collected from November to December 2019. There were difficulties in scheduling a single meeting with all the professionals, given the specificities and individual demands. Therefore, 2 focus groups were held at different dates and times, previously agreed with the participants. The suggestions obtained through the focus groups were transcribed and analyzed by the researchers both within each focus group and comparatively between the 2 focus groups carried out to identify suggestion patterns. The quantitative data were collected using a Likert scale evaluation tool, which allowed objective measures to be obtained in relation to participants' opinions about the app prototype. This tool was adapted from a preexisting questionnaire [16], with the necessary changes and adjustments in relation to the theme addressed in this study. It has 5 levels of judgment regarding the items: no, in parts, not sure, yes, and certainly. The options yes and certainly were grouped and represent the adequacy of the item. To determine the adequacy

of the app prototype, a minimum concordance index of 80% was determined among the participants [17]. The set composed of options yes (Y) and certainly (C) should comprise at least 80% of professionals' responses to determine the quality of the app. Thus, concordance index was calculated by the mathematical formula: (Y+C)×100/total responses. Each item that obtained concordance index below 80% was analyzed and the app was improved according to the participants' suggestions, scientific literature, and clinical evidence.

Ethical Aspects of the Research

This research project was sent to the Research Ethics Committee of the College of Health Sciences of the University of Brasilia (CEP/FS-UnB) and approved by Opinion 2.608.031, CAAE: 71348417.7.0000.0030.

Results

Profile of the Research Participants

For the mobile app evaluation, the sample consisted of 8 professionals, including nurses, doctor, medical physicists, and communication network engineer. Regarding gender, 5 were women and 3 were men. The age of the professionals ranged from 24 to 43 years (mean 32 [SD 6] years), while educational background ranged from 2 to 20 years (mean 8 [SD 6] years) and that of working in the subject area from 1 to 20 years (mean 7 [SD 6] years). Regarding the highest academic degree, 6 participants had master's degrees and 2 were specialists.

Process of the Mobile App Design Assessment

The professionals' evaluations (N=8) were analyzed quantitatively. In the evaluation tool, the options yes and certainly were grouped to represent the adequacy of the item. Table 1 shows the judgment of the experts and the concordance index for each item of the evaluation tool. The focus was to investigate the participants' opinion regarding the usability of the mobile app and the possibility of it being recommended for wide use by patients with breast cancer undergoing radiotherapy. Only item 19 did not reach the minimum concordance index established, reaching 75% of agreement among the experts. All other items reached a minimum concordance index of 80% (range 88%-100%).

In item 19, the professional who marked the option "in parts" gave the following justification for their choice: "I believe that the initial guidelines for tomography and symptoms—as presented in the text—are not simple for patients with different levels of education (E4)."

Table 1. Professionals' assessment regarding the usability and functionality of the mobile app prototype.

Evaluation items	Experts' levels of judgement (N=8)					Concordance index (%)[a]
	No	In parts	Not sure	Yes	Certainly	
1. It seems to be easy to understand the concept and manipulation of the app.	0	0	0	1	7	100
2. The app appears to be self-explanatory.	0	0	0	0	8	100
3. The tutorial is useful to optimize the use of the app.	0	0	0	1	7	100
4. The organization of the menu is logical.	0	0	0	1	7	100
5. Icons are clear and intuitive.	0	0	0	1	7	100
6. The look of the app (design and layout) is attractive.	0	0	0	2	6	100
7. It appears to be easy to navigate the app screens.	0	0	0	1	7	100
8. The sequence of actions in the app is consistent.	0	0	0	1	7	100
9. The app has useful functions.	0	0	0	2	6	100
10. The app appears to be accurate in performing its functions.	0	0	0	1	7	100
11. It seems easy to find information in the app.	0	0	0	2	6	100
12. It seems easy to insert personal information in the app.	0	0	0	2	6	100
13. It seems easy to insert events and medications into the app.	0	0	0	3	5	100
14. The texts in the app are easy to read.	0	0	0	2	6	100
15. The illustrations are important to complement the texts and facilitate the use of the app.	0	0	0	0	8	100
16. The screens are visually pleasing and seem to encourage the use of the app.	0	0	0	1	7	100
17. Using the app seems simple and accessible.	0	0	0	2	6	100
18. It seems possible to maintain interaction between the user and the app.	0	0	0	2	6	100
19. The app can be used by users of different educational levels.	0	1	1	4	2	75
20. I believe that most users would learn how to use the app.	0	0	1	2	5	88
21. The app can be used anywhere, such as at home, hospital, or street.	0	0	1	1	6	88
22. I would recommend the app to be used by women with breast cancer undergoing radiation therapy.	0	0	0	0	8	100

[a]Concordance index was calculated by the sum of yes and certainly judgments: (Yes+Certainly)×100/total of responses.

Research Participants' Suggestions

After analyzing the suggestions of the focus groups, the changes proposed by the participants and the researchers' decisions regarding whether to accept such changes in the final version of the app are described in Table 2. It is worth mentioning that the communication networks engineer was the professional that suggested the most number of changes, which are mainly related to the functions and resources of the app.

Table 2. Summary of the participants' proposed changes and the researchers' decision.

Items (list of changes)	Participants' changes proposed	Decision
Icon	Change the app title "A.M.O.R. Mama" to "AMOR Mama"	Accepted
Tutorial		
1	Replace "About the app" (from Portuguese *Sobre o app*) with "Tutorial"	Accepted
2	Add an introduction screen to the tutorial	Accepted
3	Add information about the home page	Accepted
4	Replace "Clicking on this icon at the navigation bar (…)" (from Portuguese *Clicando neste ícone na barra de navegação(...)*) with "Here you will find your diary, where you will be able to insert (…)" (from Portuguese *Aqui você encontrará o seu Diário, onde poderá registrar (...)*)	Accepted
5	Replace "Clicking on this icon at the navigation bar (…)" with "On this icon you will access your calendar, where you will be able to insert (…)" (from Portuguese *Neste ícone você terá acesso a sua Agenda, onde poderá cadastrar (...)*)	Accepted
6	Replace "Clicking on this icon at the navigation bar (…)" with "Here you will be able to change your personal data and obtain information about (…)" (from Portuguese *Aqui você poderá alterar seus dados pessoais e obter informações sobre (...)*)	Accepted
7	Add a tutorial completion screen	Accepted
Home page	Add a home page that includes the information recorded daily in the schedule	Accepted
About radiation therapy		
1	Add explanatory videos recorded by the team and in the real treatment environment	Accepted
2	Add links to informational content available on the web	Not accepted
3	In "Steps of the Treatment" (from Portuguese *Etapas do Tratamento*), include the possibility of adding the date and time of the tomography	Accepted
4	In "Adverse Effects" (from Portuguese *Efeitos Adversos*), add a direct link to the schedule, allowing the insertion of appointments already scheduled at the institution	Accepted
Diary		
1	Add "Export data" (from Portuguese *Exportar dados*) next to the download icon	Accepted
2	Add the possibility to select the period and data to download	Accepted
3	Replace "Symptoms" (from Portuguese *Sintomas*) with "Signs and Symptoms" (from Portuguese *Sinais e Sintomas*)	Accepted
4	In "Signs and Symptoms," include a postmastectomy chest wall image	Not accepted
5	In "Care" (from Portuguese *Cuidados*), replace the checkboxes with radio buttons	Accepted
6	In "Care," include information about the water intake goal	Accepted
7	In "Notes" (from Portuguese *Anotações*), include the possibility of adding photos next to the user's comments	Accepted
Schedule		
1	Add a screen that highlights the 2 features of this topic ("Events" from Portuguese *Eventos* and "Medicines" from Portuguese *Medicamentos*)	Accepted
2	In "Events," allow the exclusion of an event previously included (add an "X" next to the notification symbol)	Accepted
3	In "Medicines," allow the exclusion of a drug previously included (add an "X" next to the notification symbol)	Accepted
4	In "Medicines," add mechanisms that facilitate their insertion	Accepted
5	In "Medicines," add a list of possible drugs to be added	Not accepted
Settings		
1	Add a screen that highlights the 3 features of this topic ("Registration" from Portuguese *Cadastro*, "Tutorial," and "About the App")	Accepted
2	In "About the app," add "Contact Info" (from Portuguese *Contato*), "Terms of Use" (from Portuguese *Termos de Uso*), and "Privacy Policy" (from Portuguese *Política de Privacidade*)	Accepted

Discussion

Main Results

The design of the mobile app "AMOR Mama" was based on an educational manual developed and validated in a previous study named as "Orientations Manual: breast radiation therapy" [11]. The features and functionality of the app were then defined and associated with the textual content of the validated manual. The participants' judgments were generally consistent (Table 1). Only 1 item of the evaluation tool, which was related to the potentiality of the app to be used by users of different educational levels, obtained a concordance index <80%, considering that 1 expert chose the option "not sure" and another chose the option "in parts" for that item. One of the experts believed that the guidelines presented in the text are not accessible for people with different levels of education. One way to reduce the difficulties in reading and facilitate communication is by using images that are associated with the textual content. Thus, to create a visual representation and illustrate the app, figures and photos obtained in the real treatment environment of patients undergoing radiation therapy were included.

Remote access to health information through mobile technologies contributes to the solution of the patient's needs without restriction of time and space, thereby promoting the overcoming of barriers and both, the extension of assistance, and the reach of health benefits [18]. In this way, caregivers and family members who are often unable to be present in the treatment environment of patients can help those who have a low level of education, especially in relation to reading and interpreting the information offered by an app that can be accessed freely in any place at any time of the day. Furthermore, a suggestion that emerged during a discussion in one of the focus groups and which was accepted to be implemented in the app was to add explanatory videos related to the stages of radiation therapy, with the health team as actors in a real environment of treatment. This suggestion is very pertinent and useful to complement the textual content and facilitate the understanding for users, especially for those who have a low level of education. In the following study of coding and evaluation of the software, the stages of preparing the scripts, training the team, and recording and editing the explanatory videos to be inserted in the app will also be carried out. Therefore, the content offered by the app must be intelligible, informative, succinct, objective, and delivered to the user in an appropriate manner, that is, through correct texts in relation to spelling and concordance and associated with representative images, which assist in the interpretation of the information provided. The aesthetics must be pleasant, reducing distractions and favoring the interaction between the user and the software [13]. The content must also be constructed consistently. The formatting of the text and its font style, size, and color must be the same throughout all the screens developed, thereby maintaining a standard. In any software design model, consistency is an attribute that must be considered. The graphic design must consist of a pattern of style, aspects, and colors, which provides a consistent interface in relation to the interaction, navigation, and display of content and functionalities [13]. Therefore, a graphic design with well-planned mechanisms provides spontaneous and intuitive interaction with the user. In this study, the interface of the app was designed to be simple, easy to understand, visibly pleasant and attractive, as proposed by a study that focused on the development of an app for teaching the International Classification for Nursing Practice. The development of this app also took into account the importance of attractiveness and objectivity so that some aspects such as the choice of textual content and its font and size as well as the colors of the design provided visual and dynamic comfort in the delivery of information [19]. However, in addition to consistency, the app must have an identity. The aesthetics of the interface must provide affinity with the user to whom the software will be directed [13]. In the elaboration of the app prototype proposed in this study, female aspects were taken into consideration, such as the choice of the predominant color and the images related to the female universe (clothing being illustrated by images of dress and bra and skin care being illustrated by photographs of a woman and female breasts) in addition to the communication being directed to the female gender. Regardless of the information or functionality provided by the app, the screen layout is responsible for shaping the user's perception of the software, creating a medium of communication between them. In this context, a software user expects to find content and functions relevant to their needs in addition to intuitive and predictable navigation. Without adequate graphic design, an app for mobile devices may be quite functional, but it would not be attractive and, in turn, would not have good usability [13].

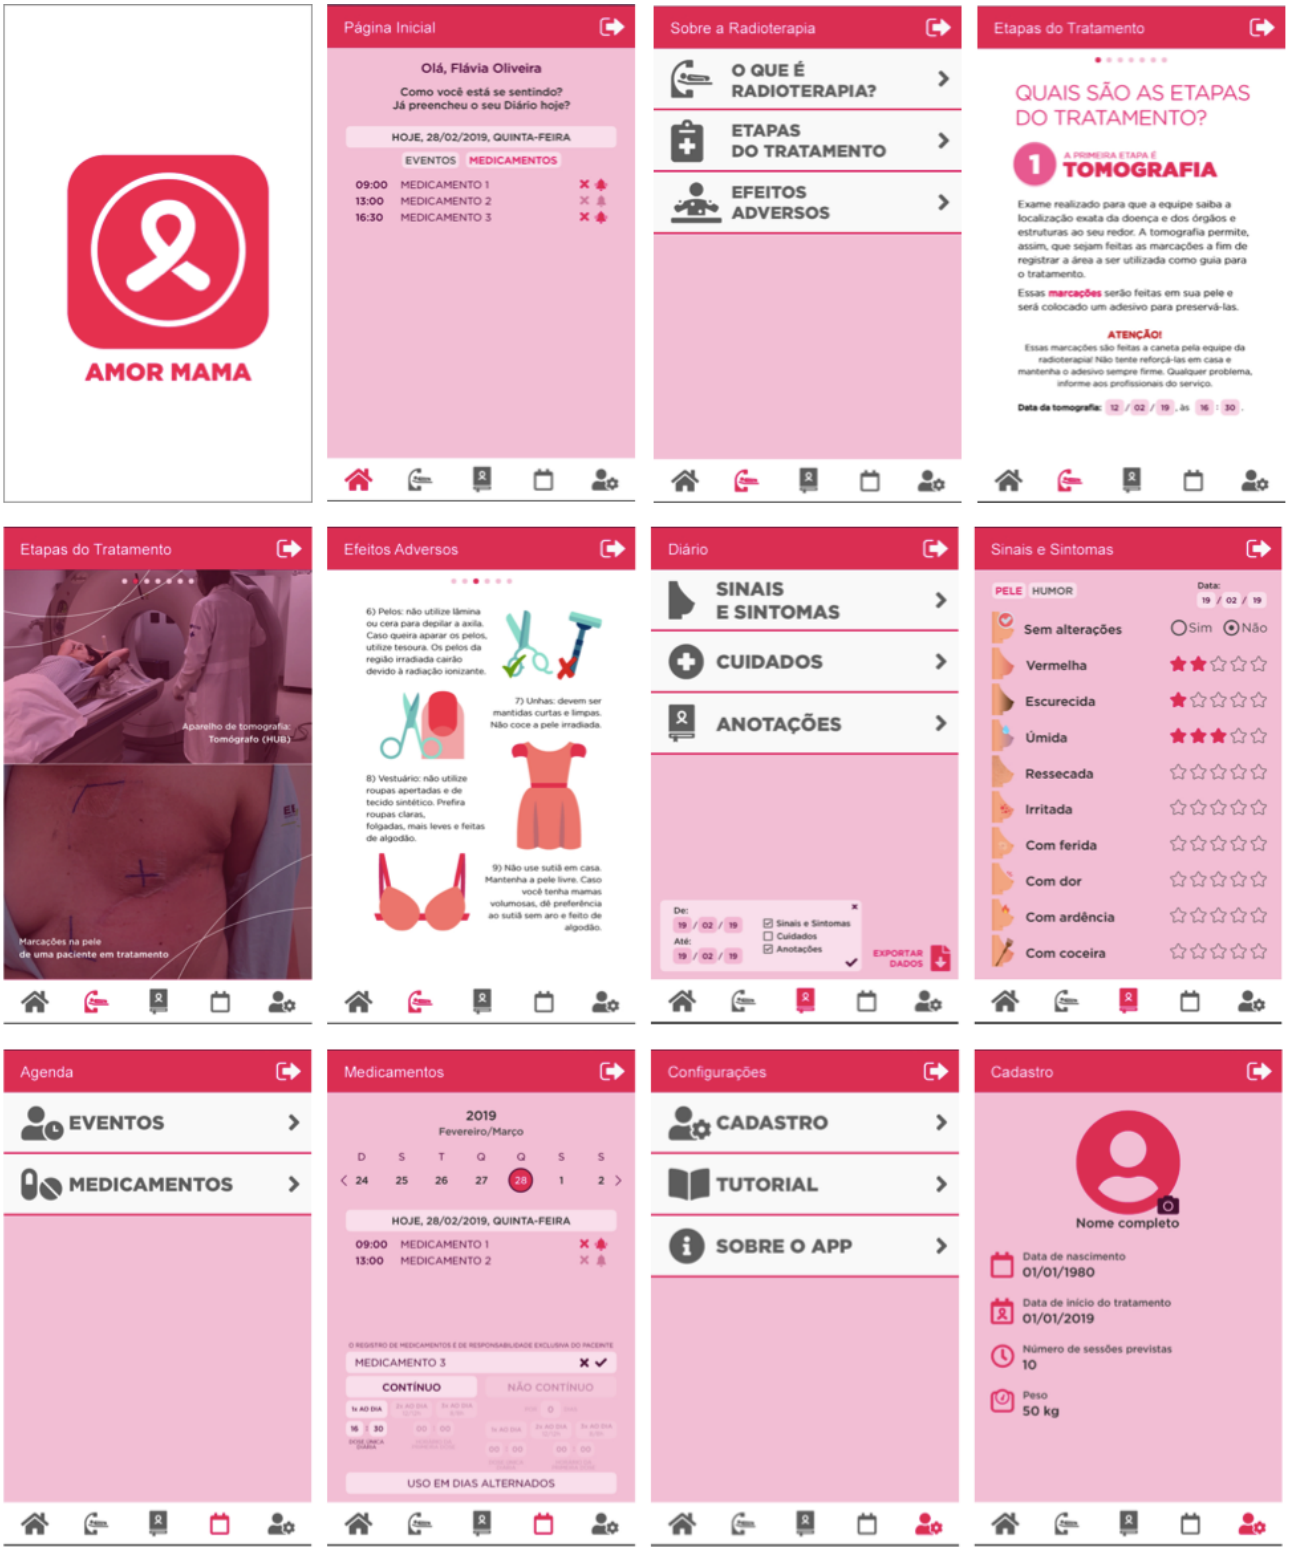
Among the features and functionality available in the prototype of the app proposed in this study, we can mention the registration of events in a calendar, with the possibility of generating automatic reminders through notifications with 24 hours in advance. The user's freedom of choice in relation to enabling or disabling notifications is an important aspect that was already foreseen in the project and was reinforced during the discussion of one of the focus groups. This possibility of adapting to different users is very relevant, considering that an interface must be able to provide flexible interaction since different users may have different preferences for interacting with the app [13]. This customization is also found in the registration where the user can insert a photo and her personal information such as name, weight, date of birth, start date of treatment, and number of sessions planned. Body weight is initially used to calculate the goal of daily water intake, which should be 30 to 35 ml/kg for adults and 25 mL/kg for the elderly, considering the variations according to the symptoms and tolerance presented by each patient [20].

A study also included the possibility of personalization in the development of the proposed app. This app can be useful for recording and monitoring various personal health data such as results of laboratory tests, medications in use, immunization, allergies, body weight, and blood pressure in addition to information related to physical activity, nutrition, and sleep. The modules are customizable and flexible since users can make choices according to their own needs, thereby hiding or showing different information [21]. The suggestion to include links in the app that direct to informative content available on the web

was not accepted. The researchers believe that the information already validated by specialists and available on the app is sufficient for the adequate guidance of users. An exaggerated amount of information can be harmful, as suggested by a study that evaluated the effects of an app on the anxiety levels of patients undergoing breast cancer surgery [22].

The authors of this study also have no control over external content inserted in the app through links and are not responsible for its availability and the updates. In addition, the direction and access to the content available on the web depends on the internet connection, which hurts the initial proposal of offline browsing for the app proposed in this study. Therefore, after making the changes suggested by the participants, the final product of the elaboration and improvement of the app prototype resulted in a model ready to be coded as software, with essential content for patients with breast cancer undergoing radiation therapy and with an interface that favors communication, interactivity, and its use, as shown in Figure 2.

Figure 2. Screenshots of the AMOR Mama app.



Limitations

The limitation in this study was related to the difficulty in conducting only 1 focus group, including all participants at once in the design assessment of the mobile app, given the specificities and individual demands of each professional. However, this limitation was overcome by the fact that the focus group was used as a complementary technique to the quantitative assessment, which occurred individually and allowed to obtain objective measures about the evaluation. Another limitation is related to the number of participants included. Despite the recommended minimum of 8 participants, it is believed that a larger sample could have improved the design assessment of the mobile app.

Conclusions

The mobile app prototype entitled "AMOR Mama," after having been improved based on the participants' suggestions, was considered adequate. This indicates its contribution as a technology for health education aimed at the dissemination of guidelines and monitoring of women with breast cancer undergoing radiation therapy. This app will be developed through software codification, and studies with the target population must be carried out to assess the performance and quality of the app during its use.

Abstract

Digital mental health technologies such as mobile health (mHealth) tools can offer innovative ways to help develop and facilitate mental health care provision, with the COVID-19 pandemic acting as a pivot point for digital health implementation. This viewpoint offers an overview of the opportunities and challenges mHealth innovators must navigate to create an integrated digital ecosystem for mental health care moving forward. Opportunities exist for innovators to develop tools that can collect a vast range of active and passive patient and transdiagnostic symptom data. Moving away from a symptom-count approach to a transdiagnostic view of psychopathology has the potential to facilitate early and accurate diagnosis, and can further enable personalized treatment strategies. However, the uptake of these technologies critically depends on the perceived relevance and engagement of end users. To this end, behavior theories and codesigning approaches offer opportunities to identify behavioral drivers and address barriers to uptake, while ensuring that products meet users' needs and preferences. The agenda for innovators should also include building strong evidence-based cases for digital mental health, moving away from a one-size-fits-all well-being approach to embrace the development of comprehensive digital diagnostics and validated digital tools. In particular, innovators have the opportunity to make their clinical evaluations more insightful by assessing effectiveness and feasibility in the intended context of use. Finally, innovators should adhere to standardized evaluation frameworks introduced by regulators and health care providers, as this can facilitate transparency and guide health care professionals toward clinically safe and effective technologies. By laying these foundations, digital services can become integrated into clinical practice, thus facilitating deeper technology-enabled changes.

(J Med Internet Res 2021;23(10):e27507) doi:10.2196/27507

KEYWORDS

digital implementation; digital mental health; digital psychiatry; digital technology; viewpoint

Introduction

Mental health disorders represent the leading cause of disability worldwide, with over one third of the world's population being affected by a mental health condition in their lifetime [1]. Given the increasing pressures on mental health care budgets globally, as well as shortages of health care professionals who are facing an overwhelming growing burden of chronic and recurring mental health conditions, prevention strategies and improvements in early identification and treatment are essential. To this end, mobile health (mHealth) tools such as apps can offer innovative ways to help develop and facilitate mental health care provision. Indeed, the unmet need for psychiatric services has sparked significant interest in developing apps to meet patient demand. As a result, more than 10,000 apps addressing mental health symptoms such as anxiety, low mood, and insomnia are now available on the Apple App Store and Google Play Store [2]. Furthermore, despite its catastrophic effects, the COVID-19 pandemic has been a pivot point for

digital health implementation, with some describing it as years' worth of digital transformation in just a few months [3-5]. This transformation has been made possible by the recognition from governments and regulatory bodies of the need for speed, flexibility, and action in response to the pandemic [6-8]. However, many current mHealth technologies rely heavily on patients' ability to self-diagnose and use self-help rather than being fully integrated into the clinic. In building a holistic and comprehensive digital mental health ecosystem that *augments* rather than *replaces* traditional mental health care approaches, strategies for the design, validation, and implementation of mHealth technologies should be carefully considered by innovators moving forward.

mHealth: Promise of Dimensional Psychiatry and Digital Phenotyping

Psychiatric nosology, as described in gold-standard diagnostic manuals, has often been criticized for being overly narrow, failing to capture the wide range of clinical symptoms that are endorsed by individuals with mental health conditions [9,10]. In this regard, moving away from a categorical, symptom-count approach to a transdiagnostic view of psychopathology may facilitate early and accurate diagnosis, and allow for personalized treatment strategies. Given that time is a premium in clinical settings, where relying on brief symptom-count checklists such as the Patient Health Questionnaire-9 [11] and the seven-item Generalized Anxiety Disorder questionnaire [12] is common practice, digital technologies may offer an innovative way to improve diagnostic accuracy and advance mental health care provisions. Indeed, digital technologies such as mHealth apps have the capacity for the collection of a vast range of key transdiagnostic data via active reporting (ie, self-administered symptom reporting or monitoring via an app), providing valuable information on relevant social and demographic factors as well as current and past symptom profiles [13]. Digital technologies, including adaptive/nonlinear questionnaires where patients are required to answer questions based on previous answers, can further personalize and streamline the collection of active cross-disorder symptom data.

Moving beyond active symptom data, passive data, which measure aspects of daily living and can be collected continuously in the background, such as activity rhythms, text and call logs, sleep quality, keyboard reaction time [14], speech phonation, coherence, sentiment, and language patterns [15], can be applied to better inform mental health assessments in a process called digital phenotyping [16]. Data platforms that gather information from various digital sources have started emerging with the goal of collecting large-scale epidemiological and longitudinal data to identify risk factors and invest in mental health resources effectively. An example of this approach is offered by the recently launched Mental Health America (MHA) dashboard supported by MHA and Lundbeck. The dashboard collects publicly available data and anonymized data from web screening tools offered by MHA to highlight mental health hotspots across the United States. The objective is to implement advanced targeted interventions, address disparities in a timely manner, and design policies for at-risk populations [17,18]. Furthermore, advances in mHealth platforms (eg, Apple HealthKit or Google Fit) also allow for the bundling of data from different sensors such as accelerometers, microphones, GPS sensors, and gyroscopes, enabling the collection of physical and mental health information [19].

Critically, digital phenotyping for mental health is still in its infancy, with further research into how these data fit into or build upon the current diagnostic guidelines and criteria being a necessity moving forward. Both active as well as passive data collection also raise potential serious ethical concerns, which will need to be legislated and regulated. In the future, combining data from active and passive monitoring sources may feed new data into mental state examinations, allowing for more comprehensive data collection outside the time-pressured environment of clinical consultations. In turn, mHealth technologies have the potential to streamline mental health care delivery and management by reducing the number of in-person appointments, thereby freeing up clinician time, resulting in cost savings for both the provider and patient. However, these technologies usually require patients and clinicians to engage in new behaviors, which may be accompanied by reluctance to change. As a result, uptake of mHealth tools critically depends on perceived relevance, effectiveness, confidentiality, and engagement of the end users. A way to address this is by utilizing behavior theories and engaging in codesigning approaches when designing digital mental health care solutions.

Designing mHealth Tools With Patients and Clinicians in Mind

Understanding the target patient population's need is pivotal to the design of effective mHealth tools. To this end, behavior theories such as the Health Belief Model (HBM) [20], Behavioral Intervention Technology (BIT) model [21], and behavior model for Just-in-Time Adaptive Interventions (JITAI) [22] offer frameworks that help identify key drivers and barriers to the uptake of new technology, starting from app subscription to adherence to recommendations delivered by mHealth tools [23-25]. For instance, the HBM can help mHealth developers better understand their target patient population by investigating their inclination to seeking mental health support and what drives their adherence to treatment (eg, trust in clinicians, severity of illness, social stigma). The HBM is based on the theory that a person's willingness to engage in treatment is primarily due to their health perceptions. Indeed, mental health studies have shown that the perceived severity of mental illnesses impacts treatment outcomes (eg, adherence and beliefs about treatments) [26]. Thus, using the HBM can inform developers on how to best engage patients in adhering to the use of a novel digital tool.

Similarly, the BIT model combines the understanding of technological features of mHealth tools with behavioral principles to guide innovators on how to design and implement technology that is useful and usable. For instance, motivational enhancement strategies (behavior principle) can be used in the form of push notifications (technological feature) to prompt patients to track their mood regularly. The BIT model approach can be especially valuable for researchers looking to develop

multifunctional tools for mental health, including tools for mood monitoring and treatment such as electronic cognitive behavioral therapy, as well as tracking adherence to medication. In these cases, the stepwise, structured approach of the BIT model can best inform developers on how to use different behavioral principles and technologies to achieve their clinical aims.

The JITAI model can be employed by researchers developing adaptive sampling and ecological momentary assessments aimed at collecting information at sufficient frequencies and quantities to be useful without overburdening mental health patients. Critically, a delicate balance between utility and tolerability must be sought when developing mHealth monitoring tools in mental health, especially in conditions with specific triggers (eg, social anxiety triggered by meeting strangers, harmful alcohol use triggered by stress). The behavioral model for JITAI offers a framework to systematically identify when patients are most vulnerable to experiencing symptoms and pinpoints circumstances in which patients may be most receptive to the digital intervention.

Transitioning into the digital mental health care space will also involve cultivating a collaborative approach that includes academics, software developers, computer and data scientists, investors, and health care professionals. Indeed, moving forward, the concept of codesigning will need to be at the forefront of development, involving *all* potential users and stakeholders as active collaborators in the creation of digital diagnostics and interventions. This is especially critical for mental health technologies, which require clinical support from health care professionals to encourage engagement. Moving from the view of designing a digital product to designing a technology-enabled service means that the aims, role of the practitioner, and technology are designed and evaluated simultaneously in the relevant context [27]. Shifting from the practice of designing *for* to designing *with* users can help humanize digital health care, and *augment* rather than *replace* traditional health care delivery and management systems. By laying these foundations, technology-enabled services can become a part of everyday clinical practice and set the scene for deeper technology-enabled changes. Critically, as well as leveraging on behavior theories and codesigning approaches to increase engagement and relevance, mHealth developers should also pursue implementation studies to validate and assess the efficacy of their interventions.

Clinical Trials to Build a Strong Evidence-Based Case for Psychiatric mHealth Tools

Recent studies show that the most commonly downloaded mental health apps mainly fall under the umbrella of well-being apps offering relaxation, meditation, or mindfulness skills rather than validated treatments, and that the scientific language used to support claims often lacks corresponding evidence in the literature [28,29]. Although these apps can be incredibly useful and helpful for some patients, they may not be effective for more severe mental health concerns. Furthermore, many of these mHealth tools rely heavily on patients' ability to self-diagnose and use self-help rather than being fully integrated into clinical service delivery. In building a holistic and comprehensive digital mental health ecosystem, innovators are encouraged to design technology in a more sophisticated manner, moving away from a one-size-fits-all well-being approach to embrace the development of clinically validated and integrated treatments.

Clinical trials and observational studies can help mHealth developers build a strong clinical case for their technologies and differentiate them from digital wellness apps. Moving forward, it should be noted that randomized controlled clinical trials typically bear little resemblance to clinical settings. Often, recruitment favors clinicians and patients who are interested in using digital health technologies and are therefore more likely to adhere to them. However, these participants may represent only a small proportion of potential users. It should then come as no surprise if digital technologies fail in general health care settings. Thus, innovators should carefully consider the opportunity to conduct the evaluation of digital mental health technologies within the intended context, and to assess both its effectiveness and implementation requirements [27]. This so-called hybrid pragmatic trial design can assess both treatment effects and implementation strategies [30] in real-world patient populations with outcome measurements routinely used in clinical practice [31]. Thus, implementation and sustainment strategies become integral to the clinical evaluation process and part of the intervention design from the very beginning. Importantly, performing clinical studies and citing published literature in the descriptions of digital tools can only partially address the difficulties encountered by providers, payors, and patients in assessing and choosing effective digital interventions. Standardized evaluation frameworks introduced by regulators and health care providers can create transparency and guide health care professionals toward clinically meaningful technologies, with efforts being made in this direction.

Defining Appraisal Frameworks for mHealth Solutions

Several academic groups have contributed to the design of evaluation frameworks. For instance, the American Psychiatric Association (APA) has developed an app evaluation framework [32] that has been used by the New York Department of Health in the construction of an app library. Following the APA model, Lagan et al [33] designed a health app evaluation model, which harmonized 45 preexisting frameworks and where answers can be either binary or numeric to permit an objective evaluation of (1) background and access, (2) data safety and privacy, (3) app effectiveness and clinical foundation, (4) user engagement, and (5) data integration. The app evaluation model can be used by clinicians and patients to inform decisions on the suitability of candidate apps for the intended clinical use. Mental health apps often require patients to disclose sensitive personal information; thus, data safety and privacy are fundamental. To this end, the framework assesses apps on the possibility of deleting data, the format in which data are shared (nonanonymized, deidentified, anonymized), and whether data are shared with third parties. Thus, data handling procedures should be clearly stated in an app's description or privacy policy.

Ultimately, compliance with data security statutes and regulations (eg, Health Insurance Portability and Accountability Act and General Data Protection Regulation) is paramount for mental health apps collecting sensitive patient data. Clinicians will only recommend apps that fulfill data security requirements and that can easily be integrated into existing clinical workflows.

Regulators and health care providers are introducing additional ways of evaluating and certifying digital health technologies that do not fall under hardware medical device regulations. Innovators should work with regulatory bodies and be aware of the innovation plans for appraisal frameworks. The Food and Drug Administration (FDA) developed the Digital Health Innovation Action Plan to provide a more streamlined and efficient regulatory oversight of digital health technologies [34]. The Plan includes the Software Precertification Pilot Program, which precertifies organizations, not individual products [35]. An "excellence appraisal" is conducted to give the FDA the assurance that the organization is capable of producing high-quality, safe, and effective medical software products so that individual product reviews are carried out more rapidly and swiftly. An international approach to one-off regulatory appraisals also emerged with the Medical Device Single Audit Program (MDSAP), piloted in the United States, Australia, Brazil, Canada, and Japan. The objective of the MDSAP is to develop a single regulatory audit process that can satisfy the needs of multiple regulatory jurisdictions [36]. Europe stands as an observer in the MDSAP, and the new Medical Device Regulation mainly focuses on hardware devices; however, steps have been taken toward a more software-specific approach [37]. In the United Kingdom, the National Health Service (NHS) X developed the beta version of Digital Technology Assessment Criteria for health and social care, which outlines baseline assessment criteria to validate the suitability and function of digital health technologies for use by the NHS, social care staff, or directly by citizens [38]. Trade associations such as the Digital Therapeutics Alliance (DTA) are promoting industry standards and evaluation frameworks to enhance the understanding, adoption, integration, and reimbursement of clinically evaluated digital therapeutics into mainstream health care. The DTA's member companies include large pharmaceutical companies such as Novartis and Otsuka, as well as digital therapeutics developers such as Pear Therapeutics and SilverCloud, along with technology companies such as Philips, demonstrating the interdisciplinary efforts in pushing forward digital health technologies.

Compliance with data security regulations, assessment against commonly used frameworks, and certifications issued by regulatory bodies can help innovators build transparency and trust with their stakeholders. Importantly, presenting efficacy data and privacy matters in clear terms is essential to engage providers in the uptake of novel digital tools. In other areas of medicine, a clear evidence base, ease of use, and swift integration into clinical workflows have proven to facilitate the uptake of digital health technologies [39,40]. Experts have suggested that the introduction of novel technologies in health care could be facilitated by a dedicated health care profession called a "digital navigator," whose task in hospitals and clinics would be to select evidence-based apps, troubleshoot, and interpret digital data outputs in a clinically meaningful way [41]. However, mHealth developers should not heavily rely on the presence of specialized personnel; rather, they should focus on communicating evidence transparently, designing tools that fit into current care pathways and information technology system provisions, and providing actionable patient data. Consequently, the use of digital tools will not be limited to settings that have specialized staff members, and as uptake of these apps increases, it will become cost-effective to train and employ digital navigators to support further, more complex implementation of digital health tools.

Conclusion

Digital mental health technologies can enable the early identification of conditions, and facilitate disease management and treatment while empowering patients to make better informed decisions about their own health. Critically, there has been a movement toward technology that replaces the human element, rather than complementing and enhancing the invaluable involvement of health professionals in patient care. However, it is important not to throw decades or even centuries of clinical knowledge overboard. The way forward to building a digital mental health ecosystem must be more nuanced and sensitive. By developing patient-centric solutions, we can enable earlier and more accurate diagnoses, and in turn connect people with the most appropriate and effective treatment and care. As we move toward a postpandemic world, building the digital mental health ecosystem will require optimizing and adapting traditional mental health care services with considered step-wise innovation approaches, allowing health care professionals and patients to adapt to change. Innovative solutions will not come from leaps forward in technology but rather from new models of codesign, careful use of behavior theories, new pragmatic approaches to clinical evaluation, unprecedented collaboration in defining industry standards, and an open mind to trial-and-error implementation approaches.

The long-term goal for digital mental health technology innovators should be to design tools and services that can easily become so engrained in the health care ecosystem that what is now referred to as *digital health* will simply be called *health*.

Abstract

Background: Many pregnant women use the internet to obtain information about pregnancy and childbirth. Over 50% of pregnant women use pregnancy apps and must search through thousands of pregnancy or women's health–related apps available on app stores. The COVID-19 pandemic is changing how women receive prenatal care. Mobile health apps may help maintain women's satisfaction with their prenatal care.

Objective: Our objective is to identify pregnancy mobile apps and to evaluate the apps using a modified APPLICATIONS (app comprehensiveness, price, privacy, literature used, in-app purchases, connectivity, advertisements, text search field, images/videos, other special features, navigation ease, subjective presentation) scoring system.

Methods: A list of pregnancy apps was identified in the first 20 Google search results using the search term "pregnancy app." After excluding irrelevant, inaccurate, malfunctioning, or no longer available apps, all unique apps were downloaded and evaluated with the modified APPLICATIONS scoring system, which includes both objective and subjective criteria and evaluation of special features.

Results: A list of 57 unique pregnancy apps was generated. After 28 apps were excluded, the remaining 29 apps were evaluated, with a mean score of 9.4 points out of a maximum of 16. The highest scoring app scored 15 points. Over 60% (18/29) of apps did not have comprehensive information for every stage of pregnancy or did not contain all four desired components of pregnancy apps: health promotion/patient education, communication, health tracking, and notifications and reminders. Only 24% (7/29) of apps included a text search field, and only 28% (8/29) of apps cited literature.

Conclusions: Our search yielded many high-scoring apps, but few contained all desired components and features. This list of identified and rated apps can lessen the burden on pregnant women and providers to find available apps on their own. Although health care providers should continue to vet apps before recommending them to patients, these findings also highlight that a Google search is a successful way for patients and providers to find useful and comprehensive pregnancy apps.

KEYWORDS

app; app store; mHealth; mobile health; prenatal; pregnancy; women's health

Introduction

The internet and smartphones are increasingly popular both as a means to access health care information and as tools for health care management [1]. During the COVID-19 pandemic, in-person health care visits dropped and patients sought care via different methods [2]. Recent data shows that 21% of prenatal visits in March 2020 were impacted (ie, cancelled, rescheduled, or conducted remotely) [3]. In April 2020, 26% of prenatal visits were impacted [3]. For those that had remote phone or video visits, less than half felt they received the same amount or more information and care as compared to that received during a traditional visit [3]. The pandemic has also caused a 25% increase in mobile health app downloads as compared to the same time last year [4].

Internet use during pregnancy is common [5]. The majority of women in the United States own a smartphone and past studies have shown that over 50% of pregnant women download apps focused on pregnancy, downloading an average of three during the prenatal period [6-8]. Women who use mobile prenatal care apps and have fewer prenatal visits have no reduction in patient satisfaction [9]. Health care–related apps account for a large market share of the apps available on the US iOS App Store, with almost 100,000 apps as of 2017 [10]. A 2013 study showed that pregnancy apps are the most used health apps [11]. Although 94% of pregnant women reported that a smartphone changed their lives for the better, there are many apps to choose from and the market for apps is constantly growing [6].

Due to the number of apps available to pregnant women, knowing what apps are available, how to select among them, and what information and features women are seeking is important. Wang et al [12] surveyed 535 women and showed that the most common reasons women used apps were to monitor fetal development (83%) and to obtain information on nutrition (26.2%) and antenatal care (23.9%). Lee et al [8] evaluated 47 apps that were identified by surveying 193 women and reported that most women decided to download an app after evaluating its content themselves (61.7%), and that the most frequently cited benefit was convenience (35.8%), while the most common weakness was lack of credibility (39%).

These studies provide information about why and how women use apps, but there have been no critical quantitative analyses done to evaluate and rate these apps in terms of their usefulness and benefit to pregnant women. The purpose of this study is to identify and evaluate pregnancy apps recommended to women on the internet. Our study additionally sought to create a comprehensive list of app features and a quantitative measure of comprehensiveness.

Methods

This study did not require review by the Institutional Review Board at the Icahn School of Medicine at Mount Sinai as it did not involve human subjects. We used the web search engine developed by Google, using the search term “pregnancy app” in March 2019. Search engines and online reading are top ways that consumers discover apps, and we selected Google’s search engine because it accounts for over 90% of all search queries [13,14]. The first page, with an average of 10 search results, accounts for 91.5% of traffic, while the second page accounts for 4.8% [15]. We confirmed that the results displayed were nearly identical when searched through different devices (eg, computer, iPad, and iPhone) and from different geographical locations. Google Incognito mode was used to limit variation of results based on the user’s browser cookies.

We downloaded all apps mentioned within the first 20 search results. We noted characteristic information—such as app name, app store, and app icon—and evaluated app content using an adapted APPLICATIONS (app comprehensiveness, price, privacy, literature used, in-app purchases, connectivity, advertisements, text search field, images/videos, other special features, navigation ease, subjective presentation) scoring system. APPLICATIONS is an acronym for components of apps that can be scored to help determine the rating of the app [16]. The usefulness and benefit of the apps was determined by the app comprehensiveness score, which judges the ability of an app to provide useful pregnancy information, and by the other components of the APPLICATIONS scoring system, which judge other aspects that have been shown to make apps successful [16]. This score was devised based on availability of information on the four distinct portions of pregnancy care, as well as the top four functions of the most commonly used pregnancy apps, as per Lee et al [8].

Other modified components of the original APPLICATIONS scoring system are described here. “Price” and “Paid subscription” were combined into one “Price” score. “Privacy” was added because while the initial APPLICATIONS scoring system was created with providers in mind, this study is evaluating patient-facing apps, and patients have expressed security and privacy concerns as an important consideration when choosing whether to use an app [17]. “Interdevice compatibility” was removed as each app denotes the proper platform to use. “Images/videos” was added, which was part of “Other components” previously. The “Other components” category was therefore renamed “Other special features” and the scoring was expanded due to the numerous special features provided on pregnancy apps, as the initial APPLICATIONS scoring system was intended for pregnancy wheel dating apps, which serve a more targeted, specific function and are less likely to have numerous other features.

One author (GF) checked the apps in the app stores to see if there were in-app purchases and also downloaded and opened the apps in airplane mode to evaluate the connectivity component and determine if functionality was dependent on internet access. All three authors evaluated the remaining features using the APPLICATIONS scoring system, as shown in Table 1. App comprehensiveness was determined as shown in Textbox 1. The “Other special features” category was tabulated in Multimedia Appendix 1. Navigation ease and subjective appearance were scored using a Likert scale with 1=poor, 2=below average, 3=average, 4=above average, and 5=excellent.

Table 1. The APPLICATIONS scoring system [16,17].

Component	Maximum score	Description
App comprehensiveness	3	0=none, 1=1-2 components, 2=3-5 components, 3=6-8 components
Price	1	0=priced, 1=free
Privacy	1	0=none, 1=privacy statement or login
Literature used	1	0=no references, 1=references used
In-app purchases	1	0=present, 1=absent
Connectivity	1	0=internet required, 1=internet not required
Advertisements	1	0=present, 1=absent
Text search field	1	0=no search field, 1=search field present
Images/videos	2	0=absent, 1=images or videos, 2=images and videos
Other special features	2	0=absent, 1=1-4 special features, 2=5-9 special features
Navigation ease	1	0=ease of navigation score <3, 1=ease of navigation score ≥3
Subjective presentation	1	0=subjective presentation score <3, 1=subjective presentation ≥3
Total	16	Sum of all scores

Textbox 1. App comprehensiveness criteria [8].

Criteria:

- Health promotion/patient education
- Patient communication
- Health tracking
- Notifications and reminders
- Preconception information
- Antepartum information
- Intrapartum information
- Postpartum information

Scoring: 0 points if no components were present, 1 point for 1-2 components, 2 points for 3-5 components, and 3 points for 6-8 components.

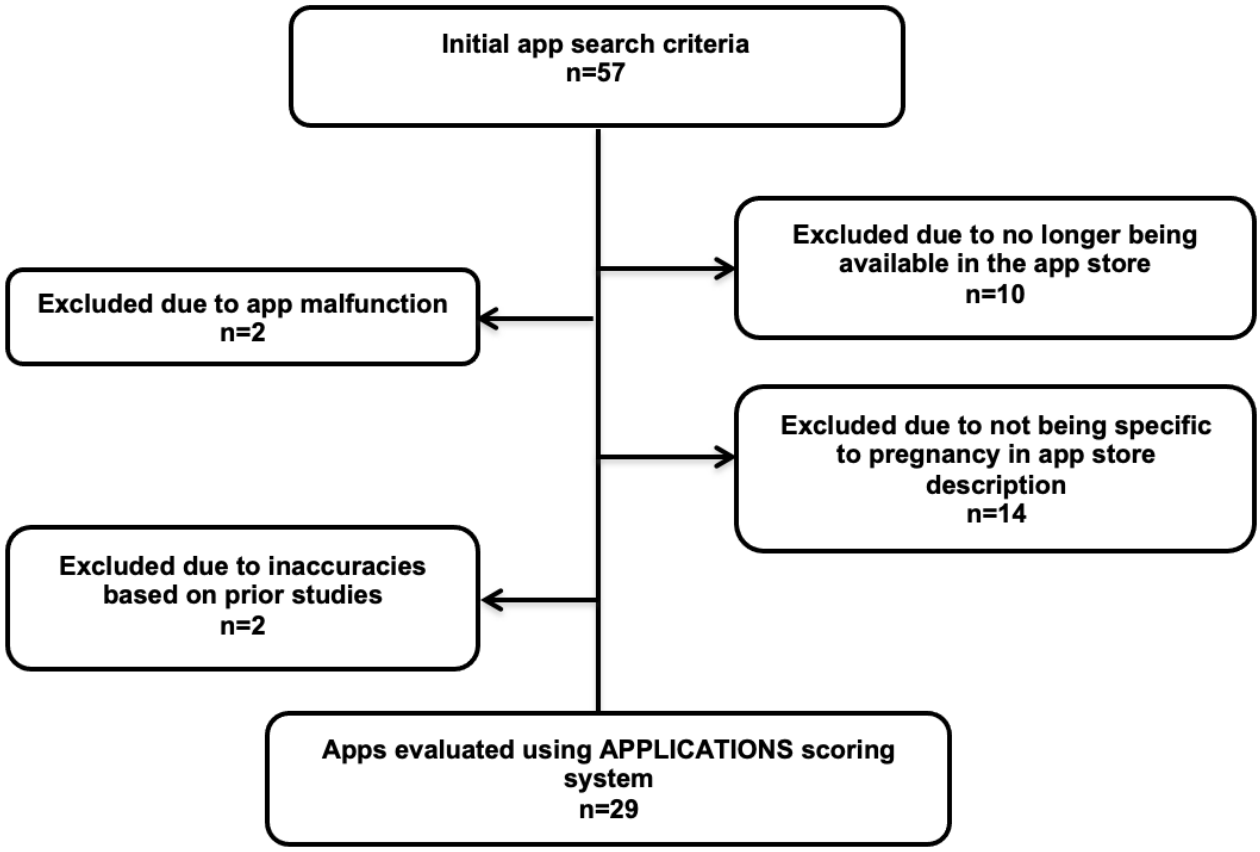
To account for any interobserver differences, we reconciled ratings and recorded objective errors. Our reconciliation process included a meeting of all authors during which we discussed each feature of each app. When there was a discrepancy, we determined whether it was a transcription or misclassification mistake and arrived at 100% consensus for the objective components of each app. For navigation ease and subjective presentation, we averaged reviewers' scores and awarded 0 points for an average rating of <3 and 1 point for an average rating of ≥3. We subsequently calculated a final total score for each app.

Results

The first 20 search results from the first two pages of a Google search on a computer for the term "pregnancy app" were recorded. The results were either specific apps (n=4) or articles about apps (n=16). All the apps listed in each result were noted and this search yielded 57 apps.

A total of 28 apps were excluded for the following reasons (Figure 1): 12 apps were no longer available or did not work, 14 apps were not related to pregnancy based on not having the word "pregnancy" in the description on the app store, and 2 were deemed inaccurate based on prior studies [18,19]. The remaining 29 apps were all downloaded on the Apple App Store or Google Play Store and evaluated between July-November 2019.

Figure 1. Google search for pregnancy apps. APPLICATIONS: app comprehensiveness, price, privacy, literature used, in-app purchases, connectivity, advertisements, text search field, images/videos, other special features, navigation ease, subjective presentation.

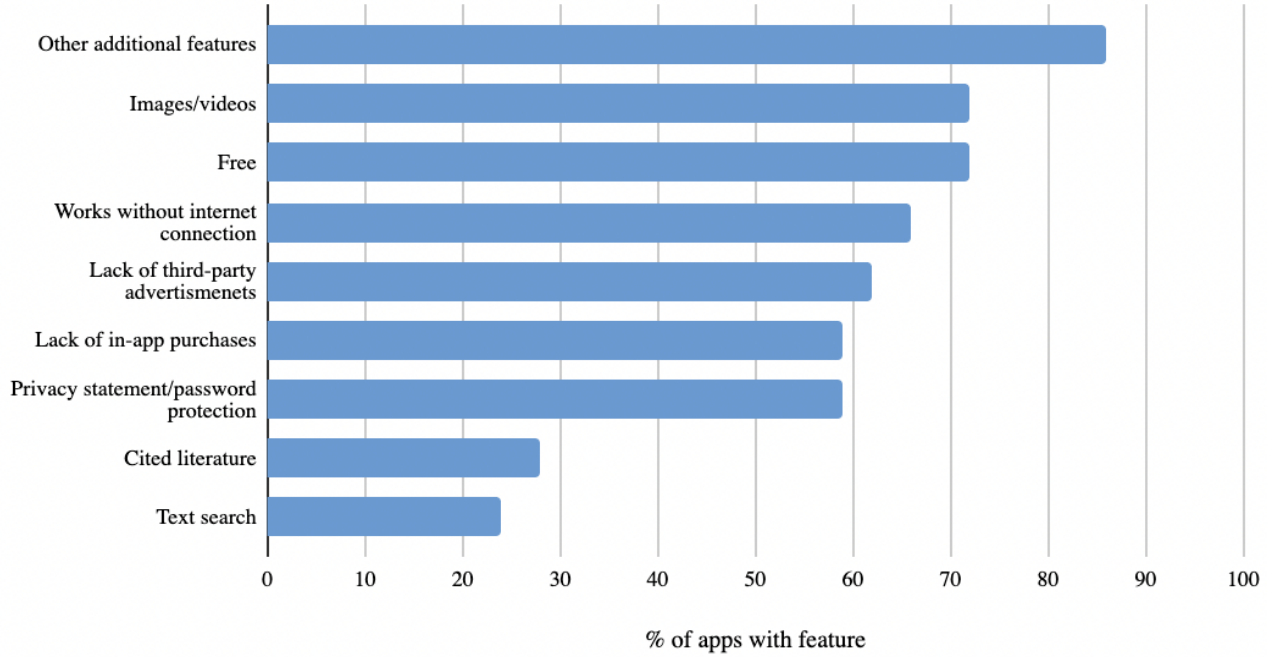


The 29 remaining apps were scored using the APPLICATIONS scoring system by all authors (Multimedia Appendix 1). The highest scoring app earned 15 out of 16 possible points. In addition, 11 apps scored above the mean score of 9.4. The lowest scoring app earned 4 points.

We determined that 41% (12/29) of apps included ≥6 comprehensiveness components out of 8, while 24% (7/29) of apps only included 1-2 comprehensiveness components out of 8, signifying missing information with regard to all stages of pregnancy or desired functionalities of pregnancy apps: health promotion/patient education, communication, health tracking, and notifications and reminders.

Evaluated features and functionality are shown in Figure 2. Common features and functionality included special features (25/29, 86%), free cost (21/29, 72%), images and/or videos (21/29, 72%), offline functionality (19/29, 66%), including a privacy statement or password protection (17/29, 59%), lack of third-party advertisements (18/29, 62%), and lack of in-app purchases (17/29, 59%). Use of cited literature (8/29, 28%) and text search (7/29, 24%) were rare features.

Figure 2. Features and functionalities of apps.



The objective component reporting error rate was 31 of 435 (7.1%), meaning that the authors independently assigned the same score to a given objective component of an app 92.9% of the time.

Discussion

Principal Results

In this study, we simulated how pregnant women would find apps by performing a Google search and then we evaluated and rated the identified apps. Although our results present several high-scoring apps, few contain all the components and features that make up an accurate and comprehensive app. More research is needed to survey patients and providers about which features are the most highly desired and needed. Many apps were missing cited sources, making it difficult to interpret accuracy. The rarest component was a text search, which can make it difficult for women to sift through information and quickly find what they are looking for. The most common app-specific features were contraction timers, journaling/photo uploads, and appointment trackers, checklists, and calendars. The least common were tools for obtaining safety information and health/fitness, despite these being common reasons pregnant women seek out apps [12].

Comparison With Prior Work

Prior studies have evaluated apps by asking pregnant women directly what apps they are using or through a systematic search of the app store. We sought to evaluate the most likely common apps that pregnant women are to encounter, which we did through a Google search [14]. Furthermore, to our knowledge, pregnancy apps have not previously been scored with the APPLICATIONS scoring system. App stores have an abundance of options, requiring consumers to sift through apps that may not be relevant (such as humorous apps for fake pregnancy tests), which can easily result in them feeling overloaded [20]. As most of the Google search results were written articles describing apps, erroneous and irrelevant apps from the app store are less likely to be included. This study is able to provide patients and providers with a curated list of rated apps and their features.

Clinical Implications

The information found in this study may be particularly useful to women during the COVID-19 pandemic. Pregnant women often seek information on the internet and do not discuss much of what they find with their physicians [21]. Due to the pandemic, half of adults say that they or someone in their household has skipped seeking medical care due to anxiety about contracting COVID-19 [22]. Prenatal visits have needed to be rescheduled or modified, and many women are not satisfied with the level of information they are receiving through phone or video visits. The combination of these factors has likely led to the increase in pregnancy app downloads, which has occurred at a time when pregnant women have fewer touchpoints with doctors where false information could be corrected, emphasizing the need for high-quality and accurate pregnancy apps [4].

Limitations

Given the dynamic nature of Google search results and the app store, several factors limit our analysis. This was evident in our search, as 12 of the apps initially identified were either no longer available or did not work by the time we tried to evaluate them. Additionally, we decided to use only the first two pages of Google search results as they account for most views. It is possible that other apps present on later pages were useful and comprehensive.

Conclusions

The current method of app selection by the majority of women is to download the app and search the content themselves [12]. Although this may yield good results, it also means women must download multiple apps, as well as pay for many of these

apps. On average, Lee showed that users download over three apps and are more likely to download a free app versus a paid app [8]. By using a Google search, we were able to identify many high-scoring apps that may be used during pregnancy. The identified rated apps can lessen the burden on pregnant women and providers to search for useful and comprehensive apps on their own. As telehealth continues to expand, more research is needed in the area of pregnancy app development.

Conflicts of Interest

Abstract

Background: Providing parents with resources that aid in the identification and management of acute childhood illnesses helps those parents feel better equipped to assess their children's health and significantly changes parental health-seeking behaviors. Some of these resources are limited by accessibility and scalability. Remote locations and staffing limitations create challenges for parents aiming to access their child's health information. Mobile health apps offer a scalable, accessible solution for improving health literacy by enabling access to health information through mobile devices.

Objective: The aim of our study is to create an inventory of acute childhood illness apps that are available to North American parents and caregivers, assess their quality, and identify the areas in which future apps can be improved.

Methods: We conducted an environmental scan to identify and summarize app information for parents and digital health researchers. The Google and Apple app marketplaces were used as search platforms. We built a list of search terms and searched the platforms for apps targeted at parents and related to acute pediatric illnesses in the United States and Canada. We assessed apps meeting the inclusion criteria using the Mobile App Rating Scale (MARS), a validated tool for assessing the quality of health apps. The MARS examines apps on 5 subscales: engagement, functionality, aesthetics, information quality, and subjective quality. Data were analyzed by MARS subscale averages and individual item scores.

Results: Overall, 650 unique apps were screened, and 53 (8.2%) were included. On a scale of 1-5, apps had an average engagement score of 2.82/5 (SD 0.86), functionality score of 3.98/5 (SD 0.72), aesthetics score of 3.09/5 (SD 0.87), information quality score of 2.73/5 (SD 1.32), and subjective quality score of 2.20/5 (SD 0.79). On the same scale of 1-5, app scores ranged from 2.2/5 to 4.5/5 (mean 3.2, SD 0.6). The top 3 MARS-scored apps were *Baby and Child First Aid* (4.5/5), *Ada* (4.5/5), and *HANDi Paediatric* (4.2/5). Taken together, the top 3 apps covered topics of emergency pediatric first aid, identification of (and appropriate response to) common childhood illnesses, a means of checking symptoms, and a means of responding to emergency situations. There was a lack of Canadian-based app content available to parents in both marketplaces; this space was filled with content originating primarily in the United Kingdom and the United States. In addition, published evidence of the impact of the included apps was poor: of 53 apps, only 5 (9%) had an evidence base showing that the app had been trialed for usability or efficacy.

Conclusions: There is a need for evidence-based acute childhood illness apps of Canadian origin. This environmental scan offers a comprehensive picture of the health app landscape by examining trends in acute childhood illness apps that are readily available to parents and by identifying gaps in app design.

Introduction

Background

The unexpected COVID-19 outbreak has affected how health information is communicated, how individuals seek health information and services, and how these services are delivered [1,2]. Families are delaying seeking health care for children, introducing consequences for their current and future health outcomes by delaying emergency care and wellness visits [3-6]. Notably, there has been a 57% reduction in pediatric emergency department (ED) use, with use inversely correlated with pandemic severity [7]. Although on the surface this may look encouraging, this decrease was primarily due to a drop in low-acuity visits [7]. Providing resources to parents that aid in the detection and identification of childhood illnesses helps them to feel better equipped to assess their child's health and significantly changes parental health-seeking behaviors [8]. For context, these illnesses could include conditions such as gastroenteritis, bronchiolitis, and asthma.

Traditionally, parents obtained health information primarily from friends, family, and physicians [9,10]. In clinical settings, conventional modes of communicating complex health information to parents include information sheets and pamphlets [11]. In Canada, another common health resource for parents is teletriage, accessed by calling 811 in all but one province and one territory (Manitoba and Nunavut, respectively), where nurses answer health- and illness-related questions. This service is highly used: for example, in the province of Alberta, 694,313 calls were made among a population of 4.3 million in 2018 [12]. However, more recent studies in health information–seeking behavior suggest that this may be changing, with an Australian pediatric children's hospital survey indicating that 96% of the parents use the internet and 63% use a smartphone to search for health information [13]. In conjunction with Google searches, this behavior is used to establish a cause of illness, access means of assessing symptom severity, and exercise prudence regarding visiting a physician [14]. Parents also search for support through web-based forums, and this means of information gathering provides additional reassurance and validation [15].

However, some of these information resources are limited by accessibility and scalability. Remote locations (ie, geography) and staffing limitations create challenges for parents aiming to access health information about their child [16,17]. These challenges are compounded by the existing variance in parents' health literacy and language skills [11] and their willingness to ask others for health information; for example, many parents feel unable to express their anxiety about their child's health because of fear that they will be perceived as worriers [18,19]. In addition, 30% of the Canadian parents who have children presenting to the ED have low health literacy [20], which accounted for 940,637 of the 3,135,457 children's visits to Canadian EDs in 2018 [21]. Notably, parents with low health literacy are 3 times as likely to bring their child in for nonurgent conditions [22]. It is therefore vital to the mission of delivering equitable health care that resources are made accessible to parents with lower health literacy.

Mobile health (mHealth) apps offer a potential solution for improving health literacy by enabling access to health information through a new medium: the app marketplaces found on mobile devices such as phones and tablets [23]. A large study of 4974 American adults demonstrated that significant associations exist between adequate health literacy and the use of health information technology such as patient portal apps [24]. More than 96% of Americans [25] and 87% of Canadians [26] own a mobile phone, and smartphones are owned by 81% and 78%, respectively. Of mobile phone owners, more than 97% use an Android- or Apple-based operating system [27]. In 2017, nearly a third of the Canadian adults used mHealth apps to monitor their health [28]. Importantly, increased use of health apps has been shown to have a significant correlation with improved health behaviors [29].

Previous studies examining parents' internet search patterns for health information have indicated that a variety of information-seeking strategies are used and that information is trusted differently based on its source (eg, information found from searching university- and hospital-based websites was considered far more accurate and safer than information found within public search engine results) [30]. However, little is known about parents' interactions with health apps. A recent review suggested that existing app assessment tools are targeted at expert users, and nonexperts such as parents and caregivers still lack these resources to make an informed decision about which apps to use [31]. An investigation of patient-facing apps showed that the participants were unable to complete 57% of the relevant tasks because of a lack of confidence with the app and frustration with its design and navigation, but paradoxically they remained interested in using apps to self-manage care [32].

There are differing opinions on the current use of apps for parents. It has been pointedly suggested that "apps don't help parents of sick kids" [33]. However, this viewpoint drew its conclusions from a review that included only 3 digital interventions found in scientific studies [34]. As another review of apps pointed out, there is little crossover between scientific studies and app marketplaces: in a review of pain-related apps, those seen in the marketplace are not seen in scientific studies and vice versa [35]. Given the large and increasing number of health-related apps available (more than 300,000 in 2017 [36,37]), there is a disparity between the size of the health app landscape and its representation in scientific studies. To create an actionable set of information for parents and caregivers, it will be useful to look beyond apps that appear in scientific studies.

Health App Landscape

To create an inventory of the apps available to parents in North America that provide acute pediatric health information, we conducted an environmental scan, a review technique rooted in

business that is designed to summarize information for decision-makers [38,39]. Environmental scans are conducted to identify trends and avoidable pitfalls in a specific area of inquiry, be it related to product, policy, or strategy. We used the results of this scan to create a picture of the health app landscape by examining trends in apps related to acute pediatric health that are readily available to parents and identifying the gaps in app design that can be addressed.

Methods

Overview

To carry out a structured environmental scan, we designed a search strategy that worked with the algorithms of Google's and Apple's app marketplaces. The finalized search strategy was applied by 2 reviewers (JB and MC) to these 2 app marketplaces in Canada and the United States. Next, 2 reviewers (JB and MC) screened the apps based on predefined inclusion criteria and extracted attributes about each app. We built evidence tables describing app characteristics (eg, number of reviews) and app quality (eg, quality of information) using items from the Mobile App Rating Scale (MARS) [40] and analyzed the results for trends. It should be noted that although this approach includes elements of previously suggested search strategies for apps (eg, the 7 strategies for assessing apps proposed in the study by Boudreaux et al [41]), some elements of such a strategy (eg, searching app clearinghouses) are no longer widely used, and others (eg, piloting the apps) are beyond the scope of this environmental scan.

Search Strategy

We designed a set of 17 search terms in collaboration with a research librarian to identify relevant apps in the Google Play Store and Apple App Store. We limited our searches to these stores, given that the scope of this scan was to investigate apps that are likely to be accessible to North American parents. As other environmental scans that were drawn from for our approach have discussed [42], there is little formal knowledge publicly available about the specifics of how either store's search function works, beyond testing for specific functionality (eg, the Google Play Store's search used Boolean terms, whereas the Apple App Store's did not). The results presented here will be *best available* knowledge based on internet searches and responses to information requests.

On the basis of responses to the queries sent to the Google Play Store and Apple App Store support teams, we learnt that the Google Play Store app search currently integrates data from title, publisher, and app descriptions. The results displayed are then limited by their search rank for the specific search term used. The Apple App Store app search has different input parameters: it uses app title, keywords, and primary category to search, whereas the app's promotional text does not affect search rank and the search does not use the app's full description. However, keywords are not displayed for apps, making it difficult to expand search terms directly based on visible information.

Apps not available in a particular country's store or on a particular device were not visible in the results. Similarly, personalization of results (demonstrated by 2 users entering the same search term and generating different lists of results based on hidden user metrics) makes it difficult for a researcher to be sure that their queries are returning all relevant apps. We addressed this issue by building software using the Google Play Store's and the Apple App Store's application programming interfaces (the intermediary that communicates among different pieces of software) for both the Canadian and US stores and conducted tests to ensure that personalized results were not being returned and that the same set of results would be returned when different users ran the same search. This approach to remove result personalization addresses the inconsistency of personalized search results among users.

We examined the first 10 apps relevant to our scan that appeared using plain-language search terms (eg, child illness) for vocabulary in the stores' description related to the app's intended purpose and compiled a list of 17 search terms using language that appeared frequently: *Child illness*; *Pediatric illness*; *Paediatric illness*; *Child symptoms*; *Pediatric symptoms*; *Paediatric symptoms*; *Child care illness*; *Pediatric care illness*; *Paediatric care illness*; *Child diagnosis*; *Pediatric diagnosis*; *Paediatric diagnosis*; *Parent care child*; *Parent child illness*; *Child carer*; *Pediatric carer*; *Paediatric carer*.

Search and Screening

These terms were searched 4 times on September 14, 2020, for 4 marketplace locations (the US Apple App Store, US Google Play Store, Canadian Apple App Store, and Canadian Google Play Store), and a maximum of 50 results per search term per store returned (for a maximum of 850 apps returned per store location across all searches). We built custom software in Python (Python Software Foundation) that used app marketplace application programming interfaces and stored search results in a comma-separated values database. We confirmed with test searches that the same set of results was returned on 2 different devices. The results were imported into an Excel spreadsheet (Microsoft Corporation). The MARS was adapted to a spreadsheet-ready format to allow for ease of charting.

Three inclusion criteria were used to screen apps:

1. The app contained content related to acute child (age 0-21 years) illness.
2. The app's intended audience included parents or informal carers (eg, non–health care professionals).
3. The app still existed in the Google Play Store or Apple App Store when being assessed.

In addition, ad hoc reasons were recorded when apps included in the screening process could not be assessed with the MARS (eg, once downloaded, the app contained no content).

The title and description of each app were independently assessed by 2 researchers (JB and MC) for inclusion. In cases of ambiguity or where disagreement occurred after the results were compared, photos of the app depicting examples of its appearance and content on the Google Play Store or Apple App Store were used to gather additional information for inclusion and exclusion. The 2 researchers discussed this information to reach consensus.

App Quality Assessment

We based the app assessments on the MARS, a validated tool designed for health app assessment [40,43]. The MARS has high internal consistency and interrater reliability, designed to classify and rate the quality of novel health apps; it is also used as a tool for guiding app design. The MARS assesses app quality based on 5 subscales: engagement, functionality, esthetics, information quality, and subjective quality. Each section includes a number of items that are directed questions. All items are scored out of 5, with a higher score indicating a better outcome. Each subscale score is determined by taking a mean of the subscale item scores. The MARS subscales can be found in its entirety in Multimedia Appendix 1.

To determine interrater agreement, 2 reviewers (JB and MC) conducted the MARS assessment for 10% of the apps, consistent with previous work [44]. We calculated the interrater agreement by identifying occurrences of major differences in the item scores (differences greater than 1) [42] and assessing the agreement between the 2 reviewers using the Cohen κ [45]. After excluding one app from comparison because of an unresolvable difference in app accessibility among the test devices, the interrater agreement among the remaining app items was found to be substantial at 0.69 [46], above the 0.60 threshold indicating that significant disagreements exist [47], and 1 reviewer conducted the remaining assessments.

Individual app assessments were conducted by installing each app on an Android or Apple device (if the same app was available on both devices, we compared the 2 versions for major differences and assessed the Android version). The apps were then launched and browsed for 10 minutes. When necessary, an account was created for apps that required a log in to access the app's content. After exploring the app, the MARS was applied, with the app accessed as necessary to gather information for specific scale items. The characteristics of apps that the MARS collects include information such as the app's rating, date of last update, and intended age group; a complete list is shown in Multimedia Appendix 1, Table S1. The 23 MARS items, grouped by subscale, are presented in Multimedia Appendix 1, Table S2. To determine whether the app appeared in the literature, Google Scholar was searched for occurrences of the app's name.

Analyses

The item scores for app quality were averaged across dimensions to create a set of 5 scores for each app. The app scores were averaged across items in the engagement, functionality, esthetics, and information subscales to create a final app score. Data were treated as interval level data, consistent with the recommendations by Norman around the increased robustness of parametric tests [48,49]. The scores were converted to a score out of 5 for consistency with the MARS scoring. The scores of the top 3 apps were compared with the mean score of all apps on each MARS item and subscale using two-tailed *t* tests.

The apps were then grouped based on app cost (free vs paid); the 6 paid apps averaged Can $3.66 (US $2.89) per app, with a range of Can $1.99-$6.99 (US $1.57-$5.52), and the group scores were compared among the MARS subscales. This analysis was repeated by grouping the apps into 2 categories reflecting the duration since their last update: apps last updated less than 6 months ago and apps updated more than 6 months ago.

Separate from the MARS scores, we conducted a quantitative examination of the types of apps available in each store. The apps were grouped into 3 functional categories, and these groups were compared among the 4 stores for significant differences using chi-square tests. The 3 app categories were informational, actionable, and consultatory. The apps were classified into 1 of these 3 groups based on their primary functionality. If an app contained elements of more than one category, we examined the app's description to determine how the developers intended the app to be used. Informational apps primarily provided information about children's illnesses, whereas actionable apps guided users to care recommendations, and consultatory apps provided a telehealth-based *virtual physician* service.

We also examined how the top 3 apps for childhood illnesses differed from the average app scores by dimension and scale item and compared them using *t* tests.

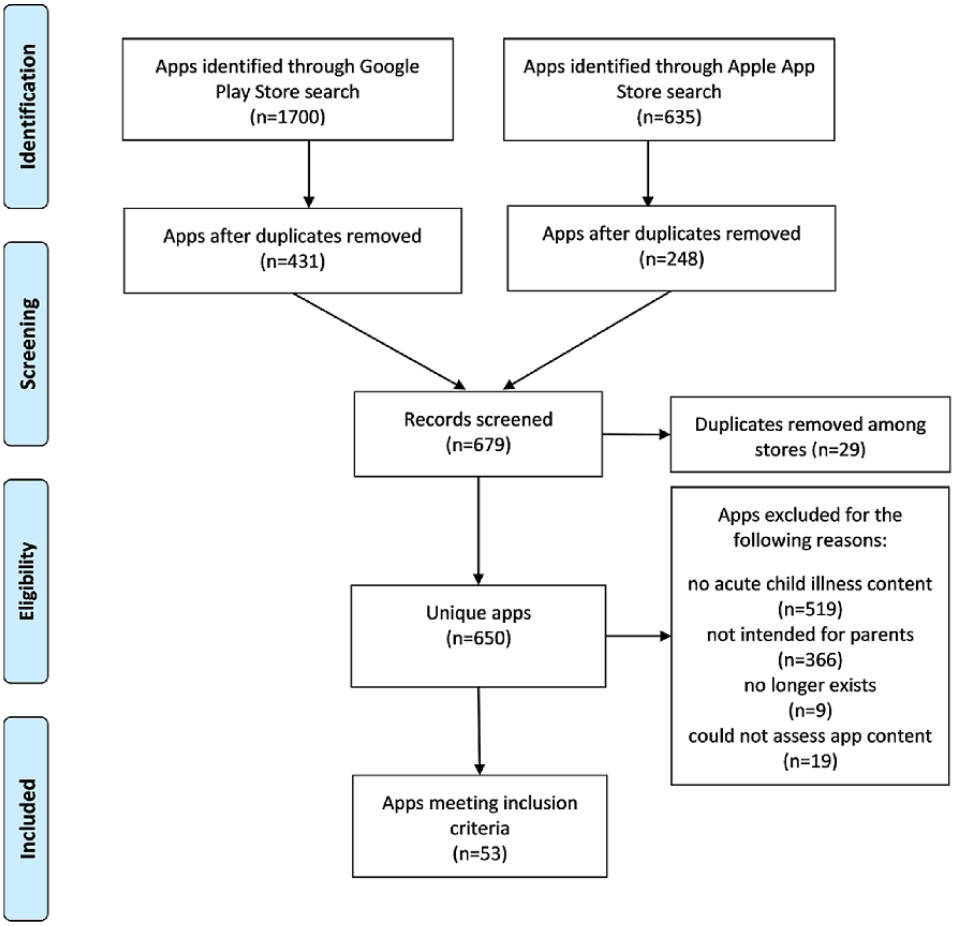
Results

Overview

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram (Figure 1) provides an overview of the search and screening process [50].

Our searches identified 2335 apps: 1700 (72.81%) from the Google Play Store and 635 (27.19%) from the Apple App Store. Of these 2335 apps, 650 (27.84%) were unique and 1685 (72.16%) were duplicates. After we applied our inclusion criteria to the 650 unique apps, 70 (10.8%) were considered potentially relevant; of these 70 apps, 17 (24%) were excluded, leaving 53 (76%) of apps for analysis. A total of 62% (33/53) of apps were available through the Google app marketplace and 55% (29/53) through the Apple app marketplace (9/53, 17%) of apps were available on both platforms).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram showing the environmental scan search and app screening process.



App Characteristics

All 53 apps focused on physical health: 19 targeted goal setting as a focus, whereas 18 targeted behavior change. A total of 50 apps had a theoretical background based in information or education delivery, 46 apps provided advice, tips, strategies, or skills training, 25 focused on assessment, and 17 dealt with information monitoring or tracking.

In all, 37 apps had a commercial affiliation, whereas 9 were government-affiliated, 3 had an affiliation with a nongovernmental organization, and one was affiliated with a university. Two apps—Asthma Action Hero and Pediatrics for All—did not fall into the MARS classification: the development of these apps was affiliated primarily with 2 individual physicians, Dr Helena K Bentley and Dr Hugo Rodrigues, respectively. Of the 53 apps assessed, 50 were targeted at young adults and adults, whereas one app was targeted at these groups as well as older adolescents, and 2 apps were targeted at general audiences, including children aged below 12 years. It should be noted that these findings are not in conflict with our inclusion criteria of an app's target audience consisting of parents: apps can target multiple user ages while including parents as an intended audience, and all age groups included in the MARS (with the exception of children) could include parents.

In terms of app requirements and functionality, 8 apps allowed password protection, 23 had sharing features (eg, options for posting to Facebook or Twitter), 19 had a visible app community, 27 required internet access to load all parts of the app (including advertisements), and 7 required users to have an account and log in. A total of 9 apps did not seem to contain any of these features.

MARS Ratings

The MARS subscales assess engagement using 5 items (mean 2.8/5, SD 0.86), functionality using 4 items (mean 4.0/5, SD 0.72), esthetics using 3 items (mean 3.1/5, SD 0.87), information quality using 7 items (mean 2.7/5, SD 1.32), and subjective quality using 4 items (mean 2.2/5, SD 0.79). The item scores for each dimension are summarized in Table 1.

Table 1. Mobile App Rating Scale item and subscale score averages for the assessed apps (N=53).

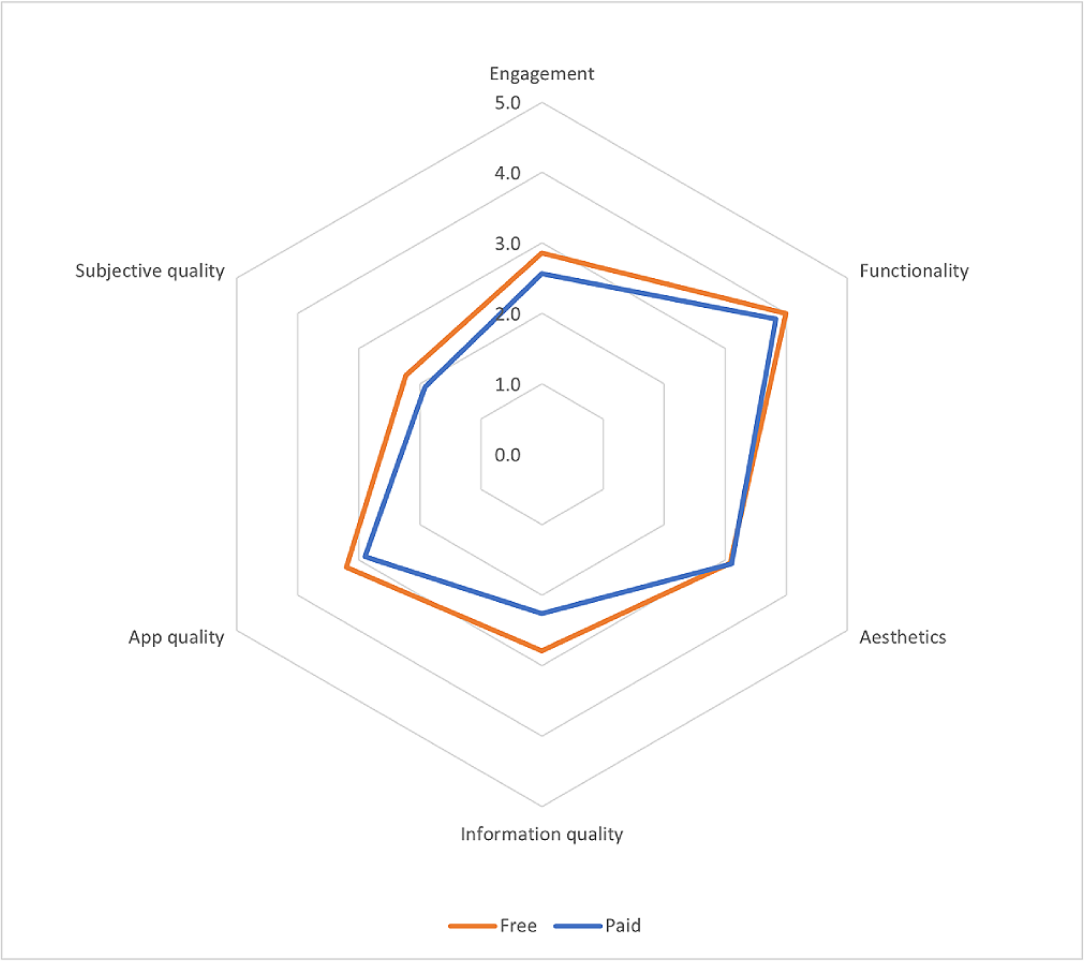
Subscale and item	Values, mean (SD)
Engagement	
Entertainment	2.2 (0.57)
Interest	3.1 (0.97)
Customization	2.0 (1.07)
Interactivity	3.3 (0.69)
Target audience	3.7 (0.92)
Engagement average	2.8 (0.86)
Functionality	
Performance	4.0 (0.81)
Ease of use	4.0 (0.68)
Navigation	3.9 (0.52)
Gestural design	4.1 (0.81)
Functionality average	4.0 (0.72)
Esthetics	
Layout	3.5 (0.75)
Graphics	3.0 (1.08)
Visual appeal	2.7 (0.72)
Aesthetics average	3.1 (0.87)
Information quality	
Description accuracy	4.3 (0.91)
Goal setting	2.5 (2.24)
Information quality	3.6 (0.95)
Information quantity	3.0 (1.09)
Visual information	3.0 (1.14)
Credibility	2.6 (1.47)
Evidence base	0.3 (0.89)
Information average	2.7 (1.32)
Subjective quality	
Recommended app	2.8 (1.31)
Frequency of app use	1.5 (0.54)
Willingness to pay for app	1.2 (0.71)
Subjective star rating	3.3 (1.17)
Subjective average	2.2 (0.79)

Of the 53 apps assessed, the average user rating across all versions of all apps was 4.4/5, and the apps had been rated a total of 386,024 times (median 6, IQR 0-68). Because there was a large SD of 39,730 ratings, we normalized the rating by n ratings for a weighted average rating of 4.7/5 across all apps, excluding the apps without ratings. Of the 53 apps, 6 had to be purchased for use, and all other apps were free to use. The MARS subscale summary scores, grouped by paid versus free apps, are presented in Table 2. A comparison between the paid and free app scores by MARS subscale is shown in Figure 2. The free apps scored slightly higher on the overall MARS score and on 4 of the 5 subscales, although the differences were not significant.

Table 2. Mobile App Rating Scale subscale summary scores for app cost and duration since last update (N=53).

Mobile App Rating Scale subscale	Cost			Duration since update		
	Free (n=47), mean (SD)	Paid (n=6), mean (SD)	*P* value	Less than 6 months, mean (SD)	More than 6 months, mean (SD)	*P* value
Engagement	2.9 (0.63)	2.6 (0.61)	.32	3.0 (0.80)	2.7 (0.48)	.16
Functionality	4.0 (0.58)	3.8 (0.58)	.53	4.0 (0.41)	4.0 (0.49)	.95
Esthetics	3.1 (0.70)	3.1 (0.81)	.94	3.3 (0.51)	3.0 (0.35)	.24
Information quality	2.8 (0.80)	2.3 (0.74)	.15	2.9 (1.26)	2.6 (1.02)	.38
Subjective quality	2.2 (0.79)	1.9 (0.86)	.42	2.4 (0.75)	2.1 (0.54)	.32

Figure 2. Comparison between paid and free app scores by Mobile App Rating Scale subscale.



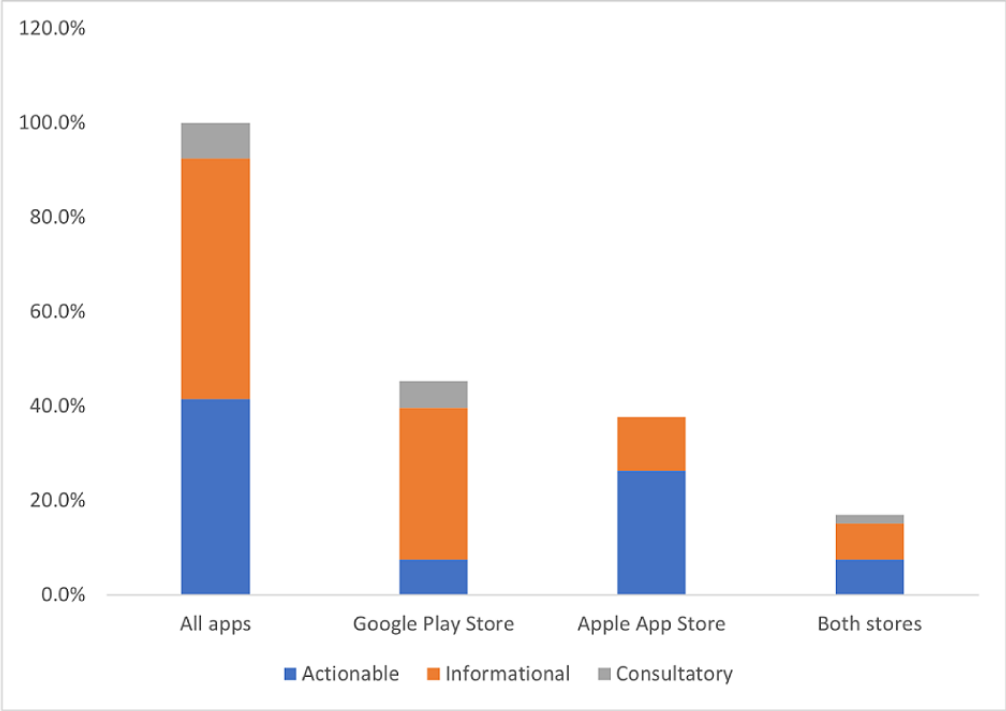
The apps were last updated, on average, on June 19, 2019, with a range of most recent updates between February 9, 2016, and August 31, 2020. Of the 53 apps assessed, 20 (38%) had been updated within 6 months at the time the marketplace searches were conducted. The differences in the app scores when grouped by duration since the last update are shown in Table 2. Those updated within 6 months scored slightly higher overall and on 4 of the 5 MARS subscales, but the scores were not significantly different.

Outside of the MARS assessments, we found that all the assessed apps could be sorted into one of three categories: primarily informational (eg, e-books), actionable (eg, tools), and consultatory (eg, telemedicine). On examining the distribution of these 3 categories between the Apple and Google app marketplaces, we found that the 2 stores had a different division of app types, as shown in Table 3 and Figure 3.

Table 3. Proportion of acute childhood illness apps available by store, grouped by primary functional category (N=53).

	Actionable	Informational	Consultatory
All apps, n (%)	22 (42)	27 (51)	4 (8)
Google Play Store	4 (8)	17 (32)	3 (6)
Apple App Store	14 (26)	6 (11)	0 (0)
Both app stores	4 (8)	4 (8)	1 (2)
Difference, *P* value	.002	.03	.08

Figure 3. Types of apps available in each marketplace.



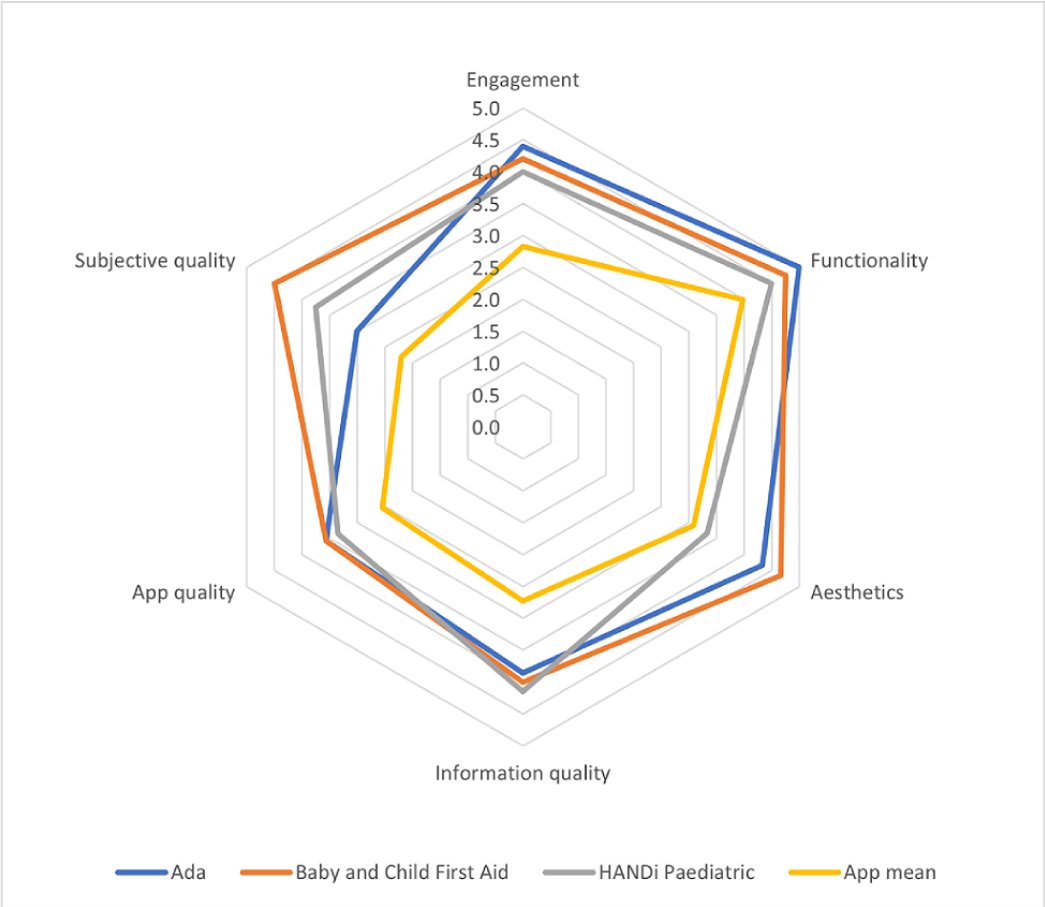
Of the 53 apps assessed, the top 3 on the MARS scale were Baby and Child First Aid by the British Red Cross (4.5/5), Ada by Ada Health (4.5/5), and HANDi Paediatric by Musgrove Park Hospital (4.2/5). Baby and Child First Aid provides common and emergency first aid scenarios and advice to parents. HANDi Paediatric has a similar focus on children's health, but it provides illness-related information rather than first aid advice. Ada is an artificial intelligence–enabled symptom checker that asks a series of diagnostic questions to users to suggest illnesses, and it can be used for third parties (eg, children). A visual representation of all MARS items is presented in Figure 4, which shows the average rating of all apps (in blue), and a comparison of the 3 apps that had the top ratings on each subdimension of the MARS. The top 3 apps were also examined by MARS subscale scores (Table 4; Figure 5).

Figure 4. Mobile App Rating Scale app radar for top three apps versus the mean score of all 53 apps.

Table 4. Top apps by Mobile App Rating Scale subscale score.

Mobile App Rating Scale subscale	App mean (SD)	Subscale score			Top 3 mean versus app mean, *P* value
		Baby and Child First Aid	Ada	HANDi Paediatric	
Engagement	2.8 (0.86)	4.2	4.4	4	<.001
Functionality	4 (0.72)	4.8	5	4.5	.01
Esthetics	3.1 (0.87)	4.7	4.3	3.3	.11
Information quality	2.7 (1.32)	4	3.9	4.1	<.001
Subjective quality	2.2 (0.79)	4.5	3	3.8	.06

Figure 5. Radar graph of top apps by Mobile App Rating Scale subscale.



Regarding the information provided within the apps, the source of information was often unlisted or unclear. However, we noted that some apps had matching information: 26% (14/53) of the apps contained content matching text from the Schmitt-Thompson Clinical Content nursing triage guidelines [51] and were similar in appearance and functionality. Predominantly, these apps were owned by individual children's hospitals in the United States (10/14, 71%). The 4 other apps used guidelines developed by the UK-based National Health Service clinical commissioning groups; each was developed for region-specific deployment (eg, Suffolk).

App Marketplaces

With regard to the differences between the app marketplaces, after pooling the results from both marketplaces, we noted that 4 apps were available in Canada but not in the United States, whereas 14 were available in the United States but not in Canada. However, with the exception of Baby and Child First Aid, the apps available in Canada but not in the United States were of low quality (mean MARS score 2.4/5, SD 0.20). Furthermore, of the apps available in the United States but not in Canada, 71% (10/14) were local hospital apps.

Discussion

Principal Findings

The purpose of conducting this environmental scan was to generate a comprehensive picture of the app landscape for parents in North America trying to make the best health decisions for their acutely ill child and for health care researchers to identify gaps in the app ecosystem. Given the observed trend of parents not seeking health care services for their children during the COVID-19 pandemic [7], it is important to address the gap we observed in Canadian context–specific evidence-based information to support parental health care decisions for their children. With the large changes in pediatric ED use during the COVID-19 pandemic [7], there is a need to create information access that identifies when interventions are necessary, rather than the current trend of parents delaying treatment of their children's less serious illnesses.

Our scan of the Apple App Store and Google Play Store in Canada and the United States identified 53 apps that we appraised using the validated MARS tool. The mean MARS score was 3.2/5 (SD 0.60), scoring slightly higher than the scale's *average* category of 3/5. The apps had a high overall functionality score, with especially strong gestural design (ie, whether interactions such as taps and other screen-based gestures in the app were consistent and intuitive when examining all app pages). Gestures worked in the apps with few errors. The esthetics score rated slightly below the app mean score, primarily because of a low visual appeal score, but it was bolstered by strong app layouts.

The app design choices were often outdated, an unsurprising finding considering the long average update time of 453 days. If only those apps that were updated within 6 months are

considered, the visual appeal score of the 20 included apps is slightly higher (although not significantly so). The low average information quality of apps was caused primarily by a low evidence base score (ie, proof that the app has been trialed, as verified by evidence in published scientific studies). This seems to diverge from mHealth app studies in other health disciplines such as pharmacy, which found that information quality had the highest scores among the subscales [52]. When we examined the literature for occurrences of app names, we found mention of only 4 apps: Ada, Kinsa (a digital thermometer companion), HANDi Paediatric, and WebMD Baby. Information quality was buoyed by a strong description accuracy (mean 4.3, SD 0.91; ie, whether the app's described content matched its actual content) and information quality (mean 3.6, SD 0.95). The average scores in subjective quality app ratings (mean 3.3, SD 1.16) were similar to the overall assessed scores, whereas willingness to pay for an app (mean 1.2, SD 0.71) and projected app use (mean 1.5, SD 0.54) were low. However, these low scores may better reflect the fact that most of the apps were designed primarily for ad hoc use during acute illnesses, rather than for regular use in chronic health situations.

We found that the apps included in each store seemed to have different foci. On closer examination, the Google marketplace apps were noted to be primarily information-focused (eg, e-books), with 4 times as many (17/53, 32%) information-focused apps as action-oriented apps (eg, symptom-tracking tools; 4/53, 8%). The Apple marketplace apps had the opposite trend: there were more than twice as many action-oriented apps (14/53, 26%) as information-focused apps (6/53, 11%). This finding suggests that a parent's choice of mobile device brand may not be incidental: beyond this choice leading to different information availability, there is a difference in the format of information presented. Specifically, unless parents have access to both Android and Apple devices, they will only have access to apps available on one app store. Depending on the device available, these differences may affect how effectively parents are able to find and use an app to help their child. For example, the Apple and Google app stores differ in how apps are assessed for quality and how their search algorithms work, as well as in quality requirements for app developers [53]. As has been previously suggested, the mode in which information is presented matters [54-56], and this difference has the potential to affect how parents learn more about their child's illness. In the same manner, the fact that there are apps that are available in one country but not in another also affects parents' ability to find health information. User characteristics also present a possible barrier to accessing health information: a Dutch study concluded that app use differed based on user demographics (eg, app use was higher in younger, more educated users) [57].

When we examined app pay practices, we found that the paid apps scored slightly lower (although not significantly so, based on two-tailed *t* tests assuming equal variances based on similar domain and overall variances) on 4 of the 5 MARS subscales—engagement (P=.29), functionality (P=.51), information quality (P=.13), and subjective quality (P=.36)—and higher on one subscale: aesthetics (P=.93). Limiting the interpretation of this finding is the small number of paid apps compared with that of free apps (6 vs 47, respectively). We also examined whether the apps that were updated more than 6 months ago differed in quality from the more recently updated apps. Although only small differences were seen among the apps, it will be interesting to investigate in future studies whether, as noted with previous work [58], some apps worsen with time in domains such as privacy. Trust is an increasingly important dimension of apps, given their status as an emerging health technology [59], and it has been shown to be an important consideration in app adoption in some groups such as the Deaf [60]. A limitation of the MARS is that it does not assess app credibility to the depth suggested by other app assessment frameworks such as the mHealth App Trustworthiness checklist [59]. Future research could assess apps using such a checklist to discover how items important to accessibility, such as customization, correlate with app trustworthiness dimensions such as user autonomy and empowerment.

On examining the top 3 apps, we noted that Baby and Child First Aid presents 17 common first aid scenarios (eg, *allergic reaction*) to parents, with a set of causes and steps to follow (eg, basic triage, ideal action to take, and action to take in an emergency). This app also allows parents to self-assess the effectiveness of the teaching videos and other materials available through quizzes. This app is highly relevant, comes from a credible organization, and is updated regularly (at the time of writing, the most recent update was within 6 months, on October 12, 2020). However, this app's credibility could be improved by demonstrating its effectiveness in peer-reviewed studies. Ada is an artificial intelligence–based symptom checker that uses a series of questions to reach a list of possible diagnoses, ranked in order of likelihood. It provides options to check another person's symptoms, track symptoms, and centralize health information (eg, medications and insurance). Ada benefits from a presence in scientific studies [61,62]. HANDi Paediatric provides parents with home assessment guidelines and information about common childhood illnesses. Notably, it includes nearby ED locations and the ability to call emergency services if needed. Taken together, these 3 apps give parents information related to emergency pediatric first aid, identification of (and appropriate response to) common childhood illnesses, 2 ways to check symptoms, and a means of responding to emergency situations. Two of the top apps (Ada and HANDi Paediatric) have a substantial, published evidence base [63-65], and there is a significant difference between their scores and the mean score of all apps for this item (Ada=3/5, HANDi Paediatric=3/5; item mean 0.28/5, SD 0.89; P<.001). A comparison of these top 3 apps with the app average shows that the top 3 apps are significantly different in terms of engagement (P<.001), information quality (P<.001), and functionality (P=.01), with no significant differences for subjective quality and esthetics.

Among all the apps reviewed, there was a lack of app presence in published studies (MARS item evidence base: Has the app been trialed or tested? Must be verified by evidence [in published scientific literature]; mean 0.28/5, SD 0.89). However, information quality and quantity were above average and average (mean scores 3.6 and 3.0, respectively). Therefore, there seems to be a gap between the app's provision of quality content

and the ability to make published claims about the effectiveness of accessing that content. This is an area that has been examined previously: a 2014 study found that there was no crossover between academic and commercial app offerings for pain-related apps [35]. The lack of rigor in assessing apps gave rise to the concern that a lack of peer-reviewed apps has resulted in an unregulated and uncertified set of apps available to consumers and that this could be addressed by scientists leveraging decreasing app development times and costs to offer more evidence-supported apps [66]. As one recent investigation into symptom checkers concluded, apps must be assessed on the accuracy of their results in the context of coverage of available conditions and patient populations if these apps do not give results for some subgroups (eg, children) [67].

In assessing these apps, a key gap for parents to be aware of, and for developers to note, was the lack of Canadian-developed content available to parents. Although apps for children's illnesses were developed using knowledge from US and UK sources, there were no apps that seemed to use Canadian-based information. Among the top 3 apps, Ada develops medical content through an internally peer-reviewed process, using a team of physicians in the United States [68]. HANDi Paediatric bases its information on consultants and general practitioner and hospital clinical guidelines in the United Kingdom [69]. Baby and Child First Aid does not list a source of information. This strongly suggests that although high-quality information for childcare is available in apps, Canadian parents must rely on guidelines developed elsewhere. It also means that Canadian interests, values, and approaches to pediatric illnesses are not well represented in the app marketplaces. This lack of representation is concerning and suggests a gap in availability of an app for parents based on Canadian evidence-based health guidelines.

Limitations

When we scrutinized the app stores, we found that the Google Play Store does not recommend similar apps if the app being examined is not compatible with the user's devices, and the Apple App Store does not show apps that are unavailable on the user's current device. Spellings and idioms were important: searching *pediatric* returns apps from North America first, whereas *paediatric* returns UK- and Australia-based apps. The mechanisms behind each store's search parameters are unique and undisclosed, and the differences in search mechanisms that are described do not support the use of a single systematic process used to search both stores. Therefore, there is no way to guarantee that all relevant and currently available apps have been captured during the Play Store and App Store searches. We attempted to mitigate this limitation through our use of multiple search terms co-designed with a research librarian and having 2 reviewers assess all apps for inclusion. In addition, the testing of each app was conducted by 1 evaluator (with a second evaluator assessing 5/53, 10% of apps); having more evaluators comparing ratings would decrease the possibility that the rating agreements occurred by chance. Our examination of peer-reviewed study availability relating to single apps was limited to a single search engine (Google Scholar), and rigor could have been added to this method by triangulating results with PubMed and directly checking developer websites.

Conclusions

This study examined 53 apps for parents related to acute childhood illness using the MARS assessment tool. Overall app quality was rated slightly above average, driven by high scores in functionality, whereas there was scope for the apps to improve their information content through increased presence in peer-reviewed studies. There was a strong need identified for evidence-based apps of Canadian origin. These apps should be developed in a way that ensures accessibility of content, transparency of information sources, and effectiveness as demonstrated through peer-reviewed studies. In the case that developers are unable to test for effectiveness, demonstrating that the app was created using evidence-based, peer-reviewed information would give parents a basis for trusting the app's content. Considering these findings in relation to the current practice of most parents of using internet searches as their clinician-adjunct source of health information, there is a clear opportunity for clinicians and scientists to collaborate to create apps that increase parents' confidence in their health knowledge.

Acknowledgments

The authors thank Ms Liz Dennett at the University of Alberta's JW Scott Health Sciences Library for her help in designing a search strategy and examining the characteristics of app marketplaces. The authors also thank the Stollery Children's Hospital Foundation, which supported this study through the Stollery Science Lab. Abstract

Background: Integrated community case management (CCM) has led to reductions in child mortality in Malawi resulting from illnesses such as malaria, pneumonia, and diarrhea. However, adherence to CCM guidelines is often poor, potentially leading to inappropriate clinical decisions and poor outcomes. We determined the impact of an e-CCM app on the referral, reconsultation, and hospitalization rates of children presenting to village clinics in Malawi.

Objective: We determined the impact of an electronic version of a smartphone-based CCM (e-CCM) app on the referral, reconsultation, and hospitalization rates of children presenting to village clinics in Malawi.

Methods: We used a stepped-wedge, cluster-randomized trial to compare paper-based CCM (control) with and without the use of an e-CCM app on smartphones from November 2016 to February 2017. A total of 102 village clinics from 2 districts in northern Malawi were assigned to 1 of 6 clusters, which were randomized on the sequencing of the crossover from the control phase to the intervention phase as well as the duration of exposure in each phase. Children aged ≥2 months to <5 years who presented with acute illness were enrolled consecutively by health surveillance assistants. The primary outcome of urgent referrals to higher-level facilities was evaluated by using multilevel mixed effects models. A logistic regression model with the random effects of the cluster and the fixed effects for each step was fitted. The adjustment for potential confounders included baseline factors, such as patient age, sex, and the geographical location of the village clinics. Calendar time was adjusted for in the analysis.

Results: A total of 6965 children were recruited—49.11% (3421/6965) in the control phase and 50.88% (3544/6965) in the intervention phase. After adjusting for calendar time, children in the intervention phase were more likely to be urgently referred to a higher-level health facility than children in the control phase (odds ratio [OR] 2.02, 95% CI 1.27-3.23; *P*=.003). Overall, children in the intervention arm had lower odds of attending a repeat health surveillance assistant consultation (OR 0.45, 95% CI 0.34-0.59; *P*<.001) or being admitted to a hospital (OR 0.75, 95% CI 0.62-0.90; *P*=.002), but after adjusting for time, these differences were not significant (*P*=.07 for consultation; *P*=.30 for hospital admission).

Conclusions: The addition of e-CCM decision support by using smartphones led to a greater proportion of children being referred to higher-level facilities, with no apparent increase in hospital admissions or repeat consultations in village clinics. Our findings provide support for the implementation of e-CCM tools in Malawi and other low- and middle-income countries with a need for ongoing assessments of effectiveness and integration with national digital health strategies.

Introduction

Malawi has one of the world's lowest doctor-to-patient ratios [1], with ≤1 doctor per 50,000 people [2-5], which is considerably lower than the World Health Organization's recommendation of 1 doctor per 5000 people. In order to improve access to essential health services for many of Malawi's marginalized communities, the Malawi Ministry of Health started an Emergency Human Resources Program in 2005 when it recruited and trained selected community members to become health surveillance assistants (HSAs) [6]. HSAs are allocated to hard-to-reach areas, each serving a population of approximately 1000 [7]. They have several duties they are expected to carry out (eg, family planning, environmental health, and HIV counseling), of which community case management (CCM) is integral [8]. HSAs are encumbered by an overwhelming workload, insufficient day-to-day professional support (including training opportunities), and inadequate remuneration [7]. These competing pressures may lead to further progress in disease control and childhood survival. CCM is a paper-based clinical decision aid that enables frontline community health workers known as HSAs in Malawi to recognize and manage the major causes of mortality among children aged ≤5 years in low- and middle-income countries (LMICs), specifically malaria, pneumonia, diarrhea, and malnutrition [9]. CCM uses simple signs and symptoms to help HSAs identify self-limiting conditions that can be managed in the community and more serious illnesses that require medical attention from clinically trained health personnel (eg, nurses) at higher-level health care facilities or hospitals. The introduction of this strategy has provided access to basic health care that many children would otherwise have been denied [10].

While mortality rates among the under-fives have steadily declined since the introduction of CCM in 2009, concerns have begun to surface about inconsistent standards of delivery of CCM; it has been observed that HSAs do not always follow all the steps in the protocol when assessing children, potentially resulting in inappropriate clinical management decisions [11]. In Malawi, HSAs deliver CCM from village clinics; in a country where 84% of the population resides in rural locations [12] more than 8 km from facility-based health providers, CCM has helped provide equitable access to health care for many communities that were previously underserved [13]. CCM is widely implemented in LMICs and has demonstrated some success in improving the management of children with acute illness and reducing mortality. For example, the CCM of pneumonia reduced pneumonia-associated mortality by 70% in some developing countries [14,15]. As the adoption of CCM in Malawi in 2008, this strategy has contributed to significant reductions in under-five mortality from 97.8 per 1000 live births to 52.7 in 2017 [16].

The implementation of CCM is based on the diagnostic and prognostic value of certain signs and symptoms; children with uncomplicated illness are managed in the community with symptomatic treatment, whereas those with *danger* signs are urgently referred to a health facility that can provide a higher level of care. Accurate and timely urgent referral is an integral component of CCM and is a prerequisite for improving health outcomes among acutely unwell children. Aside from preventable mortality, failure to refer at the appropriate time can overburden constrained resources at higher-level facilities needed for treatment of severely unwell children, lead to unnecessary hospital admissions, or involve caregivers repeating inconvenient journeys to village clinics because their child's condition has not resolved or is deteriorating.

However, there is considerable evidence of suboptimal management decisions from field studies, including poor HSA adherence to the required steps of CCM [17]. HSAs do not always follow all the steps in the protocol when assessing children, potentially resulting in inappropriate clinical management decisions [11]. Indeed, because CCM is delivered using a paper-based tool, it is easy for relevant fields to be overlooked or for clinically invalid data to be recorded, contributing to inappropriate management decisions. Poor adherence to CCM is further compounded by factors such as transportation costs or distance to higher-level facilities or medication supply chain issues that further impede the potential impact of CCM.

The proliferation of mobile phones and cellular networks in LMICs has prompted the development of several mobile health (mHealth) technologies as alternative platforms for delivering

childhood intervention strategies [18]. Decision support systems within these technologies can facilitate clinical decision-making and offer potential advantages over paper-based tools [19,20]. The potential advantages of e-CCM over paper-based CCM include shorter consultation time and a greater likelihood of correct diagnostic and treatment decisions, as noted in previous studies [21,22]. However, adopting mHealth tools as an adjunct (or replacement) for current paper-based assessment and reporting tools requires considerable initial and sustained investment. Therefore, demonstrating the impact of mHealth on health care outcomes is crucial. This study aims to determine the effectiveness of smartphone-based CCM on urgent referral, reconsultation, and hospitalization of children aged ≤5 years in Malawi.

Methods

Study Design

The full study protocol has been published [23]. In summary, we used a stepped-wedge, cluster-randomized design trial to compare paper-based CCM with a mobile phone app version of the CCM that was developed by the Supporting LIFE research team (SL e-CCM app) [24]. Village clinics were grouped into 6 clusters based on geographic proximity, and clusters were randomized to determine the sequence of crossover from the control (using paper CCM alone) to the intervention (using paper CCM as well as SL e-CCM) and the duration of exposure (2-7 weeks) in each phase. Children aged ≥2 months to <5 years were triaged using paper CCM or paper CCM+SL e-CCM app depending on when they presented to village clinics.

This study was conducted in 102 village clinics across Nkhata Bay and Rumphi districts in northern Malawi, where Chichewa, Chitumbuka, and Tonga are the principal languages spoken. Cassava farming is the main occupation of the 215,429 inhabitants of the Nkhata Bay District, situated on Lake Malawi. Rumphi district, which extends west from Lake Malawi to the Zambian border, is principally a tobacco farming community with 166,460 inhabitants. According to the National Statistic Office of Malawi, 23.4% and 17.4% of the adult population (defined as those aged ≥15 years) are illiterate in Nkhata Bay and Rumphi, respectively. Village clinics are typically basic community structures equipped only with rudimentary diagnostic aids (eg, stopwatch) and medical supplies (eg, oral rehydration therapy and artemisin-based combination therapy). Each clinic is operated by a single HSA, who is a government-employed community health worker responsible for assessing and managing acutely unwell children using CCM. HSAs are people who possess a Malawi School Certificate of Education or Junior Certificate of Education. They are frontline health workers who work in the village clinic [7]. A village clinic serves a catchment area of approximately 1000 people [10,25]. Both districts are predominantly rural, with 30%-35% of the population residing more than 8 km from a health facility with qualified clinical staff [26].

Participants

A total of 102 HSAs were recruited to participate (men: 77/102, 75.4%; women: 24/102, 23.5%; not disclosed: 1/102, 0.9%). The ages of these HSAs ranged from 27 to 59 years, and they had been working as HSAs for between 1 and 27 years (mean 10.1 years). Before the trial, 101 HSAs already had phones, of which 36.6% (37/101) were smartphones.

HSAs consecutively enrolled eligible children aged ≥2 months to <5 years from November 2016 to February 2017, who presented with acute illness but were not unconscious, convulsing, or previously enrolled in the study. Because of high rates of illiteracy in Nkhata Bay and Rumphi districts, caregivers were required to verbally consent in their preferred language for their child to be enrolled to avoid limiting participation by literacy levels.

Randomization and Blinding

Village clinics were grouped into 6 clusters based on geographic proximity. Clusters were then randomized using a web-based random number generator to determine the sequencing of crossover of clusters from the control phase (paper CCM) to the intervention phase (paper CCM+SL e-CCM), as well as the duration of exposure (2-7 weeks) in each phase. Neither the participants nor the researchers were blinded to allocation. Baseline data were collected during the index visit and recorded in the village clinic register (VCR) in the control arm and in the SL e-CCM app during the intervention phase.

HSA Training

Before commencing recruitment, we engaged with national and district-level health authorities to explain to them the objectives of the clinical trial and the procedures to be done. HSAs recruited by the study team attended a 1-day training workshop to learn study procedures for the control and intervention phases of the trial, as well as how to operate the SL e-CCM app and the smartphone (details of the hardware and development and functionality of the app are described in full elsewhere [23]). Before crossover from the control to the intervention phase, HSAs attended a further 2-day training workshop to familiarize them with study procedures and the technology specific to the intervention phase. Training workshops were conducted in English with a member of the research team fluent in the regional dialects of Chichewa, Tonga, and Chitumbuka to facilitate communication. HSAs were permitted to use their clinical discretion if they disagreed with the care recommendations provided by the SL e-CCM app.

Procedures

During the control phase, HSAs used paper-based CCM to assess and manage children for 2-7 weeks (depending on the assigned order of clusters after randomization). Details of clinical presentations were recorded by hand in the VCR, as per standard practice. During the intervention phase, HSAs recorded clinical presentations synchronously in both the VCR and SL e-CCM apps. Form validation ensured that HSAs were required to complete every field on the e-CCM app [11]. A complete inventory of the data collected by HSAs during each phase of the trial has been reported elsewhere [23]. Outcome data were collected retrospectively using local nursing students or graduates who traveled to village clinics and higher-level health facilities within an assigned catchment area on a weekly basis to manually abstract data from patient records. Enrolled children were reidentified at clinical sites by cross-referencing each

child's full name, date of enrollment, date of birth, and sex along with caregiver name and contact details prepopulated on clinical research forms. Given that caregivers can represent to any village clinic and higher-level health facility, child identifiers and subsequent attendances at health facilities were verified by caregivers via cell phone beforehand, to improve the efficiency of data collection. Clinical data were recorded in the VCR during both the control and intervention phases of the study in order to fulfill local reporting requirements for village clinics and district health authorities.

Outcomes

The primary outcomes were urgent referrals to higher-level health facilities, reconsultations to village clinics, and hospitalization within 7 days of study enrollment.

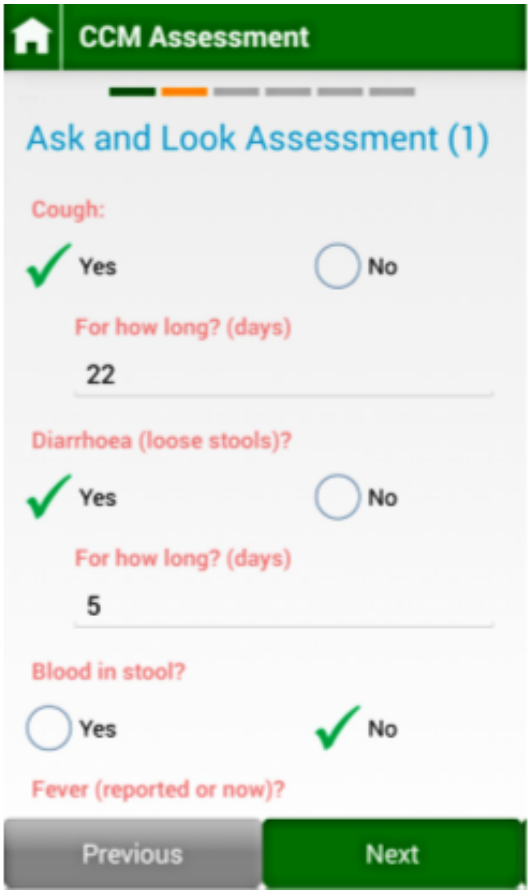
Outcomes were determined by case note review of VCR and health facility records undertaken 2-weeks after study enrollment. Reconsultations were defined as reattendances to any village clinic for a health concern related to the reason for presentation recorded in the VCR at baseline, and hospital admissions related to an inpatient stay in a secondary or tertiary care facility for ≥1 day because of deterioration of illness recorded in the VCR.

Description of SL e-CCM App

The SL e-CCM App was developed and implemented by the Supporting LIFE research team and is an android-based smartphone app that replicates the paper-based CCM decision support tool routinely used by HSAs in Malawi and across sub-Saharan Africa [27]. The tool enables HSAs to enter the information they would usually gather using the paper CCM form, answer a series of clinical questions, and obtain selected clinical measurements (eg, breathing rate). Data are entered directly into the app via touch screen technology, either by selecting the appropriate option or by entering free text [23,28]. The app provides treatment recommendations, including medications, referral to health facilities, and health education for parents. The app requires that users complete all steps (ie, questions and prompts) before the user can proceed to the next step. Figures 1 and 2 show the dashboard of the Supporting LIFE App.

Figure 1. The Supporting LIFE App. CCM: community case management; IMCI: Integrated Management of Childhood Illnesses.

Figure 2. CCM assessment using the Supporting LIFE App. CCM: community case management.



Statistical Analysis

Descriptive analyses were used to examine the individual-level baseline characteristics of children between the control and intervention periods across all clusters. Participant characteristics included the child's age, sex, the district in which the child was recruited, and the treatment decision by the HSA at the index visit. For continuous measures, we reported the mean and SD. For categorical measures, we reported counts and proportions. The 2-tailed *t* tests and chi-square tests were used to determine bivariate differences for continuous and categorical measures, respectively.

Following an intention-to-treat principle, we evaluated overall differences in the proportion of children who were urgently referred to a higher-level health facility by HSAs between the control and intervention periods. For the primary analysis, urgent referrals to higher-level facilities were evaluated at the patient level using multilevel mixed effects models [29]. As all outcomes were binary, a logistic regression model with random effect of cluster and fixed effect for each step was fitted [30,31]. Potential confounders included baseline factors of age, sex, and geographical location of village clinics (ie, urban and rural). Calendar time was also adjusted for in the analysis, and the effect of time was modeled as a categorical variable [30]. Odds ratios (ORs) with 95% CI were estimated and reported. Potential effect modification by age and sex was assessed by stratification and inclusion of interaction terms with the intervention period in the model. Other main outcomes of reconsultations at village clinics and hospitalizations were also analyzed using mixed models with the same potential confounders and effect modifiers. For secondary analyses, we explored the heterogeneity in treatment effects between clusters using within-cluster comparisons between the intervention and control periods. Statistical significance was set at $P<.05$, and all tests were two-sided. All analyses were conducted using Stata version 14 (StataCorp). Patient flow, including the number and reasons for exclusion and withdrawal, was reported according to CONSORT recommendations.

Dissemination of Results

The results of this study will be disseminated through presentations in research conferences, and copies of this study will be put in the Libraries of Mzuzu University, College of Medicine, University of Washington, University College Cork, Lund University, and Imperial College London.

Results

Participants Recruited and Baseline Characteristics

A total of 6965 children were recruited, of whom 49.11% (3421/6965) were included in the paper CCM (control) phase and 50.88% (3544/6965) were included in the e-CCM (intervention) phase (Table 1). A larger number of children were recruited from the Nkhata Bay district than from Rumphi in both trial phases, reflecting the higher population in the former, as noted above. Children recruited in the control phase were significantly younger (mean age 24.6, SD 15.4 months) than those in the intervention phase (26.9, SD 16.1 months). Most children in both the control (3217/3421, 94.03%) and in the

intervention phases (3335/3544, 94.10%) were treated at home after their assessment by the HSA (Table 1).

Table 1. Baseline characteristics of participants (N=6965).

Characteristic	Control arm (paper-CCM[a]; n=3421)	Intervention arm (e-CCM app+paper CCM; n=3544)	*P* value
Age (months), mean (SD)	24.6 (15.4)	26.9 (16.1)	<.001
Sex, n (%)			
Male	1741 (50.89)	1783 (50.31)	.63
Female	1680 (49.10)	1759 (49.63)	.66
Not recorded	0 (0)	2 (0.06)	.16
District[b], n (%)			
Rumphi	1590 (46.47)	1535 (43.31)	.01
Nkhata Bay	1777 (51.94)	1962 (55.36)	<.001
HSA[c] treatment decision at index visit, n (%)			
Urgent referral	179 (5.23)	198 (5.58)	.51
Treated at home or advice given to caregiver	3217 (94.03)	3335 (94.10)	.91
Nothing recorded in village clinic register	25 (0.73)	11 (0.31)	.01

[a]CCM: community case management.

[b]Information on districts was missing for 54 participants in the control group (1.6%) and 47 participants in the intervention group (1.3%).

[c]HSA: health surveillance assistant.

Effect of Intervention on Urgent Referral

A total of 5.23% (179/3421) of children in the control phase were urgently referred to a higher-level health care facility, compared with 5.58% (198/3544) in the intervention phase (OR 1.04, 95% CI 0.83-1.29; *P*=.75; Table 2). After adjusting for the effects of time (model 1), the OR was 2.02 (95% CI 1.27-3.23; *P*=.003), in favor of the intervention. Further adjustment for age, sex, and district (models 3 and 4) provided similar strengths of association. We found no significant effect modification in the tested models. Examination of cluster-specific treatment effects, adjusted for calendar time, across the 6 clusters showed that the direction of effect was identical to the overall effect (ie, favoring intervention) in 4 of the 6 clusters but was statistically significant in only one of these (cluster 2; *P*<.001) most likely affected by sample size. In 2 of the 6 clusters (clusters 3 and 4), the direction of effect favored the control arm but was statistically significant in only one of these clusters (cluster 4; *P*=.009).

Table 2. Effects of intervention on urgent referral (N=6965).

Model	Control arm (n=3421), n (%)	Intervention arm (n=3544), n (%)	OR[a] (95% CI)	*P* value	ICC[b] (95% CI)
Urgent referral	179 (5.23)	198 (5.58)			
Model 1: unadjusted	N/A[c]	N/A	1.04 (0.83-1.29)	.75	0.128 (0.042-0.326)
Model 2: adjusted for time	N/A	N/A	2.02 (1.27-3.23)	.003	0.127 (0.042-0.325)
Model 3: adjusted for time, age, and sex	N/A	N/A	2.01 (1.26-3.21)	.003	0.125 (0.041-0.321)
Model 4: adjusted for time, age, sex, and district	N/A	N/A	2.15 (1.44-3.22)	<.001	0.024 (0.000-0.054)

[a]OR: odds ratio.

[b]ICC: intracluster correlation coefficient.

[c]N/A: not applicable.

Effect of Intervention on Repeat Consultation

Repeat consultations with an HSA within 7 days occurred for 5.26% (180/3421) of children in the control phase, compared with 2.42% (86/3544) in the intervention phase (OR 0.45, 95% CI 0.34-0.59; *P*<.001; Table 3). After adjusting for the effects of time (model 1), the OR was 0.57 (95% CI 0.32-1.04), in favor of the intervention arm, but this was not statistically significant (*P*=.07). Further adjustment for age, sex, and district (models 3 and 4) provided similar ORs. We found no significant effect modification in these models. Examination of cluster-specific treatment effects showed that the direction of effect for the outcome of repeat consultation favored the control arm in 4 clusters (clusters 1, 3, 4, and 5) and was statistically significant

in only one of these (cluster 4; *P*=.04), whereas in clusters 2 and 6 it favored the intervention, but was not statistically significant (cluster 2, *P*=.79; cluster 6, *P*=.09).

A total of 219 clinical features were recorded on the children attending repeat consultations, although not all children had clinical symptoms recorded, and more than one clinical feature could be recorded in one child. The most common symptoms reported were fever for <7 days, cough for 21 or more days, diarrhea for <14 days without blood, and fast breathing (Table 3).

Table 3. Effects of intervention on repeat consultation (N=6965).

Model	Control arm (n=3421), n (%)	Intervention arm (n=3544), n (%)	OR[a] (95% CI)	*P* value	ICC[b] (95% CI)
Repeat consultation	180 (5.3)	86 (2.4)			
Model 3: adjusted for time, age, and sex	N/A[c]	N/A	0.57 (0.32-1.04)	.07	0.186 (0.063-0.435)
Model 4: adjusted for time, age, sex, and district	N/A	N/A	0.58 (0.32-1.05)	.07	0.084 (0.024-0.250)

[a]OR: odds ratio.

[b]ICC: intracluster correlation coefficient.

[c]N/A: not applicable.

Effect of Intervention on Hospital Admission

A total of 565 children were admitted to the hospital, 9.35% (320/3421) in the control arm and 6.91% (245/3544) in the intervention arm (OR 0.75, 95% CI 0.62-0.90; *P*=.002; Table 4). Of these, 51.3% (290/565) were urgently referred by their HSA, and 47.8% (270/565) were taken to the hospital by their parents (information on origination was not available for 5 children). After adjusting for the effects of time (model 2), the OR was 1.23 (95% CI 0.83-1.81), in favor of the control arm, but was not statistically significant (*P*=.30). Further adjustment for age, sex, and district (models 3 and 4) provided similar ORs. We found no significant effect modification in these models. Examination of cluster-specific treatment effects showed that the direction of effect on hospital admission favored the control arm in 4 clusters (clusters 1, 2, 5, and 6) and was statistically significant in only one of these (cluster 2; *P*=.002), and the intervention arm in 2 clusters (3 and 4), but was not statistically significant (cluster 3, *P*=.49; cluster 4, *P*=.10).

Table 4. Effect of intervention on hospital admissions (N=6965).

Model	Control arm (n=3421), n (%)	Intervention arm (n=3544), n (%)	OR[a] (95% CI)	*P* value	ICC[b] (95% CI)
Hospitalization	320 (9.4)	245 (6.9)			
Model 3: adjusted for time, age, and sex	N/A[c]	N/A	1.23 (0.83-1.82)	.29	0.034 (0.010-0.113)
Model 4: adjusted for time, age, sex, and district	N/A	N/A	1.14 (0.78-1.67)	.50	0.004 (0.000-0.036)

[a]OR: odds ratio.

[b]ICC: intracluster correlation coefficient.

[c]N/A: not applicable.

Discussion

Principal Findings

We found that the addition of e-CCM to the usual practice of assessing and treating children with HSAs using the paper-based assessment tool led to a significant increase in the proportion of children referred urgently to higher-level health care facilities. This direction of effect of the intervention was found in most but not all of the 6 clusters of clinics. The intervention was also associated with smaller proportions of children who attended a repeat consultation at the village clinic or who needed to be admitted to the hospital, but these were not statistically significant after full adjustment in the models.

We speculate that the modest effect of e-CCM on increasing the proportion of children who were urgently referred may have been because of greater adherence to the CCM decision support algorithm [32,33], as the smartphone app encouraged adherence to CCM [33], or that the smartphone app reduced errors by providing more accurate assessment than paper CCM alone. This is because when using e-CCM, there is less opportunity for the HSA to miss assessment items, as they are forced to complete all items before progressing in the assessment tool. As such, this reduces errors that may have occurred when HSAs use paper-based CCM alone, where they can choose to fill in some questions and leave out others. The effects could, however, merely represent the impact of the requirement in our trial for HSAs to double enter data (ie, on paper format and then using the app) with replication of assessment providing more opportunity to conduct the required assessment. Children in the intervention group were less likely to return for repeat consultation, which could be because of their assessment being more thorough or correct at their initial visit to the village clinic, thus reducing the need to return to the clinic for the same illness.

Our trial also demonstrated that 94.1% (6552/6965) of children aged ≤5 years presenting with acute illness are managed in the community by HSAs, with only approximately 1 in 20 being urgently referred to a higher-level health care facility. Some caregivers appear to bypass the village clinic and attend the hospital directly without being assessed at the village clinic. This implies dissatisfaction with the services provided by lower-level health care facilities, such as village clinics [25]. One reason that caregivers may bypass village clinics and go directly to higher-level facilities may be because caregivers perceive that their child needs urgent attention and may feel that going to the village clinic wastes time [34]. Indeed, previous studies have found that some community members do not have confidence in the care they receive from first-level health care providers, such as community health workers [35,36].

A major strength of our study is the use of a rigorous stepped-wedge design, which aims to minimize potential biases. Previous research has established considerable support by HSAs and the local community for planned interventions [7,10,37]. We could not conduct an individual randomized study at the child or HSA level, following guidance from local investigators. A stepped-wedge design has significant advantages over a simple before and after design as it attempts to minimize potential temporal biases and provides a more powerful study design using a control group. We selected referrals as the main trial outcome as this is a major driver of health care use, and there is currently evidence that underreferral contributes to child morbidity [38,39]. We believe that this study provides a high degree of generalizability to similar settings in sub-Saharan Africa, where CCM is used.

This study had some limitations. One involved the requirement of our study design for HSAs to continue to use the paper tool during the intervention phase, which meant that we could not assess the independent impact of e-CCM but rather its benefit. This occurred because the SL e-CCM App was not yet endorsed by the Malawi Ministry of Health, so it could not replace the paper tool. In addition, assessing outcomes was challenging because of the lack of unique patient identifiers and incomplete records at health care facilities. The study may have been underpowered to detect effects on repeat consultations and hospital admission, and we noted heterogeneity between clusters in direction and significance of effects.

Our results add to previous qualitative studies that have shown that HSAs feel empowered using apps such as the one evaluated here [21] and that these tools might support greater adherence to CCM [32]. These results support wider implementation and potential addition of further functionalities to support HSAs using smartphones to facilitate other tasks, such as reporting requirements or drug stocking. For policy makers, our study provides robust evidence on the effectiveness of this e-CCM tool that few other studies have provided to date and could therefore add evidence to support national digital health strategies in developing an integrated community health information system. However, we acknowledge that further data are needed to determine the costs (and cost-effectiveness) of the initial setup (training, smartphones, and servers), and ongoing support (technical support, hardware replacement, and software updates). For researchers in this area, evidence for the independent effects of e-CCM on outcomes is needed. These results call for additional studies on e-CCM apps and similar mHealth tools to determine the impact on other clinical outcomes, such as duration of illness and resource use. In addition, there is a need to ensure data and workflow integration of e-CCM as part of community health service delivery, management, and existing digital tools used at other levels of the health system, such as the District Health Information System, electronic medical record systems, and real-time surveillance at the community level.

Conclusions

The vast majority of children assessed by HSAs in these 2 large rural areas of Malawi are managed by HSAs in their communities. Adding an e-CCM that involved an app on smartphones to HSAs' usual paper-based CCM tool led to a significant increase in the proportion of children referred from village clinics to higher-level health care facilities. Although the effects on decreased hospital admission and decreased repeat consultation were suggestive but inconclusive, they support the hypothesis that the e-CCM tool improved decision-making at the HSA level. Combined with existing qualitative literature showing high levels of acceptability of mHealth versions of CCM by community health workers, our findings support further efforts to deploy smartphone-based tools as part of integrated digital health strategies in Malawi and similar countries in sub-Saharan Africa, with ongoing evaluation of effectiveness, cost-effectiveness, and acceptability by health care workers and community members.

Acknowledgments

The authors would like to thank the University of Malawi (College of Medicine), Mzuzu University, University of Washington, and Imperial College London for giving permission to conduct this study. This work was supported by the European Union's Seventh Framework Programme for Research, Technological Development, and Demonstration (grant 305292). The funder of this study had no role in the design of the study, collection of data, analysis of the results, interpretation of results, preparation of the manuscript, or decision to publish.

Authors' Contributions

GBC helped in the development of the questionnaire and interview guide, data collection, and writing of the manuscript. NM and TT contributed to the trial design and management and commented on this manuscript. KD contributed to the conduct of the study and commented on this manuscript. JOD conceived the study, developed the research question, participated in trial design

and management, and commented on this manuscript. PH developed the statistical analysis plan and analyzed and interpreted the data. NI managed the field data collection and contributed to the writing of the manuscript. JTSW assisted in the study implementation and communication with national and district health authorities and commented on this manuscript. All authors contributed to the interpretation of the findings, drafting of the manuscript, and approval of the final version.

Abstract

Background: Insomnia is a prevalent condition that presents itself at both the symptom and diagnostic levels. Although insomnia is one of the main reasons individuals seek medicinal cannabis, little is known about the profile of cannabinoid use or the perceived benefit of the use of cannabinoids in daily life.

Objective: We conducted a retrospective study of medicinal cannabis users to investigate the use profile and perceived efficacy of cannabinoids for the management of insomnia.

Methods: Data were collected using the Strainprint app, which allows medicinal cannabis users to log conditions and symptoms, track cannabis use, and monitor symptom severity pre- and postcannabis use. Our analyses examined 991 medicinal cannabis users with insomnia across 24,189 tracked cannabis use sessions. Sessions were analyzed, and both descriptive statistics and linear mixed-effects modeling were completed to examine use patterns and perceived efficacy.

Results: Overall, cannabinoids were perceived to be efficacious across all genders and ages, and no significant differences were found among product forms, ingestion methods, or gender groups. Although all strain categories were perceived as efficacious, predominant *indica* strains were found to reduce insomnia symptomology more than cannabidiol (CBD) strains (estimated mean difference 0.59, SE 0.11; 95% CI 0.36-0.81; adjusted P<.001) and predominant *sativa* strains (estimated mean difference 0.74, SE 0.16; 95% CI 0.43-1.06; adjusted P<.001). Indica hybrid strains also presented a greater reduction in insomnia symptomology than CBD strains (mean difference 0.52, SE 0.12; 95% CI 0.29-0.74; adjusted P<.001) and predominant sativa strains (mean difference 0.67, SE 0.16; 95% CI 0.34-1.00; adjusted P=.002).

Conclusions: Medicinal cannabis users perceive a significant improvement in insomnia with cannabinoid use, and this study suggests a possible advantage with the use of predominant indica strains compared with predominant sativa strains and exclusively CBD in this population. This study emphasizes the need for randomized placebo-controlled trials assessing the efficacy and safety profile of cannabinoids for the treatment of insomnia.

KEYWORDS

medicinal cannabis; insomnia; symptom management; linear mixed-effects

Introduction

Background

With the growing interest in the therapeutic and medicinal uses of cannabis, there is an increased need to better understand the harms and benefits of acute and long-term therapeutic use of cannabinoids. Among individuals who use medicinal cannabis in Canada, 42% report using cannabis 2-3 times a day, with 40% of users reporting their consumption to be >14 grams per week [1]. In fact, rates of medicinal cannabis authorization in Canada rose from 8000 in 2014 to 340,000 in 2018 [2]. Similarly, with nationwide cannabis legalization in October 2018, general cannabis use rates in Canada increased from 14% to 18% between 2018 and 2019 [3].

Despite the paucity of randomized placebo-controlled trials, both recreational and medicinal cannabis users report perceptions of a broad spectrum of benefits from cannabis. Among these benefits of the use of cannabis is aiding sleep [4]. In fact, in addition to pain and anxiety, insomnia has commonly been reported to be among the top reasons individuals seek medicinal cannabis [2]. This association is very relevant considering the high rates of insomnia in the general population. It is estimated that approximately 10% of adults experience chronic insomnia [5], and nearly one-third of all adults suffer from occasional or intermittent insomnia symptoms annually [5]. Longitudinal studies have found that nearly 70% of individuals reporting insomnia symptoms at baseline continue to report symptoms a year later [6], and 50% continue to report having symptoms 3 years later. Insomnia is also one of the most common complaints in primary care, often presenting itself at both symptom and diagnostic levels [6]. Characterized by difficulty in falling asleep, staying asleep, or having a nonrestorative sleep, insomnia negatively affects functioning, quality of life, and mental health [7]. In addition, insomnia often co-occurs with common medical and psychiatric conditions [6]. Individuals experiencing these comorbidities report greater impairments in psychosocial and cognitive functioning compared with individuals without sleep disturbances [6-10].

Cannabinoids for Insomnia

Recent reviews have concluded that the current evidence of the benefits of using cannabinoids for insomnia symptoms are largely driven by clinical trials that used cannabinoids for the treatment of other conditions, such as pain or multiple sclerosis [11-13]. Similarly, although some previous studies have examined recreational and medicinal cannabis use in naturalistic samples, very few have focused on insomnia as a primary outcome [14,15]. In one study, 95 medicinal cannabis users were surveyed on the effects of cannabis products used for various conditions and symptoms [14]. The results indicated a statistically significant preference toward *Cannabis indica* products to help with sedation and sleep [14]. In addition, the same study reported that users also preferred these products for insomnia, encouraging further research focusing on the condition [14]. In another study, a mobile app collecting data on medicinal cannabis in naturalistic conditions was used to measure the self-reported effectiveness and side effects of cannabis [15]. The study examined 2332 users across 10,535 tracked cannabis sessions [15]. The results indicated significant reductions in symptom severity across all reported symptoms, with significantly more relief in anxiety- and depression-related symptoms than pain symptoms [15]. Notably, in this particular study, insomnia was examined as a symptom of anxiety and presented the largest symptom relief score across all examined symptoms following cannabis consumption [15].

Most relevantly, a recent naturalistic study that examined cannabis use for insomnia in a sample of 409 participants across 1056 sessions reported significant reductions in symptom severity; however, these findings were limited to raw, natural medical cannabis flowers and lacked information on the perceived efficacy of various cannabis product forms. Furthermore, this study was limited by a lack of information on patient demographics, as the information collected from users did not include key demographic data, such as age and gender [16]. Since the legalization of cannabis in Canada in 2018, research regulations for the drug remain quite stringent [1]. Similarly, because of its status as a schedule 1 drug in the United States, it is underinvestigated for therapeutic purposes [17-20]. Therefore, not only is there a major gap in studies assessing insomnia as the primary outcome, but also a lack of scientific literature on the use of cannabis products that are currently being consumed by the general public [11-13]. To help address these gaps, we conducted a retrospective study to investigate the perceived effectiveness of the use of cannabinoids in treating insomnia symptoms in a large, naturalistic sample of Canadians. We also describe the key demographic characteristics of these individuals, such as age and gender distribution, types of cannabinoid use, and methods of ingestion.

Methods

Overview of Strainprint App

We conducted a retrospective study examining cannabis use for the management of insomnia symptoms using anonymous archival data obtained from the medicinal cannabis–tracking app Strainprint (Strainprint Technologies Ltd). Strainprint is a Canadian app with a large database of medical and recreational cannabis users with >90 million data points and 2 million reported patient outcomes. The app allows users to track and monitor changes in their symptoms as a function of different doses, strains, and forms of cannabis. It engages users through a loyalty rewards system where users earn points for tracking sessions of cannabis use. Through Strainprint, users are able to record medical conditions, symptoms being treated, methods of ingestion, doses, emotive effects, pre- and postmedication ratings, and cannabis product constituents by batch for each tracked session. Tracked information can also be shared with health care providers. On initial use of the app, individuals are prompted to enter basic demographic information, such as year and month of birth, gender, and the conditions and symptoms that they wish to treat. When individuals are ready to track their medication session, they open the app before using cannabis and select the relevant symptoms they wish to treat from a dropdown list of their previously chosen symptoms. Users are then taken through a set of steps where they are first prompted

to rate the severity of their symptoms on a 11-point numeric rating scale (0=least severe and 10=very severe) before medication. Next, individuals select the cannabis they are using by product name and batch. Strainprint prepopulates the app with lab-verified cannabis constituents by batch for all medical cannabis products sold by licensed producers in Canada. Data on cannabis content are pulled directly from cannabis distributors. Users then select the product form (flower, oil, capsule, edible, vape pen, or concentrate), route of administration (vape, oil, smoke, edible, pill, tincture, spray, concentrate, dab bubble, dab portable, oral, topical, or transdermal), and dose (drops, mg, ml, or puffs) for that specific session. After an onset period defined by the chosen route of administration (eg, 20 minutes for smoke and 60 minutes for pill or edible), users are prompted with a push notification (8 hours later for sleep) to complete their session by rating their symptom severity postmedication on the same 11-point numeric scale.

Strainprint also provides individuals with a complete history of their use, along with product recommendations based on other users' experiences with the same symptoms. As part of Strainprint's terms of service, individuals agree to share their anonymous information for research and other purposes. In this study, we examined the data of individuals who used medicinal cannabis to manage the severity of insomnia symptoms for the condition of insomnia. Specific variables for this study were determined before data extraction, and the information was subsequently provided by Strainprint stripped of identifiers.

Study Sample

Our study included all tracked sessions between February 27, 2017, and February 28, 2020. The final sample consisted of 991 Canadian medicinal cannabis users with insomnia who used the app to monitor changes in insomnia symptoms across 24,189 recorded sessions. The sample comprised 42.6% (422/991) self-identified male participants and 56.1% (556/991) self-identified female participants (13/991, 1.3% of users did not report gender), ranging in age from 18 to 74 years (mean 36.32, SD 11.65). Additional descriptive statistics on the sample are presented in Figure S1 of Multimedia Appendix 1.

Statistical Analysis

First, we completed a descriptive analysis of the data set by generating information on the specific cannabis use profile for the management of insomnia symptoms. In particular, we examined the frequencies of categorical cannabis use variables such as use time of day, strain categories, product forms, and ingestion methods. These data were further stratified to investigate cannabis use trends by both age and gender. For inferential analyses, our primary analysis focused on the perceived efficacy of cannabis for the management of insomnia symptoms. Efficacy was calculated as the change in insomnia symptomology between pre- and postmedication rates, as reported by users.

Generally, this type of statistical modeling would be completed as a standard regression analysis; however, a standard regression analysis assumes that observations are independent. In this particular data set, users reported multiple observations, and a standard regression analysis would not account for between-person variability in tracked sessions across users. Therefore, we used linear mixed-effects modeling, a type of regression model that estimates random effects (accounting for between-subject variability) in addition to standard fixed effects (accounting for within-subject variability) regardless of differences in the number of reported observations per user. In essence, this mixed-modeling method estimates random intercepts and slopes, which are then used to make more accurate inferences at the fixed-effects level without violating the independence assumption.

Assumptions for each model were checked to ensure the validity of the models used. Residual plots were examined and were determined to not deviate from the assumptions of linearity, normality, and homoscedasticity. The assumption of independence was met by accounting for tracked session nesting within participants using mixed-effects models. For this analysis, linear mixed-effects modeling was used to predict changes in the perceived efficacy of cannabis use with regard to demographic information (ie, age and gender) and cannabis use information (ie, use time of day, product form, and strain category) across tracked sessions. In addition, although several studies have challenged the labeling of strain categories in commercial products, in this naturalistic study, we analyzed this variable as a commercialized label influencing purchasing choices. In all analyses, P values were corrected for multiple comparisons using the stringent Bonferroni correction ($P<.05$, Bonferroni corrected).

Ethical Approval

Ethical approval for this research was granted by the Hamilton Integrated Research Ethics Board (project #7162). The study was designed to be compliant with the Health and Information Protection Act, 2016.

Results

Strain Categories for Insomnia

Descriptive statistics examining the percentage of each strain category (ie, predominant sativa, sativa hybrid, predominant indica, indica hybrid, balanced hybrid, or cannabidiol [CBD]) used for the management of insomnia symptoms across 24,189 tracked sessions are presented in Table 1. Overall, predominant indica and indica hybrid strains were the most commonly used strains for insomnia, whereas predominant sativa and sativa hybrid strains were used least for the management of insomnia symptoms. Notably, although CBD is not traditionally considered a strain category, Strainprint recognizes the variations in tetrahydrocannabinol (THC) or CBD content across different strains and presents a CBD-predominant product category as a strain on the app. Further descriptive statistics of strain categories stratified by age and gender are presented in Figures S2 and S3 in Multimedia Appendix 1.

Table 1. Descriptive information on frequency of strain categories used across 24,189 tracked sessions (N=24,189).

Stain category	Sessions, n (%)
Indica	9263 (38.29)
Indica hybrid	6468 (26.74)
CBD[a]	3327 (13.75)
Balanced hybrid	3068 (12.68)
Sativa	1098 (4.54)
Sativa hybrid	605 (2.5)

[a]CBD: cannabidiol.

Cannabis Product Forms and Ingestion Methods for Insomnia

Descriptive statistics examining the frequencies of cannabis product forms (ie, flower, oil, capsule, edible, vape pen, or concentrate) used for the management of insomnia symptoms across 24,189 tracked sessions are presented in Table 2. Because of the relatively small number of data points, products in the form of vape pens and concentrates were combined to form an *other* group. Across all age groups and genders, cannabis was most often used in the form of flowers, followed by oil products, for the management of insomnia symptoms. Table 3 presents descriptive statistics examining the frequencies of cannabis ingestion methods (ie, vape, oil, smoke, edible, pill, tincture, spray, concentrate dab bubbler, dab portable, oral, topical, or transdermal) across all tracked sessions. Again, because of the relatively small number of data points, the categories of concentrate, dab bubbler, dab portable, oral, topical, and transdermal were combined to form a single category. Vaping was the most popular ingestion method across all age groups and genders. All reported results were stratified by age and gender.

Table 2. Frequency and percentage of cannabis product forms used across 24,189 sessions between genders and age groups (N=24,189).

Product form	Sessions, n (%)								
	By gender			By age (years)					Overall
	Female	Male	Unknown	18-24	25-34	35-44	45-54	>55	
Flower	6767 (43.82)	8517 (55.2)	160 (1.04)	1712 (11.09)	3954 (25.6)	5622 (36.4)	1934 (12.5)	1997 (12.9)	15,444 (100)
Oil	5407 (70.2)	2222 (28.9)	70 (0.9)	336 (4.4)	1332 (17.3)	2401 (31.2)	1609 (20.9)	1887 (24.5)	7699 (100)
Capsule	793 (94.5)	44 (5.2)	2 (0.2)	1 (0.1)	341 (40.6)	179 (21.3)	47 (5.6)	269 (32.1)	839 (100)
Edible	121 (96)	5 (4)	0 (0)	15 (11.9)	21 (16.7)	6 (4.8)	0 (0)	73 (57.9)	126 (100)

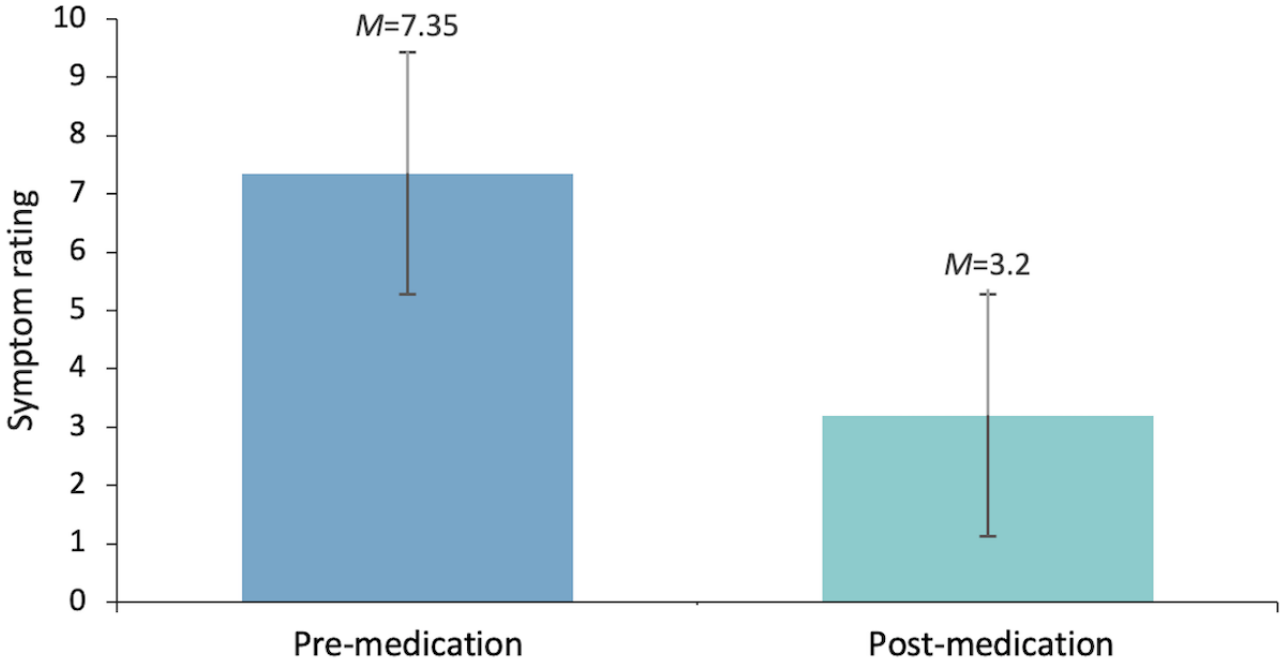
Symptom Severity Ratings

Mean symptom severity ratings were examined before and after cannabis use across tracked sessions (N=991 users across 24,819 sessions; Figure 1). Before cannabis use, the mean symptom severity rating across sessions was 7.35 (SD 1.88), whereas the mean symptom severity rating after use was 3.20 (SD 2.37).

Figure 1. Mean symptom severity ratings pre- (mean 7.35, SD 1.88) and post-(mean 3.20, SD 2.37) cannabis use.



Linear Mixed-Effects Model Predictions of Perceived Efficacy

We first examined the perceived efficacy of cannabinoid use for insomnia as a function of gender and found it to be significant across both genders (Table 4). The perceived efficacy of cannabinoid use for insomnia was also significant across all age groups (Table 5). Comparisons between gender and age can be found in Multimedia Appendix 1 (Tables S1 and S2).

Table 4. Efficacy by gender. The efficacy was tested using linear mixed modeling (β coefficient was not standardized).

Gender	Estimate (SE)	*t* test[a] (*df*)	*P* value
Female	3.4289 (0.1696)	26.814 (852.4)	<.001
Male	3.5282 (0.1288)	27.399 (868.3)	<.001

[a]Tests were two-tailed.

Table 5. Efficacy by age groups. The efficacy was tested using linear mixed modeling (β coefficient was not standardized).

Age (years)	Estimate (SE)	*t* test[a] (*df*)	*P* value
18-24	3.43291 (0.16118)	21.298 (2073.5)	<.001
25-34	3.35234 (0.11098)	30.206 (1656.2)	<.001
35-44	3.72108 (0.10826)	34.370 (1604.7)	<.001
45-54	3.12995 (0.13658)	22.916 (1894.7)	<.001
>55	3.76299 (0.15390)	24.251 (2242.4)	<.001

[a]Tests were two-tailed.

Next, we examined whether the time of cannabis use predicted perceived efficacy and found that efficacy was significant regardless of the time of day (Table 6). Because of the nature of the data, information on shift work was not available; therefore, we did not compare efficacy across different use times during the day. More detailed frequency and percentage information of sessions for each use time of the day can be found in Table S3 of Multimedia Appendix 1.

Table 6. Efficacy by use time of day. The efficacy was tested using linear mixed modeling (β coefficient was not standardized).

Time of day	Estimate (SE)	*t* test[a] (*df*)	*P* value
Morning	3.668345 (0.102629)	35.744 (488.1)	<.001
Afternoon	2.754512 (0.225454)	12.218 (120.1)	<.001
Evening	3.369924 (0.119686)	28.156 (391.6)	<.001
Overnight	3.449696 (0.089454)	38.564 (739.5)	<.001

[a]Tests were two-tailed.

We also examined perceived efficacy as a function of cannabis product forms and found that all product forms were perceived as efficacious (Table 7). Notably, for some product forms (ie, vape pen and concentrate), there were too few observations to warrant inclusion in primary analyses, even when combined to form a single category. Therefore, of all available product forms, only those making up at least 0.005% of the data set were included in the analyses. There were no significant differences in efficacy among product forms (all *P*>.05; Table S4, Multimedia Appendix 1).

Table 7. Efficacy by product form. The efficacy was tested using linear mixed modeling (β coefficient was not standardized).

Product form	Estimate (SE)	*t* test[a] (*df*)	*P* value
Capsules	3.79417 (0.34792)	10.9054 (25.7)	<.001
Edible	4.15951 (0.56358)	7.3806 (7.9)	<.001
Flower	3.43969 (0.08728)	39.4100 (737.0)	<.001
Oil	3.47823 (0.11693)	29.7470 (374.8)	<.001

[a]Tests were two-tailed.

Finally, we examined perceived efficacy as a function of strain category and found that cannabis was efficacious regardless of the specific strain being used (Table 8). Interestingly, predominant indica strains were found to be more efficacious than CBD (estimated mean difference 0.59, SE 0.11; 95% CI 0.36-0.81; adjusted *P*<.001) and predominant sativa strains (estimated mean difference 0.74, SE 0.16; 95% CI 0.43-1.06; adjusted *P*<.001). Indica hybrid strains were also found to be more efficacious than CBD (estimated mean difference 0.52, SE 0.12; 95% CI 0.29-0.74; adjusted *P*<.001) and predominant sativa strains (estimated mean difference 0.67, SE 0.16; 95% CI 0.34-1.00; adjusted *P*=.002). Balanced hybrid strains were also found to be more efficacious than CBD (estimated mean difference 0.39, SE 0.13; 95% CI 0.14-0.64; adjusted *P*=.03) and sativa strains (estimated mean difference 0.54, SE 0.17; 95% CI 0.20-0.88; adjusted *P*=.03; Table 9).

Table 8. Efficacy by strain categories. The efficacy was tested using linear mixed modeling (β coefficient was not standardized).

Strain categories	Estimate (SE)	*t* test[b] (*df*)	*P* value
Balanced hybrid	3.461359 (0.112701)	30.713 (300.8)	<.001
CBD[a]	3.074027 (0.114947)	26.743 (367.7)	<.001
Indica	3.661426 (0.094507)	38.742 (673.9)	<.001
Indica hybrid	3.589259 (0.097939)	36.648 (469.1)	<.001
Sativa	2.916945 (0.163117)	17.883 (86.4)	<.001
Sativa hybrid	3.470149 (0.171074)	20.285 (92.0)	<.001

[a]CBD: cannabidiol.

[b]Tests were two-tailed.

Table 9. Efficacy comparisons between strain categories. The efficacy was tested using linear mixed modeling (β coefficient was not standardized).

Strain categories	Estimate (SE)	*t* test[b] (*df*)	*P* value
Balanced hybrid versus CBD[a]	0.387332 (0.125752)	3.080 (167.3)	.03
Indica versus balanced hybrid	0.200067 (0.107863)	1.855 (208.6)	.98
Indica hybrid versus balanced hybrid	0.127900 (0.104839)	1.220 (128.9)	.99
Balanced hybrid versus sativa	0.544414 (0.170767)	3.188 (72.0)	.03
Sativa hybrid versus balanced hybrid	0.008790 (0.181109)	0.049 (75.1)	.99
Indica versus CBD	0.587400 (0.114173)	5.145 (216.2)	<.001
Indica hybrid versus CBD	0.515232 (0.115805)	4.450 (197.1)	<.001
CBD versus sativa	0.157082 (0.163729)	0.959 (58.6)	.99
Sativa hybrid versus CBD	0.396122 (0.181141)	2.187 (82.9)	.48
Indica versus indica hybrid	0.072168 (0.083424)	0.865 (183.5)	.99
Indica versus sativa	0.744481 (0.159664)	4.663 (69.6)	<.001
Indica versus sativa hybrid	0.191277 (0.162713)	1.176 (68.4)	.99
Indica hybrid versus sativa	0.672314 (0.164905)	4.077 (73.6)	<.001
Indica hybrid versus sativa hybrid	0.119110 (0.166813)	0.714 (82.5)	.99
Sativa hybrid versus sativa	0.553204 (0.201776)	2.742 (65.5)	.12

[b]Tests were two-tailed.

Discussion

Principal Findings

Results from this large naturalistic sample of medicinal cannabis users who tracked their insomnia symptoms before and after cannabis use suggest significant improvements in insomnia symptoms, with no gender differences in perceived efficacy. Notably, this study uses a naturalistic design by analyzing crowdsourced data from a medicinal cannabis–tracking mobile app. With increasing advances in technology, this study presents a unique perspective on a health management self-monitoring tool that examines data on a population scale.

Analyses of product forms and ingestion methods found that cannabis was most often used in the form of flowers or oils and most often ingested via vapes, oils, or smoking. In addition, although all strains were reported to be beneficial for the management of insomnia, predominant indica and indica hybrid strains were found to be more efficacious than CBD and predominant sativa strains. This finding is in contrast with those of a previous study reporting that strains with significantly higher concentrations of CBD were generally preferred by individuals using cannabis to treat symptoms of insomnia [21]. Despite this, our findings are in line with results from previous studies that have reported indica and hybrid strains to be among the most frequently used strains for insomnia [16]. This same study reported that the most used strains were fairly high in THC content and were combined with high to moderate CBD content.

Another study investigating multiple doses of cannabinoids for sleep reported that administration of both 5 mg/5 mg and 15 mg/15 mg of THC/CBD demonstrated a decrease in stage 3 sleep when compared with placebo, with the higher dose also showing increased states of wakefulness [22]. THC administration on its own demonstrated no significant changes to sleep architecture from placebo; however, the same study found that high doses of THC alone or in combination with CBD resulted in increased subjective sleepiness [22]. From this, the researchers concluded that CBD may have dose-dependent effects on alertness and that the activating and sedating properties of CBD and THC, respectively, could work together to induce sleep and counteract daytime sleepiness [22]. Although few clinical trials have objectively analyzed cannabinoids for sleep with sleep outcomes as primary measures, some preliminary trials have shown that administration of THC and THC-derivatives, alone or in combination with CBD, were associated with subjective improvement in sleep outcomes [11-13]. In addition, previous studies examining strain preferences have also reported increased preferences toward indica strains for sleep [14,23,24]. In one study, indica was preferred for sedation and sleep, whereas sativa was preferred to increase energy [14]. Another study investigating qualitative responses reported that patients using medicinal cannabis preferred using indica at night to improve sleep [24]. In essence, to better understand the efficacy of cannabinoids for insomnia, randomized placebo-controlled studies are needed.

The human endocannabinoid (eCB) system has been increasingly implicated in body and brain homeostasis, including sleep. For instance, the eCB system is thought to play an active role in regulatory processes, such as pain perception, memory, and sleep modulation [25,26]. Although the neurobiological basis of cannabis for sleep is still being understood, overlaps between the neuronal circuitry of sleep and wake states and the eCB system suggest that cannabinoids can contribute to

sleep-related mechanisms and physiology [27-29]. Therefore, the eCB system has become a growing target in sleep research [25-30]. Despite the perceived benefits of cannabinoids, there remains a lack of placebo-controlled trials that have examined the effects of the drug using validated sleep measures or objective sleep outcomes [11-13]. In addition, the current literature on the existence of potential risks, harms, and side effects associated with cannabinoid treatments remain extremely sparse for sleep disorders; however, there is growing evidence that suggests an increased risk of both acute and chronic cognitive impairments [31,32]. Although these risks are poorly understood, research suggests that the prevalence of these effects is increasing [31]. Future clinical trials should focus on the benefits and potential harms through the use of validated objective and subjective measures. Because of the highly comorbid nature of insomnia and other sleep disorders, additional variables such as medication interactions, potential side effects, and comorbid diagnoses are also worth investigating.

Limitations

Some limitations should be considered when interpreting the results of this study. First, individual conditions and symptoms were subjectively reported by users on the Strainprint app. Therefore, it is unknown whether subjects will meet the full criteria for insomnia or any other sleep-related disorder. Moreover, individual user data are restricted to the information collected by Strainprint; therefore, additional information that may affect cannabinoid efficacy (eg, medical history, body size, other concurrent medications, or tolerance) could not be assessed. Another limitation of this study is the lack of a placebo control group. Because data were collected from a sample of medicinal cannabis users, it is possible that individual expectations of cannabinoid efficacy may have attributed to positive postmedication ratings. In other words, the large magnitude effect-size observed reflects pharmacological effects and response expectancy (placebo) effects, and the proportionate contribution of each, fundamentally, cannot be ascertained. It is also possible that this study examined the data of individuals who were more likely to find cannabis to be effective, as the Strainprint app is geared toward individuals who wish to improve therapeutic outcomes by tracking their cannabis use. As a result, the sample may disproportionately represent users who benefit from using cannabis. In addition, the Strainprint app primarily collects data on cannabis use and has very limited data on its potential side effects. Therefore, beyond perceived efficacy, it was not possible to ascertain from the available data whether users experienced any negative side effects from cannabis use.

This study also examined various strain categories; however, distinctions between these strains remain the subject of much debate [33-35]. Cannabis has historically been classified into two separate species (*C.sativa* and *C. indica*) with distinct biological effects. However, years of breeding and hybridization have rendered potential distinctions often meaningless [34-37]. As recreational cannabis use has become increasingly popular, commercialization of the plant has led to the emergence of products marketed as derivatives or hybrids of these species [23,35,36]. Among consumers, the terms *sativa*, *indica*, and *hybrid* are used colloquially and are associated with perceived effects [37]. Sativa has been associated with stimulating effects, indica with sedating effects, and hybrids are perceived to be bred from the former two to fit the more personalized needs of consumers [23,24,35,37]. Interestingly, a recent study collected data characterizing various commercial products classified as *sativa*, *indica*, or *hybrid* and used supervised and unsupervised machine learning algorithms to subjective effect tags [36]. The models indicated a clear division among *sativas* and *indicas*, with *hybrids* in between, suggesting distinct subjective effects among the categories [36].

Despite these perceived effects, strain categories are largely baseless [34-37]. Instead, many researchers hold that the differences in perceived effects between strain categories may be owing to other components of cannabis (ie, terpenes), which are rarely accurately reported to consumers [34,36,38,39]. Interestingly, some studies have found that products labeled as *indica* and *sativa* have similar concentrations of major cannabinoids but distinctly different concentrations of terpenes [23,40,41]. To date, hundreds of different cannabinoids and terpenes have been identified, all with varying pharmacological properties and outcomes [38,42]. These cannabinoids and terpenes are also known to interact synergistically with one another to exert *entourage effects*, which can have enhanced therapeutic benefits for consumers [38,39,42-44]. Given this, it remains unclear whether the perceived therapeutic effects are a result of the individual components of cannabis products or the combined effects of interacting cannabinoids and terpenes. Although strain categories are largely arbitrary, many researchers continue to examine their perceived effects to better understand consumer choices [16,24,44-47]. The nature of our data allowed us to do the same, providing insight into the naturalistic setting of cannabis use. In essence, although the analysis of strain categories in this study provides valuable research on how efficacious various strains are perceived to be, it is worth noting that the perceived efficacy and differences between strains may be driven, at least in part, by self-selection and placebo effects.

Furthermore, previous studies have found inconsistencies between product labels and content, as well as differences in cannabinoid content reporting among labs [48,49]. With recreational cannabis products, the accuracy of product labels relies heavily on growers, suppliers, and dispensaries; however, there are currently no standardized procedures or reliable methods for verifying strains or cannabis content in commercialized products [35]. Despite this, consumers greatly rely on product labels for information on the cannabis content of a product, often using these labels to communicate preferences for desired effects [24,35,36]. One study even reported that demand for *indica* and *sativa* products was similar, with hypothetical purchasing tasks suggesting that consumer decisions were determined by the perceived effects of each strain in the context or setting of the typical activity-based purpose [23]. Unfortunately, because the Strainprint app prepopulates product data from multiple sources, variability across products is an issue, and we were unable to measure the accuracy of cannabinoid content for each product.

For addressing the limitations discussed above, similar future studies should investigate the effects of various terpenes and cannabinoids on perceived efficacy. Previous research has also suggested addressing strain variability by classifying cannabis products according to chemical phenotypes and pharmacological characteristics [35,43,50]. A necessary next step toward accurately classifying cannabis subgroups and creating more precise product labels for consumers is a better understanding of the association between the chemical composition of individual products and the perceived effects experienced by cannabis users. As the colloquial use of strain categories is likely to persist in the commercial marketplace, it is also necessary that future studies attempt to genetically profile samples of commercialized cannabis products, such that genotypes of the same strain are at least comparable. In addition, randomized placebo-controlled trials are necessary to ultimately test the efficacy and safety of cannabis-based treatments for insomnia.

Despite these limitations, this study is strengthened by its ecological validity, as data were obtained from a large naturalistic registry of medicinal cannabis users who prospectively tracked changes in their insomnia symptoms before and after cannabis use. The results of this study can help in designing future clinical trials to ultimately test the efficacy and safety profile of different cannabinoids in the management of insomnia.

Conclusions

The results of this study suggest that individuals using medicinal cannabis to manage insomnia symptoms report significant symptom reduction after use. This general perceived improvement in insomnia symptoms highlights the potential for cannabis to be used as a treatment option for sleep disorders. Future research should investigate the benefits and harms of cannabinoids for insomnia through rigorous randomized placebo-controlled trials.

Conflicts of Interest

JM is a principal and senior scientist in BEAM Diagnostics, Inc, and a consultant to Clairvoyant Therapeutics, Inc. This study was also funded by a Michael G DeGroote Center for Medicinal Cannabis Research Graduate Scholarship (NK). The other authors have no conflicts of interest to declare.

Abstract

Background: Fitness inspiration or *fitspiration* is a term used to describe web-based images of fit people, people in the gym, health foods, or inspirational quotes relating to diet and fitness being shared and consumed via visual social media. The popularity of this content is most notable via the *Instagram* platform. Currently, the majority of fitspiration research has focused on women's experiences; however, increasingly, studies have pointed to the need to explore the gendered ways by which people engage with this content.

Objective: The aim of this study is to explore how young men and women engage in fitspiration content on Instagram and provide a gendered analysis of how and why they consume this content.

Methods: This study used a cross-sectional web-based survey (N=1213) of UK-based fitspiration users aged 18-24 years consisting of closed-ended questions to capture quantitative data.

Results: The majority actively using Instagram for fitspiration (therefore eligible participants) were women (826/1175, 70.30%). Men were more likely to view content posted by athletes ($\chi^2_{1, N=1153}$=71.8; *P*=.001) and bodybuilders ($\chi^2_{1, N=1153}$=32.8; *P*<.001), whereas women were more likely to view content related to weight loss ($\chi^2_{1, N=1153}$=36.8; *P*<.001), diet plans ($\chi^2_{1, N=1153}$=11.9; *P*<.001), and celebrities' content ($\chi^2_{1, N=1153}$=33.5; *P*<.001). Men were more likely to use fitspiration as a source of inspiration to exercise to gain muscle or get stronger ($\chi^2_{1, N=1147}$=17.9; *P*<.001), whereas women were more likely to use fitspiration as inspiration for healthy eating ($\chi^2_{1, N=1147}$=37.7; *P*<.001), or to exercise to diet or lose weight ($\chi^2_{1, N=1147}$=13.5; *P*<.001). Women were more likely to engage in passive behaviors such as viewing content on their feed ($\chi^2_{1, N=1139}$=7.9; *P*=.005) or scrolling through accounts ($\chi^2_{1, N=1139}$=15.2; *P*<.001), whereas men were more likely to engage in active consumption by tagging fitspiration accounts in posts ($\chi^2_{1, N=1139}$=7.2; *P*=.007), commenting on posts ($\chi^2_{1, N=1139}$=8.1; *P*=.004), and posting fitspiration content ($\chi^2_{1, N=1139}$=6.4; *P*=.01).

Conclusions: Female fitspiration consumers engaged with content that reinforced the feminine *thin but shapely* ideal, whereas male users sought out content that reinforced the masculine *muscular* ideal. Male users were more likely to engage actively with content (eg, posting fitspiration content), while female users were more likely to engage passively (eg, scrolling through accounts, posts, or images). Future research should consider how fitspiration consumption reflects and reproduces oppressive gender ideology.

Introduction

Background

Social media is becoming embedded within our everyday lives, with 68% of people and 98% of those aged 16-24 years within the United Kingdom using web-based social networking platforms [1]. Among their many purposes, web-based social media platforms are used for communication, community building, information gathering, and as a source of inspiration within multiple contexts. One such context is that of *fitspiration* or *fitspo*, commonly used abbreviations for the term *fitness inspiration* [2], which describes web-based content such as images of fit people, people in the gym, health foods, or inspirational quotes relating to diet and fitness shared and consumed habitually via social media. Increasingly, academic research has demonstrated numerous perceived positive outcomes associated with consuming the fitspiration content on social media [2-5]. These studies explore how web-based fitspiration can provide wider access to reliable health information [2-5] and motivate individuals to engage in healthy behaviors [3], including by providing motivation to exercise [4] and in helping to create a sense of community [2].

While fitspiration is widespread on multitudinous social media platforms, it is particularly common on Instagram [6]. Instagram is a predominantly mobile app, with over 400 million global users [7] including 29% of women and 26% of men in the United Kingdom [8]. With regard to fitspiration, a recent Instagram search (July 11, 2019) of #fitspo yielded over 66 million posts [9] demonstrating the popularity of this specific content. A key reason for complementarity between this visual platform and fitspiration is that Instagram has a unique focus on sharing and consuming *snapshot photography* or self-selected images in which individuals are portrayed in an attractive light [10] making it particularly harmonious with imagery that showcases fit and healthy *ideal* bodies and lives, reinforcing social norms regarding health and fitness. Furthermore, Instagram offers users the opportunity to edit and apply filters to images to distort reality into an ideal to be shared, making the potential impact on well-being and appearance concerns more pronounced when compared with other platforms [11]. It is therefore imperative that research focuses on this unique platform to adequately inform policy regarding the health and well-being of young adults (<24 years).

Users of Instagram are exposed to multiple *idealized* images of peers and other people or organizations (with public accounts) actively shaping visual ideas about beauty regarding *acceptable* or *desirable* bodies [12]. Those who engage with fitspiration on Instagram specifically (eg, by following or scrolling through specific accounts or searching for hashtags) are exposed to idealized *fit* bodies and unsubstantiated, often unrealistic (and occasionally incorrect) advice regarding diet and fitness, shaping the body's ideal narrative and reinforcing social norms regarding the body. Research exploring the nature of fitspiration on social media and Instagram has demonstrated that the content displays multiple potentially harmful themes and includes objectifying images that depict idealized bodies [2-4], can depict extreme and often restrictive healthy-eating content linked to disordered eating [13], and can promote increased symptoms of orthorexia nervosa [14], a term coined to describe an obsession with proper or *healthful* eating [15]. Fitspiration content also promotes exercising for appearance-related reasons [16], which has been associated with negative body image [17], higher measures of disordered eating [18], and positive correlations with higher depressive and erectile dysfunction symptoms [19]. The aforementioned research often draws upon theoretical knowledge such as objectification [6,11] and social comparison theories [4,20] to explore the potentially negative implications of consuming fitspiration content on both mental and physical health.

The paradoxical findings on the relationship between fitspiration consumption and well-being reflect a small yet emerging body of research exploring the impact of fitspiration content on the lives and experiences of consumers. Despite this, research conducted on fitspiration to date focuses on the nature of the fitspiration content as opposed to the individuals that consume it [6,16,21]. While exploration into fitspiration content has valuable implications for policy, researchers have called for further inquiry exploring how individuals use fitspiration and the role it plays in their lives [2] to better support those who value it as meaningful content.

Currently, the majority of research exploring fitspiration focuses specifically on women's experiences [11,22,23] and the nature of woman-centered content [4,24]. This is because women are more likely to use visual social media platforms [25,26] and are the biggest consumers of fitspiration images [21], and because fitspiration images are more likely to be women, with (36.4%) posts depicting female participants compared with 27.5% of posts depicting a male participant [21]. Associated findings demonstrate that exposure to fitspiration on Instagram may negatively influence women's appearance-related concerns [11] and promote an often unrealistic and unachievable fit or thin body ideal [4,23,24]. These findings reflect broader cultural and media trends surrounding the ideal female body of one that is simultaneously very thin, and exceptionally fit and toned without displaying excess muscularity [16,27]. While fitspiration may be considered a healthy alternative to *thinspiration*, which communicates an unhealthy thin body ideal [24], the fitspiration ideal communicated to women within these contexts could be seen as oppressive, narrow, and contradictory and can promote women to engage in extreme exercise behavior [13]. There is also an emergent body of academic research that focuses on men's experiences with fitspiration and the content that they are exposed to [21,28,29]. This research is valuable, as data suggest that a significant minority (30%) of fitspiration images on social media targets men [4,21]. Reviews of fitspiration content aimed at men reflect a heavily gendered muscular ideal [21,29] that provides a stark contrast to the message communicated to women through cultural discourse. Palmer [28] recognizes the pervasive nature of this form of social media content, demonstrating that it has the ability to influence men's ideas regarding masculinity, and can encourage users to compare physiques to dominant *ideals*. This dominant discourse regarding male body ideology depicts participants who are highly muscular and nearly always have visible abdominal, bicep, and pectoral muscles, and compared with women these ideals demonstrate

less emphasis on thinness or weight loss [21]. Therefore, the culturally pervasive ideological body identified in fitspiration targeting men reflects an ongoing cultural trend in the media, which has demonstrated a rapid increase in male muscle mass over time [30], aggregating the pressure on men to conform to increasingly unrealistic and unachievable body ideals.

Gendered analyses have also shown significant differences in the nature of the fitspiration images depicting men and women's bodies, with women being more likely to be objectified and sexualized, and images with a greater focus on the participant's buttocks [21], whereas posts of men were more likely to show the participant's face [4]. Evidence also suggests that male fitspiration content on Instagram is more likely to focus on fitness as opposed to diet and alternative weight loss methods, with Tiggemann and Zaccardo [4] noting that 68.2% of male fitspiration focused on fitness-related activities, compared with only 58% for women. There are also clear gendered differences in how genders interact with and experience fitspiration content. In their study exploring male fitspiration use on Instagram, Fatt et al [29] identified that the frequency of viewing fitspiration posts was not significantly correlated with body satisfaction, appearance-based exercise motivation, and health-based exercise motivation in men. These results contrast with previous findings that demonstrated positive correlations between viewing frequency, body dissatisfaction, and disordered eating for women, signifying that fitspiration may psychologically impact men and women differently [11,13]. However, researchers have identified that fitspiration content consumption is linked to less body satisfaction when men internalize the muscular ideal and make more appearance comparisons [29]; therefore, certain men may experience the negative impacts of fitspiration in a similar way to women if they internalized male body ideals and made body comparisons.

Objectives

The aim of this study is to explore how young (18-24 years) people engage with fitspiration content on Instagram and provide a gendered analysis of how and why they consume this content. This is in response to the aforementioned research that demonstrates the gendered nature of their consumption experiences in terms of the ideologies communicated through fitspiration, the composition of images, and the ways in which men and women interact with the content. While previous studies provide some light in terms of exploring how fitspiration consumption and the impact of fitspiration on individuals are gendered, because of the popularity and cultural relevance of this form of consumption, there is a great need for further research exploring the motivations for engagement, patterns of consumption, and perceived impact of fitspiration from a gendered perspective. This research will allow for greater exploration into how and why this experience is gendered, which can be used to help support digital literacy training and support for consumers of this content.

Methods

Study Design

The research used a cross-sectional web-based survey consisting of closed-ended questions to capture quantitative data to meet the study's aim of exploring how those aged 18-24 years in the United Kingdom engage with fitspiration on Instagram using a gendered perspective. The survey was informed by the existing literature (outlined above), specifically by a previous survey-based fitspiration research study [2], and took approximately 10 minutes to complete. Ethical approval for the study was granted by an institutional ethical review (Bournemouth University).

Setting

Data were collected during a 1-week period in May 2019 using a web-based insight exchange platform (Cint database) to request a representative sample from appropriate users registered to a range of web-based survey panels. A minimum sample size of 1000 was requested, which was achieved and exceeded, a benefit of using the insight exchange platform. However, it is important to note that the number of participants contacted is unknown owing to the nature of the participant recruitment platform.

Participants

The eligibility criteria were that participants (n=1213) had to be aged 18-24 years (in line with previous research [21,31,32]) and broader demographic data [7,33], lived in the United Kingdom, and had reported viewing fitspiration on Instagram. In line with previous research, for the purposes of this survey, fitspiration was defined as photographs of fit people, people in the gym, health foods, or inspirational quotes relating to diet and fitness. Self-reported eligible participants also completed screening questions to ensure that they met the inclusion criteria (reporting a frequency other than *not at all* for the question "How often do you check Instagram?" or a frequency other than *never* to the question "How often do you view *fitspiration* on Instagram?").

Variables

Tested Variables

The following variables were measured (a copy of the questionnaire is available on request from the authors): demographic characteristics (age, BMI, gender, sexuality, and educational level), use (frequency of use and duration of use), and content and engagement (content engaged with while online, means of engaging with content, and reasons for engagement).

Demographic Characteristics

To allow for adequate description of the sample, a number of demographic characteristics were collected, including gender, age, sexual identity, and highest level of education completed. BMI was calculated using participants' self-reported height and weight.

Instagram Use

To determine how the sample used Instagram, participants indicated how often they checked the platform using a 9-point scale adapted from previous research [11,17,29] (0: *not at all*; 9: every 5 minutes). In addition, participants were asked to specify how long they spent on Instagram on a typical day (*1-5 minutes or less* to *8 hours or more*) on an 8-point scale.

Fitspiration Use

To ascertain how the sample used fitspiration, participants indicated how often they viewed this content (as defined above) using scales adapted from previous literature [11] based on pilot study feedback on Instagram. The final scale had 8 points (1: never to 8: every time).

Fitspiration Content

Participants indicated the types of fitspiration they engaged with on the platform by selecting from a checkbox list informed by previous research [21] listing the following types of content: weight loss or fitness or body transformation journeys, personal trainers, athletes, celebrities or models, bodybuilders or strength content, clean eating, cleanses or detox, diet plans, fitness challenges, influencers, and fitspiration quote pages. Prevalent examples of fitspiration content were included, and participants were able to tick as many options that applied to them as it was anticipated (based on pilot study feedback) that they may have engaged with multiple forms of fitspiration.

Fitspiration Engagement

In line with previous fitspiration research [2] and based on feedback from the pilot study, participants identified how they engaged with fitspiration content by selecting from a list of nine engagement behaviors that ranged from active (post content; comment on posts; tag fitspiration accounts in posts; tag friends in posts; share content with friends; and like posts) to passive (follow accounts or view on Instagram feed, scroll through individual accounts posts or images, and search hashtags). Collecting these data helped address a research gap identified by Raggatt et al [2], who drew on the work of Jenkins-Guarnieri et al [34] to explain that previous studies investigating social media have not adequately captured the different ways in which people interact with social media content.

Reasons for Engaging With Fitspiration Content

Participants' reasons for engaging with fitspiration content were collected using a predefined checkbox list of 8 reasons developed using existing literature [2] and based on feedback from piloting that included inspiration for health and well-being; healthy eating; to exercise to improve body shape, tone, or size; to gain muscle or get stronger; to diet or lose weight; to improve health and well-being; facilitate improvements in appearance; to help learn about health and well-being or because friends or peers view or like it.

Bias

A small incentive was offered in terms of points that participants could accumulate to gain future cash rewards, rather than simply offering cash incentives to try to minimize any subsequent bias. This is designed to discourage *professional* respondents whose primary motivation is to gain payment for completion.

Analysis

Data were analyzed using IBM SPSS for Windows (version 25), with charts produced using Microsoft Excel. Given the nonparametric nature of the data, basic descriptive statistics were used to describe the nature of the sample, and chi-square analyses were undertaken to explore the relationships between gender and Instagram use in terms of the variables outlined earlier.

Results

Description of Sample

Following the screening questions, the survey was completed by 1213 eligible participants with a median age of 21 years. Response rates to individual questions varied and are reported as such. Where there were missing data, responses were deleted. A full breakdown is provided in Table 1; however, to summarize, most (68.10%) participants identified as female, compared with 28.19% identifying as male and 0.57% identifying as nonbinary or gender queer. In terms of sexuality, most of the sample identified as straight (83.47%). BMI calculations showed that over half of the respondents had a BMI within the normal range, 11.10% were categorized as underweight, and almost one-third (32.85%) were overweight or obese. Finally, most were educated to either Advanced or Advanced Subsidiary level (UK qualifications offered across a range of participants to school-leavers; 29.6%) or degree level or higher (33.70%).

Table 1. Description of sample.

Characteristics[a]	Values, n (%)
Gender (n=1213)	
Female	826 (68.1)
Male	342 (28.2)
Nonbinary or genderqueer	7 (0.6)
Sexuality (n=1090)	
Female straight	647 (59.4)
Male straight	263 (24.1)
Female bisexual or pansexual	106 (9.7)
Male bisexual or pansexual	23 (2.1)
Female gay	21 (1.9)
Male gay	15 (1.4)
Other	6 (0.6)
Nonbinary and genderqueer, bisexual, and pansexual	4 (0.4)
Nonbinary and genderqueer and gay	2 (0.2)
Nonbinary and genderqueer and other	1 (0.1)
BMI category (n=1108)	
Underweight	621 (56.0)
Normal	232 (20.9)
Overweight	132 (12.0)
Obese	113 (11.1)
Highest educational qualification (n=1184)	
Undergraduate degree or higher	399 (33.7)
A or AS level	350 (25.3)
GCSE[b] or O level	207 (17.5)
Higher qualification below degree level	181 (15.3)
Postgraduate degree	113 (9.5)
Other	47 (3.97)

[b]GCSE: General Certificate of Secondary Education.

Fitspiration Content

With regard to the fitspiration content on Instagram, 49.38% (599/1213) viewed content at least once per day, 32.32% (392/1213) at least once per week, and 18.30% (222/1213) less often. A total of 56.86% (714/1213) reported checking the platform at least once every hour, while 88.13% (1069/1213) checked it at least once every few hours. On average, 67.39% (812/1205) of participants spent an hour or more per day on Instagram with 18.50% (223/1205) spending over 4 hours and 2.99% (36/1205) spending over 8 hours on the platform. A categorical gender comparison between men and women (there were insufficient data to test differences with those who identified as nonbinary or genderqueer for any variables) using a chi-square test of independence demonstrated that women were more likely to check Instagram more regularly than their male counterparts ($\chi^2_{1,\ N=1168}=19.1$; $P=.008$); however, there was no significant difference between the amount of time spent on Instagram per day for men and women ($\chi^2_{1,\ N=1160}=13.8$; $P=.06$).

The most common types of fitspiration viewed by all participants were content from celebrities or models (717/1196, 59.95%), weight loss or fitness journeys or body transformation stories (641/1196, 53.60%), and influencers (473/1196, 39.55%). Gender differences in terms of engaging with specific forms of content are outlined in Table 2. Categorical gender comparisons between men and women using chi-square tests of independence showed male participants were more likely to view content posted by athletes ($\chi^2_{1,\ N=1153}=71.8$; $P<.001$) and bodybuilders ($\chi^2_{1,\ N=1153}=32.82$; $P<.001$) than their female counterparts and women were more likely to view content identified as weight

loss or fitness journeys or body transformation stories ($\chi^2_{1, N=1153}$=36.8; *P*<.001), celebrities or models ($\chi^2_{1, N=1153}$=33.5; *P*<.001), clean eating ($\chi^2_{1, N=1153}$=26.5; *P*<.001), cleanses or detox ($\chi^2_{1, N=1153}$=30.8; *P*<.001), diet plans ($\chi^2_{1, N=1153}$=11.9; *P*=.001), fitness challenges ($\chi^2_{1, N=1153}$=6.9; *P*=.009) and from influencers ($\chi^2_{1, N=1153}$=22.8; *P*<.001). The results are detailed in Table 2.

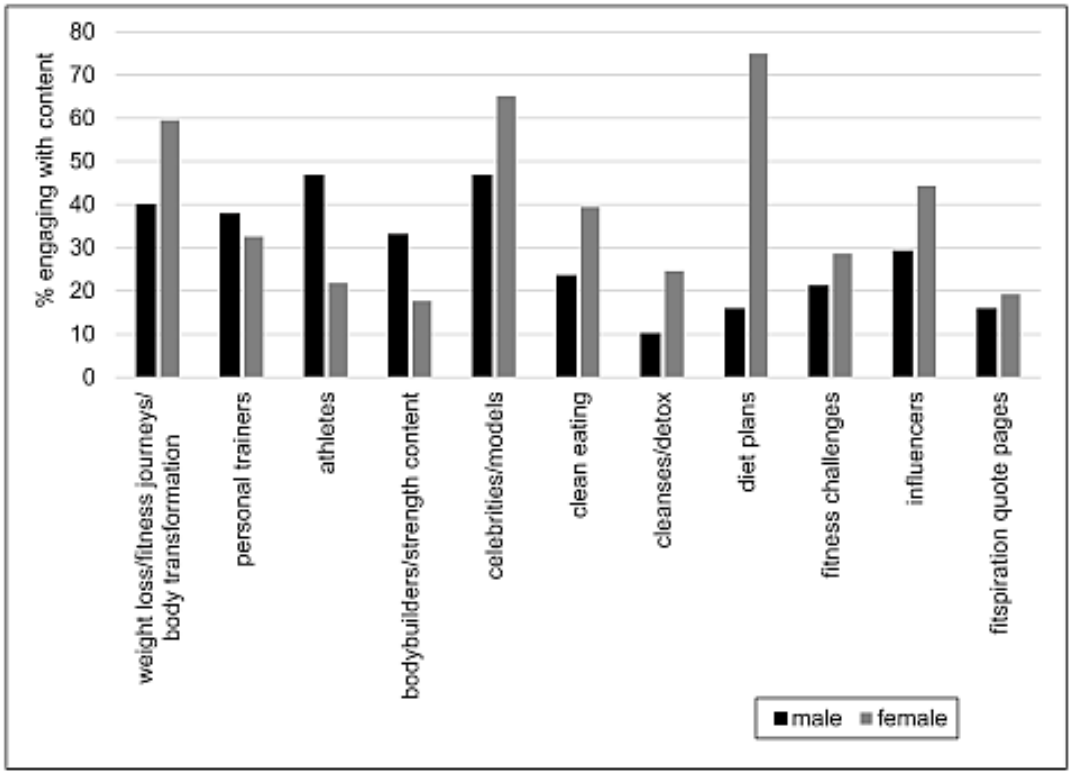
Figure 1. Gender and fitspiration content.



How Participants Engaged With Fitspiration on Instagram

In terms of gender and engagement with fitspiration, a number of differences emerged, as highlighted in Table 3.

Figure 2 shows gender and fitspiration engagement.

Women were significantly more likely than men to engage in passive consumption behaviors such as follow accounts or views on Instagram feed ($\chi^2_{1,\ N=1139}$=7.9; *P*=.005) or scroll through individual accounts, posts, or images ($\chi^2_{1,\ N=1139}$=15.2; *P*<.001). Conversely, men were more likely than women to engage in active behaviors such as tag fitspiration accounts in posts ($\chi^2_{1,\ N=1139}$=7.2; *P*=.007), comment on posts ($\chi^2_{1,\ N=1139}$=8.1; *P*=.004), and post fitspiration content ($\chi^2_{1,\ N=1139}$=6.4; *P*=.01).

Table 3. Gender and engagement with fitspiration (n=1139).

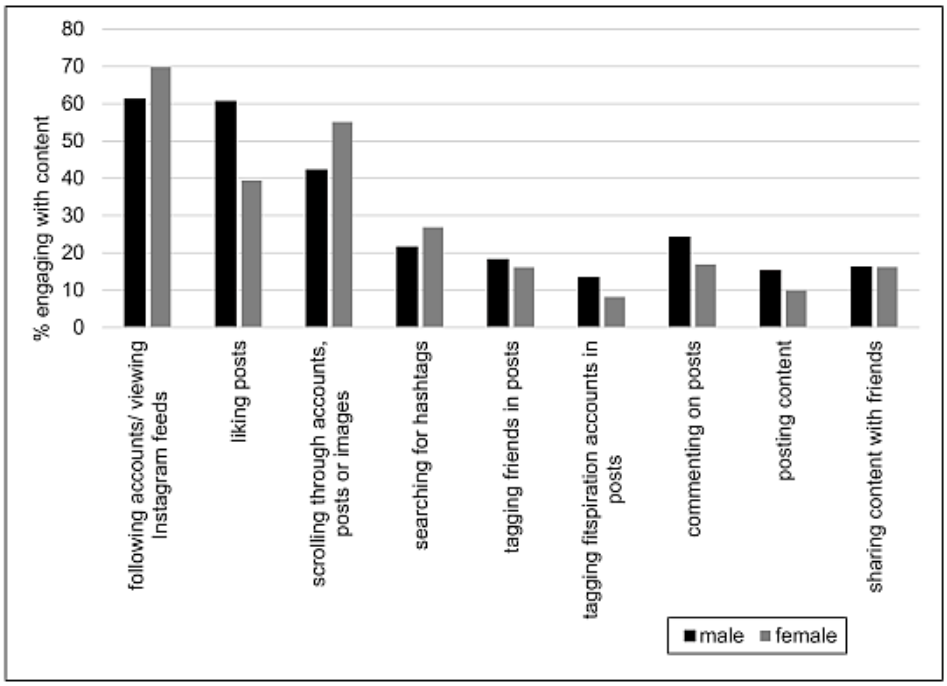
Figure 2. Gender and fitspiration engagement.



Why Participants Engaged With Fitspiration on Instagram

The main reasons for viewing fitspiration content selected by participants were to improve their health and well-being (669/1189, 56.27%); inspiration to exercise to improve body shape, tone, or size (636/1189, 53.49%); and inspiration for healthy eating (630/1189, 52.99%). There were clear gender differences between men and women in terms of the reasons for viewing fitspiration. Men were more likely to use fitspiration as an inspiration to exercise to gain muscle or get stronger ($\chi^2_{1, N=1147}$=17.9; *P*<.001) or because friends or peers view or like it ($\chi^2_{1, N=1147}$=5.5; *P*=.02) than women, and women were more likely to use fitspiration as inspiration for healthy eating ($\chi^2_{1, N=1147}$=37.7; *P*<.001); inspiration to exercise to improve body shape, tone, or size ($\chi^2_{1, N=1147}$=8.9; *P*<.001); or inspiration to exercise to diet or lose weight ($\chi^2_{1, N=1147}$=13.5; *P*<.001) than their male counterparts. The reasons for engagement with fitspiration by gender are listed in Table 4.

Figure 3 shows gender and reasons for fitspiration engagement.

Table 4. Gender and reasons for engagement (n=1147).

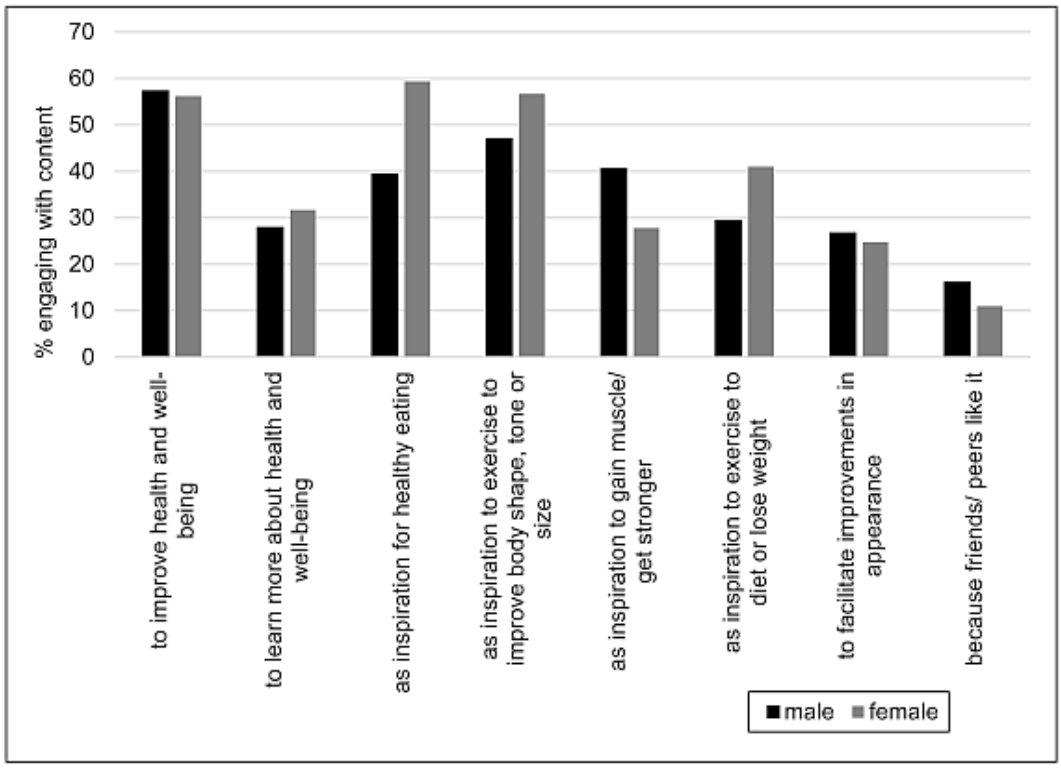
Figure 3. Gender and reasons for fitspiration engagement.



Discussion

Principal Findings

This quantitative survey of young Instagram fitspiration users reveals important insights regarding how and why consumers in the United Kingdom engage in this form of digital content. Most participants actively using Instagram for fitspiration (therefore eligible to take part in the study) were women (826/1175, 70.30%), consistent with previous academic research [21] and large-scale surveys [26], which suggests that women are more likely to engage with Instagram as a platform than men. However, this study makes a unique contribution to the existing body of knowledge in demonstrating that men and women have significantly different experiences in terms of what, how, and why they engage with the fitspiration content on Instagram. The findings relating to content preferences and motivations for viewing are gendered in a way that reflects clear dualistic gender ideals that are communicated through and reinforced by the digital content men and women consume, and the associated consumption behaviors.

The Masculine Muscular Ideal

Historically, the dominant body ideal for men has increasingly shifted toward muscularity, with a specific emphasis on muscular definition and tone [35-37]. This trend has emerged as the masculine *muscular ideal*, which has been suggested to affect the ways in which many men view and critique their bodies [35]. In line with this, the study demonstrates that men are explicitly attracted to fitspiration content from athletes and bodybuilders, as inspiration to exercise to gain muscle and become stronger. These findings align with previous research that suggests web-based fitspiration images of men are far more likely to show bodies with visibly high levels of muscularity than those of women [21]. The study demonstrates that male fitspiration users are more likely to engage with content from professional sportsmen as opposed to models, celebrities, and influencers. This suggests that men may privilege fitspiration content from sports professionals with active performing bodies, as opposed to celebrities, models, and influencers who have perhaps constructed visually esthetic bodies to be admired and idealized.

Some scholarly work exploring the masculine body ideal has suggested that in addition to promoting muscularity, men are increasingly interested in reducing body fat to promote *leanness* [38]. Specifically, research has identified two separate dimensions of fat loss as a drive for thinness and a drive for leanness with men, perhaps having a tendency to strive toward a lean toned body as opposed to the thin ideal, which may be more attractive to women [39]. Despite research suggesting that men are increasingly interested in fat loss, the findings indicate that men are less likely to engage with content promoting weight loss and diet or use fitspiration to support healthy eating, diet, or weight loss than women. It could therefore be hypothesized that either fitspiration content promotes the *thin* as opposed to *lean* ideal or that diet or weight loss fitspiration content was predominantly focused on women and their bodies or lifestyles.

Moreover, it could be suggested that fitspiration users are more likely to privilege a large muscular (as opposed to lean body) ideal compared with the general population. This aligns with previous research suggesting that male fitspiration users are significantly more likely to internalize a muscular body ideal when compared with nonusers [29]. While muscularity is still privileged in terms of male fitspiration, this could be down to this content focusing uniquely on achieving peak physical fitness, thus identifying a cultural prejudice toward traditional representations of masculinity [28].

The Feminine Thin but Shapely Ideal

Critical research has suggested that the dominant body ideal for women is a contradictory body [4,23,24,27], simultaneously very thin, and exceptionally fit and toned without displaying excess muscularity [16]. This demonstrates a contrast to the masculine ideal body presented above, which honors muscular size. The notion that women privilege thinness is reinforced in this study, with female users being significantly more likely to consume fitspiration content promoting thinness through diet and weight loss than male users. This is also clear through women's consumption motivation behavior, as they are significantly more likely to use fitspiration as inspiration to lose weight through diet and exercise than men. These preference and behavioral findings align with existing literature that demonstrates that the content of fitspiration aimed at women is more likely to show thin bodies and reflect a thin ideal than those aimed at men [4,21].

The findings also demonstrate that women are significantly more likely to consume fitspiration content from celebrities or models and influencers than their male counterparts, who, as noted above, are more likely to engage with athletes and bodybuilders. While numerous athletes and sportspeople monetize their use of Instagram [40,41], it could be argued that the promotion of a consumptive ethic and level of brand endorsement is more common within the accounts of influencers for whom this is often their sole intention or form of employment, and celebrities or models who increasingly yield salaries exclusively or in the main using social media. It could therefore be suggested that women who use fitspiration are likely to be marketed to or actively purchase goods to conform to an ideal body constructed in line with consumptive ethic, thus reinforcing the economic oppression that they have historically faced within Western society [42]. It could also be seen as reflective of the oppressive nature of the consumptive ethic [42] that emphasizes (active) male production and (passive) female consumption of goods and services, locating the power firmly in the hands of men.

Gender and Active or Passive Engagement

While women are significantly more likely to engage in passive fitspiration consumption behaviors such as following, viewing, and scrolling through individual accounts, posts, or images, men are more likely to engage in active engagement, such as tagging fitspiration accounts in posts, commenting, and posting fitspiration content. This is in contrast to previous research [43], which suggests that women are consistently more likely to engage in social media activities by commenting, sharing, or liking. Therefore, based on these findings, it could be posited that fitspiration provides a unique social media context in which men engage more actively than women. This may be because of the emphasis on fitness and muscularity within fitspiration images reinforcing traditional masculine ideals, as opposed to content such as thinspiration, which promotes a thin ideal typically associated with femininity.

Ultimately, the finding that men are significantly more likely to report posting fitspiration content than women provides an interesting texture to the existing research narrative, as previous content research demonstrates that the majority (67%) of fitspiration images depict women as opposed to men [4]. There are a number of potential explanations for this. First, it may be that while men post more fitspiration content, it could be of images other than their own bodies, especially given that the fitspiration definition adopted is relatively broad (photographs of fit people, people in the gym, health foods, or inspirational quotes relating to diet and fitness). This could also be explained by drawing on research that explores the gendered nature of (self) objectification [11,39], which suggests that women are more likely to view their bodies as objects to be evaluated and may therefore be more inclined to offer images of their bodies for assessment. It may be that fewer women posted a higher volume of fitspiration images. This could be explained by the fact that women who meet gendered body ideals may be more likely to post a higher volume of images. Women not meeting gendered body ideals may be less inclined to label images of their bodies as fitspiration or failing to accurately report their active engagement or that men were posting images of women and coding them as fitspiration content.

Study Strengths and Limitations

This study has numerous strengths and limitations that require consideration to adequately interpret the study findings. First, these findings reflect a large sample (n=1213) of fitspiration users in the United Kingdom and shed valuable light on their motivations for engagement, patterns of consumption, and the perceived impact of fitspiration from a gendered perspective. These user-centered data are especially enlightening, as they can be used to support the largely content-driven literature in this area. However, while this provides an alternative perspective, this study does not explain the relationship between content and consumption in terms of how they intersect, and to what extent consumption is driven by content. Furthermore, the research method provides a breadth of existing knowledge but sacrifices some depth that could potentially be achieved through qualitative interviews and questionnaires, or naturalistic observation and walk-through methods.

While the consumer-driven focus of the study is rationalized based on the absence of this focus from the existing research narrative, there are aspects of the consumer experience that have been neglected. More in-depth exploration could have involved exploring the gender differences in terms of body-part focus to build on existing literature [21] and by exploring the extent to which consumers engage with fitspiration images of bodies representing a gender other than their own; for example, women looking at images of men's bodies. While there is a rationale for research in these areas, it was not considered to be the focus

of the current research and therefore could be considered a limitation.

Generalizability

As with any such survey, the representativeness of any sample can always be questioned. Although a random sample was drawn from a larger panel, it is difficult to judge the extent to which such samples are truly representative of the actual population; for example, it may be that women may be more likely to engage with web-based surveys; hence, the results must be treated with some caution. The use of nonvalidated measures could also be identified as a potential issue, even given the descriptive nature of the items, and this could be addressed in future research.

Third, this study explores the gendered nature of fitspiration consumption and yields some important findings regarding the differences in what fitspiration young UK-based men and women were consuming, and how and why they chose to consume it. However, because of the statistical nature of the analysis, this study did not go into any depth regarding individuals identified as nonbinary or genderqueer (7/1175, 0.6%) as opposed to males or females. This 0.6% is comparable with estimates for the general UK population that suggest 0.4% of adults in the United Kingdom identify as nonbinary or genderqueer when faced with it as an option alongside males and females [44]. Nonbinary or genderqueer individuals are likely to have unique experiences of consuming content largely related to the gendered bodies on the internet, and this was neglected in this study.

Finally, as with any study involving multiple analyses, the risk of false positives is always present. No adjustments were made for this within the analysis for two reasons: first, the research provides findings that are aligned with previous empirical work and theory, and second, that there was a general degree of consistency within the findings. While the risk remains, it would seem to be small, and given the exploratory nature of the study, further work and analysis may not be necessary to strengthen confidence in the analyses presented here.

Future Directions

This study and the evaluation above highlight several valuable directions for future fitspiration research. First, there is a need for research to explore the relationship between content and consumption in terms of how they drive each other and the uniquely gendered nature of each. This could take the form of qualitative research exploring the fitspiration consumption process in more depth, or scholarly work focusing on fitspiration producers, who are likely to also be actively engaged consumers.

Furthermore, this survey could be used as a template to explore generational and cross-cultural differences and compare the unique ways in which these consumption patterns are gendered. It would be especially interesting to explore if and how this content is consumed in non-Western, majority world countries, with alternative ideas regarding body ideals and gender roles to make comparisons. In addition, to provide a comprehensive understanding of how representative this and other research on fitspiration use and UK consumers, there is a need for large-scale quantitative work that explores the prevalence of this web-based behavior both in the United Kingdom and globally.

While this research provides an exploration into the fitspiration consumption experiences of young people aged 18-24 years who represent around 24.1% of all UK-based Instagram users, additional research should focus on younger participants and adolescents who, despite using Instagram less (representing 8.1% of UK-based users [33]) may be more vulnerable to body ideals communicated via social media, and the negative aspects of fitspiration as they are at a crucial stage in the development of positive or negative body image [45].

There is also a need to explore how people who identify as nonbinary or genderqueer as opposed to male or female consume fitspiration, and the challenges that they face in being confronted by large volumes of this content that largely seems to be coded as either male or female. There is also a need for content-driven research exploring fitspiration content created by and for genderqueer and nonbinary individuals. It is also important that future research looks to further unpack the finding that women were more likely to consume fitspiration on Instagram, while men were more likely to create content. There is a need to explore possible explanations to ascertain whether men are less likely to post images of their bodies as fitspiration than women, such as posting images of women and coding them as fitspiration content that women fail to accurately report their active engagement, or suggest an alternative explanation. Finally, future research needs to explore whether male fitspiration users are indeed a unique subculture, and whether the male muscular ideal is broadly still dominant, as theorists have suggested that there is movement away from hypermasculine male stereotypes in the general media, with the strong hard man ideal becoming diminished in favor of more diverse forms of masculinity [46].

Conclusions

The purpose of this study was to explore how young men and women engage with fitspiration content on Instagram and to provide a gendered analysis of how and why they consume this content. The key findings of this study achieved this aim in demonstrating the gendered way in which consumers engage with the fitspiration content on Instagram. Specifically, while all fitspiration consumers engaged with content that reinforced traditional body ideals, ideals were extremely gendered. Furthermore, male users were more likely to engage actively with content than female users who consumed content more passively, indicating that the experiences of men and women consuming fitspiration are vastly different. Therefore, based on these findings, it is suggested that any interventions designed to address the potential harm of this web-based content for young people should be gender-specific to adequately address the heavily gendered body ideals and experiential differences for young men and women.

Abstract

Background: e-Cigarette use, also known as vaping, has increased dramatically over the past few years, especially among younger demographics. However, researchers have found that a large number of e-cigarette users want to quit. Little is known about the unique aspects of vaping cessation, which is critical to informing the development of relevant resources and interventions for e-cigarette users who want to quit. Social media forums such as Reddit provide opportunities to understand the experiences of behavior change such as quitting vaping from the perspective of end users.

Objective: This study aims to examine a quit vaping subreddit to understand how e-cigarette users are experiencing and approaching vaping cessation. Specifically, we examine methods used to approach quitting, reasons for quitting, and barriers and facilitators to quitting.

Methods: A total of 1228 posts were collected. The posts were inductively coded to generate categories and subcategories using conventional content analysis. Data were analyzed using the NVivo 12 qualitative data analysis software.

Results: Most users reported a preference for approaching quitting through gradual reduction, particularly through the use of their own devices by tapering the nicotine content. Their reasons for quitting were primarily related to experiencing negative physical consequences associated with vaping, especially in relation to their lungs (eg, tight chest), and tired of feeling stuck to the vape because of nicotine addiction. Top barriers to quitting were related to withdrawal symptoms and intensity of addiction. The top facilitators to quitting were related to using distraction techniques (eg, hobby, gaming, and mindfulness exercises), as well as having a positive mindset.

Conclusions: The findings of this study reveal unique aspects that encompass the process of quitting vaping. These findings have significant implications for both policy and intervention development.

KEYWORDS

qualitative research; electronic nicotine delivery systems; vaping; cessation; social media

Introduction

Vaping with nicotine, or using e-cigarettes, has become a popular global phenomenon in recent years. Compared with 2011, whereby 7 million people worldwide used e-cigarettes, the number of e-cigarette users had increased to 41 million in 2018 [1], with youth and young adults representing the largest users of e-cigarettes [2]. Despite how vaping has grown in popularity, recent evidence indicates that a large number of e-cigarette users actually want to quit [3-6]. A focus group study in Canada found that >40% of youth and young adults who vaped indicated a strong desire to quit, and >40% had tried to quit in the past year [5]. Another study in the United States found that 45% of youth were interested in quitting, and 25% had tried to quit in the past year [4].

Although it is encouraging that many e-cigarette users want to quit, there remains a lack of cessation services to support their quit efforts. Researchers acknowledge that most cessation advice mimics smoking cessation [7] and that there is a dearth of resources tailored specifically to vaping [4,5]. The 2020 Surgeon General's report on smoking cessation called for research to develop and understand safe and effective e-cigarette cessation guidelines and interventions [8]. A critical step toward developing effective cessation resources is to first understand the experiences and preferences of e-cigarette users as it relates to quitting vaping. However, no studies to date have examined how vapers quit and what might help them with quitting.

Web-based forums serve as particularly fruitful platforms for gathering information on end user experiences and preferences. Reddit, the most comprehensive forum on the internet [9], has several e-cigarette–related discussion topics. The use of social media such as Reddit to understand vaping cessation experiences is particularly important given that engagement on social media platforms for sharing and gathering health information is highest among youth and young adults [10,11]. Researchers have studied Reddit discussions to generate important information about e-cigarette flavors [12], the health effects of e-cigarette use [13,14], e-cigarette use patterns [9,15,16], reasons and attitudes surrounding underage e-cigarette use [17], and underage buying and selling [18]. However, no researchers have examined the quit vaping communities that are now on Reddit. This user-generated content around vaping holds significant potential to inform best practices for cessation guidelines and services. Therefore, we examined a quit vaping subreddit to understand how e-cigarette users experience and approach vaping cessation. Specifically, we examined methods for approaching quitting, reasons for quitting, and barriers and facilitators to quitting.

Methods

Overview

Similar to other studies involving Reddit [17-19], the examined subreddit contains publicly available threads and comments. No personal information (eg, account details) was included, and the usernames of the Reddit posters were not presented in this study. As such, this study was classified by the University of British Columbia Okanagan's Behavioural Research Ethics Board as research not involving human subjects and was, therefore, not subject to institutional review board jurisdiction.

Data Collection

We examined the subreddit r/QuitVaping community for this study. This subreddit was created in 2015 and designed to help vapers motivate each other to quit. This subreddit contained 4700 subscribers. Posts (including original posts and all responses) were collected retrospectively during a 4-week period (August 1, 2020, to August 31, 2020) by using the *top posts of this month* feature. The *top posts of this month* means that the posts with the most upvotes over this period were selected for analysis. This approach to data collection is supported by other content analyses of subreddit communities (eg, see work by Sowles et al [19]). The posts were first copied and pasted onto Microsoft Word, which were then uploaded onto the NVivo 12 qualitative analytic software (QSR International Pty Ltd) for coding. A total of 1228 posts were collected and analyzed.

Data Analysis

The posts were inductively coded to generate categories and subcategories using conventional content analysis [20]. Both authors engaged in collaborative coding via UBC Zoom to code three original posts and 10 responses (13 total), which resulted in the assignment of 44 codes. The authors developed a coding legend and assigned preliminary codes directly onto the Microsoft Word document via the *comments* feature. The authors then independently reviewed an additional set of three original posts and eight responses (11 total). Each author assigned >35 codes. Only six discrepancies in coding were noted, which were then discussed, resolved, and worked into the coding framework. The second author then independently coded the remaining posts, consulting with the first author regularly as needed. Once all the posts were coded, authors met again and refined and collapsed the framework with subcategories under the four major categories of quitting methods, reasons for quitting, barriers to quitting, and facilitators to quitting.

Results

Users

In total, 318 unique users were represented in this sample of posts. A little less than 10% (29/318, 9.1%) of the represented sample indicated their age, with most (24/29, 83%) of them in the young adult age range (aged between 18 and 35 years), and the remaining outliers were aged <18 years (2/29, 7%) and >35 years (3/29, 10%). This may indicate a relatively young sample overall.

Posts

Of the 1228 posts, 189 (15.39%) were original posts, and 1039 (84.61%) were responses to these posts. The average number of responses per original post was 5.5 (SD 5.55), and the range in the number of comments per post was 0-50, with most posts within the range of 5-10 and only one post with 50 comments. This one post is noteworthy, as the engagement was garnered through a call to action for mutual support and accountability. The post is as follows:

> *Everyone who is actively quitting/trying to quit/already did quit and wants to keep it that way, comment on this post. I will send each of you a message on reddit every single day checking up on you, and sending you motivational things to aid in your journey. Only asking that you try and do the same for me :) let me know!!!*

The data within these 1228 posts are broken down into the following four categories: quitting methods, reasons for quitting, barriers to quitting, and facilitators to quitting (Table 1). The most represented categories of post content in this data set were related to barriers and facilitators to quitting.

Table 1. Representation of post categories (N=1228).

Category	Values, n (%)
Quitting methods	175 (14.25)
Reasons for quitting	211 (17.18)
Barriers to quitting	441 (35.91)
Facilitators to quitting	570 (46.42)

Quitting Methods

e-Cigarette users' method of quitting was reflected in 14.25% (175/1228) of posts. Most of these posts (117/175, 66.9%) reflected a preference for a gradual reduction approach. This was accomplished primarily by tapering the nicotine concentration (55/175, 31.4%), which was followed by the use of different sources of nicotine replacement therapy (NRT; 33/175, 18.9%; eg, patches, gum, lozenges, toothpicks, and Nicorette inhalers). The most popular NRT used were patches and gum, which are often used together. Overall, 13 users reported using nicotine pouches to help them quit, and 6 stated using the vape less frequently. The *cold turkey* approach was represented in 33.1% (58/175) of the posts.

Reasons for Quitting

The reasons for quitting vaping were provided in 17.18% (211/1228) of posts (Table 2). There were eight reasons for quitting, as listed by the posters. The number one reason for quitting vaping was experiencing negative physical health effects of vaping, which included shortness of breath, chest pain, wheezing, coughing, sore throat, poor oral health, poor skin health, and poor sleep quality. The second most commonly cited reason to quit was that individuals were tired of feeling stuck to their e-cigarettes, indicating that they wanted to be free to live their lives without a dependency on a vaping device. The other most common reasons for quitting are related to the mental health and financial cost of vaping. These top reasons were then followed by a desire to improve physical health (eg, to improve running time), accommodate life changes (eg, having a baby), to gain time they would be otherwise using to vape or think about vaping, and to improve their intimate relationships (eg, spending time with partners who do not vape or smoke).

Table 2. Reasons for quitting (N=211).

Reason	Values, n (%)	Representative quotes
Experiencing negative physical health consequences	59 (28.0)	"I vaped for 3 years too, very consistently, and I really didn't have a problem with it until I felt the health issues—constant dry throat, never ending phlegm, tonsil stones, fatigue, swollen lips (from vape juice spitting), irritability, and horrible acne. I also felt like I hadn't been myself for awhile."
Tired of feeling stuck to the vape or nicotine	47 (22.3)	"Last night, I had a moment of clarity. My whole life basically revolves around my vape. It's my first thought when I wake up every morning, I have to constantly have it with me, and everything ends with a vape. Anytime I'm without it, I'm just looking forward to the time I can use it. It's honestly hard to imagine life without it, but I know I don't want to be a 70-year-old vaper."
Experiencing negative mental health consequences	28 (13.3)	"I'm fed up with feeling that anxiety and irritability when I'm not vaping."
Financial loss	28 (13.3)	"I had to get to a point where I hated what it was doing to me and my finances."
Wanting to improve physical health	17 (8.1)	"I was hoping quitting would help me with my run times before being winded (which currently doesn't take too long)."
Need to adapt to life changes	17 (8.1)	"But with Covid and everything happening, I want to kick this addiction to the curb."
Improve use of time	6 (2.8)	"Vaping sucks so much it makes you procrastinate, it makes you feel lazy and it makes you run away from things that need to get done."
Prioritizing intimate relationships	6 (2.8)	"Now I'm married and have a 1 year old child and my wife hates me vaping especially since she found out how poisonous the vape juice is for children and she's always concerned about me accidently leaving my vape around our child."

Barriers to Quitting

Barriers to quitting were reflected in 35.91% (441/1228) of the posts. Nine barriers were found, which were listed in the order of most saturated to least saturated (Table 3). The most challenging barrier was related to nicotine withdrawal, with reports of intense withdrawal symptoms associated with trying to quit. The second most common barrier was related to nicotine dependence, with many users citing heavy addiction because of the nicotine salt devices that many of the posters were using (eg, JUUL). The third barrier was related to proximity to others who vape as a major barrier to quitting, which included both web-based (eg, seeing friends vaping on social media) and offline interactions. The fourth barrier to quitting was related to existing mental health challenges, whereby users described

how their stress, anxiety, or depression made it harder for them to quit. The fifth barrier was related to the use of other substances, including smoking traditional cigarettes and other drugs. The sixth barrier was related to vaping becoming habitual and associated with routine things such as commuting to school or work. The seventh cited barrier was related to the accessibility of vaping from both a purchase standpoint as well as from a use standpoint, as users could vape in areas where smoking is prohibited. Other barriers to quitting included the enjoyment of vaping and experiencing weight-related issues after stopping.

Table 3. Barriers to quitting (N=441).

Barrier	Values, n (%)	Representative quote
Intense withdrawal symptoms		
Insomnia; fatigue; sweats; headache; brain fog; chest pain; cough; sore throat; dizziness; anxiety; depression; irritability	137 (31.1)	"I'm 2 days in from daily use but my pulse is around 90-100 bpm when I'm just sitting is this normal? People already told me being anxious 24/7 is common but I feel like my heart won't stop beating fast all day and night. I feel like I can't sleep because I'm so anxious about nothing and my heart won't stop beating quick."
Dependency on high nicotine		
JUUL; using >20mg/ml	116 (26.3)	"I'm telling you, the nic salts will get you every time. Juuls are just icing on the cake."
Proximity to those who vape		
Face-to-face interactions; web-based interactions	41 (9.3)	"I used to see vapes on peoples social media and I would get insane cravings out of nowhere."
Mental health challenges		
High stress; suffer from anxiety or depression	39 (8.8)	"Convinced myself it would help with the stress and anxiety of everything going on."
Other substance use		
Smoking cigarettes; other drugs	34 (7.7)	"Add in that I took Adderall daily, which if anyone doesn't know, makes your desire to smoke increase x10000000. So breaking into pod #3 in a day wasn't unheard of."
Habit or routine associations		
Commute; other day-to-day habits	25 (5.7)	"I'm a delivery driver and I think I connect vaping with driving also. But of course now, I vape all the time. In bed, at least 20 minutes after waking up, want it after a meal and an absolute must have when I'm drinking alcohol."
Accessibility of e-cigarettes		
Easy to purchase; can use anywhere	19 (4.3)	"Vaping I did 10x more than smoking! So easy to do anywhere."
Other		
Enjoyment of vaping	13 (2.9)	"Also a non-drinker and I feel it's my only guilty pleasure [...] I haven't tried to stop yet."
Increased appetite or weight gain after stopping	13 (2.9)	"When does the binge eating stop? I've been 2 weeks nicotine free and still wanna eat constantly and gained so much weight."

Facilitators to Quitting

Approximately 46.42% (570/1228) of posts provided a description of facilitators to quit vaping (Table 4). Nine facilitators to quitting were identified. The most cited facilitator to quitting was distractions, with the number one distraction strategy relating to keeping their minds and hands busy through hobbies, movies, games, and mindfulness exercises. Another common distraction strategy was by replacing puffing on an e-cigarette with eating, chewing gum, drinking water or tea, or chewing on flavored toothpicks. Finally, users spoke about the key role that exercise plays in their quitting efforts from running to weight lifting to yoga.

The second most cited facilitator to quitting was related to having a positive mindset or a positive view of self. Individuals described the need to believe in themselves, encourage themselves, care for their mind and body, grace with themselves, and reward themselves. In addition to self-love was the value of social support for quitting vaping. Although the primary source of support drawn upon was others in the Reddit community, some described the positive support received from family, friends, and even quit buddies to help them quit.

Making vaping less available or desirable was another facilitator to quitting vaping, which was achieved through a variety of strategies, including tossing the device, having someone hide the device, and purposely using undesirable flavors to dissuade them from vaping. Another facilitator to quitting was through the use of behavioral support interventions, which was primarily sought through the *Quit Vaping* app, followed by Alan Carr's

book "Quit smoking the easy way," and then websites that provide information on vaping cessation.

Experiencing the negative effects of vaping, being reminded of their reasons to quit vaping, experiencing the benefits of quitting, and changing their environment (eg, staying away from people who vape, switching up routine, and taking a vacation) were also listed as facilitators to remain vape free.

Table 4. Facilitators to quitting (N=570).

Facilitator	Values, n (%)	Representative quote
Distractions		
Keeping mind or hands busy (hobby, entertainment like movies and gaming, and mindfulness exercises); eating, chewing gum, drinking water or tea, and toothpicks; exercise	279 (48.9)	"I am trying to just live in the moment instead of having to pacify every single discomfort with nicotine. A workout program I follow always says 'get used to the discomfort' and that thought has been on repeat in my mind. Deep breaths and meditation have been helping a lot too."
Positive mindset or positive self-concept		
Resilient mindset; progress mindset (winning streak); self-care, grace, or rewarding	63 (11.1)	"This time feels a lot different though. I am being nice to myself. Letting myself be irritated, eat as many snacks as I want, and really feel my feelings."
Social support		
Support from others (Reddit community, friends, and family); quitting with someone	54 (9.5)	"This little community has made a huge difference on my mindset on quitting!! We all want the best for each other."
Making vaping less accessible or less desirable		
Tossing device; having someone hide device; using undesirable flavors	54 (9.5)	"When I used zero [nicotine], I just kept my device somewhere completely across the house so it was never instantly accessible. It's much easier to say no when you think about how little you actually get for the effort of going to grab it."
Behavioral support		
App (*Quit Vaping*); Allen Carr *Quit smoking the easy way;* quit help websites	34 (6.0)	"And use some app like quit vaping [app name]. Being able to easily see milestones and achievements is very motivating at the start."
Other		
Awareness of negative effects of vaping	23 (4.0)	"I always thought it helped with my anxiety but it honestly only ever made it worse."
Reminders of reasons to quit	17 (3.0)	"I was actually in one of those zones thinking, 'It wasn't so bad, maybe I just "like" vaping' when I started writing this post. By the end of writing it, I remembered how bad my experience really was and haven't had a craving since."
Experiencing benefits of not vaping	11 (1.9)	"I quit two months ago and have only recently started to really feel the positive benefits, but from what I've experienced, it's totally worth it."
Changing environment (social or routine)	11 (1.9)	"I am moving into a house with some very supportive people and I've found that when in a new setting, cravings are a lot lower."

Discussion

Principal Findings

This study is the first of its kind to examine a quit vaping community on Reddit to understand the process of quitting vaping from the perspective of e-cigarette users. The findings of this study shed light on what quitting vaping is like and how it aligns with quitting smoking. The findings reveal that the process of quitting vaping with nicotine, although similar to quitting combustible cigarette smoking in many respects, is also unique in several noteworthy ways.

Quitting Methods

Both cold turkey and gradual reduction are relevant to vaping cessation. However, significantly more e-cigarette users opted for gradual reduction compared with cold turkey. This is unique compared with smoking, whereby most smokers opt for the cold turkey approach [21]. Interestingly, a large portion of those who chose gradual reduction chose to do so by tapering their vaping device. The fact that e-cigarette users are trying to figure out how to quit on their own in this way reflects the dearth of evidence-based support available to those who want to quit and is indicative of the urgent need to develop resources and guidelines to help e-cigarette users with quitting. There are concerns about e-cigarette users turning to their devices to quit. One particular concern is that of ongoing use. In studies that examined the efficacy of using e-cigarettes to quit smoking, although some users were able to successfully quit smoking, almost all were still vaping a year later [22,23], indicating that the use of e-cigarettes promoted ongoing addiction to nicotine compared with the use of approved pharmacological cessation support (eg, NRT).

Similar to this study, an analysis of >3000 Twitter tweets revealed that a gradual approach to quitting by JUUL users was popular, especially by tapering the nicotine concentration of their pods or changing their devices [24]. In contrast, adolescents in the study by Kong et al [25] used the cold turkey approach more frequently. This difference may be because of the length of nicotine product use, where adolescents may more easily quit cold turkeys because of a shorter timeline of use. The differences found indicate that guidelines and interventions should be tailored to different age groups, with attention to the time using nicotine products as well as the type of products used. The use of high-nicotine salt devices such as JUUL appears to lead to more intense addiction, which may make a cold turkey approach more difficult. The variability of nicotine concentration in vaping devices leads to complexity in relation to cessation, which is different from combustible smoking.

Reasons for Quitting

In this study, the most commonly cited reasons for quitting vaping were related to experiences of negative health consequences and addiction. Several studies reveal that experiencing negative health consequences and dependence are consistently among the top few reasons for quitting e-cigarettes [3,5,24,25]. Of particular note is the finding around current health effects. In an analysis of 2000 text responses to a question about reasons to quit vaping from the evidence-based e-cigarette cessation program for youth and young adults, "This is Quitting," researchers found similar findings [3]. They found that the top-rated reason for quitting was health, especially current and general health, compared with future health [3]. The study by Ungar et al [24] also found that experiencing negative health consequences was the top-rated reason to quit. This reason to quit vaping, which is experiencing negative health consequences in the present, is different from the top-rated reason to quit combustible smoking, which is future health [26]. The fact that e-cigarette users are experiencing adverse health effects early in their vaping trajectory brings forward the need to pay more attention to the immediate health effects of vaping. There needs to be particular attention on the effect of vaping on the lungs given that users in this study primarily reported adverse pulmonary outcomes from vaping, including tight chest, sleep apnea, cough, wheezing, and breathlessness.

Barriers and Facilitators to Quitting

In this study, users reported intense withdrawal symptoms and dependency on high nicotine levels as the top barriers to quitting. This is not surprising given that the most popular e-cigarette devices enable the delivery of very high concentrations of nicotine to the brain (eg, JUUL is typically approximately 50 mg/ml) [27], the amount of nicotine that you would expect to see a heavy smoker consuming. These high-nicotine devices appear to be particularly problematic when trying to quit. This is not surprising given that the largest population of e-cigarette users are youth and young adults [28,29], those at an age when the brain is still developing [30,31], and that a developing brain is most vulnerable to long-term and intense nicotine addiction, which makes quitting much harder [27,31-33]. Countries such as Canada, which are taking a strong stance in limiting the nicotine concentration of e-cigarettes [34], are playing a critical role in protecting developing brains from early and long-term addiction. The findings of this study confirm that taking action to limit the nicotine concentration of these devices is critical. However, cessation services and advice must be reflective of the current state of use, which is when high-nicotine concentrations are allowed, as well as be ready to adapt to future use. Researchers should explore and evaluate how cessation advice and support may best accommodate shifts in use behaviors because of policy changes.

It is also interesting that not only offline interactions but also web-based interactions with other e-cigarette users served as a key barrier to quitting. Vaping has progressed in popularity at a time when social media use and social media influencers are rampant. e-Cigarette companies have successfully tapped into this trend and are not only lending to the uptake of e-cigarettes [35] but are also serving as a barrier to quitting, as revealed in this study. Vaping cessation efforts also need to capitalize on these web-based networks, and there are some innovative efforts being made in this regard (eg, This is Quitting by the Truth campaign) [7,36].

The findings also reveal that mental health challenges are a major barrier to quitting. Tobacco use is known to coincide with mental health issues, including among young adults [37]. Mental health disorders are increasing and are an urgent concern [38], especially in the context of the COVID-19 pandemic [39]. In light of this, attention to and screening for mental health among e-cigarette users is warranted. In addition, cessation interventions that promote positive mental health appear to align with stated facilitators to quitting, which include resiliency, self-grace, and self-love.

Another barrier to quitting is related to the accessibility of e-cigarettes. Vaping with nicotine is easily accessible via web-based sales [40], as well as the recent establishment of a large number of vape retailers that sell these products [41]. For example, in Canada, it was found that 76% of retail outlets sold vaping products in 2014 [42]. In the province of British Columbia alone, there are an estimated 90,000 vape retailers compared with only 6000 retailers that sell combustible cigarettes [43]. In addition, the policies around vaping are different from smoking; for example, you cannot be smoking indoors, but you can still vape in many indoor spaces despite several jurisdictions implementing vape-free indoor policies [44]. This is combined with the discreet and appealing designs of e-cigarettes and that e-cigarette users are left to their own devices to regulate their use. e-Cigarette advertising capitalizes on these freedoms associated with vaping and promotes users to use their vape at all times [45]. For example, a Blu commercial spends the entire 60 second advertising time to tell potential e-cigarette users that they can "smoke blue virtually anywhere" [46]. According to the users who posted on the Reddit community, being able to vape anywhere at any point in time has left them doing exactly that. This constant use has left them feeling "stuck to the vape" and is the primary reason for quitting. These findings have important implications for banning advertisements that promote vaping in this way, as well as policies for limiting where vaping can occur. The findings also hold implications in limiting the accessibility of both web-based and offline sales of e-cigarettes.

The top facilitator to quitting was the use of distractions, which ranged from things that kept the mind and hands busy to replacing the e-cigarette with other things, such as toothpicks and exercise. Similar to smoking cessation interventions such as Crush the Crave [47], the importance of including tips and opportunities to distract those who are trying to quit vaping is key. There is an opportunity for cessation interventions to capitalize on new digital technologies available to develop distractions for young vapers. Given that youth and young adults, the highest demographic of vapers, are ubiquitous on the web, focusing on innovative efforts in this context to help distract them through their cravings would likely prove quite fruitful, especially given their receptivity to receiving interventions for cessation through these media [5].

Future Research

These findings bring forward several areas for future research. First, the unique aspects of vaping cessation call for urgent research focused on developing cessation guidelines tailored to e-cigarette use. The development of these guidelines should establish both pharmacotherapy and behavioral support recommendations. For pharmacotherapy, it is interesting that a large portion of vapers used NRT to support their quit attempts, and they primarily used the nicotine patch and gum in tandem. There is a need to explore the right *recipe* for vapers who are trying to quit. This is especially critical, as the common use of high nicotine concentrations in e-cigarettes may mean that vapers need a different approach to NRT compared with smokers. For behavioral support interventions, the reported reasons for quitting, barriers and facilitators to quitting, and benefits of quitting could inform the development of interventions that resonate with vapers. Indeed, the findings offer a beginning framework and structure for exploring and developing recommendations.

Longitudinal research that tracks how cessation is approached is needed. It would be interesting to explore whether approaches to quitting shift over time with the introduction of new resources and policies. For example, whether fewer vapers resort to tapering their own devices to quit if pharmacotherapy options are tailored to vaping. It would also be interesting to conduct research on which facilitators are linked to successful long-term abstinence rates and for whom so that various populations have access to more tailored options to help them quit. Finally, there is a need to explore predictors of vaping so that we can identify high-risk populations before engaging in e-cigarette use.

Limitations

The findings of the study are based on data during a time when there was a pandemic, which may have influenced the experience of quitting. In addition, this study was conducted when few resources were available to support the cessation efforts of e-cigarette users. In addition, the findings are limited to data provided on one platform during a 4-week period. Another limitation of this study is the inability to definitively determine the demographic details of the Reddit community users, limiting the ability to note nuances in experiences and preferences based on demographic variables. However, Reddit users are known to skew toward being young and male [48], indicating that the results may represent the experiences of young males more than any other group. Finally, we could not determine how many users were still vaping and how many were vape free nor we could link particular facilitators to quitting success.

Conclusions

The findings of this study reveal the unique aspects that encompass the process of quitting vaping from the perspective of e-cigarette users. This work not only validates the need for more stringent policies around e-cigarette consumption and use but also brings forward some important gaps in relation to efforts to meet the needs of e-cigarette users who want to quit. The findings offer some recommendations and a beginning framework for steering e-cigarette policy and intervention efforts so that they resonate with e-cigarette users.

Abstract

Background: Gaming disorder, including internet gaming disorder (IGD), was recently defined by the World Health Organization as a mental disease in the 11th Revision of the International Classification of Diseases (ICD-11). Thus, reducing IGD is warranted. Maladaptive cognitions related to internet gaming (MCIG) have been associated with IGD, while impulsivity, self-control, parental influences, and peer influences are key risk factors of IGD. Previous literature suggests that MCIG is associated with the aforementioned 4 risk factors and IGD, and may thus mediate between these risk factors and IGD. These potential mediations, if significant, imply that modification of MCIG may possibly alleviate these risk factors' harmful impacts on increasing IGD. These mediation hypotheses were tested in this study for the first time.

Objective: This study tested the mediation effects of MCIG between intrapersonal factors (impulsivity and self-control) and IGD, and between interpersonal factors (parental influences and peer influences) and IGD among adolescents in China.

Methods: An anonymous, cross-sectional, and self-administered survey was conducted among secondary school students in classroom settings in Guangzhou and Chengdu, China. All grade 7 to 9 students (7 to 9 years of formal education) of 7 secondary schools were invited to join the study, and 3087 completed the survey. The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*) checklist was used to assess IGD. MCIG was assessed by using the Chinese version of the Revised Internet Gaming Cognition Scale. Impulsivity, self-control, and parental or peer influences were measured by using the motor subscale of the Barratt Impulsiveness Scale, the Brief Self-Control Scale, and the modified interpersonal influence scale, respectively. Structural equation modeling was conducted to examine the mediation effects of MCIG between these risk factors and IGD.

Results: The prevalence of IGD was 13.57% (418/3081) and 17.67% (366/2071) among all participants and adolescent internet gamers, respectively. The 3 types of MCIG (perceived rewards of internet gaming, perceived urges for playing internet games, and perceived unwillingness to stop playing without completion of gaming tasks) were positively associated with IGD. Impulsivity, self-control, parental influences, and peer influences were all significantly associated with the 3 types of MCIG and IGD. The 3 types of MCIG partially mediated the associations between the studied factors and IGD (effect size of 30.0% to 37.8%).

Conclusions: Impulsivity, self-control, and interpersonal influences had both direct and indirect effects via MCIG on IGD. Modifications of the 3 types of MCIG can potentially reduce the harmful impacts of impulsivity and interpersonal influences on IGD and enhance the protective effect of self-control against IGD. Future longitudinal studies are warranted.

KEYWORDS

cognition; adolescent health; health risk behaviors; internet; self-control; China

Introduction

After the inclusion of internet gaming disorder (IGD) in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) in 2013 [1], World Health Organization (WHO) recognized gaming disorder (online and offline) as a disease in the 11th Revision of *International Classification of Diseases* (*ICD-11*) in 2019 [2]. The reported range of prevalence of IGD among Chinese adolescents is wide (2.4% to 21.5%), possibly due to methodological differences [3]. Adolescents are vulnerable to IGD, which has many adverse consequences (eg, loneliness and depression [4-6]).

Maladaptive cognition is an important intrapersonal factor of addictive behaviors like pathological gambling [7] and internet addiction [8]; maladaptive cognitions related to internet gaming (MCIG) have also been associated with IGD [8-10]. A systematic review of 36 studies of MCIG proposed a 4-factor cognitive framework (ie, overvaluation of gaming rewards, maladaptive rules, gaming for self-esteem, and gaming for social acceptance) [11]; the 4 types of MCIG were all positively associated with IGD among adolescents [9]. A recent validation study modified this 4-factor model and revealed a new 3-factor model (ie, perceived rewards of internet gaming, perceived urges for playing internet games, and perceived unwillingness to stop playing without completion of gaming tasks) that demonstrated satisfactory psychometric properties [12]. The 3 domains of MCIG were all positively correlated with IGD [12]. The revised scale was used in this study.

Impulsivity and self-control are 2 important intrapersonal factors of addictive behaviors, including substance use [13,14], smoking [15], alcohol drinking [16], internet addiction [17], and IGD [4,18-21]. Impulsivity and self-control fit into the dual-process theories of decision-making for risk behaviors [22-25]. Impulsivity represents reactive, intuitive, and affective processes with high responsiveness to temptations and prompt actions without deliberation [24]. In contrast, self-control reflects the reasoned process and ability in regulating impulses deliberatively [26,27]. The 2 processes jointly affect decisions in the performance of risk behaviors [22-25]. Adolescents with high impulsivity may exhibit heightened spontaneous responses to behavioral cues to internet gaming, while those with low self-control may find it difficult to resist the temptation of playing internet games and stop playing.

Interpersonal influences are important factors of IGD. Empirical studies have reported positive associations between interpersonal influences (eg, parents' invitations of playing internet games and intensity of peers' gaming behaviors) and IGD or internet addiction among high schools students [28,29]. Interpersonal influences may affect IGD in different ways. Significant others' direct invitations to play internet games may trigger prompt engagement in internet gaming. According to the health belief model, such invitations to play internet games represent cues to action, which is an important determinant of health-related behavior [30]. Frequent invitations may increase adolescents' gaming intensity, which is associated with risk of IGD [28]. In addition, the reciprocal determinism construct of social cognitive theory (SCT) postulates that one's environment, personal factors, and health-related behaviors interact with each other [31]. Having significant others playing internet games frequently forms a social environment that may increase adolescents' gaming frequency. More importantly, SCT postulates that observational learning is an important factor of health-related behavior [31]; adolescents may play internet games frequently through observational learning from their significant others' frequent internet gaming.

Importantly, MCIG are potential mediators of the association between impulsivity or self-control and IGD. Brand's model [32] proposes that dysfunctional personality traits increase addictiveness to specific internet applications (including internet gaming), through mediation of changes in related cognitions (eg, expectations). Cognition of outcome expectancy regarding addictive behaviors has been shown to partially mediate the associations between impulsivity (a type of dysfunctional personality trait) and addictive behavior (eg, substance use and alcohol drinking) [33,34]. These studies, however, did not look at IGD. Following Brand's model, this study hence tested whether MCIG would mediate the association between impulsivity and IGD. This contention is indirectly supported by a study that reported a partial mediation of the association between maladaptive personality traits (ie, negative affectivity, detachment, and psychoticism) and IGD via the cognition of expectancies related to using internet gaming to escape from reality [35]. That study, however, did not include other types of MCIG. Furthermore, we did not locate studies that looked at MCIG as a mediator between self-control and IGD. This study thus sought to fill some of deficiencies in the relevant literature.

The mediation between interpersonal influences and IGD via MCIG was also tested in this study. The hypothesis is supported by the theory of triadic influence, which is a framework that incorporates influential factors of addictive behaviors from a number of psychological and sociological theories [36]. It distinguishes between distal or ultimate factors that influence proximal factors of changes in health-related behaviors [37]. According to the theory of triadic influence, interpersonal factors are distal or ultimate variables while cognitive factors related to a certain behavior are proximal variables [36]; the theory suggests that cognitive factors (eg, outcome expectancy) mediate between interpersonal influences and health-related behaviors [38,39]. Such mediations were found for some addictive behaviors (eg, substance use [40], alcohol drinking [41], and internet addiction [29]). One study also reported full and partial mediation of the cognition of positive outcome expectancy of internet gaming between interpersonal influences (peers' positive attitude toward gaming, intensity of peers' internet

game use, and the frequency of peers' invitation to play internet games) and IGD among high school students [28]. To our knowledge, however, no study has looked at the mediation effects of other types of MCIG.

We thus investigated the factors of IGD, including impulsivity, self-control, interpersonal influences exerted by parents and peers, and the 3 types of MCIG (perceived rewards, perceived urges, and perceived unwillingness to stop playing) among junior middle school students (grade 7 to 9 of formal education) in 2 populous cities in China. We then tested the mediation effects of MCIG on the associations between impulsivity or self-control and IGD, and between interpersonal influences and IGD, respectively. We hypothesized that the direct and indirect effects would be statistically significant.

Methods

Participants and Data Collection

The cross-sectional survey was conducted among secondary school students in Guangzhou and Chengdu in China from October 2018 to December of 2018. The 2 cities are located in southern and southwestern China, which had populations of 14.9 and 16.3 million people in 2018, respectively, and 0.36 and 0.40 million secondary school students in 2018, respectively [42]. Seven junior middle schools (4 out of 409 from Guangzhou and 3 out of 460 from Chengdu) were conveniently selected and participated in the study. All the Grade 7 students (7 years of formal education) in Guangzhou and all the Grade 7 to 9 students in Chengdu were invited to join the survey. The inclusion criteria were those who were full-time Grade 7 students and Grade 7-9 students of the participating schools in Guangzhou and Chengdu, respectively; and those willing to participate in the study. The procedure of data collection was described in a published study that used a subsample of the survey [12], and it is briefly introduced here. Under the supervision of well-trained field workers, students self-administered an anonymous structured questionnaire in the absence of teachers in classroom settings. They were briefed about the objectives of the survey, the return of completed questionnaires implied informed consent, and the students had the right to quit at any time without any negative consequences. No incentives were given to the students. The study was approved by the Survey and Behavioral Research Ethics Committee of the Chinese University of Hong Kong (#SBRE-18-430).

Of the 4350 students invited to participate in the present study, 3147 (72.34%) returned the questionnaire. Among all the returned questionnaires, 66 (2.10%) were removed from data analyses as there were more than 20% of missing data in their response items. Data obtained from the remaining 3081 students (97.90%) were used for data analysis (1126 from Guangzhou [36.55%] and 1955 from Chengdu [63.45%]).

Measures

Background Variables

Background information was collected, including sex, grades, being born in the studied city, whether living with both parents, both father's and mother's educational levels (junior middle school or below, senior middle school or equal, or college or above), household income level compared with their classmates (5 points: much higher to much lower), and self-reported academic performance (3 points: above average, average, and below average).

IGD Assessment

The 9-item *DSM-5* checklist was used to assess IGD [43]; it recorded the presence of addictive symptoms, including preoccupation, withdrawal, tolerance, inability to control internet gaming, loss of interest in other activities, psychological or social problems, deception, avoidance, and significant loss due to internet gaming. IGD is defined by endorsement of ≥ 5 items (yes-no response options). The Chinese version of *DSM-5* has been validated as having good psychometric properties and diagnostic validity [44,45]. The Cronbach α of the checklist was .79 in the present study.

Maladaptive Cognitions Related to Internet Gaming

MCIG was measured by using the Chinese version of the Revised Internet Gaming Cognition Scale (C-RIGCS). It consists of 3 subscales: perceived rewards of internet gaming, perceived urges for playing internet games, and perceived unwillingness to stop playing without completion of gaming tasks. Sample items are "I feel more in control when I play internet games," "I would feel bad if I was not able to play internet games," and "I feel uncomfortable thinking about my unfinished goals or objectives in internet games." The C-RIGCS has been validated in Chinese adolescents and has shown acceptable psychometric properties [12]. The items were rated with 5-point Likert scales (0=never to 4=always), with higher scores indicating higher levels of MCIG. The Cronbach α of the overall scale and its 3 subscales in the present study were .91, .86, .81, and .74, respectively.

Impulsivity

Impulsivity was measured by using the 10-item motor impulsiveness subscale of the Barratt Impulsiveness Scale, which indicates the tendency to act on the spur of the moment and with fast reactions [46]. The Chinese version made some cultural adaptations and showed good reliability and construct validity in Chinese adolescents [47]. A sample item is "I do things without thinking." The items were rated with 5-point Likert scales (1=completely disagree to 5=completely agree), with higher scores indicating higher levels of impulsivity. The Cronbach α of the scale was .91 in this study.

Self-Control

Self-control was measured by using the 13-item Brief Self-Control Scale [26], which demonstrated good psychometric properties in Chinese adolescents [48]. A sample item is "I am good at resisting temptation." The items were rated with 5-point Likert scales (1=never to 5=always), with higher scores indicating higher levels of self-control. The Cronbach α of the scale was .74 in this study.

Interpersonal Influences

Interpersonal influences were measured by revising the 6 items that assessed similar tendencies in a previous study [28]. The

items included frequency of being invited to play internet games from parents and peers, perceived parents' and peers' gaming intensity, and perceived parental influences and peer influences on current internet gaming behavior. Sample items were "How often do your parents invite you to play internet games?", "How often do your parents play internet games?", and "To what extent do you think your parents affect your internet gaming behavior?" Confirmatory factor analysis was conducted to examine the 2-factor structure (parental influences and peer influences) of the 6 items, which showed an acceptable goodness of fit (comparative fit index [CFI]=0.97, Tucker-Lewis index [TLI]=0.97, and root mean square error of approximation [RMSEA]=0.09). The items were rated with 4-point Likert scales (1=never/nil to 4=always/severe), with higher scores indicating higher levels of interpersonal influences. The Cronbach α of the overall scale and its 2 subscales in this study were .73, .63 (a Cronbach α >.60 was considered acceptable in previous literature [49,50]), and .71, respectively.

Statistical Analysis

IGD was used as the binary dependent variable. Univariate logistic regression analysis was conducted to establish the associations between the studied background variables and IGD; crude odds ratios (ORcs) and their respective 95% CIs were derived. Pearson correlation coefficients (r_p) and Spearman correlation coefficients (r_s) were derived for continuous and ordinal variables, respectively. The mediation effects were tested by using structural equation modeling (SEM) with weighted least square mean and variance-adjusted estimation. Three latent variables were created: (1) impulsivity or low self-control was derived from the scale scores of impulsivity and self-control (reversed scores), (2) interpersonal influences was derived from the subscale scores of parental influences and peer influences, and (3) maladaptive cognitions was derived from the subscale scores of the 3 types of MCIG. The paths between the 3 latent variables and IGD were fit to test the mediation hypotheses. Recommended goodness-of-fit indicators included CFI ≥0.90, TLI ≥0.90, and RMSEA ≤0.08. The SEM was conducted by using Mplus 7.0; other statistical analyses were performed with SPSS version 21.0 (IBM Corp). Statistical significance was defined as a 2-tailed *P* value <.05.

Results

Descriptive Statistics

More than half of the participants were males (1550/3081, 50.31%) and first-year students (1979/3081, 64.23%). More than one-fifth were not born in the city where the study was conducted (691/3081, 22.43%) and did not live with both parents (639/3081, 20.74%). Around one-fifth of the participants' fathers (594/3081, 19.28%) and mothers (566/3081, 18.37%) had received tertiary education or above; 12.56% (387/3081) self-perceived a lower or much lower household income level than did their classmates, and 19.47% (600/3081) self-reported a below-average academic performance (see Table 1). The mean of impulsivity, self-control, parental influences, and peer influences were 22.9 (SD 7.6, range 10-50), 44.4 (SD 7.6, range 13-65), 4.8 (SD 1.8, range 3-12), and 6.5 (SD 2.1, range 3-12), respectively. Similarly, the mean of the overall C-RIGCS and its 3 subscales were 17.0 (SD 11.6, range 0-60), 7.2 (SD 5.9, range 0-28), 3.7 (SD 3.5, range 0-16), and 6.1 (SD 3.7, range 0-16), respectively.

Table 1. Background characteristics of participants (N=3081).

Characteristic	Value, n (%)

Prevalence of IGD

The prevalence of IGD was 13.57% (418/3081; 95% CI 12.4%-14.5%) among all participants. Among those who had played internet games in the past 12 months (2071/3081, 67.22% of all participants), the prevalence of IGD was 17.67% (366/2071; 95% CI 16.0%-19.3%).

Associations Between Background Variables and IGD

The univariate logistic regression analyses showed that the background variables were all significantly associated with IGD, except for place of birth (whether born in the city where the study was conducted; Table 2). Significant factors included sex (males vs females: ORc=2.80, 95% CI 2.23-3.51), student grade (Grade 8 vs 7: ORc=1.90, 95% CI 1.49-2.44; Grade 9 vs 7: ORc=1.36, 95% CI 1.03-1.80), study site (Chengdu vs Guangzhou: ORc=2.12, 95% CI 1.66-2.69), living arrangement (not living vs living with both parents: ORc=1.54, 95% CI 1.22-1.95), household income level (self-perceived lower or much lower vs higher or much higher than other classmates: ORc=1.64, 95% CI 1.17-2.30), parental education (father's tertiary vs primary education or below: ORc=0.53, 95% CI 0.39-0.73; mothers' tertiary vs primary education or below: ORc=0.72, 95% CI 0.53-0.97), and self-reported academic performance (average vs above average: ORc=1.35, 95% CI 1.04-1.76; below average vs above average: ORc=2.53, 95% CI 1.90-3.36).

Correlations Among the Studied Variables

The 3 studied risk factors (impulsivity, parental influences, and peer influences) were all positively correlated with the overall C-RIGCS and its 3 subscales representing MCIG (r_p ranged from 0.19 to 0.39; *P*<.001) and IGD (r_s ranged from 0.24 to 0.26; *P*<.001), respectively. Self-control was negatively correlated with the overall C-RIGCS and its 3 subscales (r_p ranged from –0.45 to –0.27; *P*<.001) and IGD (r_s=–0.32; *P*<.001), respectively. Besides the above correlations, all the studied factors of IGD were significantly correlated with each other (see Table 3).

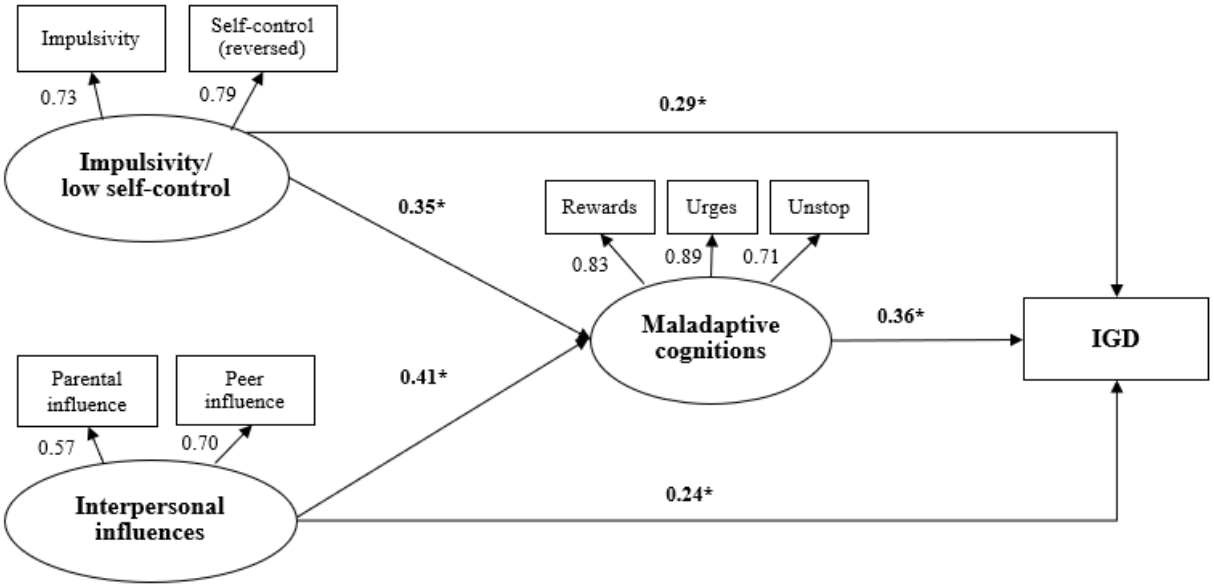
The SEM Model Testing the Mediation Hypotheses

Figure 1 presents the SEM model that demonstrated a satisfactory model fit (CFI=0.95, TLI=0.90, and RMSEA=0.08); the factor loadings of the 3 latent variables ranged from 0.57 to 0.89 (all *P*<.001). The findings revealed that maladaptive cognitions partially mediated the association between impulsivity or low self-control and IGD (mediation effect size=30.0%; *P* of Sobel test <.001), and between interpersonal influences and IGD (mediation effect size=37.8%; *P* of Sobel test <.001), respectively. Impulsivity or low self-control (standardized β=.29; *P*<.001) and interpersonal influences (standardized β=.24; *P*<.001) had significant direct effects on IGD. The standardized β values of the other paths are presented in Figure 1.

Figure 1. The structural equation model testing the mediation hypotheses. IGD: internet gaming disorder. *P<.001.



Discussion

This study revealed an alarmingly high prevalence of IGD (around 14% among all adolescent participants and 18% among adolescent internet gamers). The prevalence was comparable to the 13% among adolescents of 2 other Chinese cities [51], but much higher than the 2% among Chinese Macau adults [52] and the 3.1% among Australian adolescents [9]. These studies all used *DSM-5* criteria to assess IGD. The high prevalence of IGD signifies the need to regulate internet gaming behaviors and conduct interventions to reduce IGD among adolescents in China, as adolescent IGD has been positively associated with various behavioral problems (eg, aggression and violence [53,54]) and mental health problems (eg, loneliness and depression [4-6]).

In our study, a number of background factors were associated with a higher risk of IGD, including male sex, higher grades, not living with both parents, and self-reported below-average academic performance. First, corroborating previous studies [18,55,56], males were associated with a higher risk of IGD. This finding may be explained by the sex differences in brain responses [57], motives of internet gaming [58], and a less female-friendly gaming environment [59], among other plausible factors. Second, higher grades were positively associated with IGD in this study. Similar findings have been reported [9], but the direction of the association between age and IGD was mixed [18,60]. Future longitudinal studies are warranted to examine the associations between sex, age, grade, and IGD to develop sex- and age-specific interventions to reduce IGD. Furthermore, disadvantaged adolescents, including those of lower socioeconomic status (eg, self-perceived lower household income) and those not living with both parents were more likely than others to have IGD. Similar results were reported in previous longitudinal and cross-sectional studies [61,62]. Disadvantaged adolescents might have fewer resources for leisure activities and less parental monitoring over internet use, which may lead to more intensive internet gaming and higher risk of developing IGD [61]. A negative association between academic performance and IGD was also reported in our study, which was consistent with previous literature [18,63,64]. It is worth noting that the relationship between academic performance and IGD may be bidirectional. Frustration over poor academic performance may lead to problematic gaming as a means of escape and maladaptive coping [65], which has been associated with IGD [66]. Conversely, IGD may lead to poor academic performance [5,67]. The causal direction needs to be confirmed by longitudinal studies.

To facilitate the design of effective interventions for reducing IGD, it is important to understand the mechanisms (mediation) underlying the associations between risk or protective factors of IGD and IGD. The findings reveal that some intrapersonal (impulsivity) and interpersonal (interpersonal influences) risk factors may elevate the levels of the 3 types of MCIG, which may in turn increase the risk of developing IGD. Furthermore, self-control may reduce MCIG, which may increase IGD (a partial mediation effect). Nonetheless, the presence of significant direct effects between impulsivity, self-control, and interpersonal influences and IGD imply the existence of other unstudied mediators. For instance, coping is a potential mediator, as Brand's model postulates dysfunctional copying strategies mediate between personality traits and problematic use of the internet (including IGD) [32], while impulsivity can be considered a personality trait. Interpersonal influences may also strengthen the subjective norms of internet gaming (ie, significant others' support for internet gaming), which is a construct of the theory of planned behaviors [68]; these subjective norms are expected to be associated with MCIG. Future studies should look at other mediators.

The observed mediation effects suggest that modifications of the 3 types of MCIG can potentially reduce the harmful impacts of impulsivity or interpersonal influences on IGD and increase the protective effect of self-control against IGD. Targeted interventions to improve MCIG may include training to increase awareness of the 3 types of MCIG and skills to perform related

cognitive reconstructions [69], provision of alternative sources of rewards (eg, outdoors activities) to reduce perceived rewards of internet gaming, removal of sources of temptations and stimuli (eg, gaming devices), and introduction of distraction skills to reduce perceived urges or unwillingness to stop playing internet games [70,71].

There are also plausible explanations for why impulsivity was positively associated with the 3 types of MCIG. First, impulsivity may increase reward sensitivity that enhances adolescents' drives to seeking more rewards from addictive behaviors [72,73]; impulsive adolescents may thus possess a higher reward drive and perceive more rewards from internet gaming. Second, impulsive adolescents may be more responsive to cues of internet gaming and thus hold stronger urges for playing. Third, impulsivity in general may reduce impulse inhibitions against addictive behaviors, even in the presence of negative consequences [74-76]; adolescents with weakened inhibitions of gaming impulses may thus be less able to resist stimuli inductive to playing internet games and may perceive stronger unwillingness to stop playing. Self-control was negatively associated with the 3 types of MCIG, possibly because of the negative association between impulsivity and self-control [22-25], but other reasons may also apply. Interventions for modifying impulsivity and self-control may remove temptations and strengthen self-efficacy in regulating impulses [77]). In particular, the if-then planning intervention that specifies when, where, and how to regulate impulses is potentially useful [78]; a review reported that this type of intervention showed efficacy in reducing addictive behaviors (eg, in binge drinking and cigarette smoking) [79].

This study also found positive associations between interpersonal influences and MCIG. Having significant others who are frequent internet gamers was positively associated with MCIG. The SCT suggests that, through reciprocal determinism and observational learning, social interactions may influence both adolescents' attitudes and behavior [31]. It is likely that adolescents' parents or peers who play internet games frequently may also perceive higher levels of MCIG (eg, the 3 types of MCIG). Adolescents' maladaptive cognitions may be influenced by those of their parents via multiple means, such as social learning, subjective norms, and reinforcement. Furthermore, peers influence each other to form common perceptions regarding particular behaviors [80]. Future confirmation is needed. Family-based interventions for reducing IGD are potentially useful. A psychoeducation on maladaptive and adaptive use related to internet games showed preliminary effectiveness [81]. Another intervention that involved parental monitoring on adolescents' self-regulation practice and gaming behaviors showed short-term (3 month) efficacy in improving attitude, knowledge, self-regulation, and IGD among adolescents [82]. Although a meta-analysis showed that peer-led interventions were efficacious in reducing tobacco, alcohol, and substance use among adolescents [83], our literature search did not locate similar interventions for IGD. Future evidence-based interventions are warranted.

This study has several limitations. First, reporting bias, such as recall bias and social desirability bias, might have been introduced. Second, as the participating schools were selected based on convenience, there might have been selection bias, and generalization of the study results should be done cautiously. Third, the prevalence of IGD assessed by using the *DSM-5* checklist might have been overestimated compared with that based on the *ICD-11* criteria [84]. Fourth, we were unable to make causal inferences due to the cross-sectional nature of this study. Fifth, the revised assessment tool of interpersonal influences has not been validated although we conducted confirmatory factor analysis to test its 2-factor structure, which showed an acceptable goodness of fit. Finally, this study only investigated internet gaming but not offline video games, while both online and offline video games are included in the *ICD-11* under the category of gaming disorder, as the 2 types of gaming disorder differ in etiology, epidemiology, and treatment.

In conclusion, MCIG partially mediated the associations between impulsivity, self-control, or interpersonal influences and IGD. Modifications of the 3 types of MCIG may effectively reduce the harmful impacts of impulsivity or interpersonal influences on IGD and increase the protective effect of self-control against IGD. Future longitudinal studies are warranted to verify these findings and explore other potential mediators.

Acknowledgments

This research was funded by National Natural Science Foundation of China (grant #81373021). We would like to thank all the participants for their contribution.

Authors' Contributions

JTFL and YY conceived the study. YY, PKHM, and JTFL were responsible for the methodology. JZ and JL conducted the investigation. YY was responsible for the software and data curation, and conducted the formal analysis. PKHM and JTFL were responsible for validation. JZ, JL, and JTFL acquired the study resources. YY and JTFL wrote the original draft. YY, PKHM, and JTFL reviewed and edited the draft. JTFL conducted supervision. JL and JTFL acquired funding for the study.

Abstract

Background: Chronic obstructive pulmonary disease (COPD) is the third leading cause of death globally, and timely health care seeking is imperative for its prevention, early detection, and management. While online health information–seeking behavior (OHISB) is increasingly popular due to widespread internet connectivity, little is known about how OHISB for COPD has changed in comparison with the COPD disease burden, particularly at a country-specific level.

Objective: This study aimed to examine the trends in OHISB for COPD and how that compared with the estimates of COPD disease burden in Singapore, a highly wired country with a steadily increasing COPD disease burden.

Methods: To examine the trends in OHISB for COPD, we performed Prais-Winsten regression analyses on monthly search volume data for COPD from January 2004 to June 2020 downloaded from Google Trends. We then conducted cross-correlational analyses to examine the relationship between annualized search volume on COPD topics and estimates of COPD morbidity and mortality reported in the Global Burden of Disease study from 2004 to 2017.

Results: From 2004 to 2020, the trend in COPD search volume was curvilinear (β=1.69, t_{194}=6.64, P<.001), with a slope change around the end of 2006. There was a negative linear trend (β=–0.53, t_{33}=–3.57, P=.001) from 2004 to 2006 and a positive linear trend (β=0.51, t_{159}=7.43, P<.001) from 2007 to 2020. Cross-correlation analyses revealed positive associations between COPD search volume and COPD disease burden indicators: positive correlations between search volume and prevalence, incidence, years living with disability (YLD) at lag 0, and positive correlations between search volume and prevalence, YLD at lag 1.

Conclusions: Google search volume on COPD increased from 2007 to 2020; this trend correlated with the upward trajectory of several COPD morbidity estimates, suggesting increasing engagement in OHISB for COPD in Singapore. These findings underscore the importance of making high-quality, web-based information accessible to the public, particularly COPD patients and their carers.

online health information seeking; infodemiology; Google Trends; Global Burden of Disease study; chronic obstructive pulmonary disease; respiratory health

Introduction

Chronic obstructive pulmonary disease (COPD) is the third leading cause of death globally [1] and affected approximately 251 million of the world's population in 2016 [2]. In Singapore, it is the tenth leading cause of death [3] and affects approximately 5.9% of the general population [4] and 26% of the population aged 55 years and above [5]. The number of deaths caused by COPD in the South East Asia region is projected to increase from 1.04 million in 2016 to 1.43 million in 2030 [6]. Despite its significance, COPD still has poor awareness and understanding by both the public and health practitioners [7]. Therefore, understanding whether and how health information on COPD is accessed in proportion to the size of the disease burden is critical.

Barriers to health care seeking in COPD often lead to fewer prompt diagnoses and poorer disease management among those already diagnosed. For instance, misdiagnoses in primary care settings have been attributed to underuse of and lack of expertise with spirometry and COPD diagnostic guidelines [8]. Furthermore, patients' knowledge of COPD may be suboptimal because of the complexity of its name, not only in English but also in other languages [9]. Arguably, these barriers can be at least partially attributed to inadequate knowledge of COPD, which can be improved by making high-quality health information more accessible. According to the Health Information National Trends Survey in 2012, the internet was the first source of health information for 70% of adult US internet users [10], suggesting its increasing influence as a source of general and potentially, disease-specific health information.

Disease-specific online health information–seeking behavior (OHISB) among patients with COPD has been studied in several US-based surveys. A postal survey of 1077 patients with COPD in 2007-2008 found that 65% had internet access and 25% of this group used the internet to seek information on COPD at least once weekly. Their frequency of seeking COPD information online was associated with experiencing exacerbations or dissatisfaction with health service providers and treatments [11]. A web-based survey of 445 patients with COPD in 2016 found that physicians were the primary source of COPD information followed by the internet. The patients' online health information needs were primarily related to symptom control and COPD treatments; also, over 60% of the patients had discussed COPD information on the internet with their health care providers [12]. Another web-based survey of 176 COPD patients found that eHealth literacy, defined as the capacity to seek, locate, understand, evaluate, and apply health information from the internet, was higher in patients with more severe COPD [13]. These findings suggest that, at least in the United States, OHISB is common among COPD patients with internet access, and more frequent OHISB appears to be associated with more unmet needs in disease management.

A frequent method for examining OHISB is Google search data [14]. It is freely downloadable from Google Trends, a publicly accessible portal hosting data on aggregate search activity on the Google search engine delineated by time periods and regions. Since Google is the most popular search engine worldwide, its aggregate data are used as a surrogate indicator for OHISB at the population level.

In 2019, Boehm and colleagues [15] published a study using worldwide Google Trends data that found no change in search volume for COPD in the 15 years from 2004 to 2018. Yet, the number of deaths due to COPD was estimated to have increased by 11.7% from 1990 to 2015, despite a decrease of 41.9% in the age-standardized death rate in the general population [16]. This contrasts with other leading causes of death, such as diabetes and stroke, which have evidenced increased search volumes over the same period. The clear divergence between the rising prevalence of COPD and stagnant OHISB pattern for COPD is a cause for concern, but there are limitations in the study's methods. The analyses by Boehm et al [15] were performed on worldwide COPD search data without accounting for variation in COPD disease burden between countries and other country-level characteristics such as internet coverage; both factors are essential considerations for developing and implementing country-specific policy changes.

Our study improves upon the work by Boehm et al [15] by situating the enquiry within a single country, Singapore, and comparing Google Trends data with COPD disease burden estimates. Singapore is an opportune context for this research because of high internet penetration, popularity of Google search, and high COPD prevalence [4,5]. Furthermore, Singapore has a rapidly aging population with an increasing burden of chronic diseases. With this in mind, this study was designed to address 2 research questions. First, we aimed to examine the trend in OHISB for COPD (indicated by monthly Google search data) in Singapore from 2004 to 2020. Second, we aimed to compare online search volume with disease burden estimates to assess the extent to which OHISB for COPD reflects the disease burden reported in the Global Burden of Disease study (GBD 2017) over time. To our knowledge, this is the first study that examined trends in OHISB in conjunction with disease burden indicators in COPD.

Methods

Search Volume Data From Google Trends

Search query data relating to COPD were obtained from Google Trends, an online portal that displays search queries made worldwide on the Google search engine since 2004. The tool aggregates monthly volumes of search queries, delineated by time period and region, into a metric known as relative search interest (RSI). RSI is computed as a function of a search query's own highest query share. Its values range from 0 to 100, where 100 represents peak popularity. Google Trends excludes duplicate searches made by the same person over a short period of time. Search queries on Google Trends can be defined either as a search term (the exact search query, accounting for plural and singular forms and spelling mistakes) or a topic (groups of terms that share the same concept in any language).

Following the approach in Boehm et al [15], all search queries were defined as a topic and downloaded as monthly search data. In total, there were 198 monthly data points. When annual data

were required for comparison with GBD data, the annual averages were computed from monthly averages.

Disease Burden Data From GBD 2017

The following data relevant to COPD were obtained from GBD 2017: prevalence, incidence, disability-adjusted life years (DALY; the sum of years lived with disability [YLD] and the years of life lost [YLL]), YLD, YLL, number of deaths (mortality). GBD studies are conducted annually by The Institute for Health Metrics and Evaluation, and reports are typically issued every 2 years. These data are accessible online [17]. Currently, the data come from 195 countries and include 354 diseases and injuries. The data sources are diverse, including published literature, hospital and clinical data, surveillance and survey data, and inpatient and outpatient medical records. A detailed description of the methodology of the GBD 2017 can be found in the article by the GBD 2017 Disease and Injury Incidence and Prevalence Collaborators [2]. The most recent and publicly available GBD data were for 2017, and so the time period used for our study spanned from 2004, the first year for which Google Trends data were available, to 2017.

Statistical Analyses

As noted in previous works [18], performing Google Trend queries with similar parameters at different times can produce somewhat different data. To mitigate this problem, we performed the same query over 7 consecutive days, from June 22, 2020 to June 28, 2020. To assess the reliability of the data, two-way random model intraclass correlation coefficients (ICCs) were computed. The 7 time series data were averaged to produce a single time series for further analyses. Due to the nature of autocorrelated residuals in time series data, the Prais-Winsten estimation method was used to examine the trend in search volume. To compare search volume with disease burden estimates, a cross-correlation function was used to examine the correlation between the 2 annual time series data. The annual time series for search volume was computed by averaging the monthly search volume over the 12 months of each year.

Results

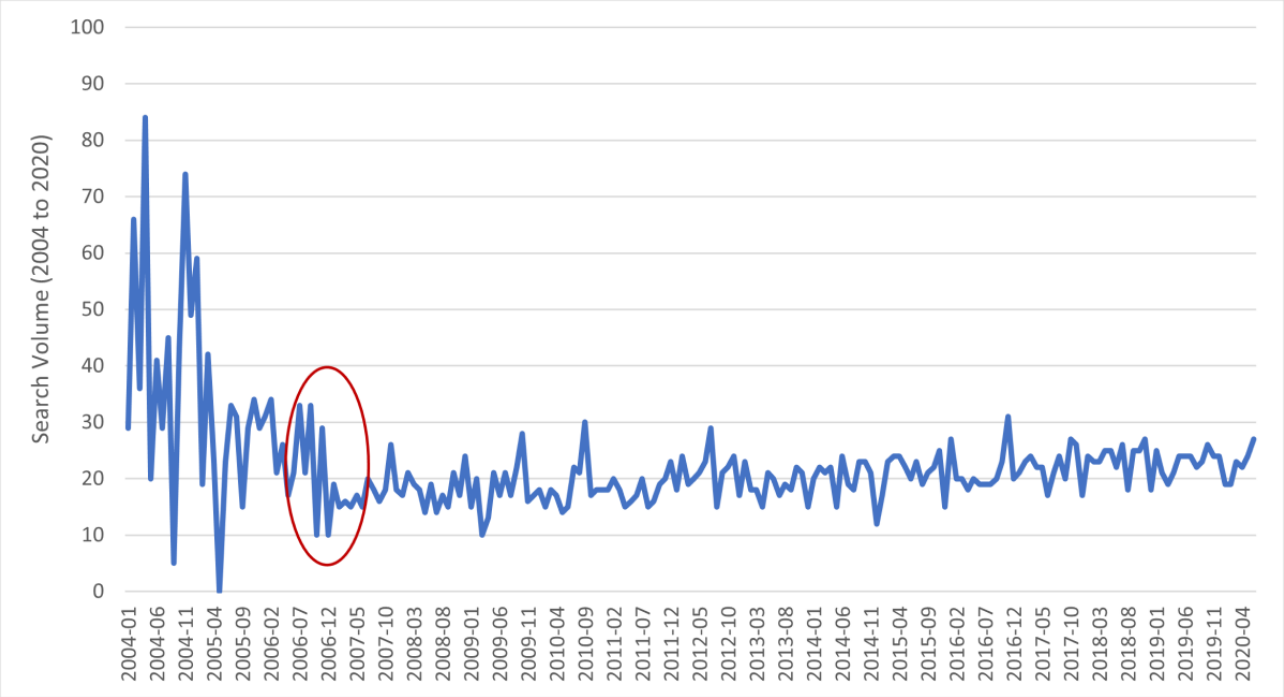
Reliability

The reliability of search volume data was moderate for the single time series data (ICC=0.55) and strong for the averaged time series data (ICC=0.90). The subsequent analyses were performed on the averaged time series data.

Trends in Monthly Search Volume for COPD From January 2004 to June 2020

The trend in monthly search volume for the COPD topic, shown in Figure 1, was examined using Prais-Winsten regression.

Figure 1. Relative search volume for chronic obstructive pulmonary disease (COPD) from 2004 to 2020. The red circle indicates an apparent slope change in search volume.



The Durbin Watson statistic [19] was 2.05. The autocorrelation coefficient was 0.09 (SE 0.72). For the overall model, R^2 was 0.22 (SE 8.16). Time demonstrated a quadratic effect on search volume (β=1.69, t_{194}=6.64, P<.001), as shown in Table 1. A quadratic effect suggests that there was 1 slope change over the entire period.

Table 1. Prais-Winsten regression examining the effect of time on monthly search volume for chronic obstructive pulmonary disease (COPD; 2004-2020).

Predictors	β[a]	*t* (*df*=194)	*P* value
time	–1.84	–7.22	<.001
time^2	1.69	6.64	<.001

[a]Standardized coefficients.

In Figure 1, the slope change appears to have happened at the end of 2006 and beginning of 2007, circled in red. To examine the trend before and after the apparent slope change, Prais-Winsten regressions were conducted for the 2 periods: 2004-2006 (36 months) and 2007-2020 (162 months). In addition, due to improvements in Google's algorithms for search volume from 2011, the trend from 2011 to 2020 was also examined. The analyses are presented in Table 2.

Table 2. Prais-Winsten regression examining the effect of time on monthly search volume during 3 different periods of analysis.

Predictor: time	β[a]	*t*	*P* value
2004 to 2006	–0.53	–3.57 (*df*=33)	.001
2007 to 2020	0.51	7.43 (*df*=159)	<.001
2011 to 2020	0.45	5.27 (*df*=111)	<.001

[a]Standardized coefficients.

From 2004 to 2006, the Durbin Watson statistic was 1.91. The autocorrelation coefficient was –0.17 (SE 0.17). For the overall model, R^2 was 0.28 (SE 16.08). Time demonstrated a negative linear effect on search volume (β=–0.53, t_{33}=–3.57, P=.001), suggesting a reduction in monthly search volume during this period.

From 2007 to 2020, the Durbin Watson statistic was 1.91. The autocorrelation coefficient was –0.03 (SE 0.08). For the overall model, R^2 was 0.26 (SE 3.25). Time demonstrated a positive linear effect on search volume (β=0.51, t_{159}=7.43, P<.001), suggesting that monthly search volume exhibited a positive linear trend from 2007 to 2020.

From 2011 to 2020, the Durbin Watson statistic was 1.99. The autocorrelation coefficient was –0.07 (SE 0.10). For the overall model, R^2 was 0.20 (SE 3.08). Time demonstrated a positive linear effect on search volume (β=0.45, t_{111}=5.27, P<.001), suggesting a positive linear trend consistent with that from 2007 to 2020, despite improvements in Google Trend's algorithms.

Cross-Correlation Between Annual Search Volume and Disease Burden Indicators (2004-2017)

Table 3 presents cross-correlations between annual COPD search volume and disease burden indicators at lags 0, –1, and 1. There were positive correlations between search volume and prevalence, incidence, and YLD at lag 0, suggesting that these pairs of variables were contemporaneously correlated. There were also positive correlations between search volume and prevalence, as well as between search volume and YLD at lag 1, suggesting that higher prevalence and YLD coincided with higher search volume 1 year later. Correlations at all other lags were nonsignificant.

Table 3. Cross-correlation analysis of annual chronic obstructive pulmonary disease (COPD) search volume and COPD disease burden indicators (2004-2017).

Disease burden indicator	Annual search volume		
	Lag –1	Lag 0	Lag 1
Prevalence	0.31	0.84[a]	0.60[a]
Incidence	0.36	0.92[a]	0.50
Disability-adjusted life years (DALY)	0.04	0.06	0.49
Years living with disability (YLD)	0.29	0.84[a]	0.59[a]
Years of life lost (YLL)	–0.00	0.08	0.41
Mortality	–0.01	0.00	0.40

[a]Exceeds the 95% CI threshold.

Discussion

This study examined the trends in OHISB for COPD in Singapore using Google search volume data between 2004 and 2020 and compared them with the trends in disease burden indicators for the same time period.

Principal Findings

The first objective was to examine the trend in search volume in COPD from 2004 to 2020. During this period, the trend in COPD search volume was curvilinear, with a slope change at the end of 2006. Further analyses examining the trends before and after this slope change revealed a downward trend from 2004 to 2006 and an upward trend from 2007 to 2020. The downward trend from 2004 to 2006 was surprising. We speculate the reason to be noisy data due to low and inconsistent search volume from 2004 to 2006, a period during which personal computing and high-speed internet connectivity were growing rapidly but not yet widespread in Singapore. From 2007 to 2020, the search volume exhibited a positive linear trend. A search of news and events from 2004 to 2020 revealed no significant events (eg, COPD health campaigns) to explain this trend. Our finding contrasts with an analysis of global data that showed no change in the trend in COPD OHIBS from 2004 to 2018 [15] and highlights the value of adopting a country-specific approach for revealing patterns that might be diluted when countries are aggregated.

The second research objective was to compare the trend in Google search volume with the disease burden indicators of COPD. From 2004 to 2017, there were positive correlations between search volume and several COPD disease burden indicators (prevalence, incidence, YLD) in the GBD study, suggesting that the trend in COPD search volume reflected the increase in some COPD morbidity indicators in the country. Search volume was not correlated with COPD mortality and YLL due to the disease, suggesting that Google search volume might be driven by the need to manage the illness for those living with COPD. This is consistent with the observation that improved health care has prolonged the living years of patients living with chronic illnesses, such as COPD.

The positive correlations between OHISB trends and COPD disease burden indicators (particularly prevalence and YLD) suggest that increased prevalence of COPD morbidity may have manifested in increased OHISB. COPD patients might be searching for health information on the internet to cope with their illness. Some of these increased searches might also have been performed by carers and family members of patients with COPD [20] or health care workers, especially those still in training. Patients with COPD appear to rely on their physicians as their primary source of information [12], but OHISB may still have a significant role when access to formal health care is limited. In Singapore, it is common for consultations with general practitioners to last for ≤5 minutes, so patients need to be well informed to optimize the brief consultation. Several patient-related barriers to timely COPD diagnoses have been reported in the literature. Patients tend to adapt to and underreport their respiratory symptoms, leading to potential underdiagnosis of COPD [21]. Older patients may also mistake symptoms such as shortness of breath as normal signs of aging [22]. Increased awareness of the significance of these symptoms among high-risk patients (eg, smokers) can increase the likelihood of a more timely diagnosis and prompt management of exacerbations.

Recommendations should be given to providers of online health information to make their materials more credible and user-friendly, reducing the barrier to timely health care seeking. Health knowledge can empower COPD patients to actively manage their own illnesses and make informed decisions about their conditions. For patients who seek health information online regularly, health care professionals can recommend trustworthy websites to complement their illness management [12].

In adopting a country-specific approach, this study seeks to present a nuanced picture of OHISB in Singapore's rapidly aging population with high internet penetration and increasing COPD burden. Heterogeneous patterns may be concealed when countries are aggregated for analysis. Furthermore, findings from single-country studies are more useful for formulating policies, which need to be tailored to the specific conditions of the target country.

Limitations

The findings of this study should be considered in the light of its limitations. First, while Google is the most popular search engine by a large margin, it nevertheless does not encompass all OHISB for COPD. Future research needs to study COPD OHISB on other platforms, such as social media, to understand how those OHISB change in accordance with COPD morbidity. Second, although Google indicated that Google Trends data should be understood as a metric of interest relative to searches on other topics, the specific way in which Google Trends data are derived is still unknown. Third, we note that the positive linear trend in COPD search volume is only moderate, and the interest level in this condition is low relative to some other health conditions. Finally, we acknowledge that this study is observational in nature, and the observed relationships were associative rather than causal. An additional analysis of search volume data on tuberculosis, a condition with a mostly static disease burden in Singapore, also revealed an upward trend, but to a lesser degree than COPD, suggesting a possible general increase in OHISB across medical conditions. Hence, increasing disease burden may be only one of the many factors driving OHISB in COPD.

Conclusion

Using Google search data, this study found an increasing trend in OHISB for COPD from 2007 to 2020 in Singapore, consistent with the increases in COPD morbidity estimates over the same time period. This suggests increasing engagement in OHISB for COPD in the population, many of whom may be COPD patients and their carers. The COPD disease burden is increasing, and timely seeking of health care is imperative for its prevention, early detection, and management. Greater public awareness is essential for minimizing the disease burden. Therefore, improving access to high-quality, web-based information on COPD is recommended for fulfilling COPD patients' information needs and improving their health outcome.

Abstract

Background: Adverse drug reactions (ADRs) affect the health of hundreds of thousands of individuals annually in the United States, with associated costs of hundreds of billions of dollars. The monitoring and analysis of the severity of ADRs is limited by the current qualitative and categorical systems of severity classification. Previous efforts have generated quantitative estimates for a subset of ADRs but were limited in scope because of the time and costs associated with the efforts.

Objective: The aim of this study is to increase the number of ADRs for which there are quantitative severity estimates while improving the quality of these severity estimates.

Methods: We present a semisupervised approach that estimates ADR severity by using social media word embeddings to construct a lexical network of ADRs and perform label propagation. We used this method to estimate the severity of 28,113 ADRs, representing 12,198 unique ADR concepts from the Medical Dictionary for Regulatory Activities.

Results: Our Severity of Adverse Events Derived from Reddit (SAEDR) scores have good correlations with real-world outcomes. The SAEDR scores had Spearman correlations of 0.595, 0.633, and −0.748 for death, serious outcome, and no outcome, respectively, with ADR case outcomes in the Food and Drug Administration Adverse Event Reporting System. We investigated different methods for defining initial seed term sets and evaluated their impact on the severity estimates. We analyzed severity distributions for ADRs based on their appearance in boxed warning drug label sections, as well as for ADRs with sex-specific associations. We found that ADRs discovered in the postmarketing period had significantly greater severity than those discovered during the clinical trial (P<.001). We created quantitative drug-risk profile (DRIP) scores for 968 drugs that had a Spearman correlation of 0.377 with drugs ranked by the Food and Drug Administration Adverse Event Reporting System cases resulting in death, where the given drug was the primary suspect.

Conclusions: Our SAEDR and DRIP scores are well correlated with the real-world outcomes of the entities they represent and have demonstrated utility in pharmacovigilance research. We make the SAEDR scores for 12,198 ADRs and the DRIP scores for 968 drugs publicly available to enable more quantitative analysis of pharmacovigilance data.

Introduction

Background

Adverse drug reactions (ADRs) are among the leading causes of mortality and morbidity in the United States, affecting hundreds of thousands of people and costing more than US $500 billion every year in the United States alone [1,2]. An ADR is characterized as "an appreciably harmful or unpleasant reaction resulting from an intervention related to the use of a medicinal product" [3]. A drug's ADRs are primarily derived from clinical trial data and augmented through postmarketing surveillance [4]. The ADR labeling process for each drug is based on the frequency of the ADRs in the treated populations and the severity of the outcomes associated with each ADR. The severity of an ADR is traditionally classified into one of three categories characterized by where it appears on the label: boxed warning, warnings and precautions, or adverse reactions, listed in decreasing order of associated severity [5]. Boxed warnings refer to "serious warnings, particularly those that lead to death or serious injury." Under the existing system, death is severe enough to warrant a boxed warning, but so is restlessness; therefore, it would be useful for prescribers, patients, and researchers to have systems for recognizing that death is more severe than restlessness [6]. Similarly, warnings, precautions, and adverse reactions include a diverse spectrum of ADRs, and it can be difficult for patients, prescribers, and researchers to compare the risk profiles of different drugs.

The existing categorical definitions of ADR severity limit the ability of researchers and regulators to apply quantitative methods to regulatory and pharmacovigilance efforts. For instance, tracking the regulatory performance of drug safety efforts is primarily achieved through a categorical analysis of ADR case outcomes and drug label changes. The creation of a quantitative numerical scale that provides a relative severity score for each ADR would enable these analyses to leverage the powerful tools of quantitative decision and utility theory.

The pioneering study by Tallarida et al [7] examined the ability to create a continuous ADR severity scale. A total of 53 physicians were interviewed and asked to estimate the acceptable probabilities in a set of scenarios specifying risk-benefit trade-offs. These probabilities were then used to define a set of equations and the expected benefit to the patient in each scenario. Solving the system of equations resulted in numerical severity weights that were relative to the lowest ADR severity. The effort took approximately 45 minutes per interview and resulted in relative scores for seven ordinal categories of ADR severity.

The study by Gottlieb et al [8] expanded this ADR severity ranking task using the crowdsourcing platform Amazon Mechanical Turk. Individual workers were presented with a pair of ADRs and a link to more information on these ADRs and asked to select the ADR that they perceived to be more severe. Over 146 person-days, 2589 workers produced severity comparisons for 126,512 ADR pairs composed from 2929 unique ADRs. A linear programming algorithm was used to create a unified ADR severity ranking. To validate the ranking, the ADR severities were correlated with ADR case outcomes from the Food and Drug Administration Adverse Event Reporting System (FAERS). The highest Spearman correlation, $\rho=0.53$, was associated with the proportion of cases resulting in death. This effort drastically increased the number of ADRs included in the severity ranking but was costly in terms of human time, labor, and money.

Recent work in natural language processing has resulted in numerous methods for creating vectorized word representations (also known as *embeddings*) that capture semantic meaning in a dense numerical representation [9,10]. These methods rely on the distributional hypothesis that word meaning is captured by the contexts in which a word appears [11]. The practical implication of the distributional hypothesis is that training a model to predict word context (ie, co-occurring word pairs) results in model weights that capture the meaning of the word. These model weights can then be used as a numerical representation of a given word.

Word embeddings learned on social media data sets have been deployed for pharmacovigilance previously but not for the purpose of exploring ADR severity [12]. By using a social media corpus generated by the general public, especially on pseudoanonymous social media platforms such as Reddit, researchers can capture meanings that reflect people's unfiltered experiences of, and opinions about, health and disease [13,14]. Investigating the utility, benefits, and challenges of different social media platforms and methods for pharmacovigilance has been an area of active research [15]. Previous research on Twitter data annotated samples of tweets for personal medication intake versus individuals simply mentioning a drug [16,17]. Together, the 2 studies found that approximately 40% of the tweets mentioning a drug indicated that the individual tweeting was possibly personally taking that medication. Here, we focused on ADRs, but it is likely that the individuals discussing ADRs on social media have more direct experience with the ADRs, either by being directly affected by the ADRs or being informed about the ADR experience by a close relation, than individuals selected from a pool of crowdworkers. Word embeddings trained on a corpus generated by the general public can then be leveraged as a metric for public opinion in a similar fashion to previous crowdsourced approaches. We used the RedMed embeddings trained on more than 580 million health-enriched Reddit comments from more than 10 million users [18]. These numbers dwarf the number of votes gathered in a typical crowdsourcing experiment and are therefore potentially more indicative of a representative population's perception of ADRs than traditional survey-based methods.

Objective

In this study, we used publicly available word embeddings and a network-based label propagation method to estimate the severity of 12,198 ADR concepts from Medical Dictionary for Regulatory Activities (MedDRA) terminology. The resulting Severity of Adverse Events Derived from Reddit (SAEDR) scores were validated against human rankings as well as FAERS case outcomes. We used System Organ Classes (SOCs) and other groupings within the MedDRA to examine how the SAEDR severity scores differ at various levels of abstraction and within ADR categories. We used the SAEDR scores to

compare the severity among ADRs in different sections of drug labels, ADRs with disproportionate rates between sexes, and ADRs discovered at different stages of drug development. We combined the SAEDR scores with frequency information from Side Effect Resource (SIDER)–derived drug labels to generate drug-specific aggregate side effect severity scores [19]. The SAEDR scores enabled new analyses that were not possible with the existing categorical classifications.

Methods

Data Sources and Preparation

ADR Terms and Phrases

We sourced our ADR phrases and their synonyms from the *lowest-level terms* within the terminology of the MedDRA, version 22 [20]. We filtered terms based on their semantic types within the Unified Medical Language System Metathesaurus [21] and retained terms of the following semantic types: *Disease or Syndrome* (T047), *Finding* (T033), *Neoplastic Process* (T191), *Injury or Poisoning* (T037), *Pathologic Function* (T046), *Sign or Symptom* (T184), *Mental or Behavioral Dysfunction* (T048), and *Congenital Abnormality* (T019).

Word-Embedding Model

We used the word-embedding model from the RedMed project [18]. This model was selected because it was directly optimized for medical term similarity and was trained on a corpus of Reddit comments generated by the public and preprocessed to maximize the inclusion of ADR terms. ADRs that were a phrase such as "abdominal pain" were represented using the average embedding of all terms within the phrase. In previous work, not presented here, we found that the use of average embeddings, for example, "abdominal" + "pain"/2, produced better results than the use of embedded phrases, for example, "abdominal pain."

Gottlieb Severity Data

We used the crowdsourced severity estimates included within the supplement of the study by Gottlieb et al [8], which included 2929 ADRs with rank scores.

FAERS Data

All adverse drug event data were downloaded in JSON format from the openFDA website, which includes data from both the Legacy Adverse Event Reporting System and the FAERS. Data were retrieved on August 8, 2020, and included adverse event case reports up to June 30, 2020. Drug reactions were normalized to the MedDRA, version 22. We filtered to unique case IDs using the provided duplicated flag to remove duplicate reports and case reports that did not originate in the United States. Case outcomes were normalized according to the following schema: "Death": {"Death"}, "Serious Outcome": {"Life-Threatening," "Hospitalization," "Other Serious," "Required Intervention"}, and "Disability": {"Congenital Anomaly," "Disability"}. We created an additional outcome category denoted *No Outcome* for cases with no reported outcome. We felt the need to create this category because the FAERS only allows for the reporting of serious case outcomes, and there is information in the absence of a serious outcome being reported. The outcome proportions for each ADR were calculated by dividing the number of cases reporting that ADR for a particular outcome by the total number of cases reporting that ADR.

FAERS Severity Rankings

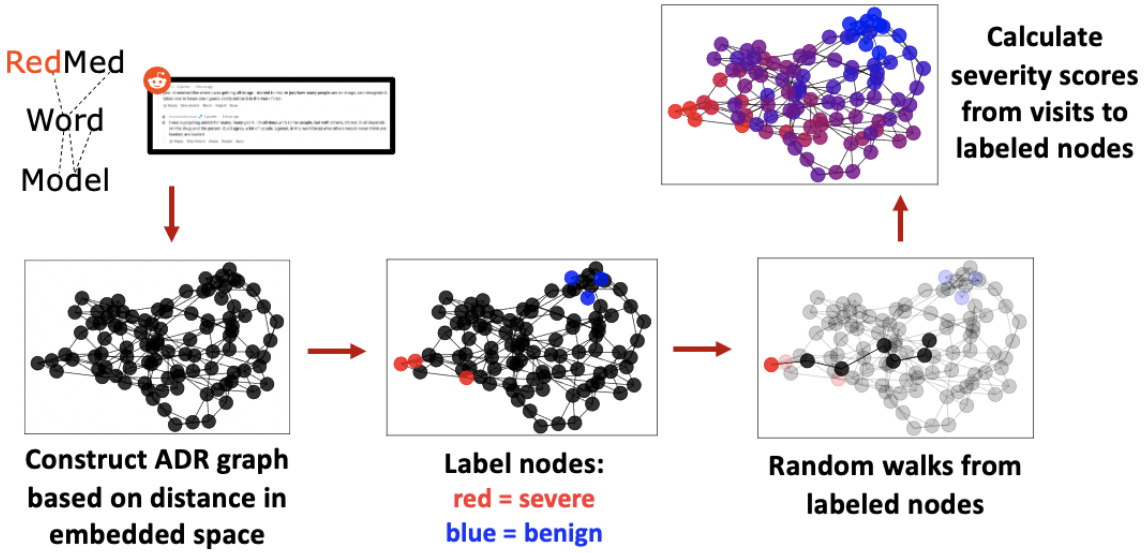
For the ranking of ADRs based on the FAERS data, we ranked ADRs based on their marginal likelihood to be included in a case with death or serious outcome as the reported case outcome. This was calculated by dividing the number of cases with the ADR that resulted in death or serious outcome by the number of cases without the ADR that resulted in these outcomes.

Semisupervised Severity Propagation

Overview

Given a word-embedding model and a set of initial, potentially noisy, seed-word labels for the severe and benign categories, we sought to propagate severity information over the rest of the vocabulary, similar to the sentiment propagation methods described in the study by Hamilton et al [22]. A graphical overview of this method is presented in Figure 1.

Figure 1. Overview of the network method for estimating ADR severity from word embeddings. Word embeddings for 28,113 ADR terms and phrases were extracted from the RedMed word-embedding model. A network is constructed based on nearest-neighbors in the embedding space. A subset of nodes is labeled as severe or benign ADRs, and random walks from these labeled nodes are conducted. The Severity of Adverse Events Derived from Reddit scores for each ADR are calculated based on the relative number of encounters in random walks initiated from severe versus benign nodes. ADR: adverse drug reaction.



Lexical Network Creation

The network was constructed by connecting words (nodes) with edges to their *k-nearest neighbors* based on the cosine distance between their embeddings. The corresponding edge weight was set to the cosine similarity of the two words (ie, the edge weight increases with term similarity).

Seed Selection From Terminology

An initial set of ranked seed terms was labeled. Biomedical terminologies and ontologies often contain many terms that are highly similar to each other. To reduce the effect of lexical similarities on label propagation, we filtered the benign and severe seed terms based on the edit ratio among the terms in each list, as defined by the ratio function in the python-Levenshtein package [23]. Only terms that had an edit ratio >0.5 from a higher-ranking term were included in the list, resulting in a reduced list of lexically distinct seed terms. Both benign and severe seed term lists were truncated to the minimum seed term list size of both seed sets.

For instance, if the severe seed term list had [“death,” “cardiac arrest acute,” “cardiac arrest”] in rank order and the benign seed term list had [“dry skin,” “yawning,” “cold sweat”] in rank order, then, after lexical filtering, the severe seed term list would be [“death,” “cardiac arrest acute”], and the benign seed term list would remain unchanged. The final seed term lists would be truncated to the minimum seed term list size, resulting in a severe seed term list [“death,” “cardiac arrest acute”] and a benign seed term list [“dry skin,” “yawning”].

Random Walks From Seed Nodes

Given a network and a set of seed nodes, we modified code from *node2vec* [24] to perform 5000 weighted random walks of length 200 from each seed node. We selected the number of random walks to ensure that all nodes within the graph were visited a nonzero number of times. We noted that this value needs to be empirically determined and will likely change based on the size and structure of the network.

SAEDR Score Calculation

The SAEDR score of a given node *u* is calculated using the following formula:

$$u_{SAEDR} = s_u / s_u + b_u$$

In the formula, s_u and b_u are the respective number of times that node *u* is encountered in a random walk from a severe node or a benign node. If node *u* was contained within one of our seed node sets, self-visits during the random walks were excluded from the calculation. To increase the robustness of these score estimates, we performed 10,000 iterations of bootstrap sampling [25] of the random walks, and the average of these bootstrap estimates was calculated. The SAEDR scores from multiple seed sets were averaged at the preferred term (PT) level, and the final combined scores were normalized to a zero to one range.

Hyperparameter Tuning for Severity Propagation

We randomly split the crowdsourced severity data into training (1778/2369, 75.05%) and test (591/2369, 24.95%) sets, with 284 ADRs dropped because of mapping. We performed a grid search over the number of neighbors used to construct the lexical network {2, 5, 10, 15, 20, 25, 30} and the percentage of nodes to label for the severe and benign seed nodes {2, 5, 10,15, 20, 25}. For example, an individual run would use the 25 nearest neighbors and 5% at each end of the training severity rank (ie, the top 5% most severe and bottom 5% least severe ADRs). We ultimately selected the parameters with the highest Spearman correlation with the training data.

ADR Discovery Group Analysis

We analyzed the SAEDR score distributions of several different categories of ADRs.

ADRs Included in a Boxed Warning

We downloaded the counts for the number of appearances of ADRs in the boxed warning section of drug labels from the supplement of the study by Wu et al [26]. ADRs that appear on a drug label based on their appearance in the SIDER but were not included in the list provided in the study by Wu et al [26] were considered to not have appeared in a boxed warning section [19].

ADRs With Disproportionate Reporting Between Sexes

A set of ADRs shown to have sex differences was identified from the supplement of the study by Chandak et al [27]. We filtered out ADRs considered borderline (mean log(ROR)<0.4 and mean log(ROR)>−0.4), as defined in the original study by Chandak et al [27]. Their study reported ADRs at the high-level group term (HLGT) level within the MedDRA, whereas our severity estimates were generated at the PT level. There are many PT ADRs per HLGT; therefore, all PTs within the specified HLGT terms were averaged to create a single SAEDR score for that HLGT. We did not use the drug information except to note distinct instances of sex-specific HLGTs (ie, HLGTs associated multiple times with different drugs each time).

ADRs Discovered at Different Stages of Drug Development

ADRs discovered at the clinical trial stage were identified based on their inclusion in a drug label in the SIDER with a non-postmarketing ADR frequency [19]. Postmarketing ADRs were identified as those included on drug labels with postmarketing frequency information and no clinical trial frequency information. OFFSIDES and TWOSIDES ADRs were discovered from the FAERS data by looking at disproportionate reporting after correcting for the effects of demographics and other case information [28]. The OFFSIDES and TWOSIDES sets are the results of a study by Tatonetti et al [28] in which propensity score matching was used to identify matched cases and controls among the FAERS cases and to also identify potentially novel ADRs based on disproportional reporting metrics. This was done to discover ADRs that were associated with a single drug, OFFSIDES, as well as ADRs that were potentially the result of drug-drug interactions, TWOSIDES. We considered both OFFSIDES and TWOSIDES ADRs discovery-stage postmarketing ADRs because they have not yet been included in the drug labeling.

Drug-Risk Profile Scores

The drug-risk profile (DRIP) scores were calculated based on our SAEDR score and the frequency of each ADR for a given drug. The DRIP score for a given drug is the sum of the severity multiplied by the frequency of each ADR on the drug label. Drug ADR frequency information was retrieved from the SIDER [19]. In situations where multiple ADR frequencies were indicated, 1000 frequency estimates were sampled from a uniform distribution with a lower bound at the minimum-reported frequency and an upper bound at the maximum-reported frequency. When there was no frequency information, we sampled 1000 estimates from a uniform distribution over the interval of 0.001 to 0.01. The final DRIP score was the average score across 1000 samples.

Results

Network Statistics

We used the ADR terms and phrases from the MedDRA, version 22.0, lowest-level terms [20] as the initial lexicon for the lexical ADR network. Although the FAERS uses the MedDRA to encode ADRs, versioning differences over the years have resulted in some FAERS ADRs not being included in the MedDRA. We were able to generate embeddings for 92.35% (2450/2653) of the unique crowdsourced ADRs, 100% (14,045/14,045) of the unique FAERS ADRs, and 68.72% (28,113/40,905) of all filtered MedDRA terms. This resulted in a final lexical network with 28,113 nodes, representing 12,198 MedDRA PTs.

SAEDR Score Performance

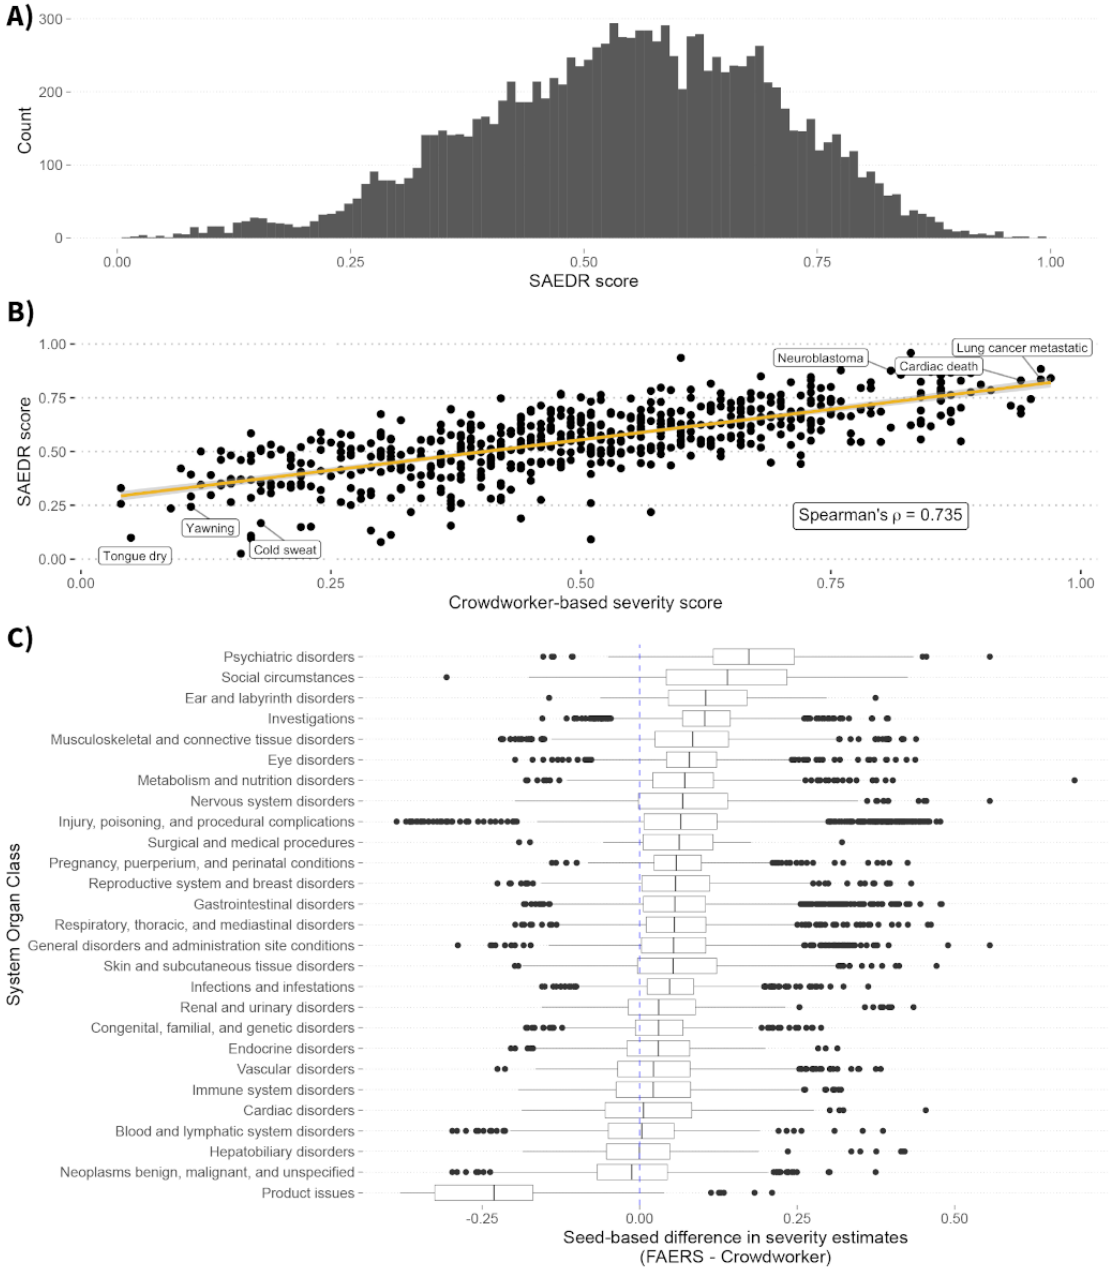
We compared our severity estimates using crowdworker-ranked seeds, FAERS-ranked seeds, and the average severity estimate across the two seed sets with two different ADR rankings: (1) a held-out test set of crowdworker-ranked ADRs (n=591) and (2) ADRs ranked by case outcome statistics in the FAERS database.

The crowdworker-seeded severity estimates had the highest training performance with a 25 nearest-neighbors graph and using 10% of the most and least severe ADRs as seeds. The Spearman correlation with the crowdworker test set was 0.747 (P<.001). The Spearman correlations for events with at least 100 reports in the FAERS were 0.595, 0.616, and −0.732 for death, serious outcome, and no outcome, respectively, with P<.001 for all (Figures S1 and S2 of Multimedia Appendix 1).

The FAERS-seeded severity estimates had the highest training performance with a 10 nearest-neighbors graph and using 10% of the most and least severe ADRs as seeds. The Spearman correlation with the crowdworker test set was 0.587. As no information from the crowdworker rankings was used to select these seeds, we can also report the Spearman correlation with the entire set of crowdworker ADRs: 0.765. The Spearman correlations for events with at least 100 reports in the FAERS were 0.509, 0.557, and −0.656 for death, serious outcome, and no outcome, respectively, with P<.001 for all (Figures S1 and S2 of Multimedia Appendix 1).

The SAEDR score—the average of the two severity estimates—had a Spearman correlation with the crowdworker test set of 0.735 (Figure 2). The Spearman correlations for events with at least 100 reports in the FAERS were 0.595, 0.633, and −0.748 for death, serious outcome, and no outcome, respectively (Figures S1 and S2 of Multimedia Appendix 1). All these correlations were statistically significant (P<.001).

Figure 2. Comparison of SAEDR scores and crowdworker severity estimates. (A) Histogram of SAEDR scores for 12,198 adverse drug reactions (ADRs). (B) Crowdworker severity estimates (x-axis) versus SAEDR scores (y-axis) for a test set of 591 ADRs. The SAEDR scores showed a strong Spearman correlation, ρ=0.735, with the human crowdworker rankings. We noted that this correlation is greater than the interrater correlation, ρ=0.71, reported in the original crowdsource study by Gottlieb et al [8]. A select set of the least and most severe ADRs based on the SAEDR score has been annotated. (C) Differences between severity estimates seeded with FAERS rankings and those seeded with crowdworker rankings (x-axis) for different System Organ Class groups (y-axis). The dashed blue line indicates where the severity would be the same for both estimates. FAERS: Food and Drug Administration Adverse Event Reporting System; SAEDR: Severity of Adverse Events Derived from Reddit.



Seed-Ranking Comparisons

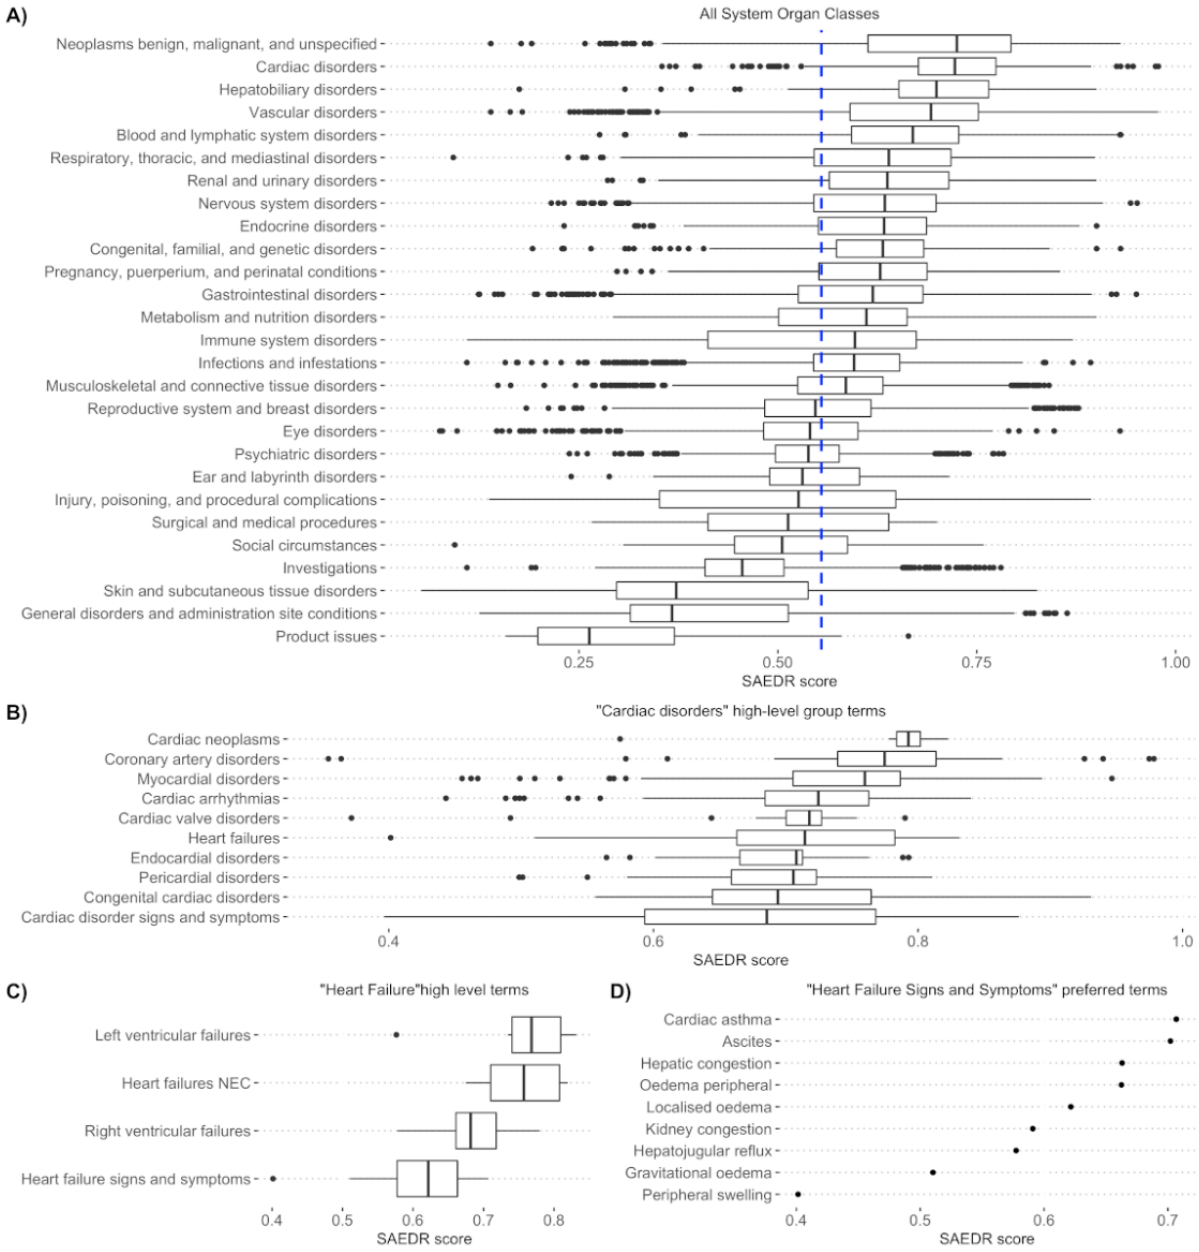
We examined the effects of seeding on the severity estimates of individual ADRs. Most ADRs were not substantially changed by the use of different seeds. We aggregated ADR severity differences at the MedDRA SOC level and found that the FAERS seeds led to increased severity estimates for *Psychiatric Disorders* and *Social Circumstances* (Figure 2). The most drastic shift in values was the decrease in severity of *Product Issue*–related ADRs using FAERS seeds compared with their severity when using crowdworker-based seeding.

SOC Severity Rankings

We compared the severity of ADRs based on the MedDRA SOC groupings as a qualitative evaluation (Figure 3). We found the ADRs related to cancer (neoplasms), cardiac, and liver (hepatobiliary) to be the most severe, with high SAEDR scores, whereas skin, general disorders, and product issues were considered the least severe, with low SAEDR scores. We performed a qualitative examination of ADRs at various other levels. We compared the severity distributions between the ADRs describing benign neoplasms and those describing malignant neoplasms (Figure S3 of Multimedia Appendix 1). A one-sided *t* test found malignant neoplasms to be significantly

more severe than benign neoplasms based on their SAEDR scores (P<.001). We found a wide range in terms of severity within the different levels of the MedDRA ADR term groupings (Figure 3). We noted that among ADRs in the *Cardiac Disorders* HLGT, cardiac neoplasms have the highest SAEDR scores, whereas signs and symptoms of cardiac disorder have the lowest relative SAEDR scores (Figure 3). When examining the level of individual ADRs within the *Heart Failure Signs and Symptoms* HLGT, we found that the ADRs that we would judge to be more severe were ranked higher than those that are more general and considered less severe.

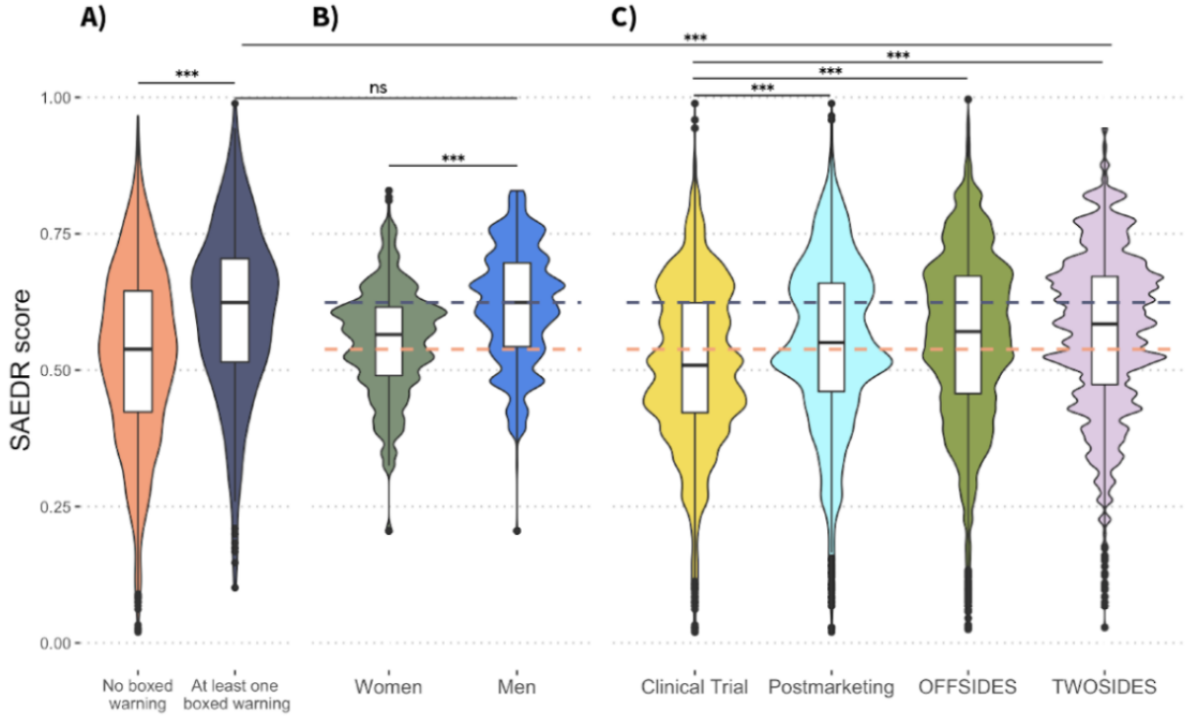
Figure 3. Severity of adverse drug reactions (ADRs) at different group resolutions. (A) SAEDR score (x-axis) for 11,981 ADRs with System Organ Class (SOC) groups (y-axis). The dashed blue line indicates an overall median SAEDR score of 0.554. The SAEDR score distributions indicate that cancers and cardiac-related side effects are considered the most severe, with product issues being the least severe. (B) Severity distributions of the Medical Dictionary for Regulatory Activities high-level group terms (HLGTs) within the Cardiac Disorders SOC. There are large differences in severity within these term groups. (C) High-level terms within the Heart Failure HLGTs show a tighter distribution of severity, with "Heart Failure Signs and Symptoms" being the least severe within this group. (D) Individual side effects within the signs and symptoms of heart failure suggest cardiac asthma and ascites (accumulation of fluid in the peritoneal cavity) are the most severe symptoms, and peripheral swelling is the least severe symptom NEC: necrotizing enterocolitis; SAEDR: Severity of Adverse Events Derived from Reddit.



Severity of ADRs Grouped by Labeling Section, Sex Effects, and Time Point of Discovery

On the basis of our estimate, we calculated that the ADRs that have never been included in a boxed warning had a median SAEDR score of 0.538, whereas the ADRs that had been included in at least one boxed warning had a median SAEDR score of 0.624. We found that among the ADRs that have appeared on a drug label, those that have been included in at least one boxed warning were significantly more severe (P<.001) than the ADRs that have never been included in a boxed warning section based on a one-sided t test (Figure 4).

Figure 4. Differences in adverse drug reaction (ADR) severity between ADR groupings and discovery periods: ADR groups (x-axis) versus SAEDR scores (y-axis). The grey dashed line indicates the median severity, 0.624, of the ADRs that have been included in a boxed warning. The orange boxed line indicates the median severity, 0.538, of the ADRs that appear on a drug label but have not been included in a boxed warning. (A) The ADRs that were listed as a black box warning at least once (n=356) were significantly more severe than those that have not appeared in a black box warning (n=3305). (B) The ADRs that are disproportionately reported for men (n=56,405) are significantly more severe than those disproportionately reported for women (n=50,801). There was no significant difference (ns) in severity between the ADRs included in black box warnings and those disproportionately reported for men. (C) The ADRs discovered in the postmarketing period (n=11,506) are significantly more severe (*** indicate *P*<.001) than those discovered in the clinical trials (n=35,450). The ADRs identified in the postmarketing period through OFFSIDES (n=350,631) and the postmarketing polypharmacy ADRs identified through TWOSIDES (n=4,210,513) are significantly more severe than those discovered in the clinical trials. The severity of all postmarketing ADR groups is significantly less than the severity of the ADRs that have appeared in a black box warning. SAEDR: Severity of Adverse Events Derived from Reddit.



We found that the ADR HLGTs that are disproportionately reported for men were significantly more severe (*P*<.001) than those disproportionately reported for women (Figure 4). The HLGTs disproportionately experienced by men were not significantly different from the severity of the ADRs that have been included in at least one boxed warning, *P*=.13, based on a one-sided *t* test.

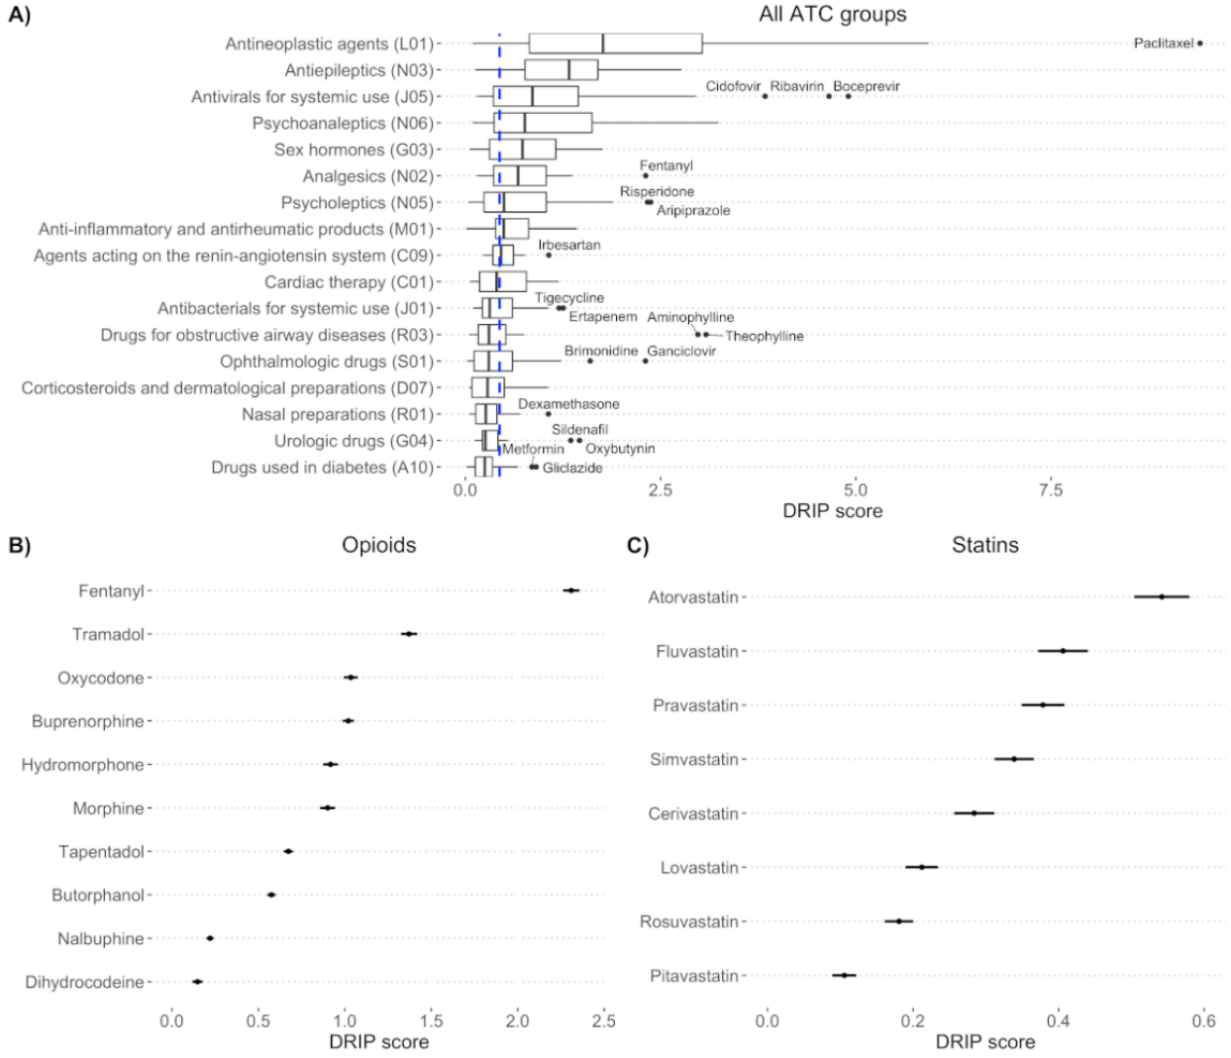
We examined the severity of the ADRs that were found during the clinical trial versus the severity of those discovered in the postmarketing period based on the SIDER label annotations. We found that the ADRs discovered in the postmarketing period had significantly higher severity (*P*<.001) than the ADRs discovered in the clinical trials based on a one-sided *t* test (Figure 4). We compared the severity of the clinical trial ADRs with the severity of those discovered in the postmarketing period using FAERS data. The study by Tatonetti et al [28] identified two different sets of ADRs: OFFSIDES is a set of ADRs disproportionately reported for a drug, whereas TWOSIDES is a set of ADRs disproportionately reported for a pair of drugs being taken concurrently, after correcting for case demographics and other information. The severity distribution of ADRs in both OFFSIDES and TWOSIDES was significantly higher (*P*<.001) than the severity distribution discovered in the clinical trials based on a one-sided *t* test (Figure 4). We found that the ADRs associated with polypharmacy, through TWOSIDES, had the highest severity of the postmarketing ADRs. All postmarketing ADRs were significantly lower in severity than the boxed warning ADRs based on a one-sided *t* test.

DRIP Score Analysis

We calculated the DRIP scores for 968 drugs using SIDER label data, with a resulting median DRIP score of 0.439. The Spearman correlation between the drugs ranked by the proportion of FAERS cases, with that drug as the primary suspect that resulted in death, and the drugs ranked by our DRIP scores was 0.377, *P*<.001.

We analyzed DRIP score distributions by the Anatomical Therapeutic Chemical (ATC) classification system for the subset of drugs with an ATC designation (Figure 5). Antineoplastic and antiepileptic drugs were the drug classes with the highest DRIP scores, indicating that the drugs in these classes have severe ADR profiles. Drugs used in the management and treatment of diabetes and urologic issues had the lowest DRIP scores, indicating that these drugs are relatively safe and have less-severe side effects. We examined individual drugs within the opioid class and found that fentanyl had a markedly higher DRIP score than other drugs in the same class (Figure 5). Drugs within the statin class were primarily below the overall median DRIP score (0.439), with only atorvastatin being markedly above the median DRIP score (Figure 5).

Figure 5. DRIP scores calculated using side effect severity and frequency. (A) DRIP scores (x-axis) for ATC classification system groups (y-axis) ordered by median severity with outliers labeled. The dashed blue line indicates the median DRIP score of 0.439 across all drugs. (B) DRIP scores (x-axis) for opioid class drugs (y-axis), as denoted by the N02A ATC group. Fentanyl, an extremely potent synthetic opioid, is ranked first as having the most severe side effect. (C) DRIP scores (x-axis) for statins (y-axis), as denoted by the C10AA ATC group. Atorvastatin, the strongest statin in broad use, is ranked to have the most severe side effect, whereas lower-efficacy statins are ranked as having less-severe side effects. ATC: Anatomical Therapeutic Chemical; DRIP: drug-risk profile.



Discussion

Principal Findings

In this study, we present the SAEDR scores and quantitative estimates of the severity of 28,113 MedDRA ADR terms. The SAEDR scores have strong correlations with both crowdworker-based severity estimates and real-world ADR case outcome statistics. We generated these estimates using a network-based label propagation approach that required only a small percentage of the terms to be labeled. This study demonstrated the feasibility of using distantly supervised techniques such as label propagation to generate quantitative values for medical concepts.

Our approach enabled us to increase the number of ADRs with quantitative severity estimates from 2929 to 28,113, an almost tenfold increase, while minimizing the human time involved in generating the estimates. Our severity estimates can be updated routinely based on the recomputation of the embeddings and reseeding of the reference severe or benign ADRs. We noted that our severity estimates had a higher correlation with the aggregate crowdworker rankings (ρ=0.735) than the crowdworker rankings had among the three replicates in the original study (ρ=0.710). In addition, our estimates had a greater correlation with real-world outcomes such as FAERS cases resulting in death (ρ=0.595) than the crowdworker rankings (ρ=0.53). Thus, our severity estimates track with both human judgments of ADR severity and real-world outcomes of consequence to patient health.

We found that our SAEDR scores had a strong negative correlation, $\rho=-0.748$, with no case outcome being reported in the FAERS. We assigned a *No Outcome* label to the FAERS cases for which none of the available but relatively severe case outcomes had been reported. We took this as an indication that the FAERS cases lacking outcomes may be a result of cases having an outcome below the level of seriousness that is reportable in the FAERS. FAERS case outcome completeness could potentially be improved by creating a lower-severity category for case outcome documentation. We also noted that

the SAEDR scores have a stronger correlation with serious outcomes in FAERS cases than with death outcomes. This can be partially explained by the fact that many more ADRs result in serious outcomes than in death, leading to poor differentiation of severity based on death for many ADRs where death is a rare or unobserved outcome.

In an effort to compare the impacts of using different methods to select the initial severe and benign ADR seed terms for label propagation, we compared crowdworker and real-world outcomes–based seed selections. We found that both methods resulted in consistently high severity scores for ADRs in the highest-severity SOC groups such as *Neoplasms* and *Cardiac Disorders*. We observed the largest differences in the *Product Issues* SOC group. Real-world outcomes–based seeds increased the severity of psychiatric disorders and social circumstances and decreased the severity of product issues. The importance and impact of psychiatric disorders may not be apparent to those not in the medical profession. Thus, it is possible that the crowdworkers did not perceive mental illness to be as severe as physical illnesses, leading to a bias in the rankings. The use of real-world outcomes–based rankings to select seeds led to more psychiatric disorders being included in the seed terms for the severity propagation. Similarly, the shifts in social circumstances and product issues are likely due to their limited presence or absence within the original crowdworker rankings because only seven ADRs in the social circumstances category were included in the 2929 ADRs ranked by crowdworkers, and no *Product Issues* ADRs were included in that ranking. This absence resulted in no ADRs from these groups being included in the initial seed set of labeled ADRs for the crowdworker-seeded method run, likely limiting the ability of the label propagation to accurately estimate the severity of these ADRs.

We found that the overall severity ordering of the SOC classes based on our SAEDR scores made intuitive sense. We were surprised by the ability of the label propagation approach to adjust the severity estimates based on particular key terms. For instance, the ADR terms for cancer (*Neoplasm*) ADRs are relatively similar on a lexical basis, but individual modifiers such as malignant and benign resulted in significantly different SAEDR scores for the respective groups of ADRs (Figure S3 of Multimedia Appendix 1). Similarly, examining groups of ADRs at different MedDRA hierarchy levels demonstrated relative severity estimates that were sensible to us, such as *Heart Failure Signs and Symptoms* having lower severity than the different types of actual heart failure.

We found a significantly higher estimate of severity among the ADRs that had been included in a boxed warning section than among those that had not. This offers further validation of the SAEDR scores because they are in agreement with past regulatory and drug labeling decisions. Our comparison of HLGTs with disproportionate rates between sexes revealed that male-associated ADRs were more severe. Notably, the SAEDR scores of the male-associated ADRs were not significantly different from those of the ADRs that have been included in a boxed warning. This is in agreement with previous work that highlighted the relatively higher severity of ADRs experienced by men [29,30].

We found that ADRs discovered in the postmarketing period are generally more severe than those discovered in the clinical trials based on our SAEDR scores. This indicates that postmarketing surveillance and ongoing regulatory discussions of risk-benefit trade-offs for particular drugs are necessary to keep the public safe [31]. These findings are not new because a recent study examining internal Food and Drug Administration data on drug labeling changes found that 35% of the ADRs added to drug labels were added to the boxed warnings and warnings and precautions sections [32]. Of the postmarketing ADRs, those involving more than one drug, as identified by TWOSIDES, were among those with the highest severity, indicating the increased risks associated with polypharmacy. This finding highlights the need for further research into the safety of polypharmacy because approximately half of the individuals prescribed a prescription drug are prescribed more than one concurrent medication [33].

One of the original aims of the pioneering study by Tallarida et al [7] was to create quantitative risk scores for individual drugs. Our DRIP scores are an attempt to do so, and we combined ADR severity with frequency information to generate a numerical estimate of a drug's risk profile. We were able to generate DRIP scores for 968 drugs using ADR frequency data from the SIDER. Our DRIP scores have a modest Spearman correlation, $\rho=0.377$, with FAERS cases that resulted in death, where that drug was the primary suspect. Generally, correlations greater than 0.8 are considered strong, but this generally assumes that the comparison is with a gold standard ground truth. Because of a lack of an objective gold standard of DRIPs, we compared with FAERS case outcomes for the drugs in question, although the case outcomes are imperfect because of reporting bias and other issues. In addition, the DRIP scores were created using estimates of ADR frequencies from the SIDER that are primarily derived from clinical trial data. These ADR frequency estimates are affected by the dosage and underlying health of the clinical trial population, both of which are only sometimes reported. High-quality frequency estimates for postmarketing ADRs are essentially nonexistent, and many challenges exist to accurately estimating their frequency [29]. These issues limit the ability of our DRIP scores to accurately quantify risk. However, despite the limitations of the benchmark data and the ADR frequency information, the DRIP scores still demonstrate a modest correlation with real-world outcomes. We interpret this as an indication that our DRIP scores track with real-world outcomes and capture signals related to a drug's safety profile that could be useful for downstream application. Further evidence of their validity is provided by the qualitative evaluation of the DRIP score distributions for the ATC groups. The relative distributions of the ATC groups make intuitive sense, with drugs used to treat cancer—antineoplastic drugs—having the most severe side effect profiles, whereas drugs used to treat diseases that are known to have safe and effective treatment options, such as diabetes, are ranked among the safest drug categories.

We present ADR severity estimates that track with both real-world outcomes and human perception, but these estimates are still limited. We used word embeddings trained on Reddit data, but other social media data could improve the severity

prediction model. We used RedMed because the model was publicly available and contained many ADR terms of interest to this study. However, Reddit as a social media platform is skewed toward men and young people, who may discuss ADRs in different ways from the general population. Learning new embeddings from social media corpora generated by the patient groups most at risk for a given set of ADR experiences or from biomedical literature might improve model performance and address issues with demographic model biases.

FAERS case outcome proportions as a benchmark for severity are limited because of the outcomes being reported at the case level by the FAERS. Because of this case-level aggregation, the ADRs in the severe category may have inflated severity. For instance, symptoms of cardiac arrest may often be reported as separate ADRs for a FAERS case of cardiac arrest, resulting in symptoms that seem to be more severe than they are when occurring independently of the severe ADR with which they are associated.

Our results indicate that men reported more severe ADRs based on sex-specific ADRs identified in the study by Chandak et al [27]. Other research efforts have reported similar findings based on ADR-reporting databases [29], but there are potential sources of bias that could have affected this result. The data underlying the sex-specific ADRs identified in the study by Chandak et al [27] were derived from the FAERS. The study method focused on the analysis of a sex-balanced cohort of case reports, with cohort creation through propensity score matching of individuals. Propensity score matching can correct for factors included in the model, but it is unable to correct for underlying biases in reporting. It has been documented that there are higher rates of ADR reporting for female patients than for male patients, whereas male patients tend to have more severe outcomes reported [30]. It is likely that male patients are enriched for severe ADRs because of this reporting bias, and ADR reports should not be conflated with all ADRs experienced by individuals because of the low rate of ADR reporting [34]. Another limitation is that sex-specific ADRs were only reported at the HLGT level, resulting in SAEDR scores that were an average of all PTs within the HLGT. Figure 3 highlights the large range in terms of severity, even within a particular HLGT. It is possible that an analysis of sex-specific ADRs at the PT level would result in a different finding. Overall, although ADRs disproportionately reported in men are more severe than those disproportionately reported in women, more research is needed to reach a complete understanding of sex-specific differences in ADR severity.

Although we captured some nuances in ADR severity, such as benign versus malignant neoplasms, we only created SAEDR scores for the ADR terms contained in the MedDRA. However, while exploring the RedMed word embeddings, we observed that individual ADR terms were often contained in phrases indicating modified severity. For instance, a report of stomach pain might be modified with an adjective such as excruciating or mild. Although the MedDRA does not contain an intensity scale component for its terms, capturing this information from patients might further enable risk-benefit trade-off calculations. The approaches for general word sentiment assignment, similar to the one used in the study by Hamilton et al [22], could be repurposed here to assign severity to ADR modifier terms.

Conclusions

In summary, we demonstrated that lexical networks and label propagation can be used quantitatively to estimate the severity of medical conditions. We showed the distributions of ADR severity among different groups of conditions, different groups of patients, and different ADR discovery time points. We combined our SAEDR scores with available ADR frequency data to generate quantitative DRIP scores and examined the distribution of the resulting DRIP scores. Our results (and future improved estimates) enable new quantitative analyses within the field of pharmacovigilance. To this end, we provide the complete set of SAEDR scores and DRIP scores in Multimedia Appendix 2 and Multimedia Appendix 3, respectively.

Abstract

Background: Antiobesity drugs are prescribed for the treatment of obesity in conjunction with healthy eating, physical activity, and behavior modification. However, poor adherence rates have been reported. Attitudes or beliefs toward medications are important to ascertain because they may be associated with patient behavior. The analysis of tweets has become a tool for health research.

Objective: The aim of this study is to investigate the content and key metrics of tweets referring to antiobesity drugs.

Methods: In this observational quantitative and qualitative study, we focused on tweets containing hashtags related to antiobesity drugs between September 20, 2019, and October 31, 2019. Tweets were first classified according to whether they described medical issues or not. Tweets with medical content were classified according to the topic they referred to: side effects, efficacy, or adherence. We additionally rated it as positive or negative. Furthermore, we classified any links included within a tweet as either scientific or nonscientific. Finally, the number of retweets generated as well as the dissemination and sentiment score obtained by the antiobesity drugs analyzed were also measured.

Results: We analyzed a total of 2045 tweets, 945 of which were excluded according to the criteria of the study. Finally, 320 out of the 1,100 remaining tweets were also excluded because their content, although related to drugs for obesity treatment, did not address the efficacy, side effects, or adherence to medication. Liraglutide and semaglutide accumulated the majority of tweets (682/780, 87.4%). Notably, the content that generated the highest frequency of tweets was related to treatment efficacy, with liraglutide-, semaglutide-, and lorcaserin-related tweets accumulating the highest proportion of positive consideration. We found the highest percentages of tweets with scientific links in those posts related to liraglutide and semaglutide. Semaglutide-related tweets obtained the highest probability of likes and were the most disseminated within the Twitter community.

Conclusions: This analysis of posted tweets related to antiobesity drugs shows that the interest, beliefs, and experiences regarding these pharmacological treatments are heterogeneous. The efficacy of the treatment accounts for the majority of interest among Twitter users.

(J Med Internet Res 2021;23(10):e24336) doi:10.2196/24336

KEYWORDS

obesity; social media; Twitter; drug therapy; pharmacotherapy; attitude; thematic analysis; quantitative analysis; drug

Introduction

Obesity is an increasingly prevalent disease, with high rates of associated morbidity and mortality [1]. The treatment of obesity remains only partially effective [2]. Moreover, the pharmacological treatment of obesity is becoming a more significant tool in the management of the disease [2]. However, frequency in the use of antiobesity drug treatments among those patients that could potentially benefit from them is minimal [3]. Moreover, both personal and social attitudes, combined with accessible information on available treatments, have been shown to be relevant for obtaining the expected clinical outcomes of pharmacological intervention [4]. Furthermore, it has been shown that social support is a potential beneficial component of weight loss programs [5,6].

In recent years, social media has become a pivotal instrument for disseminating knowledge [7]. Accordingly, the internet has modified how people communicate and how they share and seek out information regarding health [8]. Social networks are extensively used for the study of obesity, including the analysis of public attitudes, the social support of patients, patients' behavior, and treatment efficacy [9-11]. Being that information pertaining to health posted over social media is oftentimes more spontaneous in nature, it serves more as a complementary perspective to data collected from medical surveys, clinical trials, and consultancies with medical professionals [12-14].

Twitter, one of the most popular and widely used social media platforms, is currently considered to be an effective channel of communication [15]. Within this context, different agents in the health sector have realized Twitter´s potential for acquiring and distributing medical information [16,17]. In addition, Twitter users demonstrate a great interest in obesity and eating disorders [18,19]. Moreover, it has been shown that Twitter can be an effective platform for delivering interventions aimed at treating obesity [20]. The analysis of tweets about obesity, diet, and treatments is a recent relevant area of study for understanding the actual sentiments of society, patients, and health providers [21]. The trivialization, stigmatization, and mockery directed at obesity and other disorders by Twitter users have been reported [22]. Until now, however, topics of interest among Twitter users regarding the pharmacological treatment of obesity have not been identified. Furthermore, the dissemination of medication-related tweets tied to obesity remains unknown. The analysis of the feelings and experiences toward pharmacological treatment is relevant for the understanding of patients' attitudes to these drugs and the identification of concerns and needs potentially related to treatment adherence [23,24].

In this study, we performed an analysis of the content and key metrics of all the tweets generated concerning medications approved by the US Food and Drug Administration (FDA) for obesity treatment over a period of 6 weeks. We also investigated the areas of interest of those tweets containing medical content and the inclusion of links to related informative resources. Finally, we investigated the tweets' dissemination and overall sentiment.

Methods

Data Collection

In this observational quantitative and qualitative study, we focused on searching for tweets that referred to medications approved by the FDA for the treatment of overweight or obese status: Xenical, orlistat, Alli, Belviq, lorcaserin, Qsymia, phentermine-topiramate, Contrave, bupropion-naltrexone, Saxenda, Victoza, liraglutide, Ozempic, and semaglutide. The inclusion criteria for tweets were the following: being public; using any of the previously mentioned hashtags; being posted between September 20, 2019, and October 31, 2019; and being posted in English language. This 6-week period was chosen to avoid any potential bias within the content of the tweets. In addition, we obtained the number of likes each tweet generated, the date and time of each tweet, and the potential reach and impact of each hashtag.

Search Tool

We used the Twitter Firehose data stream, which is managed by Gnip and allows access to 100% of all public tweets that match a certain criteria (query) [25]. In our study, the search criteria were the previously mentioned hashtags. Tweet Binder, the search engine we employed, uses node.js and PHP language, which enabled us to analyze tweets in JavaScript Object Notation (JSON) format (used by Gnip).

Content Analysis Process

All 2045 retrieved tweets were directly inspected by 2 raters (MAAM and MLV). First, we scanned all of the tweets, excluding 945 tweets that provided information that was too limited (eg, tweets consisting mainly of hashtags), that contained only pictures, or that included hashtags of more than 1 treatment. All the remaining tweets were considered for thematic content analysis. Second, we created a codebook based on our research questions, our previous experience in analyzing tweets, and what we determined to be the most common tweet themes. Third, 2 raters analyzed 150 tweets separately to test the suitability of the codebook. Discrepancies were discussed between the raters and with another author (MAM). After the codebook was revised, the interrater reliability was reassessed

with a different set of 150 tweets. As this resulted in adequate κ values (range 0.68-0.99), the raters then proceeded to analyze 1100 tweets equally distributed among both. Each tweet, depending on its content, was categorized under side effects, efficacy, or adherence. In addition, users were classified into 3 categories: patients and relatives, health professionals, or health institutions. These categorizations were defined based on the description of user profiles and the content of user tweets. In those cases in which the nature of the user was not possible to know, they were classified as indeterminate. Finally, we analyzed any links included within a tweet, classifying them as either scientific or nonscientific. More specifically, those links attributed to a scientific source, including medical journals, academic institutions, hospitals, and official websites, were classified as scientific. The classification criteria we used and examples of tweets are shown in Textbox 1.

Textbox 1. Examples of tweets related to efficacy, side effects, and adherence (usernames and personal names have been removed).

Efficacy (the ability or inability of a treatment to provide a beneficial effect)

- "Oral semaglutide can effectively and safely reduce blood glucose, body weight and systolic blood pressure: A systematic review and meta-analysis."
- "Ozempic is superior to Invokana in reducing A1c and body weight".
- "More than just #weightloss ? Liraglutide improves hepatic steatosis and metabolic dysfunctions in a 3-week dietary mouse model of nonalcoholic steatohepatitis."
- "The PIONEER 4 trial showed that oral semaglutide is noninferior to injectable liraglutide and superior to placebo in improving glycemic control and weight loss at 26 weeks among patients with type 2 #diabetes.".

Side effects (any effect that is secondary to the one intended either adverse or beneficial; tweets discussing tolerability of the drug were also included)

- "No side effects with the Ozempic and I've been on it since July of last year. Now the metformin is a whole different story. First week or so the sight of food made me sick and it made my stomach act up. I'm actually glad to be off of it."
- "Does Contrave Make Anyone Else's Hands Shake?"
- "I saw the Saxenda results on people I know. It is fantastic. However, it comes with its challenges. Nausea, headaches and terrible moods. glucagon-like peptide 1 (GLP-1) analogs, such as liraglutide, is the possibility of developing pancreatitis. #usmle"
- "A bit personal, but I'm curious to hear others' stories. I've been taking Ozempic for a year or so, but the last 6-8 weeks I've started throwing up quite a bit. I don't have a history of this at all. Anyone else had this problem with Ozempic? Thank you!"
- "Those embalming leaves seem to have less side effects than ozempic."
- "Gallstone Disease in Patients Treated with Liraglutide: In a large randomized trial a small but statistically significant rise in this adverse event was noted."

Adherence (the degree of conformity to the recommendations about the treatment with respect to the timing, dosage, or frequency)

- "I'm a quibbler, I can't help it. There is a medicine called Qsymia that seems effective for long term weight loss. Its not without side effects or risks."
- "Morning Twitter nightmare week over. Week 21 liraglutide. Despite everything total adherence. Adherence to duloxetine not good. Quorn burger for breakfast & fruit. Happy today."

Measuring Interest and Influence on Twitter

We analyzed the number of likes generated by each tweet as an indicator of user interest on a given topic. We also measured the potential reach and impact of all analyzed hashtags in order to best assess tendencies in the dissemination of tweets. In this study, impact was defined as a numerical value representing the potential views a tweet may receive, while reach was defined as a numerical value measuring the potential audience of the hashtag.

In addition, we measured how positive or negative a hashtag was on a scale from 1 (negative) to 100 (positive). Sentiment analysis tools were used to analyze all words contained in a tweet, with each word having its own score that could vary depending on the context. The average score of all the tweets with a certain hashtag determined that hashtag's overall sentiment score. According to this score, we classified each hashtag into 3 categories: negative (0-40), neutral (>40-60), and positive (>60-100).

Ethical Considerations

This study was approved by the Research Ethics Committee at the University of Alcala.

Statistical Analysis

A descriptive study of the sample was performed. The qualitative variables are described as absolute frequency (number) and relative frequency (percentage). The percentages found were compared using the chi-square test. The numbers of retweets and likes per original tweet about the different hashtags were verified by graphs and statistical test (Kolmogorov-Smirnof test), and they did not follow a normal distribution. The differences found between the treatment groups were compared using the Kruskal-Wallis test. All statistical analyses were performed using SPSS version 25 (IBM Corp).

Results

Liraglutide and Semaglutide Accumulated the Most Interest Among Twitter Users

Our search tool provided a total of 2045 tweets, 945 of which were excluded according to the criteria of the study. Next, 320 out of the 1100 remaining tweets were also excluded because their content, although related to drugs for obesity treatment, did not address the efficacy, side effects, or adherence to the medication. Finally, we classified the content of the remaining 780 tweets.

The number of tweets with hashtags referencing the 6 drug groups approved for obesity treatment were significantly different, with the incidence of tweets related to liraglutide and semaglutide at least being 10 times higher than that related to the other 5 drug groups (Table 1).

Next, we found significant differences in the distribution of the content. Notably, the content that generated the highest frequency of tweets was that related to treatment efficacy, with liraglutide-, semaglutide-, and lorcaserin-related tweets accumulating the highest proportion of positive consideration (P<.001). In contrast, the highest percentage of tweets with a negative valuation towards efficacy was found in those posts related to bupropion-naltrexone (3/30, 10%), while those containing a mention of liraglutide (14/319, 4.4%) and semaglutide (2/363, 0.6%) had a much lower negative percentage.

Tweets with a negative valuation of side effects were mainly observed in those related to orlistat (4/15, 26.7%) and bupropion-naltrexone (4/30, 13.3%) but rarely in those mentioning liraglutide, semaglutide, and phentermine-topiramate. On the other hand, tweets with a positive valuation of side effects were minimal and were found mainly in those posts related to bupropion-naltrexone, semaglutide, and liraglutide (P=.04). Finally, the frequency of tweets with content related to adherence to treatment was low, with negative considerations predominant among liraglutide, bupropion-naltrexone, and semaglutide (P<.001). On the other hand, positive valuations of adherence to treatment were observed in those tweets related to orlistat, semaglutide, and liraglutide.

Table 1. Descriptive characteristics of the original tweets included in the analysis categorized by total amount per drug and category (side effects, efficacy, adherence, and link).

Category	Orlistat, n (%) (N=15)	Lorcaserin, n (%) (N=27)	Phentermine-topiramate, n (%) (N=26)	Bupropion-naltrexone, n (%) (N=30)	Liraglutide, n (%) (N=319)	Semaglutide, n (%) (N=363)	P value[a]
Side effects							.04
No mention	11 (73.3)	27 (100)	25 (96.2)	25 (83.3)	299 (93.7)	337 (92.8)	
Positive	0 (0)	0 (0)	0 (0)	1 (3.3)	2 (0.6)	8 (2.2)

Link							<.001
None	6 (40.0)	2 (7.4)	4 (15.4)	18 (60.0)	93 (29.2)	91 (25.1)	
Scientific	1 (6.7)	11 (40.7)	5 (19.2)	0 (0)	196 (61.4)	270 (74.4)	
Nonscientific	8 (53.3)	14 (51.9)	17 (65.4)	12 (40)	30 (9.4)	2 (0.6)	

[a]Chi-square tests were conducted to assess statistical differences.

Scientific Links Were Mainly Found Within Liraglutide- and Semaglutide-Related Tweets

We found significant differences between the distribution of those tweets including a link, whether scientific or nonscientific, among the 6 different drug groups (P<.001 Table 1). More specifically, we found the highest percentages of tweets with scientific links in those posts related to liraglutide (196/319, 61.4%) and semaglutide (270/363, 74.4%), followed by those tweets referencing lorcaserin (11/27, 40.7%) and phentermine-topiramate (5/26, 19.2%). The frequency of tweets with a nonscientific link was very low in those related to semaglutide and liraglutide; on the other hand, more than half of the tweets referencing phentermine-topiramate, lorcaserin, and orlistat included a nonscientific link.

As liraglutide and semaglutide accumulated the majority of tweets (682/780, 87.4%), we decided to investigate the use of links in these tweets depending on their content (Table 2). The use of links was mainly focused on those tweets with a positive consideration towards the efficacy of the treatment, whereas in those tweets referencing side effects and adherence to treatment, the use of links was marginal.

Table 2. Descriptive characteristics of the original tweets included in the analysis categorized by total amount per drug and category.

[a]Chi-square tests were conducted to assess statistical differences.

Semaglutide-Related Tweets Obtained the Highest Probability of Likes and Were the Most Disseminated Within the Twitter Community

We found that the probabilities of a tweet being liked between the groups were significantly different (*P*<.001). Semaglutide-related tweets accumulated the highest number of likes per tweet (median 3; 95% CI 1-12). In addition, we analyzed the number of likes received per tweet as classified by the inclusion or absence of a link. We found no differences in the median of likes per tweet between those posts including or not including a link (*P*=.27).

We found that semaglutide-related tweets had the highest potential reach and impact (2,522,621 and 4,676,763 , respectively), which was double that of liraglutide (719,382 and 1,631,062, respectively). On the other hand, both parameters were markedly lower for bupropion-naltrexone (996,398 and 1,603,556, respectively), orlistat (486,533 and 697,956 , respectively), phentermine-topiramate (183,919 and 187,094, respectively), and lorcaserin (29,420 and 30,341, respectively).

Regarding the sentiment analyses of the content of the tweets, we found that those posts related to semaglutide (mean 79.67), liraglutide (mean 61.46), lorcaserin (mean 75.14), and phentermine-topiramate (mean 60.06) received positive sentiment. However, the sentiment was neutral for orlistat (mean 43.9) and bupropion-naltrexone (mean 53.8).

Health Institutions Were the Most Active Twitter Users

We investigated the type of users that posted the tweets. Of the total number of tweets, 7.9% (62/780) were posted by users identified as patients or relatives, 16% (125/780) by health institutions, and 27.1% (211/780) by health care professionals. Of the remaining 49% (382/780) of tweets, the users were considered indeterminate.

Next, we investigated those tweets related to side effects according to the different types of users and found significant differences in the frequency and content of the postings (Table 3; *P*<.001). Patients were the users that posted most about the presence of side effects, whereas health institutions mentioned the presence of side effects the least. Moreover, we also found significant differences between users in regards to tweets about efficacy (*P*<.001) and adherence (*P*<.001). Interestingly, patients were also those who most frequently expressed a lack of efficacy or adherence (Table 4 and Table 5). On the other hand, users classified as health institutions were those that posted most frequently on the efficacy of treatment and promoted adherence to it. Additionally, we assessed who the users were that most frequently included a link within their tweets (Table 6). We found that health institutions included a link, either designated as scientific or nonscientific, more frequently in their posts than did users classified as health professionals or patients (*P*<.001). Finally, we assessed the frequency of user postings according to the different antiobesity drugs analyzed, finding significant differences among them. In particular, health institutions generated the majority of tweets concerning the latest antiobesity drugs.

Table 3. Descriptive characteristics of those tweets referencing side effects in which the user was categorized as a patient, health professional, or health institution. Tweets were further classified as either not mentioning side effects or mentioning them positively or negatively.

Side effects	Patients, n (%)	Health professionals, n (%)	Health institutions, n (%)	Total, n (%)
No mention	40 (11.59)	114 (33.04)	191 (55.36)	345 (100)
Positive	2 (66.67)	0 (0)	1 (33.33)	3 (100)

Total	53 (14.10)	122 (32.45)	201 (53.46)	376 (100)

Table 4. Descriptive characteristics of those tweets referencing efficacy in which the user was categorized as a patient, health professional, or health institution. Tweets were further classified as either not mentioning efficacy or mentioning it positively or negatively.

Efficacy	Patients, n (%)	Health professionals, n (%)	Health institutions, n (%)	Total, n (%)
No mention	27 (20.45)	34 (25.76)	71 (53.79)	132 (100)
Positive	19 (8.19)	83 (35.78	130 (56.03)	232 (100)
Negative	7 (58.33)	5 (41.67)	0 (0)	12 (100)
Total	53 (14.10)	122 (32.45)	201 (53.46)	376 (100)

Table 5. Descriptive characteristics of those tweets referencing adherence in which the user was categorized as a patient, health professional, or health institution. Tweets were further classified as either not mentioning adherence or mentioning it positively or negatively.

Adherence	Patients, n (%)	Health professionals, n (%)	Health institutions, n (%)	Total, n (%)
No mention	37 (10.60)	117 (33.52)	195 (55.87)	349 (100)
Positive	1 (12.5)	1 (12.5)	6 (75)	8 (100)
Negative	15 (78.95)	4 (21.05)	0 (0)	19 (100)
Total	53 (14.10)	122 (32.45)	201 (53.46)	376 (100)

Table 6. Descriptive characteristics of those tweets in which the user was categorized as a patient, health professional, or health institutions, and further designated as either not including a link or including a scientific or a nonscientific link.

Link	Patients, n (%)	Health professionals, n (%)	Health institutions, n (%)	Total, n (%)
None	52 (50)	39 (37.50)	13 (12.50)	104 (100)
Scientific	0 (0)	70 (31.25)	154 (68.75)	224 (100)
Nonscientific	1 (2.1)	13 (27.08)	34 (70.83)	48 (100)
Total	53 (14.10)	122 (32.45)	201 (53.46)	376 (100)

Discussion

Principal Findings

In this study, we have found that Twitter users show an interest in antiobesity drugs and mainly focus on semaglutide and liraglutide. These tweets are centered on the efficacy of the treatment and principally refer to liraglutide, semaglutide, and lorcaserin. Tweet content containing a negative consideration of side effects was mainly observed in those tweets related to orlistat and bupropion-naltrexone. The frequency of tweets with content related to adherence to treatment was marginal. The highest percentages of tweets with scientific links were observed in those related to liraglutide and semaglutide. Furthermore, those tweets referencing semaglutide obtained the highest potential reach and impact.

Diet, exercise, and lifestyle are considered relevant elements for maintaining a weight within the recommended range [26]. The prevention and treatment of overweight and obese status are considered public health priorities [27]. Currently, the use of pharmacological treatment is becoming pivotal in obesity management [28].

The outcomes of pharmacological treatments for chronic diseases are conditioned by different elements [29]. The efficacy and side effects of antiobesity drugs are critical for the success of these treatments [30]. However, the results of real-world pharmacological interventions are also dependent on treatment adherence [30]. Different factors, such as access to drug information and social considerations, modulate patients' attitudes toward treatment [31,32]. Therefore, identifying patients' areas of concern and the sources of information used are relevant for improving the clinical outcomes. Additionally, patients with health behaviors that are frequently disapproved of by society are oftentimes reluctant to disclose to health providers their noncompliance with treatment and medical advice [33]. In this context, the anonymity of social media may provide greater insight into the beliefs, interests, and experiences

of patients with regard to antiobesity drugs. Furthermore, family members of the patients, doctors, and health care providers can also participate in the social media community and post their comments related to the pharmacological treatment of obesity. The identification of the needs, concerns, and feelings of the patients related to their treatment may improve their adherence and contribute positively to achieving therapeutic objectives [34].

Interest in Antiobesity Drugs on Twitter

Our data show that antiobesity drugs are areas of interest within the Twitter community. The attention paid to antiobesity drugs is reflected in the number of tweets posted with content related to these drugs, which was higher than that reported on other medications employed to treat chronic diseases [35,36]. Furthermore, it is also significant that the majority of the posted tweets were related to the medical aspects of antiobesity drugs in contrast to the reported results of other medications in which the interest generated was nonmedical in nature [37]. In addition, the interest of Twitter users was mainly centered on liraglutide and semaglutide, which accumulated nearly 90% of the tweets. Likewise, differences in interest shown by social media users towards drugs with similar clinical indications have been previously observed, for example, in the case of statins [38].

In addition, we also studied users' areas of interest regarding antiobesity drugs. Our findings show that the one clearly predominant area was drug efficacy, but with different levels of positive consideration being present, as liraglutide, semaglutide, and lorcaserin achieved the highest valuations. With the exception of the tweets related to orlistat, the frequency of references to the side effects of the antiobesity was very low. Considering our study was conducted in the period from September 2019 to October 2019, it is notable that lorcaserin was soon after withdrawn from the market (February 2020) due to its potentially severe side effects [39].

There may be several reasons for these findings. First, differences in the efficacy could explain the different frequencies found between tweets posted about different drugs [30]. However, this factor is unlikely to prove fully conclusive as the results obtained in the clinical trials and metanalysis referencing these drugs do not wholly support the differences observed. Second, there were different patterns of side effects [30]. However, Twitter users have shown little interest in the side effects of the drugs, and it has only been a focus in relation to orlistat and bupropion-naltrexone. Thus, the references to side effects do not seem to explain the differences in interest. Third, it is possible that Twitter users might show a special interest in treatments suppressing appetite. However, this mechanism of action is not only characteristic of glucagon-like peptide-1 inhibitors but also lorcaserin, which only obtained a small number of tweets. The fourth potential factor is availability of scientific information. Liraglutide and semaglutide, the latest approved drugs, have been subject to most of the recent clinical trials involving antiobesity drugs. Furthermore, both drugs have the majority of tweets containing scientific links with content focused mainly on efficacy. Thus, it is possible that recent scientific publications and reports on clinical trials involving liraglutide and semaglutide might in part explain the significant interest toward these drugs within the Twitter community. The fifth reason may involve accessible information in the press and social media. It is known that newly launched drugs or recently approved indications receive enhanced interest from pharmaceutical companies, health providers, and the media [40]. Consequently, the fact that liraglutide and semaglutide have been the most recently approved drugs might explain the special interest towards them.

The dissemination of tweets referencing the 6 different drugs was also heterogenous, with the potential reach and impact of semaglutide clearly being the highest, demonstrating total numbers similar to those of the other 5 drugs combined. This finding could be explained by the fact that semaglutide has been the most recently approved antiobesity drug. In addition, clinical trials concerning semaglutide have been an area of interest for companies and prestigious scientific journals, which have published results in support of the approval of this treatment [41,42].

Furthermore, our data show that most of the tweets were focused on efficacy and rarely mention side effects or discuss issues related to personal adherence to treatment. Thus, there might have been a bias in the information related to these drugs. Moreover, in contrast to previous reports, most of the tweets included a link to sources supporting their content [43]. Interestingly, concerns about the efficacy or tolerability of antiobesity drugs were identified mostly in those tweets not containing a link. The sharing of personal experiences is unlikely to be associated with a link. The analysis of these tweets reveals relevant information for health care providers because many patients that question the efficacy of treatments or abandon their treatments entirely tend to withhold this information from doctors due to feelings of shame or guilt [33]. Indeed, social media has been found to identify side effects not always uncovered via traditional surveys [44]. In semaglutide- and liraglutide-related tweets, most links were scientific, whereas with the rest of the drugs, the majority of links contained a nonscientific source. This may indicate that tweets discussing issues related to semaglutide or liraglutide may be based on medical articles reporting on efficacy. This may thus imply that pharmaceutical companies, scientific journals, and researchers play a key role in Twitter conversations related to obesity medications. Therefore, it is possible that a potential increase in the investigation of the adherence to obesity treatment might increase the dissemination and relevance given by social media users to this pivotal aspect of obesity management.

The important role of social media in generating popular opinion and emotions via information distribution has been established [45], and social media has become a pivotal instrument for sharing knowledge and news [46]. The interest shown by Twitter users in antiobesity drugs support the relevance of social media in the diffusion of medical information. In addition, social media is used to carry out medical interventions, promote preventive health campaigns, and recruit participants for medical research [47,48].

Finally, we studied the sentiment of tweets and found that most drugs obtained a high score. In contrast, bupropion-naltrexone obtained a very low score. This low sentiment toward

bupropion-naltrexone may be reflective of the other indications this drug has: smoking cessation or depression. In this regard, it is worth noting the mockery of psychiatric conditions in Twitter [49]. However, this is unlikely to be the only cause of the low score obtained in the sentiment analysis because phentermine-topiramate is frequently prescribed for the treatment of psychiatric conditions and obtained an average score. Thus, it is possible to suggest that this low sentiment is due to the poor effect bupropion has on weight loss [30].

Understanding the public view of the pharmacological treatment of obesity is useful to better appraising the perceived demands for clinical care related to this condition. It could also help designing better promotional health initiatives and awareness strategies that include content of interest to social media users. In addition, this information can facilitate open conversations about a patient's most common concerns during the medical consultancy. Although this study focused on antiobesity drugs, these results provide relevant information which more than likely can be applied to other pharmacological treatments. The involvement of health institutions in related conversations over social media appears to be desirable given the interest raised by the medical content posted on Twitter.

Strengths and Limitations

First, the relevance of Twitter as a marker of patient´s voice is a matter of controversy. In addition, tweets do not necessarily reflect the overall experience of patients. Second, regarding the collection of tweets, there is the risk that some were not detected since they might have used different hashtags. However, including brand names and the active pharmaceutical ingredients minimized possible bias related to the choice of hashtags. Third, we did not determine whether the date of FDA approval affected Twitter activity differently in more recent versus less recent medications. Fourth, the codebook design and text analysis involved a degree of subjectivity. Nevertheless, this methodology is consistent with previous medical research studies using Twitter. Although computerized machine learning methods have been tested to automatically identify and classify topics in medical research in social media, we used an analysis strategy based on the raters' clinical expertise in obesity, which constitutes a qualitative advantage compared to automated strategies [50]. Finally, the inability to verify the precise identity of the majority of Twitter users posting about antiobesity drugs, in addition to a lack of geolocational data, may constitute a limitation in our capacity to interpret results.

Conclusions

This study demonstrates that Twitter users show an interest in antiobesity pharmacological treatment. The positive consideration of the efficacy of antiobesity drugs accounted for the majority of tweets. In contrast, the side effects of these treatments was only marginally described. Adherence to treatment received little interest from the Twitter community. The nature of the links included in the tweets was heterogenous between the different antiobesity drugs. Thus, this study highlights the opportunity for sharing scientific information, especially that aimed at promoting adherence to pharmacological treatment, which we have detected as being overlooked.

Abstract

Background: In response to recent policy efforts to regulate tobacco and vaping products, the vaping industry has been aggressive in mobilizing opposition by using a network of manufacturers, trade associations, and tobacco user communities, and by appealing to the general public. One strategy the alternative tobacco industry uses to mobilize political action is coordinating on social media platforms, such as the social networking site Facebook. However, few studies have specifically assessed how platforms such as Facebook are used to influence public sentiment and attitudes towards tobacco control policy.

Objective: This study used social network analysis to examine how the alternative tobacco industry uses Facebook to mobilize online users to influence tobacco control policy outcomes with a focus on the state of California.

Methods: Data were collected from local and national alternative tobacco Facebook groups that had affiliations with activities in the state of California. Network ties were constructed based on users' reactions to posts (eg, "like" and "love") and comments to characterize political mobilization networks.

Results: Findings show that alternative tobacco industry employees were more likely to engage within these networks and that these employees were also more likely to be influential members (ie, be more active) in the network. Comparisons between subnetworks show that communication within the local alternative tobacco advocacy group network was less dense and more centralized in contrast to a national advocacy group that had overall higher levels of engagement among members. A timeline analysis found that a higher number of influential posts that disseminated widely across networks occurred during e-cigarette–related legislative events, suggesting strategic online engagement and increased mobilization of online activity for the purposes of influencing policy outcomes.

Conclusions: Results from this study provide important insights into how tobacco industry–related advocacy groups leverage the Facebook platform to mobilize their online constituents in an effort to influence public perceptions and coordinate to defeat tobacco control efforts at the local, state, and federal level. Study results reveal one part of a vast network of socially enabled alternative tobacco industry actors and constituents that use Facebook as a mobilization point to support goals of the alternative tobacco industry.

Introduction

Since the introduction of e-cigarettes—also known as electronic nicotine delivery systems (ENDS)—as a commercial product in the mid-2000s, their popularity has grown significantly. In 2018, 3.2% of US adults aged 18 years or older reported using e-cigarettes every day or some days [1]. Among middle and high school students in the US, e-cigarettes were the most commonly used tobacco product in 2019, with 5.4 million (20%) of youths reporting current use [2]. The global revenue from e-cigarettes in 2019 was US $15.7 billion, with a projected growth rate of 9.2% between 2020 and 2030 equating to an estimated US $39 billion in revenue by 2030 [3].This growth in sales is troubling from a public health standpoint, with evidence showing that e-cigarette usage is associated with breathing difficulty and cardiopulmonary health risks [4] as well as a higher likelihood to engage in risky behaviors among high school students [5]. In response to this growth in use and public health concerns, government agencies such as the US Food and Drug Administration have begun to assert their regulatory authority over e-cigarettes [6,7] along with a number of US states and municipalities that have instituted a variety of tobacco control policies (eg, sales bans of flavored tobacco products, tax regimes, license requirements, restrictions on youth access) to reduce the uptake, marketing, and sale of ENDS [8,9].

An abundance of evidence has shown that as tobacco control efforts expand, the tobacco industry has responded with a variety of messages and tactics to protect its business interests, including but not limited to lobbying, shaping the evidence base to support product use or harm reduction messages, policy substitution, and litigation [10-14]. As the overall reputation of the tobacco industry has declined over time, front groups and alliances with more reputable organizations have been especially important to its political activity because they shield such efforts from negative public perception about the industry [15-20]. Smokers' rights groups were a particular group the tobacco industry used that attempted to mobilize smokers as a force to lobby policy makers to resist efforts that infringed on their "right to smoke" [17,21-23]. Although smokers' rights groups were projected as being grassroots, they were a form of astroturfing, or "artificial grassroots campaigns created by public relations firms," to increase the number of contacts that are made with policy makers in addition to traditional lobbying approaches [24].

The e-cigarette or "vaping" industry is also distinct in its structure compared to the overall tobacco industry. Specifically, the tobacco industry is highly concentrated among a few multinational corporations (China National Tobacco Corporation, Altria/Philip Morris International, British American Tobacco, Japan Tobacco International, and Imperial Brands make up approximately 82% of the global market share for cigarettes) [25]. These multinational tobacco actors also have a stake in the vaping industry as evidenced by the introduction by these companies of noncombustible products, mergers and acquisition activity with ENDS manufacturers, and other ownership of ENDS companies [26,27]. However, despite involvement from the tobacco industry, the ENDS industry has its own unique construction, including its own independent brands with national footprints (eg, Juul and the 35% share acquisition by Altria), smaller manufacturers and retailers of ENDS, and retailers independent of larger tobacco manufacturers [28]. Therefore, understanding the political resistance to expanding ENDS legislation can be informed by prior lessons learned from tobacco industry interference but will also need to evolve due to the differing landscape of actors associated with the growing ENDS industry.

A proactive leader in state-based policy efforts to regulate tobacco and ENDS is the state of California. Specifically, the state has been one of the leading jurisdictions in the United States in implementing local- and state-level tobacco control policies, including those related to smoke-free air and housing and tobacco prevention programs, which also includes measures directed at regulating ENDS [29,30]. For example, recent tobacco control legislation has included subjecting ENDS to existing antitobacco laws (Senate Bill [SB] X2-5), raising the purchasing age to 21 (SB X2-7), and imposing additional taxes on ENDS products (Proposition 56). In response, the vaping industry has been aggressive in mobilizing opposition to these policies by using a network of manufacturers, trade associations, and tobacco user communities, and by appealing to the general public in order to advocate for "vaper rights" [31-35]. One of the strategies used by the alternative tobacco industry has been to mobilize political action through social media platforms, such as the popular social networking site Facebook, which can extend the scope and reach of these antipolicy and advocacy efforts.

Previous studies examining the impact of social media platforms on the ENDS industry have identified user attitudes towards alternative tobacco products and behaviors of users [36-38]; characterized marketing tactics, sales strategies, and pricing of ENDS [39-46]; and identified geographic locations where people use ENDS [47]. However, few studies have specifically assessed how social media can influence antitobacco public policy and methods of social media mobilization among digital constituents [48,49]. This study builds on prior research by describing the membership and network structure of interest groups for alternative tobacco products on Facebook by using social network analysis (SNA). In order to observe mobilization across different online contexts, we conducted an exploratory investigation characterizing network structures of an alternative tobacco industry trade association Facebook page and a consumer-focused ENDS Facebook group.

Methods

Overview

This study used SNA to identify and characterize influential members and vape industry employees engaged with California chapters of 2 alternative tobacco interest groups. The proportion of influential members were compared between industry

employees and nonemployees. An exponential random graph model (ERGM) was then used to detect statistically significant differences between vape employment status and likelihood to engage within the network, and a timeline analysis was used to investigate alignment with national- and state-level tobacco control policy events. All data collection and statistical and SNA analyses were completed in the computer programming languages Python (Python Software Foundation) and R (The R Foundation for Statistical Computing).

Data Collection and Processing

This study used membership information available from 2 Facebook groups—the California Consumer Advocates for Smoke-Free Alternatives Association (CCASAA) and the Northern California Chapter of Smoke-Free Alternatives Trade Association (NC-SFATA)—to conduct SNA that characterizes the communication networks and identifies the position of influential members within and between these online communities.

The CASAA was founded in 2009 and describes itself as an advocacy group with an all-volunteer board and grassroots membership. It distinguishes itself as claiming to operate as a consumer organization and not a trade organization [50].The CASAA has a national Facebook page (address in New York) as well as pages for state chapters. The CCASAA Facebook page is for CASAA members residing in California and characterizes CASAA as "formed by people concerned about the continued availability of safer alternatives to tobacco" [51]. Members can "support CASAA's goals by advocating in California for reasonable laws for products such as electronic cigarettes and smokeless tobacco products." The CCASAA Facebook page has 195 members and is currently active.

The SFATA is a trade organization with a mission to "advocate for a reasonably regulated U.S. marketplace which allows our member companies to provide smoke-free products to adult consumers that are attractive in choice, while promoting a positive public image for vapor products…" [52]. Its membership includes "manufacturers, distributors, wholesalers, retailers, and the various service providers involved in their business" with membership opportunities open to the academic community and nonprofit organizations. The SFATA extends its national work into state and local level policy through its different state chapters. The NC-SFATA Facebook page characterizes SFATA as "representing the interests of the small- to mid-sized businesses by engaging with political decision makers, with advocacy at the national and state levels…SFATA is run and founded by the companies that built the vapor industry; with no ties or alliance to 'Big Tobacco'" [53]. It discloses lobbying activity at the federal, state, and local levels as part of its range of services offered to members. The parent SFATA organization (address in Washington DC) operates an active Facebook page, and there are also numerous Facebook SFATA chapter pages in other states with varying levels of activity. The NC-SFATA Facebook page has 387 followers but has had limited activity since February 2017 (eg, only 2 recent posts in January 2021.) Despite its low recent activity, the page remains available and also provides an important digital record of how the group has mobilized to influence past California tobacco control legislation.

Data mining approaches using the Python programming language were used to collect publicly available data for all posts and comments from the Facebook pages of the 2 target groups over a 15-day period, from July 1, 2020, to July 14, 2020. This allowed us to collect all Facebook posts and comments retrospectively from users prior to July 1, 2020, and prospectively until July 14, 2020. Reposts were not removed as they were used for the purpose of analyzing interactions between posts and user interactions. Data were then restructured manually to a format suitable for conducting SNA. We note that public Facebook pages do not require request for joining or membership, and all posts, comments, and other information are publicly available to any online user.

Self-reported occupation data were also collected for public accounts and group members among these 2 target pages if published on a publicly available Facebook account profile. For users whose occupation data were unavailable on Facebook, additional searches on other online platforms with professional public profiles (eg, Twitter, LinkedIn) matched to public metadata profile information were conducted to ascertain possible work position status. These additional metadata were matched based on matching names with at least 1 other identifier before cross-referencing with the Facebook data. All data generated from occupational classification were in the public domain, and no individual identifiers of these accounts are reported in this study. Occupation data from users that did not have a link to their profile page in the metadata were marked as missing, as additional data could not be cross-referenced and matched.

Social Network Analysis

SNA was conducted to detect influential members among alternative tobacco Facebook group communication networks reviewed. In the model presented in this paper, each node is a Facebook user associated with a California alternative tobacco trade association page (eg, CCASAA and NC-SFATA), and each edge (ie, link) between nodes represents reactions (eg, "like," "love," and "angry") or comments on a post. As previous research has demonstrated the importance of distinguishing between active versus passive engagement with Facebook content [54-57], comments were weighted as twice the value of a reaction (eg, a like, emoji) in order to indicate higher engagement on posts. Generally, the source node is the user who produced the original post while the target nodes are users who reacted to or commented on a post. Within the context of this study, a node with a high in-degree centrality indicated that the user received a higher number of reactions on their posts while a high-outdegree centrality indicated users who were more active within their Facebook page.

Network visualizations for the individual CCASAA and NC-SFATA groups used a spherical layout, while the visualization that included both networks used the Fruchterman-Reingold layout algorithm [58] to emphasize differences in the communication structures between the 2 groups. Eigenvector centrality, which accounts for both the number of edges of each node and the level of connectivity of

each node's connections (ie, the extent to which a node's connections is connected to others within the network), was used to measure influence within the network. Previous research has demonstrated that network structure measures such as Eigenvector centrality are reliable for detecting influential members within a network [59-61], and this measure has been validated in studies using data from both surveys and social media platforms [62-65]. Eigenvector scores were assigned to each node, with higher scores indicating higher influence within the network.

Proportions of users who were vaping industry employees were compared among the top 25% of users with the highest Eigenvector scores and remaining users with chi-square and a 2-proportion *z* test to test for statistical significance. Due to its increased usage within social network research [66] and previous work modeling social influence processes [67], a valued EGRM was used to detect a statistically significant influence between vape employee status and engagement within the network (ie, the likelihood of a tie formation) [68]. An ERGM is a statistical model that simulates alternative configurations of the observed network in order to determine the likelihood of a given structural feature, such as connections between nodes, which is referred to as "degrees" in SNA. Within the context of Facebook data used for this study, degrees correspond to the number of reactions and comments exchanged between users.

In order to model the value of the edges within the networks (as ERGMs traditionally only model binary ties), we employed an ERGM that accounts for valued edges by specifying a Poisson distribution as a reference for the distribution of edge values [69]. This study also examined homophily effects among ENDS industry–affiliated employees within the network. Homophily in social network research describes how members that share similar attributes, such as age, race, and gender, are more likely to interact with one another within a network [70] and has also been shown in health behaviors such as smoking [71]. Higher homophily among ENDS employees would indicate that users associated with the alternative tobacco industry are more likely to engage with one another on the Facebook group platform, suggesting higher coordination among members. The sum of reactions and comments for each post were calculated in order to identify influential posts based on whether the post was in the 75th percentile of engagement. Nodes with missing data for the ENDS employee status were kept in the analysis and imputed as not employed (46 nodes in total) in order to maintain network structure. This makes it possible that the models could be underestimating the strength of the effect that ENDS employee status and homophily have on the likelihood of communication ties.

Policy Timeline Analysis

A timeline analysis was also conducted to detect associations between the number of influential posts and relevant federal and California state legislative events concerning e-cigarettes during the study period. This was done in order to observe how social media activity relates to policy outcomes, with histograms created to show the number of posts for each Facebook group by the month and year they were posted. Separate analyses for both groups were conducted with consideration to the different timeframes of activity between the organizations (the CCASSA activity was from February 2019 to June 2020, while NC-SFATA activity occurred between May 2015 and June 2017). Additionally, posts were categorized as either "Top 25% engagement" or "Remaining 75%" based on whether they were in the 75th percentile of posts that received the highest number of reactions and comments.

Ethics

This study only involved the use of publicly available information in the public domain and did not include any interaction with social media users or other human participants. No personally identifiable information was included in the results of this study, and all results have been aggregated to prevent inadvertent disclosure of identifiable information. Hence, this study was not subject to ethics review.

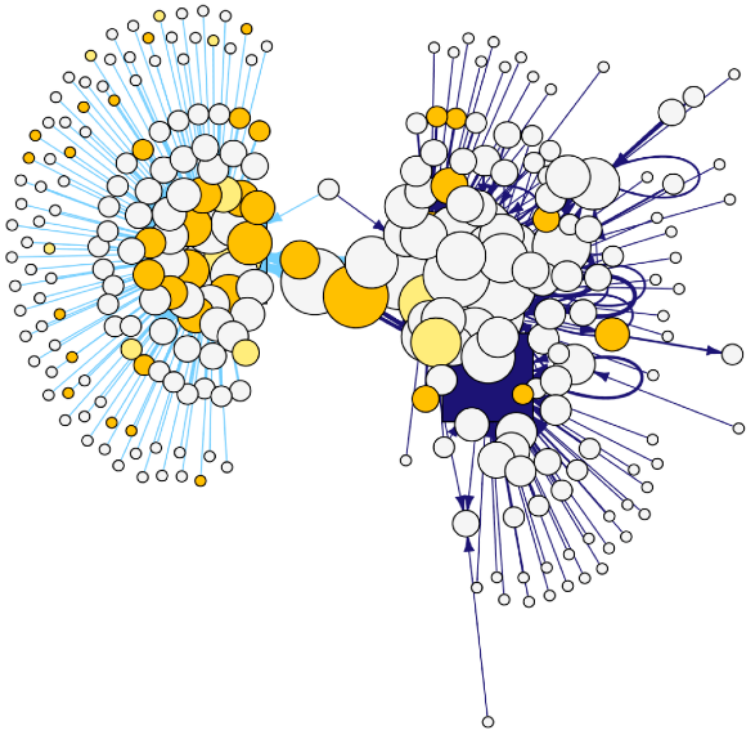
Results

Comparing CCASAA and NF-SFATA Networks

A total of 292 active users (ie, nodes) among both CCASAA and NC-SFATA Facebook groups were included in the SNA from interactions consisting of posts, comments, and reactions resulting in a total of 509 edges (ie, connections between users). Of the total users, 246 had data linking to their public Facebook account and were also reviewed for identifying occupation data. Among these 246 users, 53 (21.5%) self-reported being employed by the alternative tobacco industry, which consisted of 10 retail workers (4.1%), 24 vape shop owners (9.8%), and 19 alternative tobacco industry public relations or marketing employees (7.7%). The predominant themes of Facebook posts and comments of these users included event invitations for activities directly mobilizing against tobacco control–related policies, public mobilization messages to encourage users to take individual action against tobacco control legislation, information about a tobacco control policy or introduced bill, and negative comments and opinions on tobacco control policies from the perspective of the alternative tobacco industry and ENDS users. A more in-depth qualitative description of these themes and specific content is being developed for separate analysis.

SNA visualization of Facebook users in Figure 1 shows the overall network of both the CCASAA and NC-SFATA members while Figures 2 and 3 showcase how users are spread out among the Facebook pages. Light yellow nodes represent users who are alternative tobacco retail workers while dark yellow represents vape shop owners and alternative tobacco public relations or marketing employees. All remaining white nodes are nonalternative tobacco employee users. The source node is the user who produced the original post while the target nodes are users who reacted to or commented on a post. Edges representing online discourse on the CCASAA Facebook page are colored dark blue while activity on the NC-SFATA page is depicted by light blue edges. The size of nodes and edges depends on the weighted sum of the edge connections (ie, larger node and edge sizes equate to a higher number of reactions and comments).

Figure 1. Consumer Advocates for Smoke-Free Alternatives Association and Northern California Chapter of Smoke-Free Alternatives Trade Association networks.



Unsurprisingly, in an examination of the size of user nodes expressed in Figures 2 and 3, both the CCASAA and NC-SFATA are highly engaged within the networks as they are administrators of their respective Facebook pages. Most notably, the figures reveal that employees of the alternative tobacco industry are among some of the more engaged nodes. In Figure 1, both networks are shown to have mostly separate followings, with the CCASAA network having more engagement among nodes and the NC-SFATA network showing a more centralized, yet less engaged discourse. This is further supported when the degree distribution between networks is compared as shown in Table 1, where higher degree indicates more engagement. The mean degree for CCASSA users is 4.84 compared to 1.99 among NC-SFATA users, which shows that CCASAA users on average react, comment, or post more often. Additionally, CCASAA users have a higher degree across percentiles while NC-SFATA users consistently have a degree of 1 despite having a larger max value, which further indicates the centralized nature of the NC-SFATA communications. Network densities (ie, the ratio of the number of edges to the number of possible edges) were also calculated and show that the CCASAA network is denser (density 0.016) compared to that of the NC-SFATA (density 0.007), which is another indicator of greater activity levels among nodes within the CCASAA network.

Between the 2 groups, 8 Facebook users were identified as being active in both networks. Of these overlapping users, 6 were employed in the alternative tobacco industry, with 1 being a retail worker, 4 being vape shop owners, and 1 having served in a leadership role with the NC-SFATA. The involvement of a user with a leadership role in the SFATA chapter suggests the possibility of coordinated policy mobilization between these 2 California-based pro–alternative tobacco organizations and potential alignment of messaging and advocacy approaches. Additionally, Table 1 shows that alternative tobacco employees had a higher mean degree (mean 8.02) compared to the total network (mean 3.49), which indicates that these industry employees on average are more engaged within the groups compared to other users.

Figure 2. Consumer Advocates for Smoke-Free Alternatives Association network. The Consumer Advocates for Smoke-Free Alternatives Association is represented by the dark blue square.

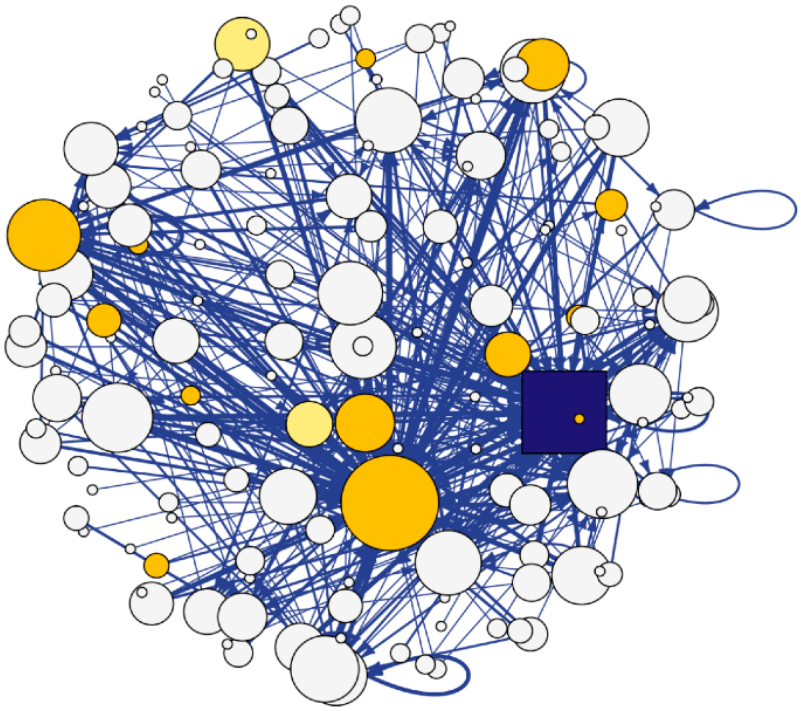


Figure 3. Northern California Chapter of Smoke-Free Alternatives Trade Association network. The Smoke-Free Alternatives Trade Association is represented by the light blue square.

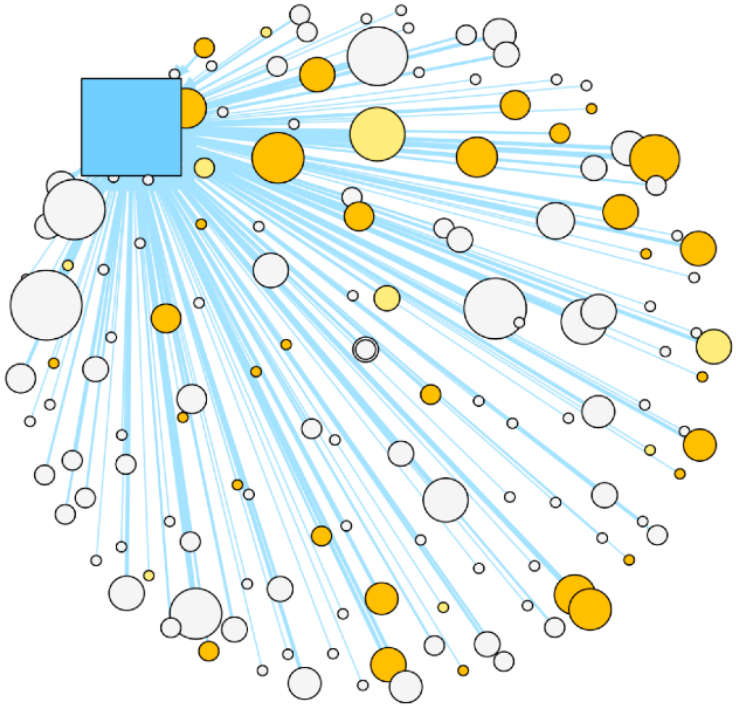

Table 1. Network statistics and degree distribution.

Statistics	Total network	CCASAA[a] Only	NC-SFATA[b] Only	Vape employee (CCASSA + SFATA)	Top 25% influential (CCASSA + SFATA)
Total nodes, n	292	148	152	53	76

[a]CCASAA: Consumer Advocates for Smoke-Free Alternatives Association.

[b]NC-SFATA: Northern California Chapter of Smoke-Free Alternatives Trade Association.

Table 2 shows that 32% (23/71) of the most influential members within the network were self-identified alternative tobacco employees compared to 17.1% (30/175) of other users, with this difference being statistically significant (*P*=.007). This indicates that alternative tobacco industry employees were more likely to be influential nodes within the communication network.

Results from the chi-square test provide further evidence of an association between alternative tobacco industry employment and network influence, which shows that the distribution of alternative tobacco employees across influential and noninfluential members were statistically different from expected probabilities based on random chance (*P*=.002).

Table 2. Chi-square and 2-proportion z test comparing vape employee status between influential and noninfluential users (N=264[a]).

Tests for detecting statistical significance	Top 25% most influential	Remaining 75%
Chi-square test[b]		
Expected probability	.25	.75
Observed count (vape employees), n	23	30
Two-proportion *z* test[c]		
Users, n	71	175
Vape employees, n (%)	23 (32)	30 (17.1)

[a]Only users with links to Facebook profiles are included.

[b]X^2_1=9.566; *P* value=.002.

[c]X^2_1=6.078; *P* value=.007.

As shown in Table 3, the ERGM was run on the networks examined to detect statistically significant effects between being an alternative tobacco industry employee and the likelihood that a tie would form within the network, which in this study would signify engagement via a reaction or comment. The variable labeled "Nodefactor: *Vape*" measures how alternative tobacco employee status (coded as a categorical variable) influences the likelihood of a tie within the network. Model 2 additionally tests for homophily among alternative tobacco employees, labeled as "Nodematch: *Vape*." The term "Nonzero" was included in the model to control for zero inflation of the network (ie, when a network is sparse but still has high interaction between nodes).

Results from Model 1 show that if a user was an alternative tobacco employee, then the log odds of sending a reaction or comment was 0.35 times greater than that of non–alternative tobacco employees when the density of the network is controlled for. This effect is statistically significant (*P*<.001) in both models. When homophily in Model 2 was tested for, there was a statistically significant negative effect (–0.27 log odds; *P*<.001) indicating that alternative tobacco users were less likely to engage with one another within the network. These findings indicate that while being an alternative tobacco employee increases the likelihood that a user engages within the CCASAA and NC-SFATA networks, these same users are more likely to interact with non–alternative tobacco industry employees within these online contexts.

Table 3. Exponential random graph model for valued edges to detect likelihood of being an alternative tobacco industry employee within the network.

Network parameter[a]	Model 1	*P* value	Model 2	*P* value
Sum (network density)	0.91	<.001	0.91	<.001
Nodefactor: Vape	0.35	<.001	0.42	<.001
Nonzero	–8.22	<.001	–8.08	<.001
Nodematch: Vape	—[b]	—	–0.27	<.001
AIC[c]	–163446	—	–163579	—

[a]Total nodes: 292; total edges: 500 (loop edges removed for the exponential random graph model); sample size per chain: 5000; thinning interval: 5000; reference distribution: Poisson.

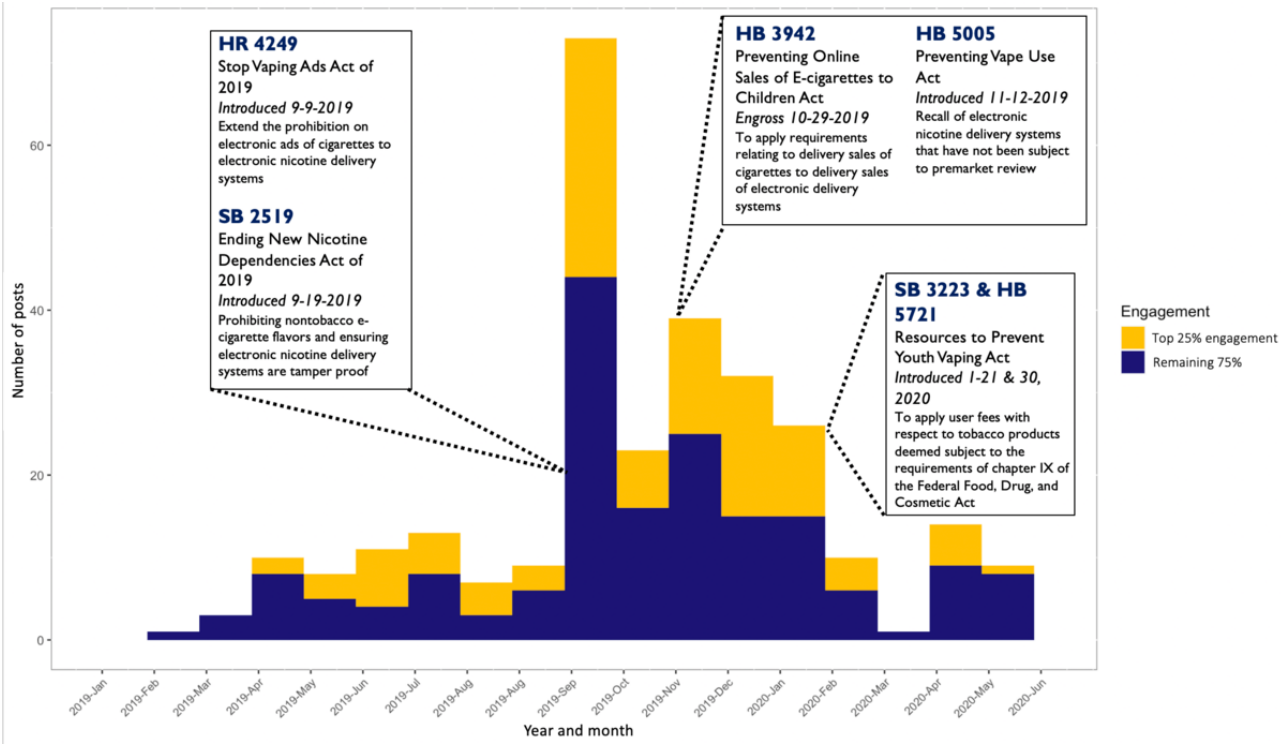
[b]Not included in the model.

[c]AIC: Akaike information criterion. AIC within the context of an exponential random graph model measures deviance based on log-likelihood, which is calculated by summing the differences between predicted probabilities and observed values.

Post Timeline Analysis

Both Figures 4 and 5 show the post timelines for CCASSA and NC-SFATA content, respectively, with the proportion of posts receiving the top 25% most engagement filled in yellow. Each timeline includes markers detailing the date and descriptions of important vaping legislation during the time period in which posts were analyzed. Although not every post explicitly mentions a tobacco control policy, it can be interpreted that different forms of provaping messaging posted around legislative events can influence the opinions and mobilization actions of users. For example, an advertisement for a vaping device that shows up on a group member's newsfeed still supports and communicates a provaping narrative whether or not it explicitly endorses a policy outcome. Users with higher exposure and engagement to pro–alternative tobacco messaging, which is the predominant theme within these Facebook groups, could be more likely to mobilize.

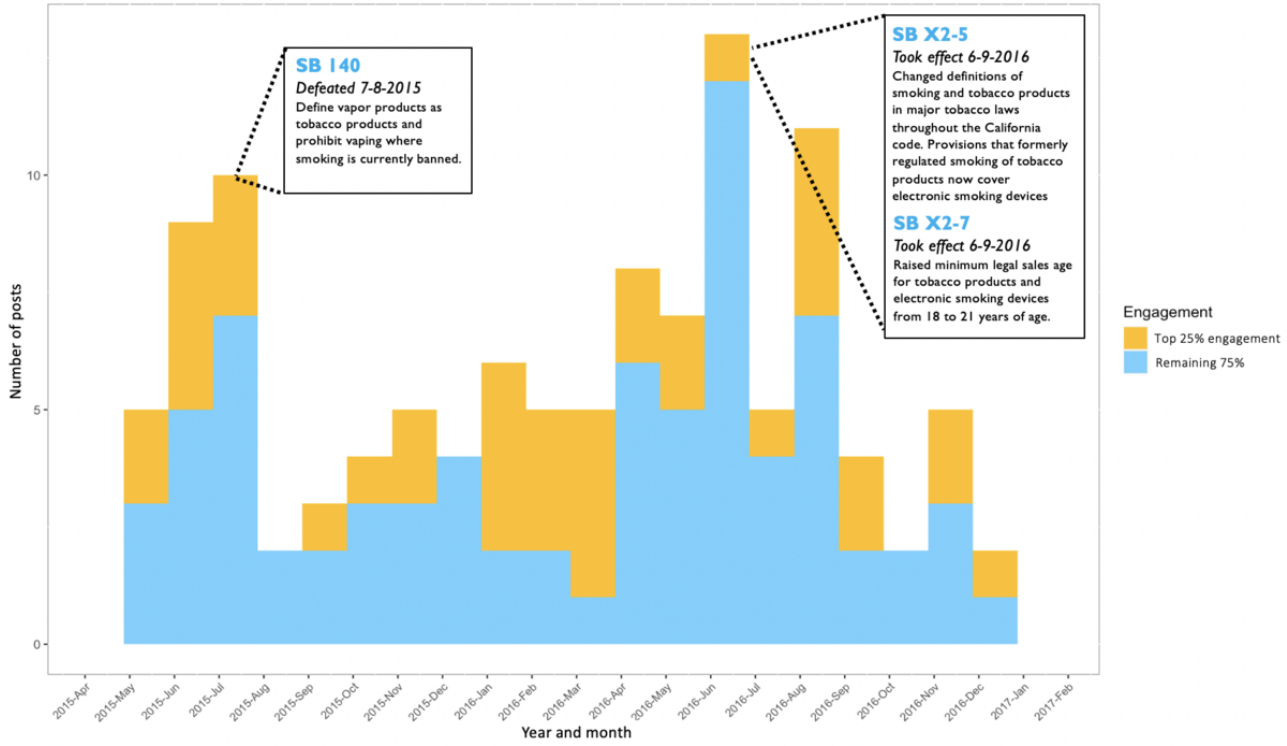
Figure 4. Consumer Advocates for Smoke-Free Alternatives Association posts timeline (2019-2020). HB: House Bill; HR: House of Representative; SB: Senate Bill.



As seen in Figure 4, the largest number and largest proportion of highly engaged posts within the CCASAA network were created in September 2019, around the same time that federal legislation regulating alternative tobacco ads and calling for prohibiting of nontobacco e-cigarette flavors were introduced (House of Representative [HR] 4249 and SB 2519). Although posts had notably dropped in the following month in October 2019, there was a modest increase in activity in November around the introduction of additional regulation to the delivery sales of ENDS (House Bill [HB] 3942 and HB 5005). Importantly, this timeline generally depicts periods of increased activity and posts among the CCASAA Facebook users during periods when federal anti–tobacco and alternative tobacco legislation was introduced, both in the US Senate and House of Representatives.

Figure 5 shows a bimodal distribution of posts within the NC-SFATA group. The first spike of posts begins on May 2015 and peaks on July 2015 around the same time that the law SB 140 was defeated in the California Senate, which would have classified ENDS products as tobacco and extended the prohibition of tobacco smoking in public places to ENDS products. The second peak of posts happened during June 2016, when the same legislation succeeded in a subsequent legislative session and began to take effect as did other tobacco control legislation that increased the legal sales age of ENDS from 18 to 21 (SB X2-5 and SB X2-7). Despite having the highest number of posts within the timeline, the proportion of high engagement posts during June 2016 was low, possibly suffering from lower user engagement as anti–alternative tobacco legislation had already been successfully passed.

Figure 5. Northern California Chapter of Smoke-Free Alternatives Trade Association posts timeline (2015-2017). SB: Senate Bill.



Discussion

Summary of Findings and Implications

Results from this study identify and characterize ways in which alternative tobacco interest groups act as virtual mobilization points across distinct online networks to influence tobacco control policy at both the federal and local level. This specifically includes our observation that alternative tobacco industry–affiliated actors are highly involved in antitobacco policy mobilization and advocacy activity with both an industry trade–focused group (NC-SFATA) that represents the interest of manufacturers, retailers, and distributors, but also a group that represents itself as a consumer organization for safer alternatives to tobacco. Specifically, our study found that there is a greater likelihood that alternative tobacco employees are within these Facebook user networks and that a higher proportion of industry employees are among the most influential members of the network. These findings are worrying as the presence of alternative tobacco employees and representatives may influence the factual narrative of tobacco and ENDS policy discussions due to financial interests and industry ties while not accurately conveying the concerns of consumers or consequences for public health outcomes.

Additionally, based on our timeline analysis, we observed that the highest number of messages with high engagement among these networks corresponded with dates tied to important tobacco control legislative events, evidencing increased activity around important policy decision-making windows. Some evidence of coordination between groups existed by examining network graphs with overlapping users in both organizations, and despite policy mobilization being active in both groups, they differed in their policy targets, with the CCASAA focusing on federal tobacco legislation and the NC-SFATA focusing on California state legislation. These results provide some indication of distinct mobilization and advocacy efforts at multiple policy-making levels. Although the purpose and messages of these activities clearly focused on disseminating information and influencing public perception for the purposes of defeating alternative tobacco legislation, levels of user engagement on these activities differed based on the group pages reviewed.

The network structure of the Facebook groups considered in this analysis differed in their density and post volume. The NC-SFATA Facebook group had lower density and more uneven distribution of engagement, while the NC-SFATA account was the main driver of posts to members. Additionally, the overall volume of posts was low compared to that of the CCASAA, and activity slowed after February 2017. The CCASAA had a

denser network structure, a larger volume of posts compared to the NC-SFATA, and a more even distribution of activity among users that continues to the present. This suggests that the sustainability of engagement levels across interest groups is highly variable and may also be influenced by the presence and interaction of other affiliated groups (eg, SFATA and CASAA parent organizations that are also both active on Facebook).

Determining the specific factors that influence levels of engagement was beyond the scope of the current analysis; differences may be due to the more formal nature of trade associations (which may lend themselves to more linear communication structure) versus that of consumer-focused groups or to other organizational changes that occurred within the CCASAA. The existing literature, however, suggests that emotion plays a strong role in the alternative tobacco market as demonstrated in previous work which found business strategies used within the alternative tobacco market to be highly contested, volatile, and interwoven with competition, emotion, and conflicting beliefs [72]. The network characteristics shown in this study may indicate a higher emotional commitment among CCASAA members, a factor important in countering their political actions.

Although independent manufacturers and retailers within the alternative tobacco industry attempt to distinguish themselves from Big Tobacco and the goals of these 2 segments of the provaping movement may differ [28,73] (eg, implications of changes in tobacco use behavior and product sales due to dual use of cigarettes and e-cigarettes vs transition from cigarettes to e-cigarettes), they nevertheless are working to the same policy ends: to minimize restrictions on the marketing, sale, and use of tobacco and alternative tobacco products. As multinational tobacco companies engage in efforts to increase their share of the alternative tobacco market and expend large sums of money to lobby and fight ENDS regulations and restrictions, the less politically powerful and poorly resourced independent entities within the alternative tobacco industry may serve the role that front groups traditionally have served for the tobacco industry [74]. Through consumer groups and trade associations, they may attempt to influence policy makers through power in grassroots-based advocacy: mobilizing numerous “legitimate” voices from consumers and small businesses against tobacco and alternative tobacco control measures.

Further, results from our study likely only represent a very small segment of political influence exercised by the tobacco and alternative tobacco industry on social media platforms. For example, our study only examined 2 relatively small California-specific group pages and chapters; although the CASAA and SFATA’s parent organizations had much higher levels of activity and engagement on Facebook and Twitter (@CASAAmedia on has 33,000 and 22,000 followers on Facebook and Twitter, respectively, while @sfataorg has 15,000 and 10,000 followers on Facebook and Twitter, respectively), there are CASAA and SFATA Facebook group chapters in Florida, Missouri, Colorado, Connecticut, Hawaii, Texas, Arizona, and Ohio, to name a few other state-specific examples. There are also other pro–alternative tobacco industry groups engaged on social media that actively advocate against tobacco control measures that were not included in this study as we only focused on those associated with the state of California. Hence, although our study is limited to a single US jurisdiction and 2 pages, it is highly probable that lobbying and digital mobilization against tobacco control legislation via social media is occurring across multiple jurisdictions and a diversity of user groups, likely with similar ties to tobacco industry–affiliated employees and actors. This socially enabled online environment represents an important public constituency that can be activated against federal, state, and local alternative tobacco control measures, necessitating further research into ties with the broader tobacco industry and other front groups.

In response to this strategic use of Facebook (and other social media platforms) by the alternative tobacco industry to mobilize efforts to influence public perception and the outcome of federal and state tobacco control policy, public health stakeholders should expand their own efforts to mitigate and counter provaping narratives, particularly if they originate from alternative tobacco employees or lobbyists and misrepresent or include misinformation about current or pending tobacco control legislation. Public health stakeholders should also make a concerted effort to engage in these almost exclusively provaping virtual communities by establishing their own counter narratives highlighting the health and addictive harms of alternative tobacco products. Specifically, the posts on these pages appear to have an echo chamber effect, in that all the posts exclusively present a provaping narrative that is disseminated among users who are members of these pages. For Facebook pages that are open to the public, these discussions could spill over to other online communities, and in the absence of effective counter marketing, fact-checking, and health promotion, could lead to protobacco messages influencing opinions of other users. Platforms should also consider requiring disclosure of industry affiliations by page users or administrators and any corresponding potential conflicts of interest that may influence the type of information presented, including on individual posts that relate to claims about tobacco control policy.

Limitations

As not every user was included in the *z* test comparing the proportion of alternative tobacco employees between influential and noninfluential users, it is possible that access to profile data could not be randomly distributed across alternative tobacco employee versus nonalternative tobacco users. If alternative tobacco employee status influences the likelihood of having available profile data, then this could have biased the results. Additionally, the results from this study only examined 2 California-affiliated organizations. More networks between local and national organizations would need to be analyzed in order to generalize findings about communication patterns in the overall alternative tobacco industry. As data were collected retrospectively, each network is also susceptible to data loss for posts collected before July 1, 2020. As mentioned in the methods section, the NC-SFATA is a Facebook page while the CCASSA is a Facebook community, which may account for many of the structural differences between communication networks. However, both formats share the same functions for interaction, so the main difference is between being listed as a group member versus only liking the page. Even if the format of the group on Facebook influences how users communicate with

each other, it is possible that choosing a particular format could be done intentionally to better align with the communication goals of the page creator. Finally, the timeline analysis was conducted to clarify the association between the number of posts and legislative events and cannot be used to establish a causal connection.

Conclusions

Future research should continue to characterize online communication strategies that differ between national and state or local alternative tobacco trade associations, consumer groups, and lobbying organizations in the social media sphere. This should include more in-depth characterization of formal coordination efforts on messaging, policy advocacy planning, and attempts to introduce misinformation about the impact of tobacco control legislation. For example, our study found that the NC-SFATA group had less engagement but a higher number of followers while the CCASSA group had fewer members but more engagement from these members. This may indicate specialization in the context of grass roots mobilization, advocacy, and policy substitution within the context of specific constituents, with SFATA focusing on mobilizing larger numbers of local and state actors and CCASSA focusing on smaller but more active engagement on federal issues. This potentially includes aligning with goals of each organization's respective national parent associations, with the aim of defeating both federal and state legislation in a strategic and coordinated fashion. Unfortunately, the same coordination that is needed among federal regulators, public health professionals, and state health agencies to promote tobacco control policies may be absent from these social networking service platforms, meaning that pro–alternative tobacco narratives may unduly influence the policy-making process, threatening future tobacco legislation and implementation of policy already in place.

Abstract

Background: Pulmonary arterial hypertension restricts the ability of patients to perform routine physical activities. As part of pulmonary arterial hypertension treatment, inhaled iloprost can be administered via a nebulizer that tracks inhalation behavior. Pulmonary arterial hypertension treatment is guided by intermittent clinical measurements, such as 6-minute walk distance, assessed during regular physician visits. Continuous digital monitoring of physical activity may facilitate more complete assessment of the impact of pulmonary arterial hypertension on daily life. Physical activity tracking with a wearable has not yet been assessed with simultaneous tracking of pulmonary arterial hypertension medication intake.

Objective: We aimed to digitally track the physical parameters of patients with pulmonary arterial hypertension who were starting treatment with iloprost using a Breelib nebulizer. The primary objective was to investigate correlations between changes in digital physical activity measures and changes in traditional clinical measures and health-related quality of life over 3 months. Secondary objectives were to evaluate inhalation behavior, adverse events, and changes in heart rate and sleep quality.

Methods: We conducted a prospective, multicenter observational study of adults with pulmonary arterial hypertension in World Health Organization functional class III who were adding inhaled iloprost to existing pulmonary arterial hypertension therapy. Daily distance walked, step count, number of standing-up events, heart rate, and 6-minute walk distance were digitally captured using smartwatch (Apple Watch Series 2) and smartphone (iPhone 6S) apps during a 3-month observation period (which began when iloprost treatment began). Before and at the end of the observation period (within 2 weeks), we also evaluated 6-minute walk distance, Borg dyspnea, functional class, B-type natriuretic peptide (or N-terminal pro–B-type natriuretic peptide) levels, health-related quality of life (EQ-5D questionnaire), and sleep quality (Pittsburgh Sleep Quality Index).

Results: Of 31 patients, 18 were included in the full analysis (observation period: median 91.5 days, IQR 88.0 to 92.0). Changes from baseline in traditional and digital 6-minute walk distance were moderately correlated (r=0.57). Physical activity (daily distance walked: median 0.4 km, IQR –0.2 to 1.9; daily step count: median 591, IQR −509 to 2413) and clinical measures

(traditional 6-minute walk distance: median 26 m, IQR 0 to 40) changed concordantly from baseline to the end of the observation period. Health-related quality of life showed little change. Total sleep score and resting heart rate slightly decreased. Distance walked and step count showed short-term increases after each iloprost inhalation. No new safety signals were identified (safety analysis set: n=30).

Conclusions: Our results suggest that despite challenges, parallel monitoring of physical activity, heart rate, and iloprost inhalation is feasible in patients with pulmonary arterial hypertension and may complement traditional measures in guiding treatment; however, the sample size of this study limits generalizability.

Introduction

Background

Remote patient monitoring can play an important role in disease management, supporting the conventional approach of face-to-face visits. In patients with chronic diseases such as left-sided heart failure, remote monitoring has been reported to have beneficial effects—reduced readmissions (possibly due to earlier treatment for symptoms detected before scheduled follow-up visits), reduced mortality, increased quality of life, increased participation in self-management of the disease, and improved knowledge of the disease [1-4].

Pulmonary arterial hypertension is a progressive, life-threatening disease that can lead to right-sided heart failure and death [5]. Dyspnea, a common symptom of pulmonary arterial hypertension, restricts physical activity, which in turn impairs quality of life. The impairment of quality of life in patients with pulmonary arterial hypertension is severe, with health-related quality of life scores comparable to those reported for patients with spinal cord injuries or cancer unresponsive to therapy [6]. However, the use of vasoactive treatment to address pulmonary arterial hypertension is usually guided by intermittent clinical measurements of the 6-minute walk distance (a routine assessment of exercise capacity in pulmonary arterial hypertension), World Health Organization (WHO) functional class, and levels of B-type natriuretic peptide (BNP) or N-terminal pro–B-type natriuretic peptide (NT-proBNP) [7]. These traditional clinical measures are assessed during regular out- or inpatient visits, usually at widely spaced intervals (eg, every 3-6 months), and therefore, provide only a snapshot of the patient's health status. In times of increased reliance on telemedicine, such as during the current COVID-19 pandemic, visits between patients and their treating physicians may not be possible. For example, patients may attempt to reduce the probability of infection by avoiding visits in hospitals, and hospitals may enact restrictions and cancel visits. Furthermore, traditional clinical parameters do not address the impact of pulmonary arterial hypertension on daily life, which may be more important to the patient than functional or laboratory measures [8,9]. Remote monitoring may provide a more complete picture by allowing continuous assessment of parameters (such as physical activity) that reflect the impact of pulmonary arterial hypertension on daily life. However, it is unclear whether digital measures of physical activity are associated with traditional clinical parameters during long-term treatment. Furthermore, physical activity has not yet been assessed simultaneously with medication intake tracking.

Iloprost, a prostacyclin-based inhaled therapy for patients with primary pulmonary hypertension (idiopathic pulmonary arterial hypertension) in WHO functional class III, has shown beneficial effects on 6-minute walk distance and WHO functional class in clinical trials [10-12]. Iloprost is administered via nebulizers such as the Breelib nebulizer (Vectura Group plc) [13], which automatically saves inhalation information (dates, times, and completeness of inhalations).

Objectives

The primary aim of our study was to track daily physical activity in patients with pulmonary arterial hypertension starting treatment with inhaled iloprost, using a commercially available smartwatch and smartphone, and to investigate the association between changes in digital physical activity measures and changes in traditional clinical measures of disease severity and health-related quality of life over a 12-week period.

Secondary aims were to assess acceptance of the smartwatch by patients and the feasibility of measuring 6-minute walk distance digitally and to identify digital measures linked to traditional 6-minute walk distance. Further aims were to digitally monitor heart rate and iloprost inhalation behavior, to explore temporal patterns in activity level and heart rate relative to iloprost inhalation periods, and to evaluate changes in clinical outcome measures, daily physical activity, heart rate, and sleep quality after initiation of inhaled iloprost therapy. The study was not designed to investigate or confirm the effectiveness and safety of iloprost (Ventavis).

Methods

Study Design

Additional details are available in a previous publication [14] and in Multimedia Appendix 1.

As part of a national, prospective, observational, multicenter, single-arm cohort study (VENTASTEP; Clinical trial.gov, NCT03293407) investigating the associations between clinical and device-reported outcomes in patients with pulmonary arterial hypertension (WHO functional class III) who were adding inhaled iloprost to existing pulmonary arterial hypertension therapy, we collected digital measures of daily physical activity, heart rate, and 6-minute walk distance using smartwatch (Apple Watch Series 2) and smartphone (Apple iPhone 6S) apps (xbird GmbH). The apps continuously captured data from the smartwatch for the purpose of analyzing physical activity and behavior patterns; the 6-minute walk distance app captured data from the smartwatch during the 6-minute walk distance test. Raw sensor data from the smartphone were not used because it was impossible to ascertain whether patients always carried the smartphone with them. Device functionality was reduced to the minimum requirements for the study. To reduce bias, the apps did not provide feedback on physical activity to patients or physicians. A nebulizer (Breelib, Bayer AG) was used to record inhalation behavior [13,15,16].

The study period consisted of baseline data collection during the period from the initial visit and decision to start iloprost treatment until the actual start of iloprost treatment (≤2 weeks), an observation period of 3 months (±2 weeks) from the start of iloprost treatment, and final data collection at discontinuation of therapy or at the end of the study (whichever was earliest). The decision to start treatment with inhaled iloprost was made at the discretion of the treating physician; the decision was made in advance and independently of inclusion in the study. Follow-up was conducted during routine patient visits to their pulmonary arterial hypertension centers.

The study was approved by the central ethics committee of the Justus Liebig University Giessen (AZ153/17) and the ethics committees of all participating sites.

Patients

In preparation for this study, a survey on acceptance of digital tracking was performed, which indicated that approximately 50% of patients were willing to participate [14].

Patients were enrolled from 7 specialized pulmonary arterial hypertension centers in Germany from February 2018 to July 2019. Patients aged ≥18 years with pulmonary arterial hypertension in WHO functional class III despite treatment were eligible for enrollment if they were willing to wear a smartwatch for the duration of the study, had no previous treatment with inhaled iloprost, and they and their treating physician had decided to initiate treatment with inhaled iloprost using a Breelib nebulizer. Patients were excluded if they were allergic to nickel and methacrylates, or if they were already participating in an investigational program that included an intervention outside of routine clinical practice. All patients who were enrolled provided signed informed consent.

Study participants were trained by site personnel or investigators to correctly use the smartphone and smartwatch. Study participants were given training on inhaler use through a patient support program (VENTAPLUS, ContraCare GmbH and Vitartis Medical-Services GmbH), which is routinely offered to patients.

Data Collection

Anamnestic data (demographic and clinical characteristics) were collected by an investigator from medical records, if available, and entered into an electronic case report form that formed part of an electronic data capture system developed and managed by a contract research organization (Institut Dr. Schauerte).

Traditional clinical measures (6-minute walk distance, Borg dyspnea score at end of 6-minute walk distance test, WHO functional class, and levels of BNP or NT-proBNP) and vital parameters were assessed at the initial and final visit to the study center; data were also recorded in the electronic case report form. Patient-reported outcomes—EuroQol 5-dimension questionnaire (EQ-5D) and Pittsburgh Sleep Quality Index (PSQI)—were documented on paper at the initial and final visits and sent to the contract research organization for analysis. Adverse events, from the periods between the first use of inhaled iloprost to 30 days after the last dose within the study period, were documented in the electronic case report form.

Digital measurements of daily physical activity and heart rate were captured continuously by the smartwatch and app. Digital 6-minute walk distance data (steps, distance walked, heart rate, and raw data from motion sensors) were collected at the initial and final visit using the smartwatch and 6-minute walk distance app (which uses step count and a stride length algorithm trained on healthy volunteer data). Inhalation data (frequency of inhalations, completeness of inhalations, and duration of inhalations) were captured by the nebulizer, transferred to the smartphone using the BreeConnect App (Bayer AG), and then transferred to the contract research organization for analysis.

All data collected by the smartwatch were stored pseudonymized on a secure cloud server (xbird GmbH) for further processing. Processed data points for all variables were transferred as pseudonymized data to the electronic data capture system and matched to other collected data after the last visit of the last patient.

Outcome Measures

The primary endpoint was correlation between changes from baseline to the final visit in digital measures of physical activity, traditional clinical measures, and in health-related quality of life. Changes from baseline were evaluated as a first step. The traditional clinical measures included in the primary analysis were the 6-minute walk distance, Borg dyspnea score after the 6-minute walk distance test, WHO functional class, and BNP or NT-proBNP levels. Health-related quality of life was assessed using the EQ-5D. The digital measures were distance walked, number of steps, number of standing-up events, and digital 6-minute walk distance (Multimedia Appendix 2).

Secondary endpoints included inhalation behavior (mean daily inhalation duration per session, mean daily number of inhalations, and mean daily proportion of complete and

incomplete inhalations) and the mean association between physical activity level (device-based) and time since the last inhalation. The change from baseline to the end of the observation period in sleep quality (PSQI) and heart rate (at rest and during the 6-minute walk distance test), the association between heart rate and other device-based measures during the whole study period, and the incidence of treatment-emergent adverse events and serious treatment-emergent adverse events were also evaluated as secondary endpoints. Other endpoints included acceptance of the smartwatch by patients, correlation of traditional and digital 6-minute walk distance measurements, and association of digital measures with 6-minute walk distance.

Statistical Analysis

Statistical analyses were exploratory and descriptive.

Based on a feasibility study conducted in 2018 and ongoing study experience, the final planned sample size was 25 to 50 patients. The minimum number of 25 patients was considered sufficient to obtain reasonably precise correlation coefficients (even with 40% missing data).

The safety analysis set included all patients who received at least 1 dose of inhaled iloprost. If a patient withdrew consent without agreeing to further use of their data, they were excluded from the safety analysis set. The full analysis set included all patients from the safety analysis set who had ≥3 days of activity measurements during the baseline period, ≥3 days of activity measurements during the last 2 weeks of the observation period, and data at the initial and final visits for at least 1 of the following clinical outcome measures: 6-minute walk distance, BNP/NT-proBNP levels, and WHO functional class. Patients identified as screening failures after enrollment (included by mistake) were excluded from the full analysis set.

Measurements per day were normalized, for an assumed 18 hours (6 AM to midnight) of activity per day if parts of the observational time period of that day were missing, based on the percentage of time spent wearing the smartwatch. If the watch was worn for less than 10% of a given day, data for that day were treated as missing.

Device-measured daily physical activity at baseline was calculated as the median of ≤14 daily assessments before the first intake of inhaled iloprost. Device-measured daily physical activity at the end of the observation period was calculated as the median of daily assessments in the last 14 days of the observation period.

Pearson correlations were calculated for complete, pairwise observations of traditional and digital measures included in the primary analysis. Missing data for these parameters were not imputed.

Regression analyses were performed with change from baseline in a traditional clinical measure as the dependent variable and changes from baseline in digital measures (distance walked, number of standing up events, and 6-minute walk distance) as independent variables.

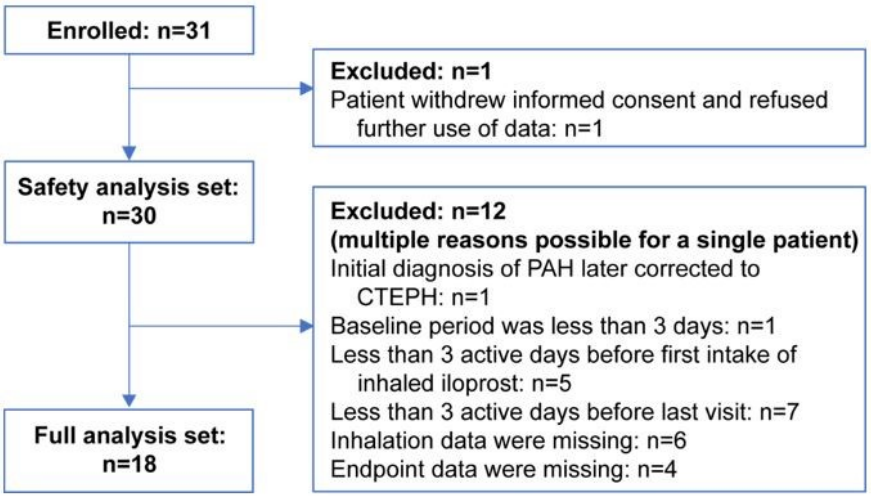
Results

Patients

We screened and enrolled 31 patients; 30 patients were included in the safety analysis set, and 18 patients were included in the full analysis set (Figure 1). Most patients in the full analysis set (Multimedia Appendix 3) were older adults (aged ≥65 years; n=12), female (n=12), and White (n=17). All patients were taking oral pulmonary arterial hypertension therapies at baseline.

The most common iloprost dose at the start and end of the observation period was 2.5 µg; 3 patients changed doses (Multimedia Appendix 4). The median number of inhalation sessions per day was 5.0 (IQR 4.3 to 5.7), and the inhalation duration per session was 5.5 minutes (IQR 3.8 to 6.3). More than 75% of the inhalations were complete—the median daily percentage of complete inhalations was 100% (IQR 100% to 100%; range 50%-100%).

Figure 1. Patient disposition. CTEPH: chronic thromboembolic pulmonary hypertension; PAH: pulmonary arterial hypertension.



Use of the Smartwatch During the Study

The median observation period in the full analysis set was 91.5 days (IQR 88.0 to 92.0; range: 34-113 days). Participants wore the smartwatch between 30 and 113 days overall (baseline period: range 4-14 days; end of the observation period: 8-14 days), for a mean time ranging from 4.8 hours per day to 11.5

hours per day (baseline period: range 4.1-14.6 hours per day; end of the observation period: range 4.7-10.5 hours per day). During the baseline period, 12 of the 18 patients (67%) wore the smartwatch for less than 7 days, and 6 of the 18 patients (33%) wore their smartwatch for at least 7 days. During the end of the observation period, almost three-quarters of the patients (13/18, 72%) wore the smartwatch every day, and all patients (18/18, 100%) wore it for at least 7 days. (Table 1). The number of hours spent wearing the watch per day decreased over the study period, but 89% of the patients (16/18) still wore the smartwatch for ≥6 hours per day on average during the end of the observation period (Table 1).

Table 1. Smartwatch use during the study (full analysis set).

Use characteristic	Patients, n (%)	
	Baseline period	Last 14 days of observation period
Number of days worn		
<7 days	12 (67)	0 (0)
≥7 days	6 (33)	18 (100)
≥10 days	3 (17)	17 (94)
14 days	2 (11)	13 (72)
Average daily hours worn		
<6 hours	2 (11)	2 (11)
≥6 hours	16 (89)	16 (89)
≥10 hours	9 (50)	4 (22)
≥14 hours	1 (6)	0 (0)
18 hours	0 (0)	0 (0)

Association Between Changes in Digital Physical Activity Measures and Changes in Traditional Clinical Measures

Comparison of Traditional and Digital Measures for 6-Minute Walk Distance

The median increase in traditional 6-minute walk distance was 26 m (Table 2). Although traditional and digital 6-minute walk distances were measured in parallel, digital 6-minute walk distance showed no substantial change from baseline (median −4.3 m, IQR −33.5 to 35.8), despite the observed change in traditionally measured 6-minute walk distance.

Table 2. Traditional and digital measures for 6-minute walk distance before and after 12 weeks of inhaled iloprost therapy.

Measure	Patients	Values		
	n	Median	IQR	Range
Traditional 6-minute walk distance (meters)				
First visit	18	339	250 to 420	196 to 546
Last visit	16[a]	366	282 to 418	207 to 585
Change[b]	16[a]	26	0 to 40	−43 to 87
Digital 6-minute walk distance[c] (meters)				
First visit	14	423.1	364.2 to 460.6	301.3 to 556.8
Last visit	14	433.9	329.2 to 486.3	267.8 to 592.6
Change	14	−4.3	−33.5 to 35.8	−69.2 to 90.0

[a]Two of the 18 patients withdrew consent during the observation period and did not perform a 6-minute walk distance test at their final visit (they agreed to the use of data that had already been collected).

[b]Patients analyzed at the first and last visit were used for the calculation of change. The median change as a robust center estimate is not necessarily the difference of the median of the total distance walked.

[c]Only for patients with available values for both baseline and final visit.

Further Traditional Measures and Health-Related Quality of Life

Borg dyspnea index increased from baseline in 7/18 patients (39%), remained stable in 6/18 patients (33%), and decreased in 3/18 patients (17%) (Table 3). WHO functional class changed from III to II in 4 patients and remained unchanged in the other 14 patients. The EQ-5D weighted index did not change considerably.

Table 3. Traditional clinical measures and health-related quality of life before and after 12 weeks of inhaled iloprost therapy.

Measure	Patients	Values		
	n	Median	IQR	Range
Borg dyspnea				
First visit	18	5.0	4.0 to 6.0	1.0 to 10.0
Last visit	16[a]	3.5	2.5 to 6.5	1.0 to 8.0
Change	16[a]	−0.5	−2.0 to 0.0	−3.0 to 3.0
EQ-5D[b]				
First visit	17	0.88	0.74 to 0.96	0.38 to 1.00
Last visit	16	0.87	0.74 to 0.97	−0.26 to 1.00

Change	8	−749	−3415 to 212	−5890 to 1888

[a]Two of the 18 patients withdrew consent during the observation period and did not perform a 6-minute walk distance test at their final visit (they agreed to the use of data that had already been collected).

[b]EQ-5D: EuroQol 5-dimension questionnaire.

Digital Measures of Physical Activity

Digital measures of daily physical activity (daily distance walked, number of steps per day, and number of standing-up events per day) increased from baseline to the end of the observation period (Table 4).

Table 4. Digital measures before and after 12 weeks of inhaled iloprost therapy.

Measure	Patients	Values		
	n	Median	IQR	Range
Distance walked per day[a] (km)				
Baseline	18	5.2	3.1 to 7.6	1.7 to 14.9
End of observation	18	6.5	4.0 to 7.8	2.6 to 15.7
Change	18	0.4	−0.2 to 1.9	−3.6 to 4.7
Number of steps per day[a]				
Baseline	18	6721	4073 to 10,258	2268 to 18,398
End of observation	18	8332	5330 to 10,101	3389 to 19,451
Change	18	591	−509 to 2413	−4605 to 6075

Baseline	18	24.2	20.4 to 25.6	0.0 to 56.5
End of observation	18	24.8	23.1 to 26.7	14.5 to 55.0
Change	18	1.7	−1.1 to 5.4	−9.9 to 25.5

[a]Average during baseline and last 14 days of observation period.

Correlation Between Changes From Baseline in Traditional and Digital Measures

Changes from baseline in traditional 6-minute walk distance and digital 6-minute walk distance were moderately correlated (Table 5). The numbers of patients with available data for BNP and NT-proBNP levels (n=6 and n=8, respectively) were too low for a meaningful analysis of correlation. A sensitivity analysis that had been planned (calculation using the complete data set instead of pairwise complete observations) was not performed because the volume of data was insufficient for further analysis.

Table 5. Pearson correlation between changes from baseline in traditional clinical parameters, health-related quality of life, and digital parameters after starting inhaled iloprost therapy.

Measure	Patients	Digital parameters, *r*			
	n	Average distance walked per day[a]	Average number of steps per day[a]	Average number of standing-up events per day[a]	6-minute walk distance[b]

[b]Two of the 18 patients withdrew consent during the observation period and did not perform a 6-minute walk distance test at their final visit (they agreed to the use of data that had already been collected).

[c]EQ-5D: EuroQol 5-dimension questionnaire.

Heart Rate

The median average heart rate at rest was 75.9 beats per minute (IQR 70.4 to 88.5) at baseline and 76.5 beats per minute (IQR 69.5 to 85.4) at the final visit. From baseline to the final visit, the average heart rate at rest showed a median decrease of −1.3 beats per minute (IQR −8.0 to 3.5).

Heart rates measured during the 6-minute walk distance test were slightly higher at the last visit compared with those at the baseline visit (Figure 2). The median changes in heart rate from 1 minute before the 6-minute walk distance test to each minute during the 6-minute walk distance test were also higher at the last visit (4.6 beats per minute to 23.9 beats per minute) than those at the baseline visit (3.0 beats per minute to 20.5 beats per minute) (Multimedia Appendix 5). Heart rate recovery immediately after the 6-minute walk distance test was slower at the last visit than that at the baseline visit (Figure 3).

Figure 2. Median heart rate Data collected by smartwatch during 6-minute walk distance test before (baseline) and under (last visit) inhaled iloprost therapy. Error bars show IQR.

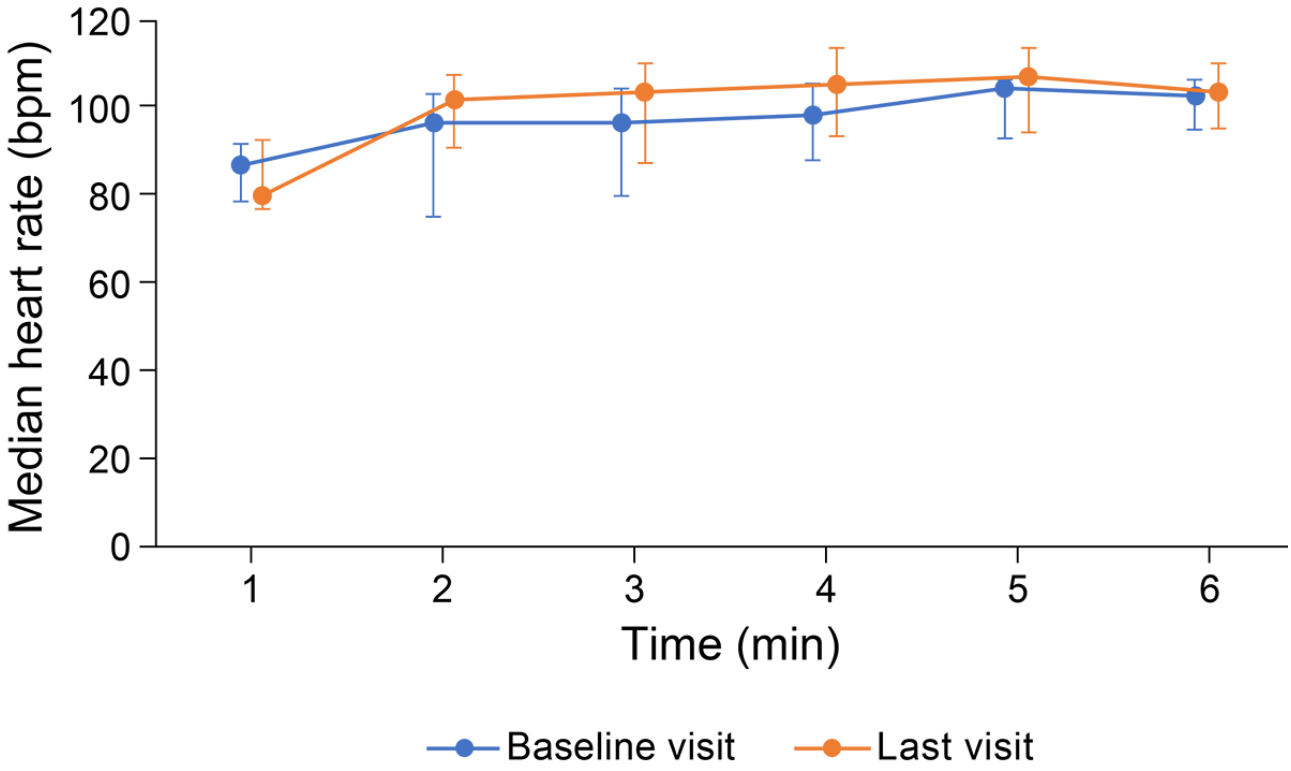

Figure 3. Heart rate recovery data collected by smartwatch at the end of the 6-minute walk distance (6MWD) test before (baseline) and under (last visit) inhaled iloprost therapy. Error bars show IQR.

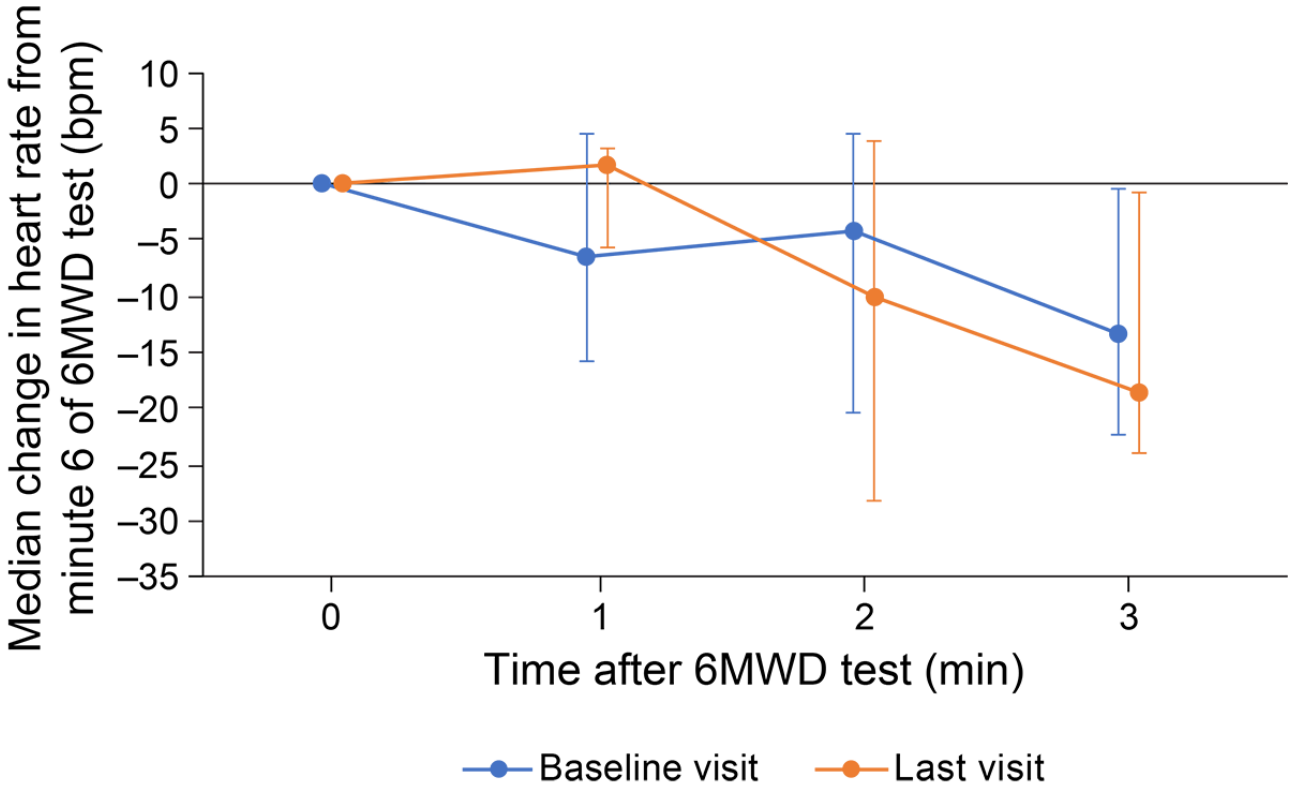


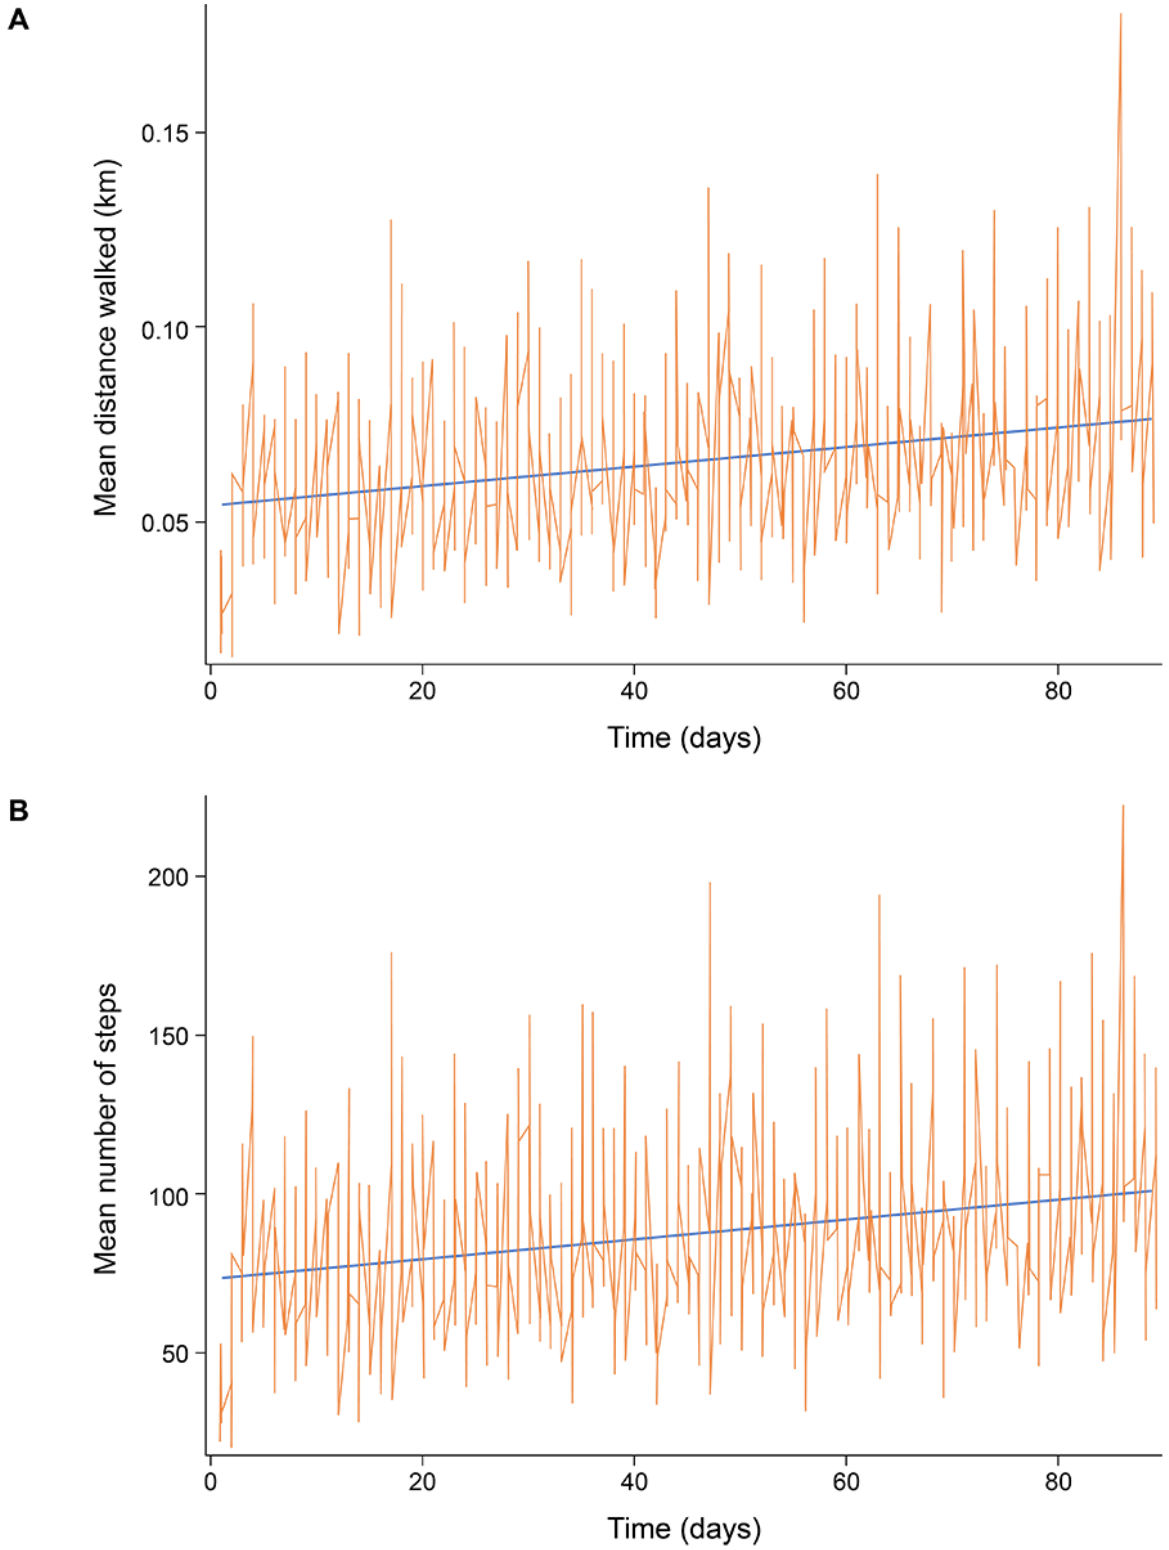
Inhalation and Changes in Heart Rate and Physical Activity

The study design enabled parallel digital tracking of iloprost inhalation, heart rate, and physical activity. An analysis of patients stratified by the median duration of iloprost inhalation and treatment month suggested that the average heart rate during iloprost inhalation showed a slight increase with duration of inhalation (Multimedia Appendix 6). Owing to large differences

in subgroup size, no clear trend for the change in average heart rate during treatment could be detected.

Distance walked (measured digitally) showed a short-term increase in activity shortly after inhalation and a long-term increase in activity over the entire observation period (Figure 4A). A similar association was observed for the number of steps (Figure 4B) but was not observed for the number of standing-up events (not shown).

Figure 4. (A) Distance walked and (B) number of steps (measured at 15-minute intervals for 3 hours after the end of each iloprost inhalation session) over the whole observation period.



For each iloprost inhalation session per day, 12 intervals (of 15 minutes) beginning at the end of the inhalation session were defined, and the distance walked per interval was recorded. The corresponding intervals for each inhalation per day were averaged for each patient (ie, the first intervals after the inhalations were averaged, then the second intervals after the

inhalations, etc) The resulting 12 average values for each patient each day were then averaged over all patients. Complete and incomplete inhalations were included. Approximately 3700 inhalations were excluded from the analysis because the watch was not worn over the entire period of 3 hours after the end of inhalation. Some of the 3-hour intervals were overlapping. The coverage for the first analyzed 15-minute interval of each inhalation could be less than 100%, which occurred about 40 times. Within 1 day, the intervals after the inhalations were not distributed equally over the day.

Additional Analyses

In regression analyses, the change from baseline in traditional 6-minute walk distance was associated with changes in digital outcomes (distance walked, number of standing-up events, and digital 6-minute walk distance). Absolute measurements of traditional and digital 6-minute walk distance were strongly correlated but not congruent at baseline (r=0.86) and at the final visit (r=0.87). Further details of these and other additional analyses are presented in Multimedia Appendix 7.

Discussion

Feasibility of Digital Monitoring

To the best of our knowledge, this study is the first to monitor physical activity and heart rate using iPhones and Apple Watches in patients with pulmonary arterial hypertension. The results demonstrate the feasibility of using digital parameters as digital biomarkers for long-term activity levels in patients with pulmonary arterial hypertension. Despite the fact that patients were blinded to smartwatch-collected data, acceptance was good—almost 90% wore the smartwatch for at least 6 hours per day at baseline (16/18, 89%) and for the end of the observation period (16/18, 89%). Although correlations between changes in digital and traditional clinical outcome measures were few, the overall directions of those changes were generally concordant. The results also demonstrated the feasibility of continuously measuring multiple digital parameters (eg, inhalations, heart rate, and physical activity) in parallel with different devices and matching the data. We were able to detect short-term increases in physical activity after each iloprost inhalation session with fine granularity. The results also highlighted some important challenges and limitations that should be considered for future digital studies in patients with pulmonary arterial hypertension.

Recruitment was limited by a lack of available patients, which resulted in a small study population. This could be partly due to the rarity of pulmonary arterial hypertension [17], the willingness of patients to undergo digital monitoring, and the suitability of the study devices for the patients [14]. Nevertheless, data were fully available in the full analysis set for most outcome variables. Thus, reasonable precision was obtained for most correlation coefficients in the primary endpoint analysis, with the exceptions of BNP and NT-proBNP levels; as no central laboratory facility was used, clinicians generally measured either BNP or NT-proBNP (rather than both) based on local availability, which meant that few patients had data for each individual laboratory parameter.

Comparison Between Clinical and Digital Parameters

Although there was general agreement between changes in digital and traditional parameters from baseline, parallel digital and traditional measurements of 6-minute walk distance were not congruent. The proprietary digital 6-minute walk distance algorithm was based on step count and the step length of healthy individuals, which in general is not valid for patients with pulmonary arterial hypertension. Substitution of the healthy step length with a patient's individualized step length could provide better estimation of distance. The current series of Apple devices includes individual and repeated measurement of step length, which may be used in future studies to better estimate distance. This feature may also enable researchers to characterize other changes in health status (eg, dyspnea) more precisely. Alternatively, measurement of distance by GPS may be suitable if the 6-minute walk distance test can be performed outdoors. Wi-Fi could be a potential alternative to GPS for 6-minute walk distance tests conducted indoors. However, measurement of 6-minute walk distance by GPS or Wi-Fi would require precise location tracking. A feasibility survey suggested that precise tracking on a long-term basis would not be accepted by patients [14]; such tracking would, therefore, need to be restricted to during the 6-minute walk distance test (eg, by designing the 6-minute walk distance app to automatically switch GPS and Wi-Fi tracking on at the start of the 6-minute walk distance test and off at the end of the test).

Previous digital studies [18-22] with patients with pulmonary arterial hypertension have shown mean step counts in the range of 3234 to 5041 and mean traditional 6-minute walk distances in the range of 343 m to 458 m. In comparison, this study population had higher step counts (median 6721 at baseline and 8332 at the end of the observation period) but broadly similar traditional 6-minute walk distance (median 339 m at baseline and 366 m at the final visit). The reasons for this are unclear but may include methodological differences and the small sample size in our study. Patients in previous studies were monitored for only short periods of time (≥3 days [18], ≥3 weekdays [20], 6 days on average [21,22], or 7 days [19]), whereas patients in our study were monitored for 30 to 113 days (including 4-14 days in the baseline period and 8-14 days at the end of the observation period). Studies [23,24] with healthy adults have shown variations in physical activity over the course of a week, with the lowest levels of inactivity occurring on Saturdays. The results in patients with pulmonary arterial hypertension for shorter duration study periods may, therefore, have been influenced by the timing of physical activity monitoring. Mainguy et al [19] evaluated patients for 7 consecutive days but asked them to avoid performing unfamiliar activities during that time; this restriction was not used in our study.

The number of standing-up events is difficult to interpret. In a recent study with patients with pulmonary arterial hypertension, sit-to-stand test results (the number of sit-to-stand movements that patients were able to complete in 30 seconds) were associated with quadriceps muscle strength, which in turn was associated with 6-minute walk distance [25]. An official statement from the European Respiratory Society [26] noted that the sit-to-stand test depends substantially more on muscle

strength, equilibrium, and gait balance than on the mechanisms of oxygen and carbon dioxide transport that are the target of vasoactive pulmonary arterial hypertension treatments. During long-term monitoring, an increase in the number of standing-up events per day could reflect an increase in distance walked or an increase in sitting-down events (in the absence of an increase in activity, the latter would suggest a worsening of the patient's condition). The assessment of standing-up events in patients with pulmonary arterial hypertension is not yet well established, and more data are needed.

The physical activity level may also be influenced by factors other than the severity of pulmonary arterial hypertension (eg, patient preferences, patient behavior, or the season in which the patient was recruited). Nevertheless, daily activity has been linked to prognosis in patients with pulmonary hypertension [27].

The abovementioned limitations provide examples of some of the many criteria that must be fulfilled to ensure a successful digital study. The criteria can be broadly categorized into 6 themes, collectively referred to as the digital real-world evidence matrix: patient (eg, patient willingness to use digital devices and preferences regarding design and features of digital devices), indication (eg, number of available patients and suitability of disease-relevant outcome measures for digital monitoring), biomarker (eg, connection of digital measure to a health-related outcome), type of sensor or device (eg, ease of use, personalization, and data security), quality (eg, accuracy of primary data capture), and endpoint (eg, transformation of sensor data into a meaningful, patient-centered endpoint). These themes were addressed in the design of the VENTASTEP study, which combined digital and traditional monitoring to provide new insights into the real-life treatment of patients with pulmonary arterial hypertension.

Changes in Digital and Traditional Measures After Initiation of Inhaled Iloprost

There was an increase of 26 m for traditional investigator-measured 6-minute walk distance from baseline after addition of inhaled iloprost to oral pulmonary arterial hypertension therapy, which is consistent with the results of previous clinical trials [10,11]. The increase in traditional 6-minute walk distance was accompanied by changes in other traditional parameters and digital measures of daily physical activity.

6-Minute walk distance assessed during an office visit may be affected by daily fluctuations in physical function and may not accurately capture long-term changes in symptoms and physical function. Furthermore, the 6-minute walk distance test reflects maximal activity, whereas daily physical activity parameters provide an average of overall activity. Digital monitoring provides new insights into patient activity, with a more complete picture of the patient's health status than traditional 6-minute walk distance alone. For example, the digital data showed that physical activity increased shortly after each iloprost inhalation session. This sheds light on the day-to-day experiences of patients with pulmonary arterial hypertension taking inhaled iloprost and may be helpful information for patients or physicians considering iloprost therapy.

The increase in heart rate during the 6-minute walk distance test was marginally greater at the final visit compared with that the baseline visit, and heart rate recovery time after the 6-minute walk distance test increased. A previous study [28] showed significant associations between the chronotropic response (peak walking heart rate minus resting heart rate) and 6-minute walk distance in patients with pulmonary arterial hypertension, which led Provencher et al [28] to suggest that a lack of chronotropic response may reflect a loss of normal physiological reserve in patients who were more unwell. Preservation of the chronotropic response may therefore be a positive sign. However, given the high variability of heart rate in our study, changes to this parameter cannot be clearly interpreted.

Despite increases in daily physical activity over the course of the study, the EQ-5D weighted index showed little change. The EQ-5D score has produced mixed results in key clinical trials of pulmonary arterial hypertension therapies [9], showing improvements in placebo-controlled trials of sildenafil [29] and tadalafil [30] but not in a placebo-controlled trial of riociguat [31], despite riociguat resulting in patients showing significant improvements in traditional measures such as 6-minute walk distance and WHO functional class. The EQ-5D is a generic instrument [9] and may therefore lack specificity to address the important health-related quality of life issues in pulmonary arterial hypertension [8]. Health-related quality of life may also be influenced by associated comorbidities such as scleroderma, liver cirrhosis, and HIV [32].

Sleep disturbance in patients with pulmonary arterial hypertension has been associated with symptom severity, psychological state, and health-related quality of life [33]. PSQI score showed slight changes in sleep quality from baseline to the final visit. A global PSQI score of 5 has been proposed as a cut-off to distinguish good and poor sleep [34]. Thus, sleep quality in the study group as a whole shifted from poor to good during the course of the study.

Strengths and Limitations

The strengths of this study include its continuous, parallel, digital measurement of inhalation behavior, heart rate, and physical activity over a long observation period. The limitations of this study include its small sample size, insufficient BNP or NT-proBNP data, and the fact that the digital 6-minute walk distance algorithm was based on the step length of healthy individuals rather than that of patients with pulmonary arterial hypertension. A substantial proportion of the study population took concomitant beta-blockers, which should be considered when interpreting the heart rate data.

Implications for Future Research

Further research is warranted to assess the association of iloprost inhalation behavior with changes in digital physical activity measures, traditional clinical measures, and health-related quality of life. The relationship between daily physical activity and traditional 6-minute walk distance requires further exploration. In addition, studies with longer-term follow-up are needed to determine if clinical outcomes (eg, mortality or time to clinical worsening) are better predicted by the change in

traditional 6-minute walk distance or the change in digital 6-minute walk distance over time.

The recruitment difficulties in this study (which focused on a rare disease) suggest that digital monitoring studies may be more feasible in indications with large patient populations, such as heart failure. In addition, most patients were older adults; recruitment may be higher among populations of younger patients who are more familiar with digital technology. Refinement of the digital 6-minute walk distance algorithm for the target patient population is also needed.

Conclusions

Although generalizability is limited because of the small sample size and other limitations, the study demonstrated the general feasibility of performing digital assessments with a commercially available smartwatch and smartphone in patients with pulmonary arterial hypertension. Digital measures of daily physical activity and traditional clinical measures showed concordant changes from baseline after addition of inhaled iloprost to oral pulmonary arterial hypertension therapies. However, the data indicate that activity tracking algorithms validated for healthy people require adaptation for patients with pulmonary arterial hypertension. Further investigations are therefore necessary.

Acknowledgments

This study was funded by Bayer AG and was conducted in collaboration with the suppliers of the patient support program VENTAPLUS (ContraCare GmbH and Vitartis Medical-Services GmbH) and xbird GmbH, which created the study app (for analysis of daily physical activity and heart rate) and the 6-minute walk distance app. Medical writing assistance was provided by Dr. Claire Mulligan (Beacon Medical Communications Ltd) and was funded by Bayer AG.

Conflicts of Interest

Abstract

Background: Continuous positive airway pressure (CPAP) is an effective treatment for obstructive sleep apnea (OSA), but treatment compliance is often unsatisfactory.

Objective: The aim of this study was to assess the effectiveness and cost-effectiveness of an intelligent monitoring system for improving CPAP compliance.

Methods: This is a prospective, open label, parallel, randomized controlled trial including 60 newly diagnosed patients with OSA requiring CPAP (Apnea–Hypopnea Index [AHI] >15) from Lleida, Spain. Participants were randomized (1:1) to standard management or the MiSAOS intelligent monitoring system, involving (1) early compliance detection, thus providing measures of patient's CPAP compliance from the very first days of usage; (2) machine learning–based prediction of midterm future CPAP compliance; and (3) rule-based recommendations for the patient (app) and care team. Clinical and anthropometric variables, daytime sleepiness, and quality of life were recorded at baseline and after 6 months, together with patient's compliance, satisfaction, and health care costs.

Results: Randomized patients had a mean age of 57 (SD 11) years, mean AHI of 50 (SD 27), and 13% (8/60) were women. Patients in the intervention arm had a mean (95% CI) of 1.14 (0.04-2.23) hours/day higher adjusted CPAP compliance than controls (P=.047). Patients' satisfaction was excellent in both arms, and up to 88% (15/17) of intervention patients reported willingness to keep using the MiSAOS app in the future. No significant differences were found in costs (control: mean €90.2 (SD 53.14) (US $105.76 [SD 62.31]); intervention: mean €96.2 (SD 62.13) (US $112.70 [SD 72.85]); P=.70; €1=US $1.17 was considered throughout). Overall costs combined with results on compliance demonstrated cost-effectiveness in a bootstrap-based simulation analysis.

Conclusions: A machine learning–based intelligent monitoring system increased daily compliance, reported excellent patient satisfaction similar to that reported in usual care, and did not incur in a substantial increase in costs, thus proving cost-effectiveness. This study supports the implementation of intelligent eHealth frameworks for the management of patients with CPAP-treated OSA and confirms the value of patients' empowerment in the management of chronic diseases.

KEYWORDS

obstructive sleep apnea; continuous positive airway pressure; patient compliance; remote monitoring; machine learning

Introduction

Obstructive sleep apnea (OSA) is the most prevalent sleep-disordered breathing condition, affecting 15%-30% of adults in Western countries [1]. It is characterized by repetitive episodes of airways collapse during sleep, causing sleep fragmentation, intermittent hypoxia, and daytime somnolence. OSA has been associated with increased morbidity and mortality, and has an impact on quality of life [2]. In this sense, increased inflammation, oxidative stress, sympathetic activation, and hypercoagulability are the main mechanisms associating OSA with hypertension; cancer; and cardiovascular, cerebrovascular, and metabolic diseases [2].

Nocturnal continuous positive airway pressure (CPAP), preventing upper airway collapse during sleep, is the treatment of choice for patients with symptomatic OSA [3]. A satisfactory CPAP compliance (≥4 hours/day) improves daytime sleepiness and overall quality of life; reduces OSA severity markers, such as the Apnea–Hypopnea Index (AHI); moderately decreases arterial blood pressure (BP), mainly in patients with resistant hypertension [3,4]; and contributes to preventing the onset of newly diagnosed hypertension [5]. Compliance is, therefore, essential for the efficacy of CPAP treatment and its optimization is an important aspect of patient management. However, up to one-third of patients underuse or even discontinue CPAP [6-8], mostly because of treatment-related side effects such as machine noise, pressure intolerance, mask displacement, or claustrophobia [9]. In this sense, issues hampering CPAP compliance during the first months of treatment are likely to have a significant impact on long-term CPAP compliance [10]. Therefore, there is a need to implement effective strategies for the promotion of CPAP compliance, especially during the first months of treatment.

So far, interventions tackling CPAP compliance, including novel educational and supportive or therapeutic strategies, have reported low to moderate evidence of success [11,12]. By contrast, when these strategies are wrapped up in comprehensive packages making use of information and communication technologies (eHealth) and targeting the initial months after CPAP prescription, the potential for success can be significantly enhanced [12-14]. In this scenario, and within the frame of the MiSAOS project, an internet of things–based intelligent monitoring system relying on machine learning [15] was developed in Catalonia, Spain, with a fourfold goal: (1) predicting patient's potential early CPAP compliance; (2) providing real-time monitoring of patient's CPAP compliance, informing both the patient and the care team, and granting decision support; (3) empowering the patient by means of feedback and recommendations; and (4) reducing patient's overall management costs. This study compares, in terms of effectiveness and cost-effectiveness, the MiSAOS intelligent monitoring system model, based on early compliance detection, compliance prediction, and rule-based recommendations, with the usual care provided to patients using CPAP in the region of Lleida, Catalonia.

Methods

Study Design

This is a prospective, open label, parallel, randomized controlled trial comparing the MiSAOS management model with care as usual for a duration of 6 months after CPAP prescription (ClinicalTrials.gov NCT03116958). The study was conducted from November 2016 to December 2017 in Lleida, Catalonia. Multimedia Appendix 1 shows the CONSORT checklist of this study.

Target Population

Eligible population included patients with OSA (AHI ≥15) being newly diagnosed in the sleep unit of University Hospital Santa Maria, Lleida, and requiring CPAP treatment according to the Spanish Respiratory Society (SEPAR) guidelines [16]. The specific eligibility criteria were aged over 18 years; having a sufficient competence in the use of smartphones; not having been previously treated with CPAP; not having impaired lung function (overlap syndrome, obesity hypoventilation syndrome, and restrictive disorders), severe heart failure, severe chronic pathologies, psychiatric disorders, or periodic leg movements or other dyssomnias or parasomnias; and not being pregnant.

Sample Size

Accepting an α risk of .05 and a β risk of .2 in a 2-sided test, 29 patients per study arm were needed to recognize as statistically significant a difference in compliance greater than or equal to 1 hour/day. The common SD was assumed to be 1.35, based on previous research of the group.

Recruitment, Randomization, and Intervention

Patients were recruited in the sleep unit and randomized (1:1) to receive 6 months of either MiSAOS or usual care management. Patients in the usual care arm were managed according to the SEPAR guidelines [16]. Randomization was based on a permuted-block design with a computer random number generator and a fixed block size of 4. Patients were fitted with a mask and given a CPAP device (AirSense 10;

ResMed) and a leaflet explaining how to use it. A short training session on how to use the CPAP device was also given to patients and partners in the sleep unit by a trained nurse with experience in the follow-up of CPAP-treated patients. This included a practical demonstration of how to put on the mask, and the correct management and cleaning of the tubes, mask, and humidifier. Information on how to turn the CPAP device on and off was provided by the homecare provider at the time of machine delivery. According to SEPAR recommendations, patients were visited after 1 month of treatment by the specialist nurse at the sleep unit. Information about CPAP, compliance (use of CPAP for ≥4 hours/day), residual respiratory events, and leaks was downloaded from the device. CPAP-related side effects, CPAP machine care and maintenance actions (ie, changes of mask), and the number of required additional visits or calls were recorded by the nurse.

Similarly, patients in the MiSAOS arm were fitted with a mask, a CPAP device (AirSense 10; ResMed), and given a leaflet explaining its use. Patients received the same training sessions from the same personnel as in the usual care arm. However, these patients' CPAP devices were equipped with mobile 2G (global systems for mobile/general packet radio service [GSM/GPRS]) technology capable of sending daily information on CPAP compliance, CPAPs, mask leaks, and residual respiratory events to the MiSAOS–Oxigen salud web database. In addition, patients in the MiSAOS arm had access to an integrated platform including a website [17] and a mobile app (MiSAOS; available for both Android and iOS), benefitting from continuous monitoring and personalized feedback. Sample screenshots of the MiSAOS app showing its main functionalities and features are presented in Multimedia Appendix 2. Similarly, sample screenshots of the MiSAOS website showing some of its functionalities and features are presented in Multimedia Appendix 3. Hospital lung specialists managing these patients and the CPAP provider (Oxigen salud) also had access to the MiSAOS website that provided relevant information and decision support according to the specific role and access rights of each professional user. Finally, the cloud-based MiSAOS platform connected all the devices for data exchange and hosted an intelligent monitoring system, based on machine learning, capable of predicting the expected compliance with the therapy by a given patient, thus providing adequate feedback and proposing personalized interventions to increase compliance [15,18]. Predictions of patient's midterm compliance were based on patient's characteristics, such as anthropometric data and clinical information, and early compliance data. Examples of the needed information and provided outcome can be found in Multimedia Appendix 3. Based on these predictions, patients were classified into 2 groups: low compliance and medium/high compliance, and recommendations were provided based on these classes. In brief, recommendations included warnings and exhortation to do better in case of low compliance, or positive reinforcement messages in case of good compliance, highlighting the key areas to be improved regardless of the compliance. This platform was also used for the monitoring of patient compliance, prompting actions when compliance was too low.

Data Collection

Baseline information was collected by sleep unit personnel during recruitment, regardless of the study arm. This included age; gender; socioeconomic level; Epworth Sleepiness Scale (ESS) score; EuroQoL-5D quality of life (EQ-5D); lifestyle habits (tobacco and alcohol consumption); comorbidities; use of medications; weight; height; BMI; neck, waist, and hip circumference; and BP. Variables of the sleep study were also recorded and included registration time, sleep duration, AHI, and percentage of nighttime spent with an oxygen saturation less than 90%.

At 3 and 6 months all patients, regardless of the study arm, were visited at the sleep unit. Patients were checked about progress and compliance with therapy and any problems with their CPAP machine. During these visits we collected data on treatment compliance (number of hours/day), ESS score, OSA-related symptoms, EQ-5D, BP, and anthropometric variables. Additionally, data on CPAP, residual respiratory events and leaks, CPAP-related side effects (mask allergies and skin irritations, dry mouth, congestion, runny nose, sneezing, sinusitis, nosebleeds, and discomfort), overall satisfaction with the therapy (questionnaire), CPAP machine care and maintenance actions (ie, changes of mask), and the number of any additional visits and calls required by the patient during the follow-up were collected. Finally, costs for each component, use of services, and visits were computed based on standard prices of the CPAP provider and on Catalan Health Department official data (CVE-DOGC-A-13051031-2013) [19]. Only direct costs were considered.

Statistical Analyses

A *t* test, or an equivalent nonparametric test, or chi-square test was used for baseline bivariate analyses, depending on variables' characteristics. Differences in the primary and secondary outcomes between the intervention and control groups at 6 months were assessed using ordinary least-squares linear models. All models were adjusted by age, and models for secondary outcomes were further adjusted by the baseline values. A 2-sided *P* value and 95% CI were used. The cost-effectiveness analysis was performed using the total costs for each arm based on intervention effectiveness (CPAP treatment compliance). A probabilistic sensitivity analysis was performed using the bootstrap method, which was represented in a cost-effectiveness plan.

The primary and secondary analyses were performed on both the intention-to-treat (ITT) and per-protocol (PP) samples. The ITT sample included all the patients who were randomized. The PP sample excluded the patients who were lost during the follow-up period. Missing data were imputed using multiple imputation consisting of chained equations, for which 10 complete databases were checked. The R package "mice" was used for these calculations. All statistical analyses and data processing procedures were performed using R software, version 3.4.4 (The R Foundation).

Ethical Considerations

This study was approved by the Ethics Committee of Hospital Arnau de Vilanova (CEIC-1283) and all patients provided

written informed consent. This project was registered in ClinicalTrials.gov (registration number NCT03116958).

Results

A total of 60 patients were randomized to receive either MiSAOS (intervention; n=30) or usual care (control; n=30) management, and up to 53 patients completed the study (Figure 1). Patients' baseline characteristics in both study arms are presented in Table 1, which show that only age was statistically different among groups.

Table 2 shows the primary and secondary outcomes of the trial according to an ITT analysis. After 6 months, the mean (95% CI) CPAP compliance was 4.89 (4.05-5.72) hours/day in the control group and 5.79 (5.20-6.38) hours/day in the intervention group, with an adjusted difference of 1.14 (0.04-2.23; *P*=.047) hours/day in benefit of intervention. Furthermore, the intervention arm had a higher proportion of patients with good compliance (use of CPAP for ≥4 hours/day) than the control arm (88.5% [23/26] vs 70.4% [19/27], respectively; *P*=.20), although this did not achieve statistical significance. Regarding secondary outcomes, ESS, BP, and the EQ-5D visual analog scale scores improved after 6 months of CPAP treatment in both arms, although the change in systolic BP was significantly higher in patients in the control arm than in those in the intervention arm (adjusted *P*=.04). Results on a PP approach were similar and are shown in Multimedia Appendix 4.

[a]Ordinary least-squares linear models adjusted by age and baseline value.

[b]ESS: Epworth Sleepiness Scale.

[c]EQ-5D: EuroQoL-5D quality of life.

[d]HUI: health utility index

[e]VAS: visual analog scale.

Patients' satisfaction with the management of their illness was excellent in both study groups (Table 3). Similarly, no differences were found in the occurrence of CPAP-related side effects. Finally, all patients in the intervention group reported the MiSAOS app to be useful; 94% (16/17) of patients reported that it was easy to use, and 88% (15/17) of patients reported the willingness to continue to use it in the future (Table 3).

Table 3. Overall patients' satisfaction and satisfaction with MiSAOS (N=45).[a]

Users' satisfaction	Control (n=26)	Intervention (n=19)	*P* value
Overall satisfaction			
The follow-up I received was sufficient to manage my health and medical needs			
Agrees/strongly agrees, n (%)	26 (100)	19 (100)	
Overall score (1-7), mean (SD)	6.38 (0.80)	6.53 (0.61)	.51
In general I am satisfied with the management of my illness			
Agrees/strongly agrees, n (%)	26 (100)	19 (100)	
Overall score (1-7), mean (SD)	6.62 (0.57)	6.53 (0.61)	.62
My contact with the hospital was sufficient			
Agrees/strongly agrees, n (%)	26 (100)	18 (95)	
Overall score (1-7), mean (SD)	6.62 (0.64)	6.21 (1.62)	.31
Satisfaction with MiSAOS (intervention only) (n=17)			
The app was useful			
Agrees/strongly agrees, n (%)		17 (100)	
Overall score (1-7), mean (SD)		6.53 (0.72)	
The app was easy to use			
Agrees/strongly agrees, n (%)		16 (94)	
Overall score (1-7), mean (SD)		6.41 (0.87)

[a]The overall satisfaction questionnaire was answered by 26 controls and 19 intervention participants. The satisfaction with MiSAOS questionnaire was answered by 17 participants.

Table 4 shows the costs of the intervention, costs of contacts with the CPAP provider and health system (not including the baseline, 3-month, and 6-month visits, as all patients regardless of study arm did them), and costs of any CPAP machine care and maintenance intervention actions (ie, changes of mask) during the 6 months of follow-up. The overall mean cost per patient was €90.2 (SD 53.14) (US $105.76 [SD 62.31]) in the control group and €96.2 (SD 62.13) (US $112.70 [SD 72.85]) in the intervention group, resulting in a nonsignificant cost difference between arms (*P*=.70). The main differences between arms were €49.5 (US $58.04) of the intervention costs (2G [GSM/GPRS] daily data transfer and activation and maintenance

costs) in the MiSAOS arm, and the €41 (US $48.07) on sleep unit visits in the usual care arm. This overall cost, combined with the results on CPAP treatment compliance (primary outcome), demonstrated cost-effectiveness in a bootstrap-based simulation analysis (Figure 2).

Table 4. Within-trial intervention and follow-up costs (average cost per randomized patient; N=60).

Concept	Control (n=30), €[a]/patient, mean (SD)	Intervention (n=30), €/patient, mean (SD)	Difference, mean (95% CI)
Intervention costs[b]			
2G (GSM[c]/GPRS[d]) daily data transfer	0 (0)	41.5 (0)	–41.5 (—)
Activation and maintenance	0 (0)	8 (0)	–8 (—)
Follow-up costs			
Sleep unit visits and consultations[e]	41 (0)	0 (0)	41 (—)
CPAP[f] provider visits and consultations[g]	9.7 (8.9)	10.0 (10.8)	–0.33 (–5.5 to 4.8)
Changes in CPAP device components[h]			
ResMed Mirage Quattro	12.5 (28.4)	10.0 (32.6)	2.5 (–13.3 to 18.3)
ResMed Mirage FX	0.8 (4.4)	3.2 (8.3)	–2.4 (–5.9 to 1.1)
ResMed Mirage Micro	0 (0)	1.1 (4.1)	–1.07 (–2.6 to 0.4)

Total	90.2 (53.1)	96.2 (62.1)	–6.0 (–35.9 to 23.9)

[a]€1 = US $1.17.

[b]Estimated costs supplied by the CPAP provider: 2G (GSM/GPRS) daily data transfer (€83 [US $97.32]/year); activation and maintenance (€16 [US $18.76]/year).

[c]GSM: global systems for mobile.

[d]GPRS: general packet radio service.

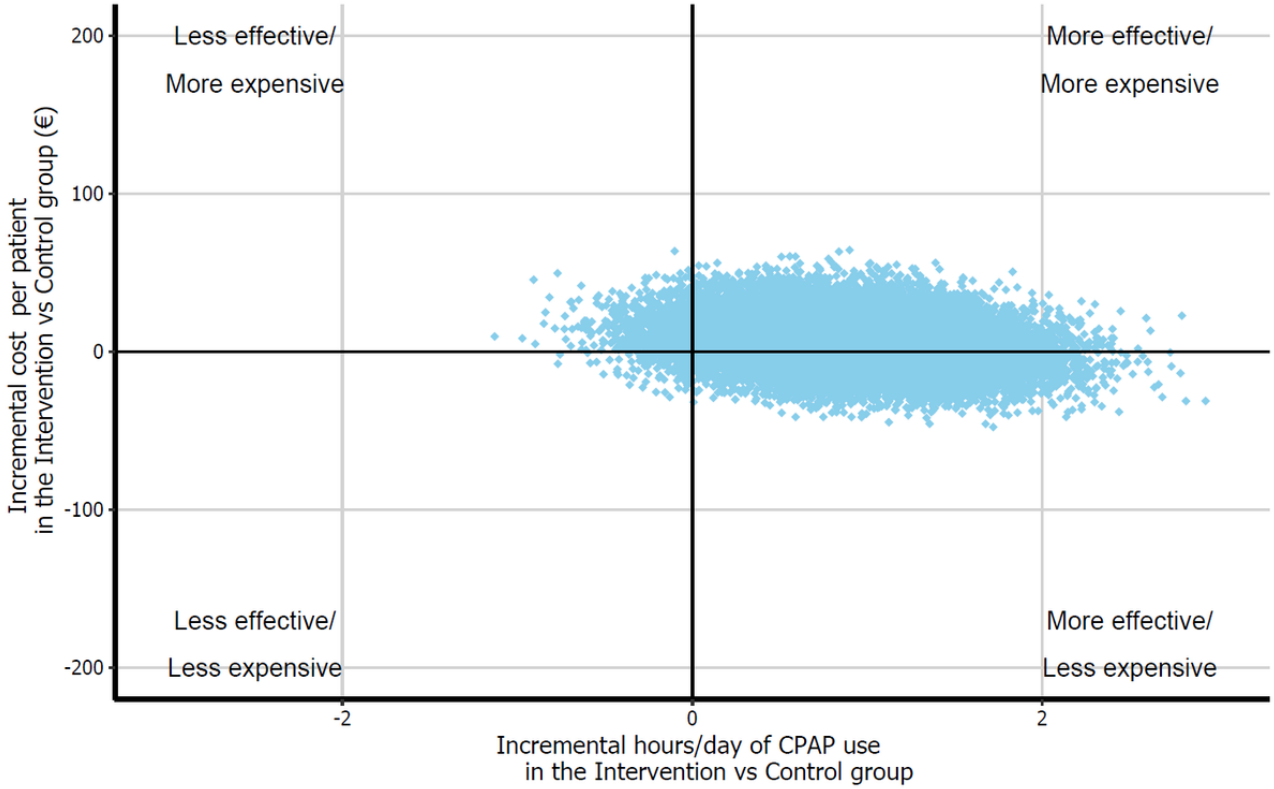
[e]Not including the baseline, 3-month, and 6-month visits, as all patients did them regardless of study arm. Costs based on the Catalan Institute of Health (CVE-DOGC-A-13051031-2013): sleep unit visits and consultations (€41 [US $48.07]/contact).

[f]CPAP: continuous positive airway pressure.

[g]Commercial costs supplied by the CPAP provider: CPAP provider visits and consultations (€10 [US $11.73]/contact).

[h]Commercial costs supplied by the CPAP provider: ResMed Mirage Quattro (€75 [US $87.94]/unit); ResMed Mirage FX (€24 [US $28.14]/unit); ResMed Mirage Micro (€16 [US $18.76]/unit); ResMed Swift FX (€45 [US $52.76]/unit); ResMed Airfit P10 (without headgear) (€40 [US $46.90]/unit); Philips Respironics Nuance gel (€73.5 [US $86.18]/unit); ResMed Airfit F10 (€75 [US $87.94]/unit); ResMed Airfit P10 (with head-gear) (€45 [US $52.76]/unit); SleepNet IQ (€22 [US $25.80]/unit); SleepNet Ascend (€24 [US $28.14]/unit); Philips Respironics Amara View (€50 [US $58.63]/unit); Philips Respironics Comfort Gel Blue (€30 [US $35.18]/unit).

Figure 2. Cost-effectiveness analysis based on treatment compliance (CPAP hours/day) and total costs for each arm, performed using a bootstrap probabilistic sensitivity analysis. CPAP: continuous positive airway pressure.



Discussion

Principal Findings

This study is the first randomized controlled clinical trial assessing the effectiveness and cost-effectiveness of a machine learning–based intelligent monitoring system aiming to improve CPAP compliance in patients with OSA. The MiSAOS intelligent monitoring system, based on early compliance detection, compliance prediction, and rule-based recommendations, was compared with usual care in the region of Lleida, showing a mean increase of 1.14 hours in daily compliance with no substantial differences in direct costs and an excellent patient satisfaction. This novel management system proved to be cost-effective and thus a viable option for the management of patients with OSA treated with CPAP.

Strengths and Limitations

This study has several strengths, including the (1) use of the same CPAP devices in both study arms; (2) use of an intelligent monitoring system model, based on early compliance detection, machine learning–based compliance prediction, and rule-based recommendations; (3) inclusion of continuous patient feedback through an app; (4) measurement of a broad range of effect measures (ie, compliance, changes in symptoms, and changes in quality of life); (5) assessment of patient comfort and satisfaction; and (6) inclusion of cost and cost-effectiveness analyses. Nevertheless, there are also some limitations to be acknowledged: (1) the slight infraestimation of the required number of study participants limited the statistical power of some of the between-arm comparisons, although this did not affect the results on the primary outcome and cost-effectiveness analysis; (2) the assessment of patient satisfaction was performed using a nonvalidated questionnaire; (3) the exclusion of patients with severe chronic pathologies and other dyssomnias or parasomnias could limit the generalizability of our results, although the included patients would be the ideal target for eHealth interventions as more complex patients could require a close follow-up in the sleep units; (4) the results of cost analyses are highly dependent on the characteristics of the health care setting in which they are conducted and, thus, extrapolation of the results to different settings should be done cautiously; and (5) the follow-up period does not allow the extrapolation of results to the long term.

Comparison With Existing Literature

Patients experiencing the MiSAOS intelligent monitoring system showed a mean increase of 1.14 hours in daily CPAP compliance when compared with patients in usual care. This result is more positive than the mean (95% CI) increase of 0.54 (0.29-0.79) hours reported by Aardoom et al [14] in a 2020 meta-analysis including 18 studies with eHealth interventions. Other recent studies exploring advanced monitoring systems have shown similarly inferior results, for instance, Pépin et al [20] reported a 0.53 hours' increase in CPAP compliance in patients with OSA with high cardiovascular risk using a multimodal telemonitoring intervention. Interestingly, granting patients an easy access to their compliance data has shown successful results in terms of increasing patient compliance [21-23]. Therefore, the combination of an intelligent machine learning–based monitoring system with the empowerment of patients, based on access to daily compliance and personalized feedback through an app, could represent a significant step forward in the promotion of CPAP compliance.

The impact of the CPAP treatment on secondary outcomes in the MiSAOS intervention was very similar to that achieved in usual care and reports in previous literature [12,20]. Sleepiness, overall quality of life, and BP improvements after 6 months of follow-up were similar in both study arms. The only difference between study arms was the significantly higher decrease in systolic BP in patients having usual care, which could be easily explained by the baseline differences in BP between study arms.

Patient's comfort and satisfaction are key drivers of compliance with CPAP treatment in the long term [9]. On the one hand, regarding comfort, the number of side effects in both arms was very similar. On the other hand, it must be noticed that in telemedicine interventions patients' satisfaction is usually similar to or lower than that of usual care [12], with privacy concerns being the main reported issue [24,25]. In this trial, all patients reported excellent satisfaction with their management, regardless of the study arm. Moreover, patients in the intervention group considered the MiSAOS app as useful and easy to use and reported their willingness to keep using it in the future. These results are better than those obtained in telemonitoring interventions in the same setting (Lleida, Spain) but not providing any direct feedback to the patients [25] and confirm that patient empowerment has a direct impact on patient satisfaction. Finally, potential issues on data privacy had no impact on the current trial results, in contrast to previous research [25], and in line with other interventions providing the patients with regular feedback on compliance [21].

A key aspect of any new management strategy is the cost of the intervention and its cost-effectiveness. In this study, the analysis of costs and cost-effectiveness showed that the MiSAOS intervention had an overall cost similar to that of usual care while providing better results in terms of treatment compliance, thus demonstrating cost-effectiveness. This result is in contrast to previous cost-effectiveness trials of telemonitoring interventions for CPAP-treated patients in Spain, where cost-effectiveness was demonstrated because of an overall reduction in costs and no significant differences in effectiveness were found [25,26]. Similarly, telemedicine platforms with automated functions to provide education or accountability have already shown cost-effectiveness in sleep medicine [23]. This suggests that the addition of machine learning data–processing functionalities together with the empowerment of patients by means of direct feedback could tip the scales toward significant increases in compliance and boost the cost-effectiveness of already existing telemonitoring interventions. Moreover, it should be noticed that a key factor of telemonitoring is the reduction in the number or duration of follow-up visits, which was quantified by Anttalainen et al [27], reporting a saving of 19 minutes in nursing time when comparing telemonitoring with usual care in the habituation phase of CPAP treatment (4 weeks) [27], and should be sufficient to mitigate the costs of telemonitoring.

Implications for Future Clinical Practice

As previously stated, the main barriers for the large-scale implementation of a novel management intervention are its costs and cost-effectiveness. In the optimal scenario, a novel management strategy should be cheaper than usual care while providing better results. The MiSAOS model has shown the potential to generate better results than usual care in terms of compliance. However, it was not cheaper than usual care. It is worth mentioning that a big proportion of the intervention's cost corresponded to the use of a 2G (GSM/GPRS) system for daily CPAP compliance data transfer. This technology could be easily replaced by a secure wireless connection to the patients' home Wi-Fi network, which would represent a huge saving and further boost cost-effectiveness. Even in rural areas such as Lleida, this scenario is rapidly becoming a reality and most homes have a suitable Wi-Fi network.

Conclusion

The use of a machine learning–based intelligent monitoring system increased daily compliance, reported an excellent patient satisfaction similar to that reported in usual care, and did not incur in a substantial increase in costs, thus proving cost-effectiveness. This study supports the implementation of intelligent eHealth frameworks for the management of patients with OSA treated by CPAP and confirms the value of patients' empowerment in the management of chronic diseases.

Acknowledgments

This work is part of the myOSA project (RTC-2014-3138-1), funded by the Spanish Ministry of Economy, Industry and Competitiveness (Ministerio de Economía, Industria y Competitividad) and Agencia Estatal de Investigación, under the framework "Retos-Colaboración", State Scientific and Technical Research and Innovation Plan 2013-2016. The work was cofunded by the European Regional Development Fund (ERDF), "A way to make Europe". JdB acknowledges receiving financial support from the Catalan Health Department (Pla Estratègic de Recerca i Innovació en Salut [PERIS] 2016: SLT002/16/00364) and Instituto de Salud Carlos III (ISCIII; Miguel Servet 2019: CP19/00108), co-funded by the European Social Fund (ESF), "Investing in your future". Funding organizations had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

Authors' Contributions

CT, EV, JB, FB, and JdB participated in the conceptualization of project. CT, AL, LP, RV, and AC conducted data collection. CT, IB and AM-M participated in data curation. IB conducted all statistical analyses. CT, IB, and JdB wrote the original draft of the manuscript. All authors reviewed the final manuscript. JB and FB secured funding for the project.

Abstract

Background: Owing to the COVID-19 pandemic, social distancing has become mandatory. Wireless endoscopy in contactless examinations promises to protect health care workers and reduce viral spread.

Objective: This study aimed to introduce a contactless endoscopic diagnosis system using a wireless endoscope resembling a mask.

Methods: The Wi-Fi–based contactless mask endoscopy system comprises a disposable endoscope and a controller. First, the effective force applied by the tip during insertion was evaluated in a simple transoral model consisting of a force sensor on a simulated oropharynx wall. Second, the delay in video streaming was evaluated by comparing the frame rate and delays between a movement and its image over direct and Wi-Fi connections. Third, the system was applied to a detailed laryngopharyngeal tract phantom.

Results: The smartphone-controlled wireless endoscopy system was successfully evaluated. The mean, maximum, and minimum collision forces against the wall of the transoral model were 296 mN (30 gf), 363 mN (37 gf), and 235 mN (24 gf), respectively. The delay resulting from the wireless connection was 0.72 seconds. Using the phantom, an inexperienced user took around 1 minute to orient the endoscope to a desired area via the app.

Conclusions: Device articulation does not pose a significant risk of laryngopharyngeal wall penetration, and latency does not significantly impede its use. Contactless wireless video streaming was successful within the access point range regardless of the presence of walls. The mask endoscope can be controlled and articulated wirelessly, minimizing contact between patients and device operators. By minimizing contact, the device can protect health care workers from infectious viruses like the coronavirus.

Introduction

With the recent outbreak of COVID-19, the importance of quarantine and contact reduction has increased. Social distancing has become mandatory to lessen the impact of the outbreak and prevent the further spread of the virus, because increased contact with infected individuals drastically increases the possibility of infection. Those who work in the medical field are at particularly high risk of exposure. According to Nguyen et al, front-line health care workers are 4 to 10 times more likely to get the disease in the United States and the United Kingdom [1].

To protect health care workers and prevent further spread of the coronavirus, contactless examination has emerged. For contactless examination and treatment, governments worldwide have started implementing various contactless infrastructure and devices. For example, South Korean health care service workers use walk-through screening centers for examination [2]. Separated by a box, respiratory splash is completely prevented with a negative pressure applied inside the booth. Experts speculate that even after the pandemic ends, with COVID-19 being eradicated or neutralized like the common cold, there will always be a possibility of another pandemic [3]. Therefore, requirements for contactless devices will persistently rise after 2021 for all medical procedures that include the risk of possible viral infection, and endoscopy will not be an exception.

The endoscope is widely accepted as an examination device for a wide range of diseases. Starting as a rigid bronchoscope, over 100 years of development have enabled endoscopes to become flexible, therefore enhancing both patient experience and accessibility to internal organs [4,5]. However, in a pandemic, even a simple endoscopy can be a serious threat to patients. According to Kovaleva et al, several microorganisms can be transferred from one patient to another during endoscopy [6]. Most infections are via direct contact with incompletely disinfected devices, but viruses and other microorganisms can be transferred by not only an infected endoscope but also aerosols generated during the procedure [7]. Especially for highly infectious diseases like COVID-19, the entire facility involved in endoscopy can be at risk. To minimize contact with patients who undergo endoscopy, several prevention methods have been suggested, from minimizing the practice of endoscopy itself [8] to completely covering patients with protective sheets. However, since endoscopy has to be performed right beside the patient, it does not afford the same degree of safety to health care workers.

Wireless endoscopy has been around for a while, but has never been practically used. Most wireless endoscopes are capsule endoscopes, whose purpose is to specifically record the gastrointestinal tract, usually with control of the magnetic force applied from the outer belt patients are asked to wear [9]. There are several reasons wireless endoscopy is not favored over traditional, wired endoscopy, such as battery depletion and a low data transfer rate. If the endoscope is flexible, flexibility is usually manifested by tension applied to the string attached to a motor, transforming the position of individual segments of the continuum robot. The endoscope can be controlled directly using the controller attached to the motor. There is no reason to split the flexible endoscope into 2 parts and, therefore, discard the wired endoscope over the wireless endoscope, unless the desired area is too deep for the cable to reach. However, in dire situations when a contactless procedure should be the new norm, a wireless endoscope with articulation can be a huge advantage over a wired endoscope.

In this study, we introduced a novel, contactless endoscopic diagnosis system resembling a mask, enabling users to put it on easily themselves. The newly designed continuum part comprises 2 articulating units rolled into the device and sliding out when needed. While the distal tip unit freely articulates in the direction the user desires, the proximal tip holds down the user's tongue, providing a better endoscopy experience. The endoscope unit is controlled by a mobile app, over a Wi-Fi connection. Once the patient wears the device, the system enables the operator to perform endoscopy without direct contact with the patient.

Methods

Development of a Wi-Fi–Based Contactless Mask Endoscope

We built a Wi-Fi–based contactless mask endoscopic system. Figure 1 depicts the overall scheme of how a Wi-Fi–based contactless mask endoscope works in the field. The device comprises 2 parts, a disposable endoscope and a controller. The disposable endoscope captures and transmits digital visual data to the controller. The controller comprises a continuum segment, motors, and a microprocessor. The controller and the operator's Android mobile device are connected over a wireless network. The controller is responsible for articulation of the disposable endoscope and transmits visual data obtained from the endoscope to the connected mobile device. On the operator's side, a specific app for the endoscope helps the operator interface with the device using a wireless connection. The app receives real-time visual data from the device, while it sends control data to the device. The communication was based on the connection between electrical components. Figure 2 describes the connection and general flow of data and electricity in the Wi-Fi–based contactless mask endoscope.

Being a portable device, the contactless mask endoscope draws electricity from a rechargeable lithium battery. Raspberry Pi Zero W, a microprocessor containing a Wi-Fi module and memory sufficient enough to serve as a simple Wi-Fi server, is the center of the device. The device is connected to 5 motors, which also draw electricity from the battery. The endoscope module is a separate pluggable module that can be unplugged for maintenance and cleaning. Connected to the endoscope control board, Raspberry Pi Zero W receives real-time video signals from the endoscope module. To communicate with each other, Raspberry Pi Zero W and the operator's Android tablet are connected within the same network. The touch-based input of the app is converted into a directional signal in the app and sent to Raspberry Pi Zero W to manipulate the continuum segment.

The detailed Wi-Fi communication flow is described in Figure 3. Both the smartphone app and the device are booted, and they are manually connected to the same network. When the Wi-Fi connection is secured, the server is automatically started in the endoscope, while the app waits for the server connection. When the server successfully starts, it immediately starts to stream video information, while listening for directional button input from the client app. The client app starts to receive the video stream and readies to send a motor signal to the endoscope server. At this point, the user can easily send a direction-steering signal to the server by pressing the directional button on the app user interface. The app saves a snapshot and the video stream, without affecting the video stream. If the Wi-Fi connection is severed, the app and server revert to the waiting stage. If the user stops the session, the app is safe to turn off.

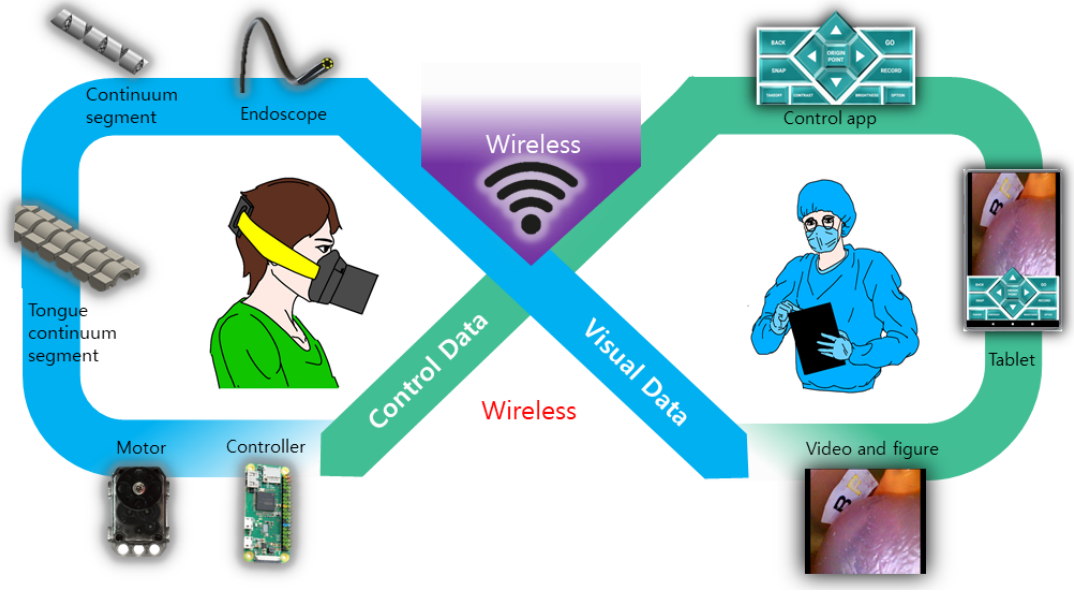

Figure 2. Electric wiring and key function of the Wi-Fi–based contactless mask endoscopic system. GND: ground; IDC: insulation-displacement contact.

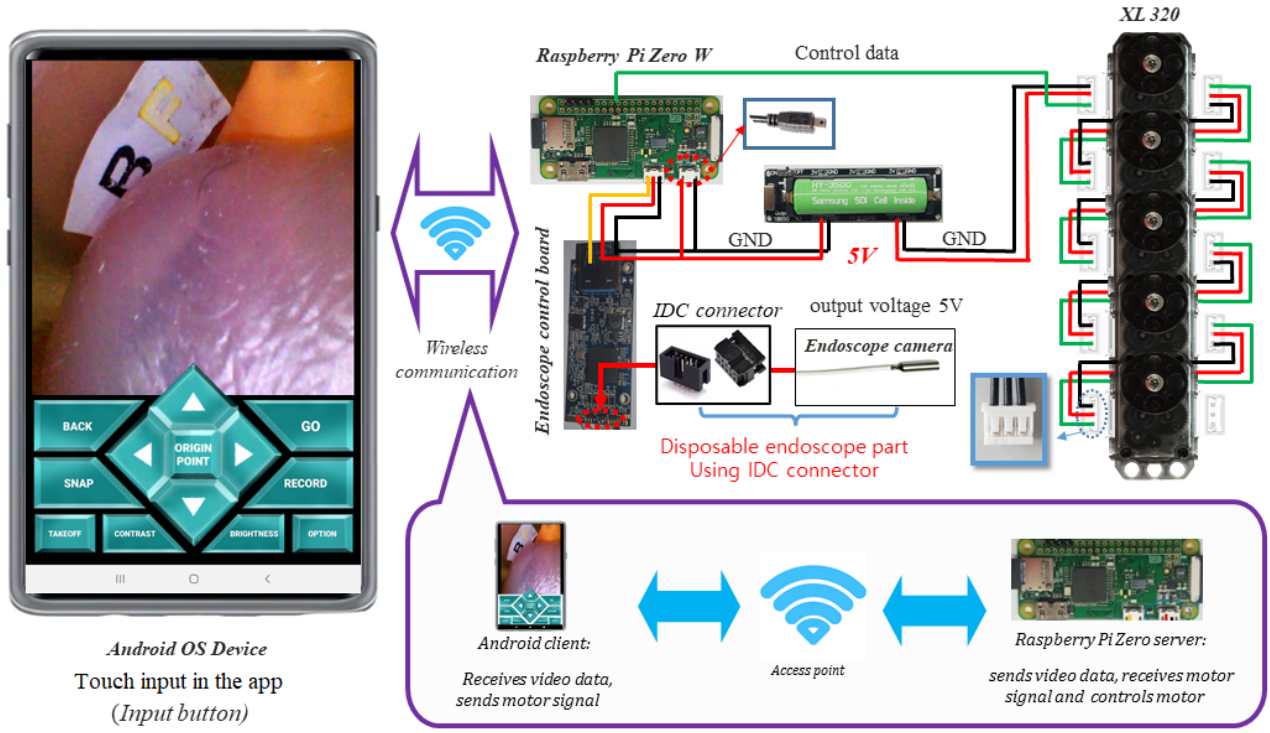

Figure 3. Flowchart of the software part of the Wi-Fi–based contactless mask endoscopic system in action.

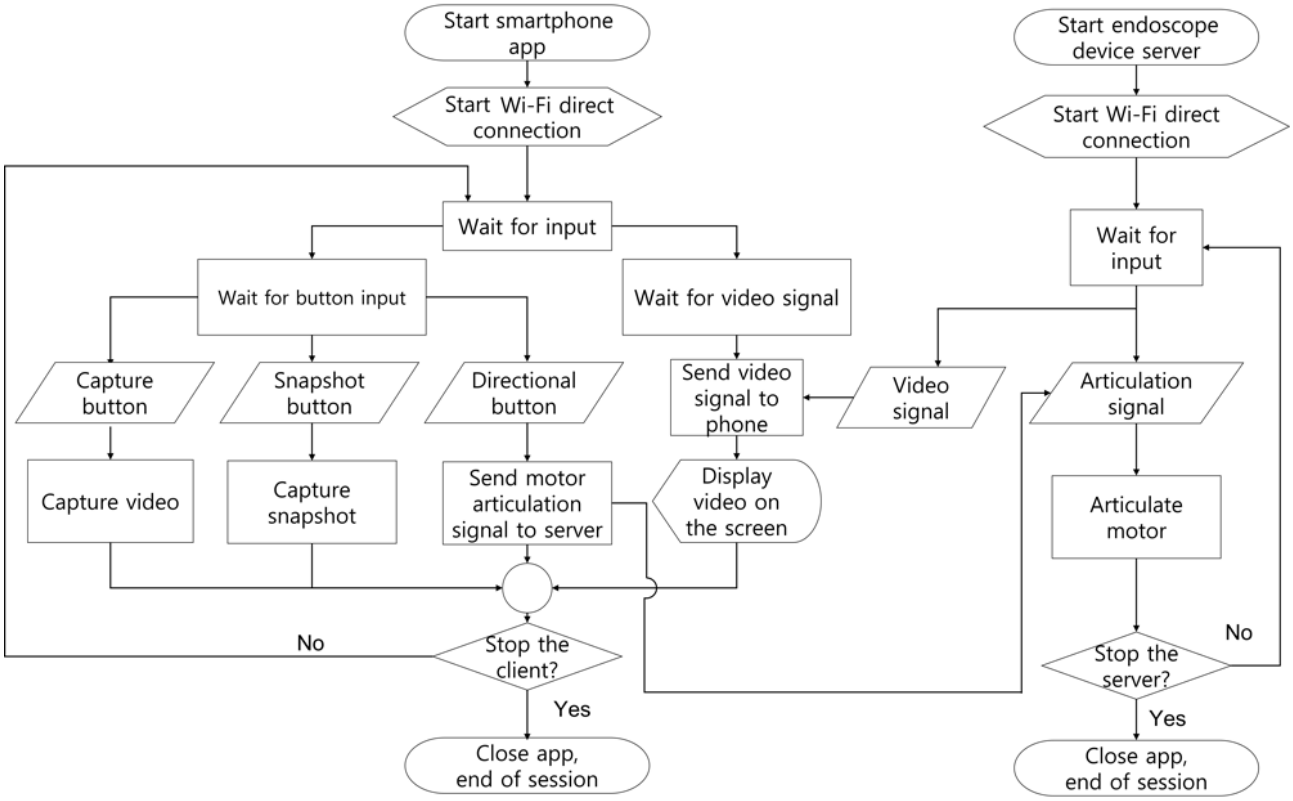
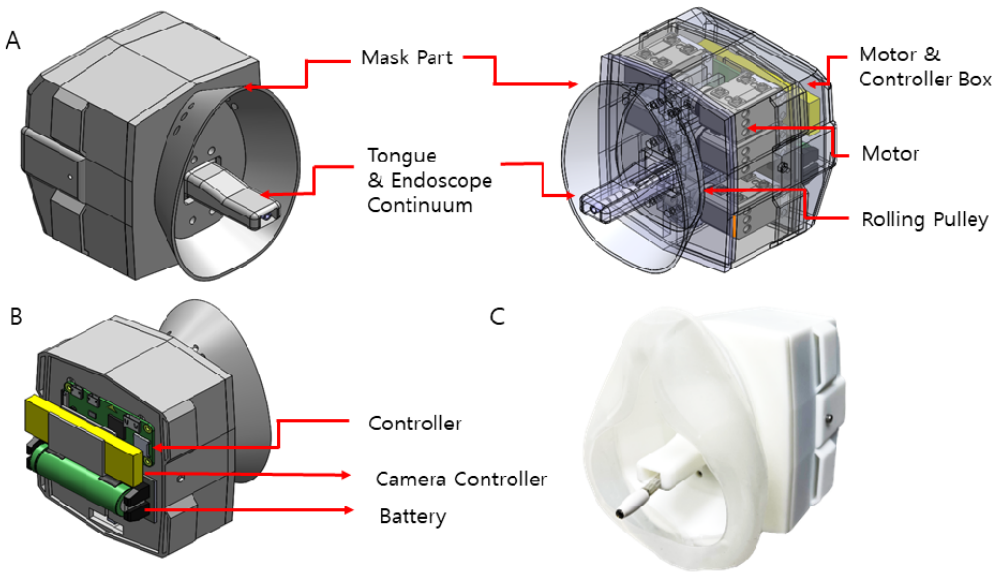


The mechanical parts of the mask endoscope are roughly divided into a mask, a motor and controller box, and a continuum. The mask is where crucial systemic components are present. The lid of the mask can be removed to place a rechargeable battery and perform maintenance of the Raspberry server. Figure 4 shows the internal and external structure of the 3D mask endoscope in 3D space. The arrangement of the motor and controller box, pulley, and controlling parts are shown on the right of Figure 4A. The motors are separated from the controller by a partition. As shown in Figure 4B, the controllers and the battery are in the outermost side of the motor and controller box, easily accessible by removing the lid. Figure 4C shows a finished prototype in 3D space. In addition to the mask, a soft support is added to improve patient experience by enhancing texture.

Figure 4. Assembled hardware parts in 3D space. (A) Rendered 3D structure of the outside shell and internal articulating parts of the hardware. (B) Position of the electronic parts of the hardware, rendered in 3D space. (C) Printed and assembled final product in real space.



The endoscopic continuum consists of individual continuum segments connected by stranded wires. As shown in Figure 5A, each segment has 4 wire holes for the articulation wire and a big central cable hole for the endoscope camera cable. The tension of the wires is adjusted by winding, and rewinding narrows the lateral gap between segments, therefore generating 2-degree-of-freedom (2DOF) omnidirectional motion [10], as depicted in Figure 5B. Two opposite-sided wire holes in the individual segments are paired to each other, making 4 wire holes in total. Each wire hole pair is responsible for the rotational steering movement between 2 segments. The collectible movements of segments create the steering motion.

The tongue continuum is quite different. Only having a slope on the front and the back side of the single continuum segment, the tongue continuum has 2 wire holes for a supportive wire on each wing of the individual segment, a central cable hole for the endoscope cable, and 2 slits at the bottom for the articulating wire, as shown in Figure 5C. The tongue continuum can bend up and down (bidirectional), as shown in Figure 5D. In addition, the wire connecting all the tongue continuum parts is not skewed in a specific direction, let alone being connected to a separate motor. Lacking an active driving force of motion, it can only be passively rolled in and out. The tongue continuum flattens the tongue to get the endoscope safely in position. Coordinated with the motor movement, the tongue continuum module can be retracted and extended by rolling it in and out of the mask, as shown in Figure 6.

As shown in Figure 6, the 4 upper motors aligned in rectangular corners are responsible for articulation of the endoscope continuum. The motor positioned at the downmost location in the mask is responsible for the extending and retracting motions of the tongue continuum. The tongue continuum is directly connected to the winder wheel, and the wheel itself serves as the winder for the endoscope module and the tongue continuum's supporting wire inside the continuum. The wire connected to the tongue continuum is flexible enough to be kept rolled up in the mask when the endoscope is not in use. As the motor turns clockwise, the tongue continuum unit unrolls from the winder, extending forward. While the tongue continuum extends forward, the other 4 motors also correspond to the motion, unrolling the wires to match the length. This results in only the tongue continuum extending forward, without any bending of the endoscope continuum. This motion corresponds with the GO button on the app controller.

When the tongue continuum is extended to the desired length, the operator can manipulate buttons in the app to control the endoscope continuum. Rolled out with the tongue continuum, the endoscope continuum is connected to separate wires that lead to the winder connected to the 4 upper motors. Each motor is in charge of unidirectional bending of 2DOF motion, that is, a pair of motors corresponds to bidirectional bending motion, as shown in Figure 7.

After imaging, the operator can press the BACK button to turn the motor counterclockwise to make the tongue continuum roll back into the mask. For the pulling motion, while the winder of the bottom motor rotates, like the device articulated in the extending motion, the other 4 motors rotate to wind the wire back up to match the retracting length of the endoscope.

Pulley and Key

Medical devices in contact with patients must be sterilized and reprocessed by thorough cleaning. However, complex medical devices, especially those with electronic parts, are difficult to sterilize without damaging the electronic parts. The contactless wireless mask endoscope is no exception. Many medical electronic devices overcome this problem by separating the parts in contact with the patient from the noncontact parts using disposable covers like a medical drape. As shown in Figure 7, our device is made of 2 detachable assemblies, a continuum module and a motor assembly module.

For separation, the device needs to connect and convey the force between parts. By employing a key on the pulley, the force from the motors can be transmitted to the continuum module directly. The pulley is designed as a simple disk with a slit that goes from the center of the pulley to the outermost rim, which appears U-shaped, as depicted in Figure 7A. The key is a small rectangular metal rod-like part, which has a small cross on the

disk attached to the tip of the long side of the rod. When fully assembled, the key is inserted into the slit of the pulley. Figure 7B shows the key-and-pulley assembly in action. The pulley is attached to the motor wheel by screws (4 holes). The pulley can be easily disassembled from the motor wheel by unscrewing the screws, but when it is screwed on, the pulley and the motor wheel are securely attached. On the other hand, the key is attached directly to the wire winder wheel, which is directly connected to each wire that is responsible for articulation. By sliding the assembled key into the slit of the pulley, the assembled motor unit and the endoscope modules are safely connected.

Results

Continuum Contact Force Experiment

The contactless mask endoscope is designed as a laryngoscope, which means the endoscope part has to go over the patient's tongue, hard palate, and soft palate to finally arrive at the vocal cord. If the flexible continuum is too rigid, it can injure oropharyngeal tissues, resulting in secondary infection. A simple transoral model was created to evaluate the end-effect force when the continuum articulates.

Assuming the continuum always collides with the oral tract, a force sensor (Honeywell International Inc) was placed where the soft palate is present, since the continuum is most likely to collide with the soft palate. The force against the surface was measured 10 times. The overall experimental setup is presented in Figure 8D. According to studies on oral anatomical structures, the hard palate length is 46.65 to 51.89 mm for adult males and females [11-16], and the soft palate length is 25.3 mm on average. The radius of the esophagus at rest varies from 12.87 to 17 mm. The angle between the soft palate and the esophagus is 130.1° to 137° [17].

Figures 8A and 8B present the oral structures and transoral model constructed from the information about oral structures. The length of the simulated oral part of the transoral model was set to 90 mm, the angle between the oral part and the esophagus was 130°, the cross-sectional area of the simulated esophagus in the transoral model was 16 mm × 22 mm, and the height was set to 83 mm. The contactless wireless mask endoscope was set in the transoral model, as shown in Figure 8C. Without articulating the endoscope continuum, the tip of the endoscope was collided with the force sensor located on the simulated oropharynx wall of the transoral model only using back-and-forth articulation of the tongue continuum. The collision was repeated 11 times with 10-second intervals.

Wireless Video Transfer Rate Evaluation

The contactless wireless mask endoscope processes raw video data in the controller and sends them to the Android tablet through an access point. There is a small delay due to the limited hardware specification and the nature of wireless communication. To evaluate the delay in the video broadcast from the endoscope, a comparison experiment was conducted. Figure 9 shows the experimental setup of the wireless and wired endoscope video delay test. From the same camera module, the video was transferred directly from the camera and broadcast from the Raspberry Pi module. Using forward articulating

movement as a standard, we compared the frame rate and delays between the 2 videos.

Figure 9. Wireless video transfer rate evaluation experiment. (A) Wireless and (B) wired articulation and video transfer between a contactless wireless mask endoscope and laptop computer. The transferred videos are displayed on the screens of both laptops.

Wireless Articulation Experiment Using a Phantom

Using a phantom resembling the real-life structure of a patient's laryngopharyngeal tract, a wireless articulation experiment was conducted to evaluate the practicality of the contactless mask endoscope.

The conjoined experiment involved a contactless mask endoscope, 2 cameras, a phantom, and an operator with an Android tablet. The abstract experimental setup is shown in Figure 10 and Multimedia Appendix 1. The laryngopharyngeal phantom was set at the center of the meeting room. The contactless mask endoscope was applied to the phantom, and the operator was outside the meeting room. The operator began to control the endoscope with the tablet through a wireless connection. The camera simultaneously recorded both sides as the operator controlled the endoscope to take snapshots and videos of stickers attached to the desired parts of the phantom. The process was repeated after changing the operator's location as follows: in the front of the meeting room, in the corridor, and in the laboratory right next to the meeting room.

The results of the continuum contact force experiment are shown in Figure 11. The magnitude of the collision force varied from a minimum of 235 mN (24 gf) to a maximum of 363 mN (37 gf). The average collision force was 296 mN (30.2 gf), which is just 6.5% of that of a commercial endoscope.

The results of the wireless video transfer rate evaluation experiment are summarized in Figure 12. Comparing wired connection and wireless communication, wireless video streaming was delayed by 0.72 seconds with the contactless mask endoscope.

In the wireless articulation experiment, we placed marker stickers in the desired areas as shown in Figure 10C and the operator of the mask endoscope controlled the device and examined the video data streamed from it while being spatially separated completely from the patient. The measured time to get the stickers in the video stream was around 1 minute in the desired separated location. From the experiment, we tried to evaluate the articulating range of the endoscope continuum and the capability of the device's wireless communication that enables users to control the device from a different space. Contactless wireless video streaming was successful within the range of the access point regardless of the presence of any material blocking the way.

In summary, the Wi-Fi–based contactless mask endoscope was controlled and articulated wirelessly, minimizing or completely avoiding possible contact between patients and device operators. By minimizing contact, contactless medical devices can protect health care workers from infectious diseases like COVID-19.

Discussion

Principal Findings

In the current COVID-19 pandemic era, physicians run risks when they evaluate a patient with fever of unknown origin or with laryngeal symptoms, such as dyspnea, hoarseness, and dysphagia. However, these symptoms are associated with laryngeal obstruction and could be exacerbated when adequate evaluation and treatment are lacking. The proposed wireless device would help protect physicians from possible contagious diseases while allowing them to promptly evaluate patients.

Previously, our team developed a mobile-based USB on-the-go (OTG) endoscope that can be articulated using an Android mobile app [10]. The Wi-Fi–based contactless mask endoscope has several advantages over the USB OTG endoscope. First, it can be controlled over a wireless network, enabling the operator to position himself/herself freely, unlike the USB OTG endoscope, for which the operator has to be close to the patient. Second, the operator of the Wi-Fi–based mask endoscope can attach the endoscope via a strap, unlike the USB OTG endoscope, which has to be held with the cell phone. This has the secondary benefit of decreasing the load on the operator's wrist and hand, providing a better user experience. Finally, modulization of the Wi-Fi–based contactless mask endoscope makes it easier to replace parts, simplifying maintenance.

As individual parts can be replaced rather than replacing the whole module, maintenance costs are reduced. The price of the USB OTG endoscope was US $473, which was one of the main advantages of the device, as it was intended to be used in underdeveloped countries. Table 1 shows the price of the Wi-Fi–based contactless mask endoscope. Considering that the cost of the 3D-printed modules can be reduced with mass production, in addition to the reduced maintenance costs, the price may be better than that of the USB OTG endoscope [10].

Table 1. Prices of hardware parts of the Wi-Fi–based contactless wireless mask endoscope.

Hardware	Price (US $)
XL320 * 5ea	97.8
3.9-mm camera module	170
3D print of the case	68.96
3D print of the tongue and endoscope continuum	152.88
Controller	60.02
Wires, etc	49.27
Total	598.93

A snake-like continuum is commonly used in flexible endoscope articulation, enabling multiple degrees of motion for clinical needs. However, complex articulation was historically reserved for larger endoscopes. Endoscopes with multiple kinds of articulating units for flexible parts have some advantages. First, they can perform different functions, such as adjusting the mechanical force applied to the articulating units to ensure patient safety [18]. Second, the multiple kinds of articulating units can exert different kinds of motion for each kind of unit, enabling users to control dynamic motions [19]. While the endoscope continuum of this contactless wireless mask endoscope serves as the conventional endoscope articulating unit, the tongue continuum has 2 other functions. First, its broad shape and stiff mechanical property flattens the tongue. During endoscopy, especially of the stomach and upper respiratory organs, the tongue gets in the way of the endoscope, hindering its movement. Therefore, it is recommended that the examiner use anesthesia before endoscopy to keep the tongue out of the way. A mouthpiece with a tongue presser can be used [20]. The tongue continuum of the contactless wireless mask endoscope also serves as a tongue presser, making it easier to enter the desired area. Second, the tongue continuum itself works as a support for the regular continuum. If the snake-like continuum is too long, due to capstan friction, forces on the end point cannot drive the end point as intended [18]. Adding a tongue continuum shortens the length of the snake-like continuum, making it easier to relay force to the tip of the endoscope and enabling precise control. In conclusion, having a semirigid

tongue continuum has the advantage of articulation control and safe delivery of the endoscope tip to the desired area.

The system's modularity also reduces contamination concerns. Endoscopes are more prone to cross-infection than other noninvasive examination devices because endoscopy involves mucosal contact. The endoscope module cannot be sterilized by autoclaving because the electronics within it are sensitive to heat, pressure, and moisture. Given that autoclaving is one of the easiest and most reliable methods of disinfection, the endoscope module must be changed regularly regardless of the cost.

To solve the contamination problem, 2 major innovations were incorporated. First, a detachable endoscope module was used. With the key-and-pulley part inside the mask, the endoscope module is fixed to the motor. When the operator decides to separate the mask and the endoscope, the 2 parts can be separated by disassembling the key-and-pulley part. The inner space of the mask can be easily accessed by opening the outer lid. Separation of parts also creates a gap between the parts, where an anticontaminant cover sheet can be applied. Therefore, by replacing the wheel, the possibly contaminated continuum and endoscope modules can be separated from the mask module, and the mask can be kept clean. The second innovation is that of a simplified inner structure. For a larger endoscope, the sheath has to have some kind of contact point because of the channel in the endoscope. However, the contactless wireless mask endoscopic system does not have such a channel, and therefore, the sheath can be simple, like a condom. Without a channel, it is much easier to sterilize the smooth surface, and there is much less chance of contamination because of the small contact point.

For conventional endoscopes, portable devices with a wireless connection are not preferred for multiple reasons. First, a wireless connection has a limited data transfer rate. The Bluetooth 5.0 connection has a 1 Mbps data transfer rate for low-energy Bluetooth [21]. The 1 Mbps rate of Bluetooth 5.0 can barely cover a standard-frame-rate 360p video stream [22]. A Wi-Fi connection is more generous in terms of the bit rate, and 802.11n families can go up to 200 Mbps, enough to stream 4K videos [22,23]. Second, since endoscopy is a medical procedure for which many trained health care experts are needed, there is less need to separate the endoscope and the operating system. However, due to the COVID-19 pandemic, there is a possibility of infecting entire medical facilities during endoscopy. Therefore, the need for separation of the operator and patient has emerged.

The current focus mainly revolves around contactless endoscopy that is performed in close proximity but remains in the clinic. While the practitioner is in a separate room, a patient can follow instructions to wear the mask. When the mask is properly worn, endoscopy can be performed remotely using the smartphone app. Should an emergency occur, practitioners waiting outside the room can interrupt the procedure and ensure the patient's safety. Otherwise, the practitioner can utilize the internet to extend the range of communication. The endoscope streams the video from the patient to the practitioner. Theoretically, by setting up a public IP address and encrypted data transfer, users can safely control the endoscope over the internet from many kilometers away. Subsequent research will involve safety and clinical trials performed at Asan Medical Center using an improved version of the articulating endoscope system.

The designed laryngoscope goes over soft areas that can trigger a gag reflex. The oropharyngeal area is sensitive, so it can detect down to 2.07 mmHg of pressure [24,25]. A gag reflex can be triggered by a slight touch of the triggering area [25]. Generally, laryngoscopy involves carefully avoiding the areas that would trigger a gag reflex [26] or using local anesthesia [27-29]. In particular, noninvasive local anesthesia can be applied easily with fewer side effects and fewer tissue injuries. Therefore, in practice, the device can be accompanied with local anesthetic application by hand or machine. Lidocaine nebulizer, spray, or ingestion would help ameliorate the gag reflex.

Limitations

While making the Wi-Fi–based contactless mask endoscope, we faced a few problems mainly due to hardware limitations. The 3D-printed parts did not achieve a tight seal and allowed air to flow through the motor box. For clinical application, improved seals combined with a filtered ventilation port would reduce the risk of aerosol transmission. Further hardware limitations mandated a tradeoff between device size and capabilities. Because the mask needs to be worn like a conventional respiratory mask, the dimensions of the attached controller and motor parts were minimized to enhance the patient's experience (Table 2). The lack of space and need to downsize the controller also lowered the performance of the control system, resulting in delays and reduced video-processing performance, which led to a 0.72-second delay in wireless video streaming.

For future research, we will compensate the space limitation in hardware with better performance, while maintaining the portable point of care–like nature of the device. In particular, the device may be widened to incorporate an additional channel for biopsy or to increase patient comfort.

Table 2. Dimensions of the Wi-Fi–based contactless mask endoscope.

Part and dimension	Value (mm)
Mask	
Width (with cushion part)	99
Height (with cushion part)	120
Depth (with cushion part)	47
Width (without cushion part)	90

Depth (without cushion part)	26
Controller and motor box	
Width	97
Height	114
Depth	77
Hardware	
Width	99
Height	122
Depth	123

Conclusions

We developed a contactless wireless mask endoscopy and diagnosis system to be used during the COVID-19 pandemic. Using Wi-Fi and an Android mobile device, we successfully articulated the endoscope and took snapshots and videos of the patient's vocal cord. The device can separate health care workers from patients, while enabling diagnosis of internal parts of the body that cannot be reached without endoscopy. In conclusion, the contactless wireless mask endoscope can help minimize chances of contamination, further minimizing the impact of the pandemic in the medical field.

Abstract

Background: Chronic obstructive pulmonary disease (COPD) is the fourth leading cause of death and is characterized by a progressive loss of pulmonary function over time with intermittent episodes of exacerbations. Rapid and proactive interventions may reduce the burden of the condition for the patients. Telehealth solutions involving self-tracking of vital parameters such as pulmonary function, oxygen saturation, heart rate, and temperature with synchronous communication of health data may become a powerful solution as they enable health care professionals to react with a proactive and adequate response. We have taken this idea to the next level in the Epital Care Model and organized a person-centered technology-assisted ecosystem to provide health services to COPD patients.

Objective: The objective is to reveal the nature of COPD by combining technology with a person-centered design aimed to benefit from interactions based on patient-reported outcome data and to assess the needed kind of contacts to best treat exacerbations. We wanted to know the following: (1) What are the incidences of mild, moderate, and severe exacerbations in a mixed population of COPD patients? (2) What are the courses of mild, moderate, and severe exacerbations? And (3) How is the activity and pattern of contacts with health professionals related to the participant conditions?

Methods: Participants were recruited by convenience sampling from November 2013 to December 2015. The participants' sex, age, forced expiratory volume during the first second, pulse rate, and oxygen saturation were registered at entry. During the study, we registered number of days, number of exacerbations, and number of contact notes coded into care and treatment notes. Each participant was classified according to GOLD I-IV and risk factor group A-D. Participants reported their clinical status using a tablet by answering 4 questions and sending 3 semiautomated measurements.

Results: Of the 87 participants, 11 were in risk factor group A, 24 in B, 13 in C, and 39 in D. The number of observed days was 31,801 days with 12,470 measurements, 1397 care notes, and 1704 treatment notes. A total of 254 exacerbations were treated and only 18 caused hospitalization. Those in risk factor group D had the highest number of hospitalizations (16), exacerbations (151), and contacts (1910). The initial contacts during the first month declined within 3 months to one-third for care contacts and one-half for treatment contacts and reached a plateau after 4 months.

Conclusions: The majority of COPD patients in risk factor group D can be managed virtually, and only 13% of those with severe exacerbations required hospitalization. Contact to the health care professionals decreases markedly within the first months after enrollment. These results provide a new and detailed insight into the course of COPD. We propose a resilience index for virtual clinical management making it easier to compare results across settings.

KEYWORDS

COPD; exacerbations; patient-reported outcomes; Epital Care Model; early interventions

Introduction

Chronic disease poses one of the biggest challenges facing Western health care systems, and with its increasing prevalence in the population, it is a major driver of health care utilization and the leading cause of death [1]. Chronic obstructive pulmonary disease (COPD) is one of the chronic diseases that weighs heavily in this scenario. Currently the fourth leading cause of death in the world, COPD is projected to be the third leading cause of death by 2020 [2] with an increasing socioeconomic burden and growing strain on health care budgets [3]. COPD is characterized by a progressive loss of pulmonary function over time with intermittent episodes of exacerbations as part of its natural history [2,4]. The long-term course of the disease depends on how well individuals can understand, manage, and act upon risk factors such as smoking, nutritional state, exercise activity, and compliance to medical treatment plans [5]. In the short-term, the prevention and treatment of exacerbations are key elements in the management of COPD according to the Global Initiative on Chronic Obstructive Lung Disease (GOLD) as the number of exacerbation is closely associated with an increased rate of hospitalization, increased mortality, decline in lung function, increased use of health care resources, and decrease in quality of life [2,4]. According to the GOLD guidelines, COPD exacerbation is defined as “an acute worsening of respiratory symptoms that results in additional therapy.” These events are classified as mild, moderate, or severe, of which the first 2 categories are characterized by the type of medication given and the latter characterized by the patient’s need for hospitalization or visits to the emergency room [2].

Early detection of exacerbations and prompt interventions with antibiotics and corticosteroids can reduce hospital admissions, decrease use of health care services, and increase and improve quality of life [6,7]. Sixteen years ago, Wilkinson et al [8] showed that early recognition of exacerbations using symptom-based diaries completed by the patient followed by prompt treatment by a physician is beneficial to the recovery of the exacerbation and can improve the burden of exacerbation-related morbidity and mortality. The authors concluded a need for initiatives to encourage reporting of early presentation of exacerbations and enhanced symptom recognition tools that are easy to use and promptly managed by health professionals.

Telehealth solutions involving self-tracking of vital parameters such as pulmonary function, oxygen saturation, heart rate, and temperature with synchronous communication of health data may become a powerful solution in this context as it enables health care professionals to react with a proactive and adequate response. Over the last decade, data from several randomized controlled trials examining the effect of telehealth and how it may assist self-monitoring and management in COPD have been reported [9-12]. Some studies suggest a potential beneficial effect with a reduction of exacerbations [13], acute hospital admissions, and mortality [14] and increased health-related quality of life [15] whereas others have not been able to verify these results [16-18]. In COPD, no studies have yet demonstrated conclusively that telehealth is neither superior nor inferior to usual care; it is noteworthy that telehealth interventions have not caused any harm to COPD patients and the technology has been welcomed by the users [10,19,20].

One of the fundamental elements of a person-centered and value-based health care provision of services is the inclusion of the patients’ self-reported data including their experiences as patients. These data are often termed patient-reported outcomes (PROs) [21]. PROs are a natural component of telehealth as they can be used to report the condition dynamically over distance to service providers. PROs may also engage the patients and increase self-management due to a better insight into their own condition [21]. In the context of COPD, PROs are a key element for patients to communicate with their health providers, enabling them to understand their condition and proactively act upon potential deteriorations [22].

Telehealth and PROs may contribute to the fulfillment of the World Health Organization framework for integrated people-centered health services as they facilitate the engagement and empowerment of patients and the reorientation of how health care can be delivered [23].

In an attempt to demonstrate how these ideas and potentials can be realized, we have developed a new person-centered service model: the Epital Care Model (ECM). We have tested the ECM in a living lab [24] and evaluated potential candidates for PROs gathered by psychometric validated instruments focusing on self-management, health literacy, and physical and mental well-being as well as clinical parameters [25]. In this study, we report on the second part, in which we, based on a newly developed algorithm and setting (to be reported elsewhere), are able to evaluate how PROs relating to the clinical condition can be used to understand the actual needs of the patient and needs of resources required from the ECM living lab to help the patient return to their habitual condition.

For this purpose, we have followed the self-tracking activities of 87 patients with COPD and the corresponding standardized responses from health care professionals when responding to signs of deteriorations of the patients’ clinical condition or if the patients need support to manage their condition.

To understand the activities and required resources, we have addressed the following research questions:

- What is the incidence of mild, moderate, and severe exacerbations in a mixed population of COPD patients?
- What is the course of the mild, moderate, and severe exacerbations?
- How is the activity and pattern of contacts with health professionals related to the participant condition?

Methods

The setup and initial data of this study has been described previously by Phanareth [24]. In short, the data for this study was collected as part of the Epital living lab project which was established in a Danish municipality in 2012 [24].

Setting

The Epital Care Model is a model designed to help organize health care services both virtually and physically with a personalized health-centered approach and with the objective of enhancing empowerment and self-management. Services and interactions are organized according to 6 levels that can be divided into three 3 settings depending on the resources allocated. In the ECM1 level, participants live an independent and active life with their condition supported by technology. When participants need medical support in relation to their condition, they are classified as being at the ECM2 level. Both ECM1 and ECM2 interactions and services can be provided at any location and are performed virtually (setting 1). If the participant's condition deteriorates and a physical visit is necessary, nurses will go to the participant's physical location and assess the condition thereby placing the participant at the ECM3 level. If regular follow-ups by nurses and medical doctors are needed, this will be offered as a patient at home service termed "outmission" at the ECM4 level (setting 2). The outmission is equivalent to services offered when admitted to a hospital but in this case, they are provided at home by a virtual medical doctor (eDoctor) and a nurse (setting 3). The eDoctor performs virtual ward rounds but the patients can receive visits from community nurses at the participant's physical location if necessary. At the ECM5 and ECM6 levels, the participant is now considered a patient and is referred to a community or hospital bed depending on the need of care and monitoring.

Population

The study period took place from November 1, 2013, to December 31, 2015, and in this period, we consecutively enrolled participants recruited by a snowball-like method based on convenience sampling. This resulted in a random sampling over seasons and an uneven period for observations defined by either the time from enrollment to the planned end of the study or a period defined as the time from enrollment to the participant's death or choice to withdraw from the study.

A total of 93 participants with COPD were enrolled into the ECM living lab, of these 27 were transferred directly from the prior pilot study and 66 were recruited throughout the period of the study. For this analysis, 5 were excluded due to not having provided any measurements after the inclusion and one due to insufficient inclusion data, resulting in a total of 87 participants.

During the study, 29 patients dropped out: 9 of whom because they died, 8 for reasons not associated to the tracked exacerbations, and 12 for other reasons. In addition, 5% (4/87) of participants dropped out within 14 days, but data from these participants are included as an objective of this study was to assess the overall activity and event of the participants.

At entry, all participants were registered with baseline data including age, sex, heart rate, oxygen saturation, forced expiratory volume for 1 second (FEV_1), and a clinical examination [25]. Based on these data, participants were classified according to the previous GOLD guidelines from 2011 [26], as the study was planned in 2013. They were classified according to the air flow limitation severity in COPD (GOLD classes I-IV) and their risk factor group (GOLD risk factor groups A-D) assessed by the number of exacerbations per year and their Medical Research Council breathless test score. We recognize that these recommendations have changed in new edition of the GOLD guidelines and our data may therefore not be directly comparable to newer data sets [26].

Context and Data Collection

The ECM is a unique, personalized health-centered living lab project that consists of an environment and service ecosystem where it is possible to investigate everyday fluctuations when living with COPD. Simultaneously, the ECM makes it possible to estimate how many resources are needed to meet the needs of the participants both when the participants live an active and independent life in ECM1 and when their condition deteriorates and they are allocated resources as described in ECM2 to ECM6.

The ECM living lab provides the participants with 24/7 access to assistance from the response and coordination center (RCC) manned by nurses supported by eDoctors. The self-tracking activities are completely regulated by the participants, driven by either curiosity or needs in relation to the ongoing changes of their condition. As the participants register their data, they are simultaneously reported to the RCC. The participants are informed that their data will be visible for the RCC staff, they can expect the RCC to respond if their condition deteriorates, and self-tracking is digital assistance helping them to manage their condition. The participants are also able to contact the RCC through their tablet using video or voice communication if they feel insecure or have any questions [24].

A third kind of communication may be initiated by the RCC staff: when they register a deterioration, they will contact the participant to investigate whether there is any need of assistance. For the participants, this data-driven approach should result in a structured and less intrusive way to live with their COPD as they only need to report their PRO data when they feel like it and only contact the RCC if they need advice, care, or treatment.

The information technology (IT) support for processes and activities in the ECM living lab constitutes 2 IT systems specially tailored for this purpose [24]: a citizen-oriented monitoring system (Appinux Care, Appinux A/S) and a medical documentation system (EpiProcess, OCEAN Process A/S).

The COPD monitoring module in the Appinux platform allows participants to deliver real-time data to health care providers. Participants used a Samsung tablet with an app to report their data used to assess their condition. The participants themselves reported a measured body temperature, increased breathlessness, increased coughing, and changed color of sputum. These data were reported together with a guided semiautomatic measurement of heart rate, oxygen saturation, and FEV_1. The initial assessment of the data is performed by the system, and an algorithm presents this assessment to the participant as a

color (red, yellow, green) along with advice on the appropriate action to take.

Based on these data, the health care professionals can, together with the participant, make informed decisions on how to best manage the change in condition. This will be based on the previous measures evaluated with graphs, including plotted trends, which enable the health professionals to better predict the course of the participant. All participants were equipped with an acute medicine box at home, to be used only when exacerbations occurred to avoid delays in the initiation of a medical treatment. The content was prescribed by the eDoctor, provided by a local pharmacy, and used only in agreement with the RCC staff. The acute medicine box contained bronchodilators (short-acting β_2-agonist and long-acting β_2-agonist), inhaled corticosteroids, prednisolone tablets, and broad-spectrum antibiotic tablets.

The medical treatment was standardized to match 3 categories of exacerbations (mild, moderate, and severe) using a stepwise approach with increasing intensity of the medication to match the severity (Table 1). The initiation of medical treatment is based on symptoms and the algorithm system using the PRO data. Based on these and the history, the participant was treated with drugs according to Table 1. The pattern of used drugs was used afterward to classify the participant's severity of exacerbation for the purpose of this study.

Table 1. Description of severity based on medical prescription.

Corresponding medical treatment	Exacerbation type
Increase of ICS[a] and LABA[b] + SABA[c]	Mild
Increase of ICS and LABA + SABA + oral prednisolone[d]	Moderate
Increase of ICS and LABA + SABA + oral prednisolone + antibiotics[e]	Severe

[a]ICS: inhaled corticosteroid.

[b]LABA: long-acting β_2-agonist.

[c]SABA: short-acting β_2-agonist.

[d]Course of 37.5 mg daily for 5 to 10 days.

[e]Amoxcillin 500 mg × 3 daily for 10 days.

Our definition of severe exacerbation differs from the one purposed in the GOLD guidelines, as GOLD classifies this as a condition requiring hospitalization or emergency room visits. In our setting, we defined a severe exacerbation as a condition where an increase of inhaled corticosteroid, long-acting β_2-agonist, short-acting β_2-agonist, oral prednisolone, and antibiotic was needed (Table 1); this resembled more a moderate exacerbation compared to GOLD. In our case, however, if a severe exacerbation treatment was initiated it triggered a series of standardized health services including a follow-up program with daily virtual ward rounds, close monitoring of the condition, and medical adjustments if needed (ECM3 and ECM4).

We therefore argue that our approach in a combined virtual and physical setting is comparable to the procedures performed during a hospitalization or in the emergency room, and therefore may be covered by the definition of severe exacerbation as proposed in the GOLD guidelines.

Statistical Analysis

At entry, we registered sex, age, FEV_1, pulse rate, and oxygen saturation for each participant. During the study, we registered participant observation period, number of exacerbations, and number of contact notes, which were coded into care and treatment notes. Each participant was at entry classified according to the GOLD classes I through IV and placed in a risk factor group A through D. Categorical data were reported as numbers and percentages and continuous data were reported as mean values with standard deviations.

Age at entry; participant days; number of mild, moderate, severe, and total exacerbations; and number of measurements per participant year were compared between the risk factor groups using 1-way analysis of variance. All statistics were performed using Excel (version 2016, Microsoft Corp).

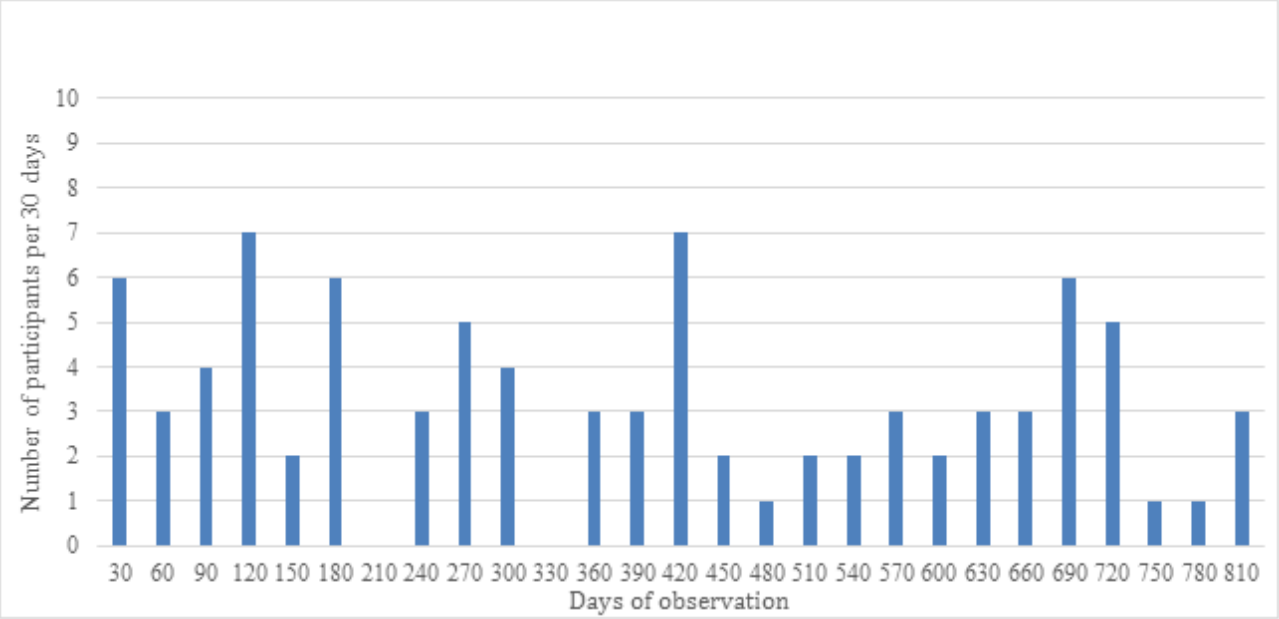
Ethics and Data Protection

As previously reported, the study was assessed and found not to need specific approval by the regional office of the National Danish Ethics Committee (H-3-2012-FSP31). The program was also registered with the National Danish Data Agency by first the University of Copenhagen (2012-41-0384) and since January 2014 by the municipality of Lyngby-Taarbæk, Denmark (20150910229). All participants were told about the study orally and with written material and informed that they could withdraw from the services at any time. Each participant signed a consent with a copy of this information. All data were handled according to Danish legislation and regulations.

Results

The study population consisted of 58 females and 29 males. The average age was 73.7 (range 47-91) years. The accumulated number of self-tracked measurements was 12,470. The accumulated number of days with self-tracking was 31,714, and the average of self-tracking days per participant was 368.8 (SD 248.7) with a range from 1 to 791 days per participant. As seen in Figure 1, only 7% (6/87) of the participants dropped out within the first month and 85% (74/87) participated for more than 3 months.

Figure 1. Observation period for the participants.



The number of participants classified both according to risk factor groups and severity is shown in Table 2. More than half of all patients were characterized with severe or very severe COPD. The mean FEV_1 and standard deviation at entry served as baseline for the evaluation of the participants during the observation period (also shown in Table 2).

Table 2. Forced expiratory volume during the first second at baseline of the study by participants' GOLD class and risk group.

GOLD[a]	A: MRC[b] score <2; 0-1 exacerbations per year, mean (SD)	B: MRC score ≥2; 0-1 exacerbations per year, mean (SD)	C: MRC score 0-1; ≥2 exacerbations per year, mean (SD)	D: MRC score ≥2; ≥2 exacerbations per year, mean (SD)	Total
I: FEV_1[c]≥80% predicted	—[d]	—	—	1.46, n=1	1
II: 50%≤FEV_1<80% predicted	1.47 (0.46), n=11	1.52 (0.46), n=23	1.49 (0.05), n=3	0.86 (0.26), n=4	41
III: 30%≤FEV_1<50% predicted	—	1.28, n=1	1.10 (0.08), n=8	0.74 (0.22), n=16	25
IV: FEV_1<30% predicted	—	—	0.97 (0.05), n=2	0.67 (0.3), n=18	20
Total	11	24	13	39	87

[a]GOLD: Global Initiative on Chronic Obstructive Lung Disease.

[b]MRC: Medical Research Council.

[c]FEV_1: Forced expiratory volume during the first second.

[d]Not applicable.

The number of participants were unevenly distributed across the severity classes and risk factor groups (Table 2). Therefore, we adjusted for observation period by normalizing data into participant years or days of observation (Table 3).

The mean number of measurements per participant days did not differ between the risk factor groups, although risk factor group D tended to have higher activity. The numbers are less than one per day and equivalent to a measurement every second to fifth day but with a wide range from 0.01 and up to 3.8 measurements per day.

The number of exacerbations divided into mild, moderate, and severe did not differ significantly among the groups, although the annual rate per patient tended to be higher in risk factor group D with risk factor group B having the second highest mean value. The mean numbers of care notes and treatment notes were similarly higher in risk factor group D, and risk factor group B had the second highest mean of care notes per participant year. The mean for treatment notes per participant year deviated from this pattern as risk factor group C had almost the same number as risk factor group B. This was primarily due to one participant in group C who had 93 treatment notes over a period of 219 days.

A total of 21 of the contact notes were related to other issues than living with COPD, 2 related to treatment of urinary tract infection, 2 to peripheral edema treated with diuretics, and 2 to acute need of hospitalization for other reasons. None of the contact notes was related to treatment or care of other somatic long-term conditions such as ischemic heart failure or diabetes.

In Table 3, the characteristics of exacerbations and contact notes distributed within risk groups are provided.

Table 3. Distribution of exacerbations and contacts within risk groups.

Characteristic	Risk factor				
	A (n=11)	B (n=24)	C (n=13)	D (n=39)	Total (n=87)

Care notes	102	382	124	789	1397
Care notes/year, mean (SD), (n=84)	23.33 (29.06)	21.94 (23.90)	12.33 (11.78)	31.13 (33.55)	24.80 (28.52)
Treatment notes	53	364	166	1121	1704
Treatment notes/year, mean (SD)	5.29 (6.90)	14.20 (22.00)	14.85 (42.40)	29.01 (32.27)	20.28 (30.60)
Total contact notes/year mean (SD)	28.62 (33.41)	37.43 (34.75)	27.18 (50.18)	57.71 (44.74)	45.31 (45.41)

The participants' total number of contacts were primarily related to ECM2 with the virtual clinical management. Less than 5.36% (165/3081) of the contact notes related to more resource-demanding activities such as evaluation in the participants' home by a mobile acute team (ECM3 and 4), referral to community bed care (ECM5) or hospitalization (ECM6). As seen with the number of exacerbations, the highest number of contacts were in risk factor group B and D (Table 4). This is partly due to the higher number of participants in these 2 groups, as the adjustment for participant years (Table 3) reduces the difference between group A and C versus group B and D. The differences, particularly in group C, may also be explained by a lower need for contacts not related to treatment as these contacts contribute to the largest difference between group C versus group B and group D (Table 3).

Table 4. Number of contact notes (%) within risk factor distributed at ECM levels.

Risk factor	ECM1[a]	ECM2[b]	ECM3[c]	ECM4[d]	ECM5[e]	ECM6[f]	Discharge notes	Total

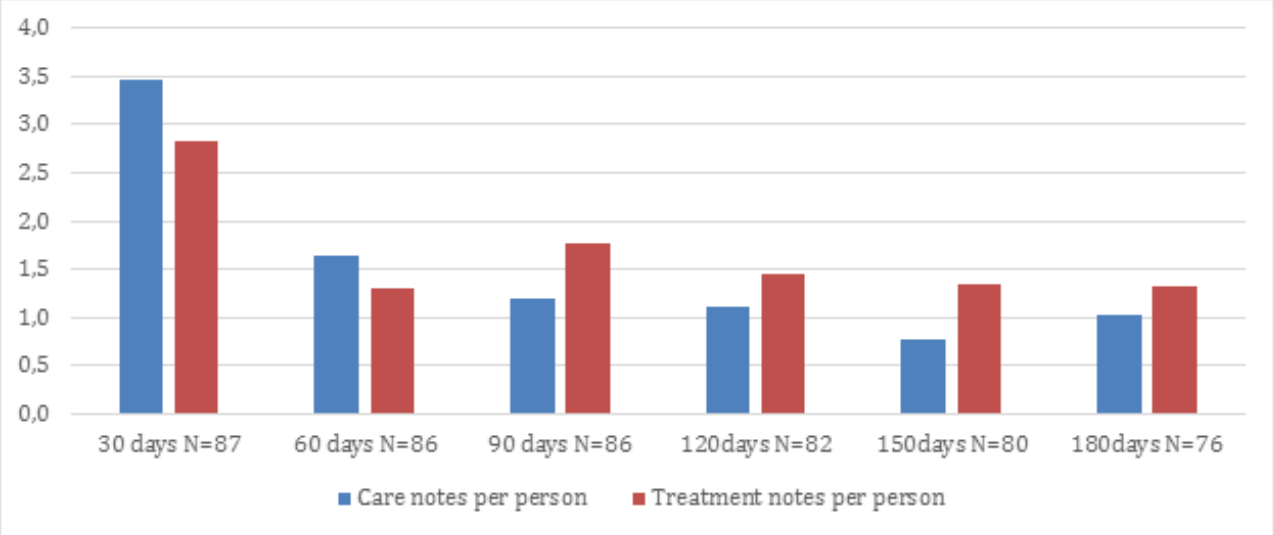
The numbers of care and treatment notes are highest in the first month after enrollment in the ECM (Figure 2). The care notes decline over time with a plateau after 3 months at approximately one-third of the initial number of care notes. The number of

treatment notes were initially lower than the care notes and reach a plateau after 4 months at approximately half of the initial number of treatment notes. Most of the care and treatment notes (2111/3060, 68.99%) were conducted in the daytime hours between 8:00 AM and 5:00 PM.

Figure 2. Number of care contact notes and treatment contact notes per person over the first 6 months after enrollment/on-boarding, reported in intervals of 30 days.



Most of the exacerbations were managed virtually in the context of the RCC (ECM2), and 69.4% (84/121) of the severe exacerbations were mitigated virtually (Table 5). Only 21.3% (54/254) of all exacerbations required more intensive diagnostics and follow-up with the majority of these belonging to the severe exacerbations. Only 7.1% (18/254) of the exacerbations required hospitalization and an equivalent number of exacerbations required hospitalization at home (ECM4).

Table 5. Number of exacerbations (%) in relation to severity of the exacerbations and the allocated resources (ECM level).

Discussion

Principal Findings

This study is, to the best of our knowledge, the first to describe the activities and interactions that take place in an environment based on telehealth and a systematic use of PRO data. An environment was designed to meet the needs of patients and provide an active and independent living in accordance with the person-centered health service model, the ECM [24].

The ECM environment with its service ecosystem offers a unique opportunity to more thoroughly explore the nature of COPD in relation to the severity described as GOLD classes and risk factor groups and the required resources to assist the participants to adequately manage their own condition.

In our study, we detected a total of 254 exacerbations in 87 patients based on PRO measures with a subsequent clinical assessment that resulted in medical treatment corresponding to either mild, moderate, or severe exacerbation (Table 1). Overall, we found 59% (150/254) of the exacerbations occurred in the high-risk group (risk factor group D) with an annual rate of 3.9 exacerbations per participant year, and we found that approximately half of these were categorized as severe exacerbations with 1.86 severe exacerbations per participant year. These results are in the higher end compared to other studies that have also examined annual rates of exacerbations. Comparison of our data with other studies is difficult as it requires a standardization of the severity of the COPD condition and a classification of severity of exacerbations across studies. Our study design builds on the 2011 GOLD guidelines and a

pragmatic approach to classification of severity taking the strength of telehealth into consideration, as described in the methods section. Wilkinson et al [8] found, in accordance with our study, a mean of 2.5 exacerbations per patient year, but 40.1% of these were not detected by the clinicians and covered a broad spectrum of patients with respect to severity.

In a review by Seemungal et al [27], the authors found an estimated annual rate of COPD exacerbations as low as 0.5 to a high of 3.5 exacerbations per patient year and hospitalization rates with a range from 0.09 to 2.4 per patient year, the latter being categorized as severe exacerbation according to the GOLD definition [26].

It is surprising that the annual rate of exacerbations in risk factor group C tends to be lower, although not significantly, than in risk factor groups B and D. This may be due to the low number of participants in risk factor group C and is thereby a statistical coincidence and not real finding. In Denmark, patients with COPD will be referred to pulmonary specialists when they move from risk factor group B to C and this may also be a factor that can explain why group C has a lower annual rate of exacerbations than group B.

Our data, which build on a 24/7 self-tracking setup with immediate response from RCC staff, provide us with a detailed insight into the nature of the COPD condition and reports of deteriorations, which may have been missed in other settings. This may explain the higher number of total exacerbations (3.9 per participant year), whereas the number of severe exacerbations is closer to the other studies. Had we used a classification of severity similar to the GOLD guidelines by only including those in need of physical contact to health professionals in a setting equivalent to an emergency room or hospitalization, the number would only have been 37 of the detected 254 exacerbations, which is 31% of the 121 considered to be severe exacerbations based on our criteria or only 15% of all 254 exacerbations. It is also noteworthy that 2 of those initially classified as moderate exacerbations resulted in hospitalization and 16 of the 121 classified as severe exacerbations resulted in hospitalization. If the stricter approach was followed, by only classifying those in ECM3 to ECM6 as severe, 21 of 37 were not hospitalized but mitigated before hospitalization.

The number of exacerbations leading to hospitalizations is similar to the 6.4% found by Wilkinson et al [8]. Whether this is a result of a lack of effect of our setting or due to our inclusion of a higher number of participants in risk factor group D remains to be explored. In a study by Pinnock et al [19] comparing telehealth with conventional care they found an annual rate of number of hospitalizations per patient to be 1.2. This is considerably higher than our 18 hospitalizations out of 87 participants with 0.21 hospitalizations per participant year.

When comparing exacerbation rates, one must therefore be careful and very aware of the lack of consensus of clear definitions of exacerbations, grading systems for the severity of the disease, the high heterogeneity among studies, and the different treatment culture among clinicians which also have an influence.

The higher overall exacerbation rates in this study may be explained by the voluntary self-tracking setup with an easy way to report PRO data, which provides far more data than one would normally get in a traditional health system. This may provide a higher sensitivity for detecting exacerbations but may also decrease the specificity in comparison to traditional systems as the threshold for acting on changes in the pulmonary condition may be lowered. The higher occurrence of exacerbations in our study compared to others, may be explained by the notion that exacerbations go unreported [8,28,29].

Whether a lower threshold for detection and an apparent increased administration of drugs will be reasonable and be considered proactive by being able to prevent a deterioration of the COPD over time by a more aggressive handling of the acute exacerbations needs further studies.

Association Between Clinical Condition and RCC-Mediated Activities

When organizing a 24/7 service available for all individuals with COPD in a geographical area, it is important to understand whom will need which services and how these needs will evolve over time. As expected, most of the severe exacerbations and hospitalizations were associated with the participants in risk factor group D. This group also had the highest number of contacts, both related to care and treatment. Most of contacts were handled at the virtual clinical management level with 84.1% taken place in relation to ECM2 and with an additional 9.1% only 6% of all contacts were in relation to the more resource demanding activities in ECM3-ECM6.

We find that the activities as estimated by contact notes were more than twice as high during the first month of enrollment into the living lab than after 3 to 4 months. Even the number of treatments notes declined, indicating that the participants learned to better manage their condition or became less distressed. This is in accordance with Kargiannakis et al [30] who, in a service ecosystem comparable to ours, found that the initial contacts per participant dropped from 7 per day to 4 within the first week. The total number of contacts over a period of 42 days with 23 participants were considerable higher with a total of 451 or approximately 14 per participant within the first month [30].

Our results are in accordance with our previous finding that the participants' emotional distress decreases over time [25]. The reduced number of contacts to the RCC may also reflect the finding that the participants reported a perception of being less active in managing their condition [25]. Based on both the previous findings and the number of contacts, will we hypothesize that the ECM living lab environment and service ecosystem contributes to the participants ability to better manage the COPD and related challenges. It should also be noted that the majority of contacts were in the daytime, which indicates a relatively low need for urgent and often more costly contacts in the evening and at night.

Another important finding is that when an exacerbation is mild when detected, the likelihood of needing physical contact to the health professionals in the course is low (< 5%) and with moderate exacerbations this increases to approximately 23% whereas approximately 31% with severe exacerbations require

physical evaluation and approximately half of these needs to be hospitalized.

Virtual Clinical Management Resilience Index

The increasing digitalization and virtualization of clinical care and the integration of services across providers call for an indicator of the resilience of the ecosystem of services that can be provided by the circles of care to individuals in a way that supports an active and independent living assisted by technology and with assistance when their condition periodically deteriorates. The ECM1 and ECM2 is an example of such ecosystem, which is supported by the blended physical and virtual services provided in the participant's own home (ECM3 and ECM4) or referral to a bed outside the participant's home (ECM5 or ECM6) in case of severe deterioration. The capacity to manage the individual in ECM1 and ECM2 relates to the competence of the health professionals to manage acute episodes remotely, their access to technology that supports their decisions, equipment in the participants' homes that enables the handing of even more complex situations, and finally the participant's and their relatives' understanding of and ability to manage the fluctuations of their condition.

As our data points to not only the classification of COPD with respect to severity and type of exacerbations, the context and resources also need to be reported in comparable manners. Instead of comparing technology and capacity of all the involved persons, we suggest an index that describes the resilience of the ecosystem of health services provided virtually as an indicator of maturity and capacity to manage participants most efficiently with focus on their well-being.

We propose a Virtual Clinical Management Resilience Index (VCMRI) that reports on the success of keeping patients within the setting of the virtual clinical environment. The ratio should be calculated as the number of cases that can be managed in a virtual clinical environment divided by the total number of patients.

In the context of ECM, a VCMRI will be a ratio of the number of exacerbations that can be reversed at ECM2. We found 121 severe exacerbations among the participants in our study and by using the formula on VCMRI with ECM2 in the denominator, we calculated a VCMRI of 0.694 for ECM2 meaning that almost 70% of severe exacerbations mitigated in ECM2. This is of interest as all services in ECM2 are performed virtually without any physical contact to the surrounding health care system. The VCMRI may be an important tool for the development of future integrated systems as it can enable the documentation and comparison of the health care services' ability to keep the patient at home, which is a service goal for most patients, who prefer receiving treatment and care in their own home [31,32]. Therefore, the VCMRI may contribute to the development of more integrated and personalized health care services fulfilling the patient's wish to be at home.

With its model for describing activities, roles, contexts, and technologies, the ECM can be used to allocate resources both within the virtual ecosystem and in the physical activities from ECM3 to ECM6. In reporting the resilience index, the efforts and resources can be reported in accordance with the structure of the ECM with respect to roles of the actors, their activities, the technology involved, and geographical locations as well as roles and certification of the involved actors. Future studies reporting in this context may map themselves into this model and compare with our results.

Strengths and Limitations

The strength of our study is the close contact to the participants in the period they are connected to the living lab. This provides our RCC staff with an insight into the everyday life of participants and how they manage their condition. The use of technology to document all the events for this study imposes a limitation as we cannot be entirely sure that all communications and actions are documented. Also, we do not have access to other health care IT systems at the individual level, which may result in an underestimation of hospital admissions relating to other conditions.

Another limitation is the recruitment of participants as it is a convenience sampling from the local community and without direct referral from hospitals or general practitioners. We may therefore miss those who were not able to use technology or were disengaged from the services where we recruited. With a more vigorous inclusion, we might be able to include more COPD patients, who have difficulties in managing their health. This could result in more severe courses including a higher rate of hospitalization as Wilkinson et al [8] demonstrated that those not seeking their GP or hospital specialists are in a higher risk of deterioration.

The observation period varied from 1 day to more than 2 years, and the lack of exclusion of the 4.6% who participated for less than a 14-day period may contribute to a lack of statistical differences between the risk factor groups with respect to the number of exacerbations and contact notes, as normalization of these data to patient year may have increased the variance of the data set. We have kept all the participants regardless of days spent in the study to conform to our research protocol, and we also find it important to keep these data as information about how early withdrawal contributes to the full picture of the population. It should be noted that all participants have been through 2 visits in their home by both a medical doctor and a member of the service team who introduced them to the equipment for self-tracking. Thus, withdrawal after only a few days signifies that despite of the enrolled participants being well informed, there is still a small group of participants who find it too difficult when left to self-monitoring. Unfortunately, for ethical reasons, we were not permitted to ask for a reason for the withdrawal.

Our study is an observational study without any controls. We are therefore not able to document the effect of the ECM intervention compared to how the participants would behave in relation to their contact pattern to conventional health services.

Perspective

We recommend future studies focus on participants who have been enrolled at least 90 days prior to observations for 2 reasons. The first is to be able to obtain a steady state situation before activities and outcomes of the intervention are observed. The second is from a resource perspective, as our data indicate that

the resources and efforts during enrollment and the first 30 days can only be justified if the COPD patients are using the services for a longer period, as their need for resources declines after 90 days (Figure 2).

Future studies should also be more focused on a more appropriate number of participants in each of the GOLD classes and risk factor groups, and they should also include matched controls or include a randomized control group.

Conclusion

The establishment of a person- and health-centered and digitally supported environment to assist people living with COPD has offered us a unique opportunity to learn about the nature of COPD over a period of up to 2 years. We find a large variation in both to what extent the participants engage themselves in self-monitoring activities and their need for contact with health professionals. The participants who are in most need of interaction with the health professionals (both virtual and nonvirtual) and have with the highest number of exacerbations belong to risk factor group D. The participants' interactions with the RCC staff were highest during the first month of enrollment as also seen in other studies, indicating that the participants develop their capability to manage their own condition over time. Our results are difficult to compare to other technology-assisted settings and we therefore suggest a resilience index, the VCMRI. Together with the ECM, the resilience index could be used as a scaffold to report on the success with mitigating participants at the virtual clinical management level and at the same time report on involved capacity. We also find a need for a classification of severe exacerbation which can translate the current GOLD recommendation of hospitalization as a criterion with resources and efforts comparable to these in a telehealth care setting including the practice of referral to hospitalization at home or community care.

Acknowledgments

KP and SV have received support from the 3P project from the Norwegian Health Foundation during the period 2016-2018 while contributing to the manuscript. The authors thank the health professionals, patients, administrators, and politicians at the municipality of Lyngby-Taarbæk for their active participation in the project. They would also like to thank Charlotte Dorph Lyng and Jakob Sylvest Nielsen for their active engagement.

Conflicts of Interest

KP is a partner in the company Epital Health, which provides services based on the ECM.

Abstract

Background: The COVID-19 pandemic has boosted the use of forced expiratory volume in 1 second (FEV_1) telemonitoring in pediatric asthma, but a consensus on its most efficient and effective implementation is still lacking. To find answers, it is important to study how such an intervention is perceived, experienced, and used by both patients and health care professionals (HCPs).

Objective: The aim of this study was to provide perspectives on how FEV_1 home monitoring should be used in pediatric asthma.

Methods: This is a qualitative, multicenter, prospective, observational study which included patients with asthma aged 6-16 and HCPs. Primary outcomes were results of 2 surveys that were sent to all participants at study start and after 3-4 months. Secondary outcomes consisted of FEV_1 device usage during 4 months after receiving the FEV_1 device.

Results: A total of 39 participants (26 patients and 13 HCPs) were included in this study. Survey response rates were 97% (38/39) at the start and 87% (34/39) at the end of the study. Both patients and HCPs were receptive toward online FEV_1 home monitoring and found it contributive to asthma control, self-management, and disease perception. The main concerns were about reliability of the FEV_1 device and validity of home-performed lung function maneuvers. FEV_1 devices were used with a median frequency of 7.5 (IQR 3.3-25.5) during the 4-month study period.

Conclusions: Patients and HCPs are receptive toward online FEV_1 home monitoring. Frequency of measurements varied largely among individuals, yet perceived benefits remained similar. This emphasizes that online FEV_1 home monitoring strategies should be used as a means to reach individual goals, rather than being a goal on their own.

Introduction

The primary aim of asthma care is to reach and maintain asthma control by early recognition and treatment of pulmonary exacerbations (PEx) [1]. In children with asthma, objective measures to aid patients, caregivers, and health care professionals (HCPs) in detecting pulmonary deterioration are crucial [1-3]. Many objective measures have been studied and proposed, but the forced expiratory volume in 1 second (FEV_1) measured by spirometry remains undefeated as both an objective measure of pulmonary deterioration and a criterion for defining PEx [4-6]. The limitation of FEV_1 is that it is usually only measured during scheduled outpatient clinic visits and not preceding asthma exacerbations. As a response to the COVID-19 lockdowns, many hospitals have reduced their outpatient clinic capacities which further decreased our ability to timely recognize PEx. Additional unplanned outpatient visits during symptoms were also harder to schedule because of COVID-19 measures in hospitals. It is therefore no surprise that telemonitoring, including FEV_1 home measurements, has become more popular during the COVID-19 pandemic [7-9].

The value of FEV_1 telemonitoring has been a subject of debate since portable spirometers became available. Although generally accepted as a feasible intervention in children with limited disease perception, concerns regarding the reliability of the measurements persist, and studies have failed to convincingly show an added value of FEV_1 home monitoring in general asthma care [1,4,10-15]. Most of these studies used strict monitoring regimes in which patients measure their FEV_1 daily in order to reduce PEx and health care consumption. As a result, monitoring adherence declined, and HCPs were left with mounts of—mostly irrelevant—FEV_1 data and eventually the primary objectives were not reached [1,12-15]. This raises the question of what role FEV_1 telemonitoring should play in pediatric asthma. With the currently rapidly accelerating interests in FEV_1 telemonitoring, it is even more important to develop perspectives on this topic.

This study aimed to develop new perspectives on how to use FEV_1 telemonitoring in the future of pediatric asthma care. To achieve this we combined FEV_1 home monitoring with an online eHealth platform [16-18]. Our main research question was "How do patients, their parents, and HCPs want to make use of FEV_1 home monitoring?" Patients who already used the eHealth platform in regular pediatric asthma care to monitor asthma control with questionnaires received FEV_1 monitoring devices which were integrated in the platform. To realistically reflect a regular pediatric care setting, no fixed measurement schedules were used and patients themselves kept responsibility on how often they measured their lung function. Expectations and experiences of both patients and HCP were studied, as well as FEV_1 device usage.

Methods

This was a qualitative, multicenter, prospective, observational study on FEV_1 home monitoring combined with an online eHealth platform for 4 months. The eHealth platform is used in regular pediatric asthma care to monitor asthma control using the validated (childhood) Asthma Control Test ([C]-ACT), and to support self-management with personalized online asthma action plans [19,20]. Details of the eHealth platform have been published previously [16-18]. For this study the platform was expanded with a module for FEV_1 home measurements. FEV_1 measurements were performed with the Spirobank Smart and automatically uploaded to the online eHealth platform with a smartphone app [21]. The smartphone app was available on both Google Play and the Apple App Store. Participants could log in to the smartphone app with the same credentials as used for the online eHealth platform. After pairing with the FEV_1 device once, participants could use the app to perform measurements. Measured values were automatically sent to the app via Bluetooth and could be uploaded directly to the online eHealth platform (Figure 1). In addition to FEV_1, the Spirobank Smart devices measured the forced vital capacity (FVC), FEV_1-to-FVC ratio (FEV_1/FVC), peak expiratory flow (PEF), and forced expiratory flow at 25%-75% (FEF25-75). Automated feedback was given for each measurement. A green, orange, or red tag was provided based on individual thresholds depending on the personal best value of FEV_1 of that patient. A green tag prompted encouraging feedback and required no intervention, while an orange or red tag (ie, usually below 80% of the patient's best value) prompted an intervention based on the personal online asthma action plan of the patient. A red tag also sent an automatic email notification to the treating HCPs which they could follow-up on if deemed necessary. FEV_1 values were plotted over time in the online eHealth platform (Figure 2). The FEV_1 is the main lung function outcome on the eHealth platform, but additional values were visible when selecting specific measurements on the platform. During this study patients kept the responsibility on how often they used their devices, and no instructions were given on how often they needed to measure their FEV_1.

Figure 1. Screenshots of the instruction screen (left panel), measurement screen (middle panel) and feedback screen (right panel) of the smartphone app. The text in the instruction screen provides a short description on how to use the FEV_1 device appropriately. The measurement screen shows a successfully performed measurement with buttons to upload (upper) or repeat (lower) the measurement. The feedback in the feedback screen is based on individual thresholds. Language is in Dutch.

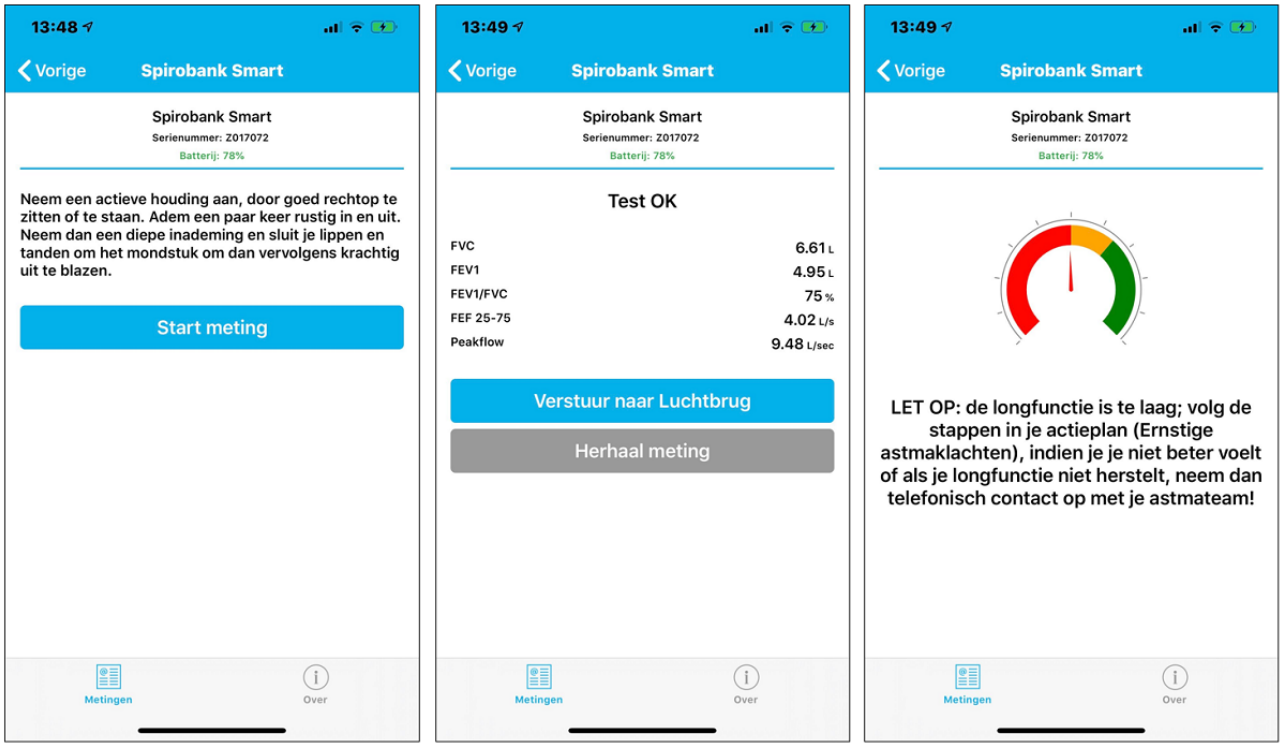

Figure 2. Screenshot of the graphical presentation of FEV_1 measurements on the online eHealth platform of one of the participants. Language is in Dutch. Colors represent individual color zones (green, orange, red).

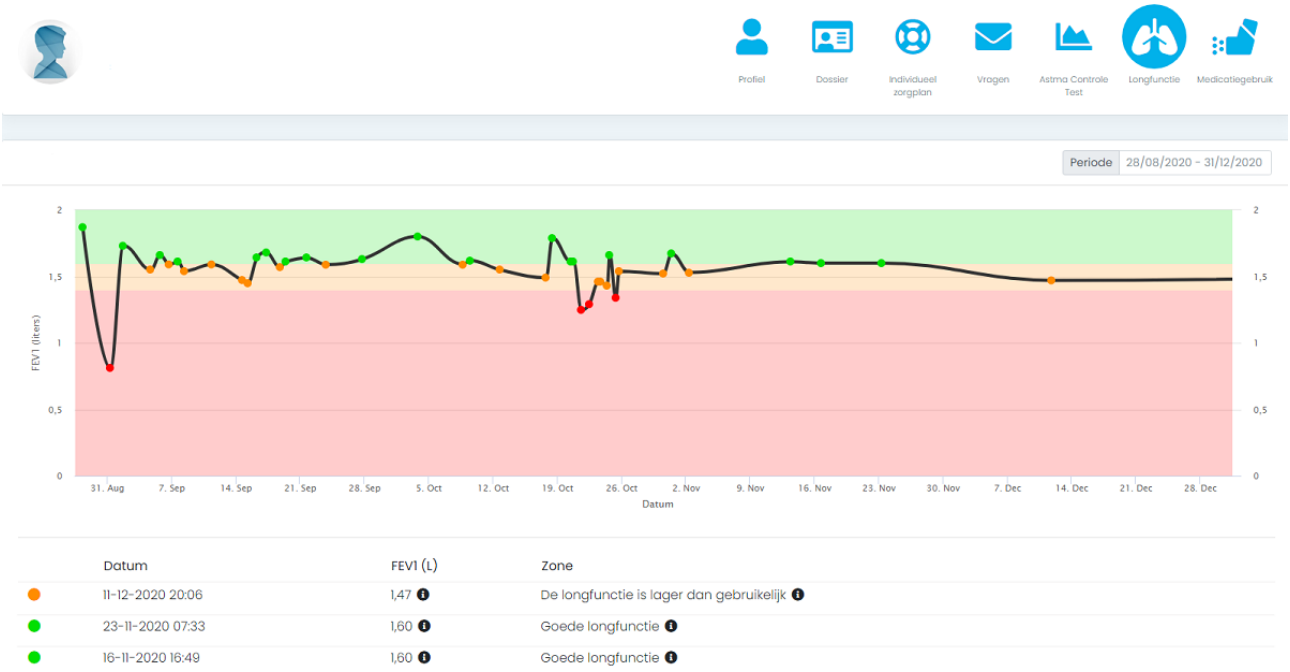

Participants were recruited during outpatient visits in specialized asthma clinics from a university hospital (Radboudumc, Nijmegen, the Netherlands) and 2 general hospital (Canisius Wilhelmina Hospital, Nijmegen, the Netherlands and Spaarne Gasthuis, Haarlem, the Netherlands). Participants were eligible for inclusion if they had a doctor's diagnosis of asthma based on the Global Initiative for Asthma (GINA) criteria, were aged 6-18 years, and already used the online eHealth platform for regular pediatric asthma care [1]. All parents and participants aged ≥12 years had documented verbal consent for the anonymized use of their data. The local ethical committee waived approval of the Medical Research Involving Human Subjects Act (WMO) considering the negligible burden of this study and the absence of imposed risks.

The primary outcome included survey results of patients (or their parents in case of young patients) and HCPs before and 3-4 months after the introduction of FEV_1 devices. We used modified validated research questionnaires originally designed by Grol et al [22] to gather information from 5 perspectives: the receptiveness for using innovations in health care, the perceived contribution of online FEV_1 home monitoring to asthma care, the perceived contribution of online FEV_1 home monitoring to patient self-management, the user-friendliness of the service, and the possible undesired effects. The surveys consisted of 21-25 questions of which most were to be answered with a 5-item Likert scale (strongly disagree to strongly agree). The online survey also asked participants to comment on experienced benefits and disadvantages, and to provide suggestions to improve the service. Survey outcomes were described and analyzed on intergroup differences at both time points and intragroup differences over time.

The secondary outcome was FEV_1 device usage over the 4-month study period. All statistical analyses were performed using Statistical Package for the Social Sciences (SPSS version 25; IBM).

Results

A total of 39 participants (26 patients and 13 HCPs) were included in this study. Patient characteristics at baseline are summarized in Table 1. HCPs were employed as pediatric pulmonologists (5/13, 38%), general pediatricians (1/13, 8%), residents (2/13, 15%), specialist nurses (4/13, 31%), or doctor's assistants (1/13, 8%). The median (IQR) age of HCP was 54 years (38.5-58). Baseline lung function was defined as a measurement recorded within 31 days of FEV_1 device reception. Two patients did not record any lung function measurements and 1 patient did not record a lung function measurement within the 31-day baseline window. One patient quit the study due to loss of interest. During this study none of the patients experienced a PEx nor were hospitalized.

Tiff (%), median (IQR)	81.87 (77.84-89.20)
z-FEF25-75, mean (SD)	–1.37 (1.07)
Color zone not green, n (%)	6 (35)

[a]Baseline lung function outcomes were defined as the first measurement within 31 days of receiving the FEV_1 measurement device. Three of the included participants did not perform a baseline lung function measurement.

[b]ICS: inhaled corticosteroids

[c]Beclomethasone or equivalent dose.

[d](C-)ACT: (Childhood) Asthma Control Test.

[e]FEV_1: forced expiratory volume in 1 second.

[f]FVC: forced vital capacity.

[g]FEF: forced expiratory flow.

Survey response rates at start were 96% (25/26) for patients and 100% (13/13) for HCPs, whereas those at the end were 85% (22/26) and 92% (12/13), respectively. Survey results and intragroup comparisons over time are summarized in Tables 2 and 3.

A total of 18 (69%) patients used their FEV_1 device more than 3 times during the study period. FEV_1 devices were used with a median frequency of 7.5 (IQR 3.3-25.5) distributed over 5.5 unique days (IQR 2.3-19.0). Two patients did not use their FEV_1 device at all, because one quit the study and another experienced technical difficulties. Most measurements were performed in the morning (154/421, 36.6%) or evening (156/421, 37.1%). 30.6% (129/421) of measurements were not in the personalized green zones, and 11.6% (49/421) of measurements were in the personalized red zone, leading to closer inspection by HCPs.

Seven patients reported that they did not want to decide themselves how often they measured their lung function (Table 2, Q12). Only 2 of these patients used their device with a frequency within the IQR of all participants. The others used their device as follows: not at all, once or twice, or very often (33 or 41 times).

Table 2. Patient survey outcomes.

Statement[a]	Start, median (IQR)	End, median (IQR)	Significance (*P* value)
Q1. I am experienced with using smartphones.	5 (4-5)	N/A[c]	—

Q19. I know which patients are eligible for home monitoring of FEV_1.	4 (4-4)	4 (3.25-4.75)	.32

[a]Responses were collected on a 5-point Likert scale, where 1=strongly disagree; 2=disagree; 3=neutral; 4=agree; 5=strongly agree.

[b]FEV_1: forced expiratory volume in 1 second.

[c]N/A: not applicable.

[d]Statistically significant change between survey outcomes at end and start.

Patients were interested in knowing all of their measured FEV_1 values. By contrast, HCPs at both start and study end were more interested in only knowing their patients' FEV_1 outcomes when they were lower than expected (*P*=.006 and .001, respectively). At the start, HCPs were significantly more likely to expect an increased time burden compared with patients (*P*<.001). However their expectations were not matched by their experiences because at study end HCPs had significantly improved opinions on time burden compared with study start (*P*=.021; Table 3, Q14). Reported benefits, disadvantages, and suggestions by HCPs and patients are summarized in Textboxes 1 and 2.

Textbox 1. Patients reported benefits, disadvantages, and suggestions at the end of the study. FEV1: forced expiratory volume in 1 second.

Benefits

- More insights into my/my child's asthma
- Improved asthma control
- Less frequent hospital visits
- Always being able to know how I am/my child is doing
- It helps me with my/my child's disease perception
- More insights into my/my child's lung function
- Facilitates easy and quick adjustment of treatment
- Signaling of low lung function

Disadvantages

- Wrong values when the measurement is performed incorrectly
- The device does not always work
- It is easy to lose the device
- It is easy to forget to perform measurements
- The FEV_1 device is less reliable than the device in the hospital
- Performing the FEV_1 measurements is time consuming
- The mouthpiece is too large for small children

Suggestions

- Reminders should be sent to perform an FEV_1 measurement
- The FEV_1 device should be easier to use
- Instructions on how to clean the device
- Smaller mouthpiece for smaller children

Textbox 2. Health care professionals' reported benefits, disadvantages, and suggestions at the end of the study. FEV1: forced expiratory volume in 1 second.

Benefits

- Provision of objective measures of asthma control
- Aids patients with disease perception
- Continuity of monitoring
- Earlier recognition of pulmonary exacerbations
- Taking a simple and quick lung function test is possible when needed
- Facilitates easy and quick adjustment of treatment

Disadvantages

- More stress for both patients and caregivers
- More emphasis on patients' asthma
- FEV_1 measurements might be performed incorrectly which can falsely comfort or alarm patients
- Compulsive FEV_1 testing and less attention for perceived symptoms
- Decreased motivation when FEV_1 remains low while symptoms are barely present
- Time consuming for both patients and health care professionals
- Technological difficulties of FEV_1 devices

Suggestions

- Good instructions at baseline
- FEV_1 devices should be calibrated at every outpatient visit
- FEV_1 home measurements should be used as a means to aid patients in achieving their individual goals. FEV_1 home measurements should not be a goal on their own
- Better instructions for patients on what to do when their FEV_1 is lower than expected
- Less notifications for health care professionals during pulmonary exacerbations
- A notification when patients are back in their green zone
- Protective case for a fragile FEV_1 device

Discussion

Our findings show that both patients/their parents and HCPs are receptive toward online FEV_1 telemonitoring in pediatric asthma care. The participants in this study agreed that FEV_1 telemonitoring in pediatric asthma care is innovative and improves asthma care, self-management, and disease perception. Most of the expectations patients and HCPs had about FEV_1 telemonitoring matched their experiences. Initially, HCPs had concerns regarding the additional time burden and increased stress and insecurities of patients. However, HCPs' experienced time burden was eventually lower than expected and increased stress and insecurities of patients were not reflected in the patients' own experiences.

In our self-paced monitoring protocol, 69% (18/26) of patients used their FEV_1 device regularly, which affirms survey-reported receptiveness of patients. However, the large interindividual range in the frequency of use between patients emphasizes the different approaches of individuals. Only 11.6% (49/421) of measurements were in the "red zone." The vast majority of measurements required no intervention or could be resolved with automatic feedback prompts using patients' personalized online asthma action plans.

To our knowledge, this is the first study on patients' and HCPs' receptiveness of FEV_1 home monitoring combined with an online eHealth platform in pediatric asthma care. The existing body of literature often reports acceptance of FEV_1 home monitoring, but it is rarely quantified [12-15]. Because of the COVID-19 pandemic, there is an increased call for research into user satisfaction and receptiveness of eHealth interventions [8,9]. Before the COVID-19 pandemic, Simpson et al [23] surveyed 187 patients with asthma and 63 HCPs on eHealth interventions and found that both groups supported the use of eHealth and preferred eHealth over paper diaries and paper asthma action plans. They also found that in both groups lung function measurements were expected to be the most contributive additional measurement for asthma control in an eHealth program [23]. This highlights the increasing demand for home monitoring of lung function among patients. In our small population, expectations of both patients and HCPs were matched by their experiences, underlining that patients and their

parents can assess for themselves whether FEV_1 telemonitoring will aid them. Therefore, we argue that patients interested in the ability of online FEV_1 monitoring should receive this opportunity to assess personal benefits.

How patients achieve personal benefits should be a result of shared decision making between patients and their HCPs. We now know that standalone FEV_1 monitoring with strict monitoring regimes in most patients does not work out [12-15]. By contrast, we believe that in the future FEV_1 devices should be used to reach personalized goals, such as reassurance, as an aid to improve symptom perception or to quantify lung function during episodes with increased symptoms. When integrated into an eHealth platform, these devices can be used at the patient's convenience and provide immediate feedback. It is our opinion that these set ups can facilitate these goals more easily and quickly than standalone FEV_1 monitoring. The results of our study support this opinion. In this study most patients wanted to keep their own responsibility on how often they measured their lung function. Subsequently, we found a large variation in frequency of use between participants, but there was a consensus nonetheless on the perceived benefits of asthma control and disease perception by both patients and HCPs. Some patients did not want to keep the responsibility on how often they measured their lung function and as a result most of these patients either rarely used the devices or overused them. This also shows that for some patients a structured monitoring regime could be indicated. Self-management depends on several factors such as individual health skills, disease perception, beliefs, and the interaction between patients and their HCP, and thus one size does not fit all. To ensure longevity and efficiency of FEV_1 telemonitoring, a personalized approach should be used: patients who want to keep the responsibility to themselves should be offered this chance, whereas those who do not want to should be offered a schedule. To better understand this personalized approach, it is important that both the clinical and perceived benefits of the different approaches are studied experimentally in more detail. It is important to identify which patients benefit most from which intervention and how we define personal benefits.

Recurring concerns of FEV_1 telemonitoring are toward the reliability of the measurements. These were also present in our population and are generally shared among the scientific community [1,4,24,25]. Although perfect correlation of FEV_1 home measurements with hospital measurements is desirable, one can argue that FEV_1 monitoring will primarily be used to ascertain an FEV_1 above a certain threshold. In that case a somewhat lower FEV_1 may not be of any clinical relevance. By contrast, invalidly low FEV_1 values at home may lead to excessive health care consumption, medication use, and disease-related stress. Online FEV_1 home monitoring should function as an aid for symptom perception and a quick objective measure during symptoms. In our opinion these aims do not require an FEV_1 outcome as sensitive as that measured by a spirometer operated by a specialist nurse. Nevertheless, reliability should be studied in more detail to rule out counterproductive measurements.

This study was limited by its small study population and short study duration, which were chosen due to the nature of this viewpoint study. Only including patients and HCPs from specialized asthma clinics who also had experience using our eHealth platform would have introduced selection bias. In our opinion this does not invalidate our findings; by selecting patients and HCPs who already have experience with the eHealth platform we avoid confounding of our qualitative outcomes by the introduction of the eHealth platform. We also still observed a large interindividual variation in FEV_1 device usage. Finally we believe that home monitoring strategies like this will be reliant on some form of selection bias as they should primarily be applied in patients that are receptive. This might imply that our results are not extrapolatable to settings without previous eHealth experience, general practitioner services, or to low-resource settings. Furthermore, we performed no post measurement quality control of the FEV_1 measurements, which may have led to technically incorrect measurements being recorded. However, the software of the FEV_1 device performs a quality check based on the American Thoracic Society (ATS)/European Respiratory Society (ERS) consensus statement [26,27].

Viewpoint

Our findings show that patients and HCPs are receptive toward online FEV_1 home monitoring combined with an online eHealth platform. Frequency of measurements varies largely among individuals, yet perceived benefits remain similar. This emphasizes that online FEV_1 home monitoring strategies should be used as a means to reach individual goals, rather than being a goal on their own. During the COVID-19 pandemic we have seen eHealth being integrated more into daily medical practice and this will undoubtedly increase even more in the near future. With this increasing use of eHealth, we will see an equal surge of different ways to monitor our patients. In this data tangle it is easy to lose sight of what really matters: patient quality of life and needs. If we want to continuously monitor our patients, we should not only study the clinical relevance, but also the experienced benefits, invasiveness, and perceptions of our patients, while keeping in mind that one size does not fit all. Even after implementation we should repeatedly monitor patient satisfaction. eHealth is a dynamic entity and strongly bound to technologic advances. Patients should have a say in how these advances will be utilized and in which way they add value to their lives. HCPs have to remember that the goal should not be to gather outcomes, but to use these outcomes to reach personal goals in a personalized way.

Abstract

Background: Continuous physiological monitoring technologies are important for strengthening hospital care for neonates, particularly in resource-constrained settings, and understanding user perspectives is critical for informing medical technology design, development, and optimization.

Objective: This study aims to assess the feasibility, usability, and acceptability of 2 noninvasive, multiparameter, continuous physiological monitoring technologies for use in neonates in an African health care setting.

Methods: We assessed 2 investigational technologies from EarlySense and Sibel, compared with the reference Masimo Rad-97 technology through in-depth interviews and direct observations. A purposive sample of health care administrators, health care providers, and caregivers at Aga Khan University Hospital, a tertiary, private hospital in Nairobi, Kenya, were included. Data were analyzed using a thematic approach in NVivo 12 software.

Results: Between July and August 2020, we interviewed 12 health care providers, 5 health care administrators, and 10 caregivers and observed the monitoring of 12 neonates. Staffing and maintenance of training in neonatal units are important feasibility considerations, and simple training requirements support the feasibility of the investigational technologies. Key usability characteristics included ease of use, wireless features, and reduced number of attachments connecting the neonate to the monitoring technology, which health care providers considered to increase the efficiency of care. The main factors supporting acceptability included caregiver-highlighted perceptions of neonate comfort and health care respondent technology familiarity. Concerns about the side effects of wireless connections, electromagnetic fields, and mistrust of unfamiliar technologies have emerged as possible acceptability barriers to investigational technologies.

Conclusions: Overall, respondents considered the investigational technologies feasible, usable, and acceptable for the care of neonates at this health care facility. Our findings highlight the potential of different multiparameter continuous physiological

monitoring technologies for use in different neonatal care settings. Simple and user-friendly technologies may help to bridge gaps in current care where there are many neonates; however, challenges in maintaining training and ensuring feasibility within resource-constrained health care settings warrant further research.

infants; Africa; medical technology design; user perspectives; in-depth interviews; direct observations

Introduction

Globally, neonatal mortality remains persistently high, with a disproportionate burden in Sub-Saharan Africa [1]. Technologies that allow for early detection of neonatal physiological instability and help guide appropriate interventions have the potential to reduce morbidity and mortality [2]. In resource-constrained health care settings where staffing shortages of trained health care providers (HCPs) may compromise capacities for adequate monitoring and management, such technologies may prove life-saving [2].

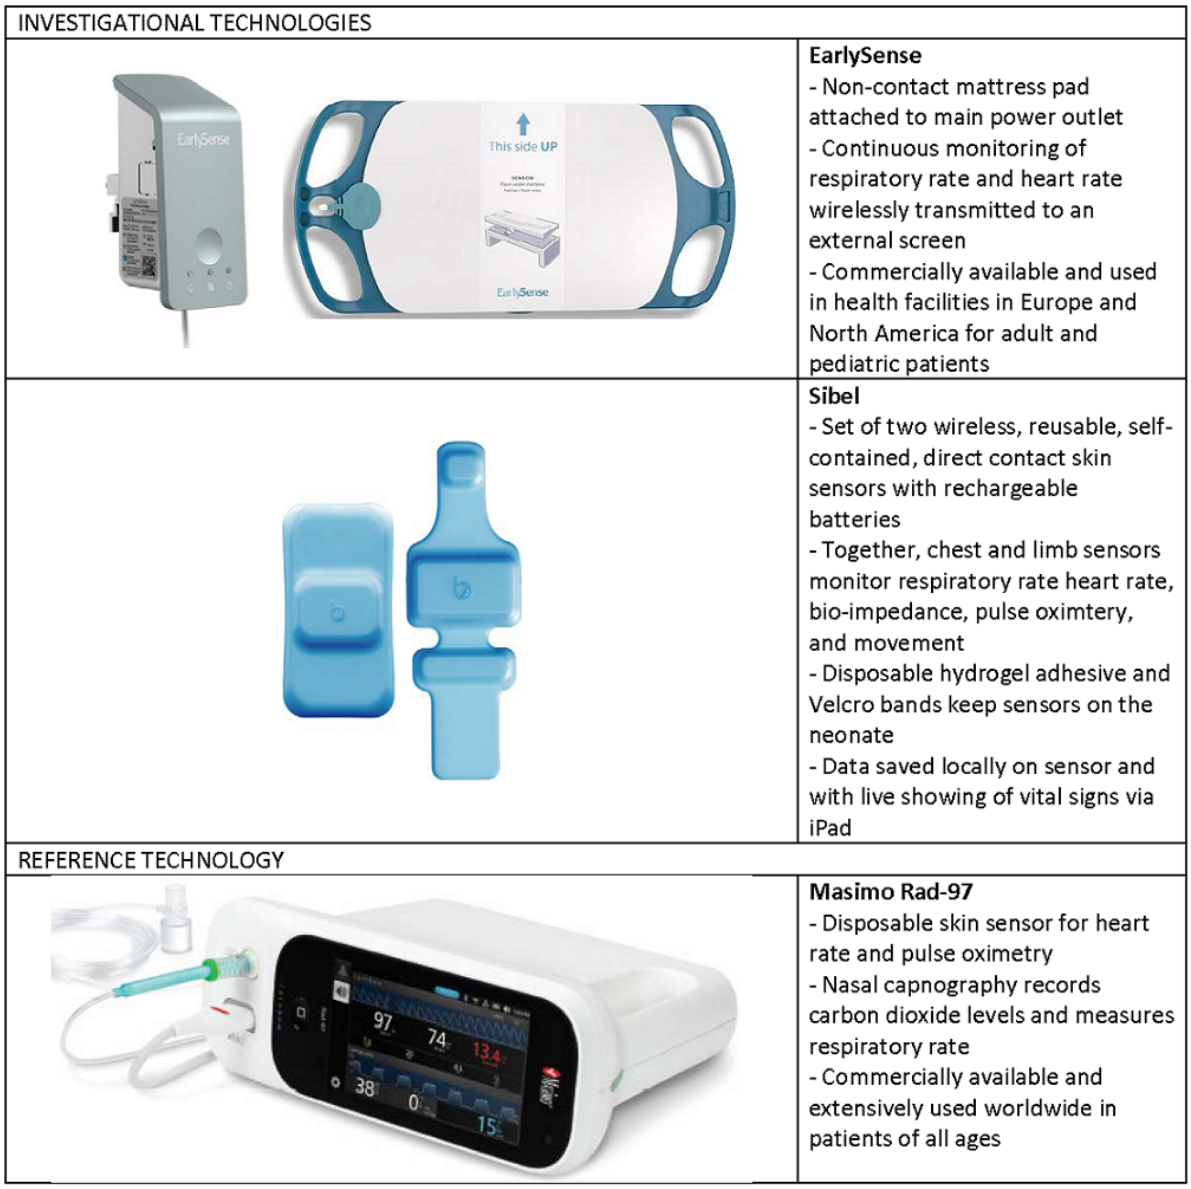
The Evaluation of Technologies for Neonates in Africa (ETNA) project was conceived with the goal of advancing and supporting development, as well as evaluation of technologies for use in neonates in resource-constrained settings. The project seeks to boost the development and optimization of promising neonatal diagnostic and care technologies that could be applied in resource-constrained settings by establishing an Africa-based evaluation platform. This is achieved through global collaboration with partners with expertise in medical technology development and evaluation, as well as neonatal and child health. Critical to medical technology design, development, deployment, and eventual uptake and acceptability is understanding user perspectives in the intended setting. Evidence of the feasibility, appropriateness, and acceptability of innovative approaches for improving maternal and neonatal health has not been adequately investigated, which has implications for scale-up [3]. We assessed the feasibility, usability, and acceptability of 2 existing noninvasive, multiparameter, continuous physiological monitoring (MCPM) technologies developed by technology developers EarlySense and Sibel for use in neonates in an African health care setting.

Methods

Study Design

We conducted a qualitative study comprising in-depth interviews and direct observations using a cross-sectional design. This substudy was part of the larger ETNA project to evaluate the accuracy, reliability, and performance of 2 investigational noninvasive MCPM technologies in neonates when compared with verified reference technologies (Figure 1) [4]. The qualitative component used a descriptive and interpretive approach to understand the meanings respondents ascribed to feasibility, usability, and acceptability [5]. Feasibility comprises systemic factors, including hospital infrastructure and operational capacities, as well as functional capacities of the HCP available [6]. Usability comprises design factors affecting user experience, including features that support or hinder the operation of the technology for its intended purpose, such as ease of and efficiency in use and frequency of errors, memorability to a casual user, and user satisfaction with the system [6,7]. Acceptability comprises 2 dimensions: the willingness of HCPs to use the technology during patient interactions and the willingness of caregivers to have the technology used with their neonates [6].

Figure 1. Overview of the 3 multiparameter continuous physiological monitoring technologies.



The study is reported based on the *Consolidated Criteria for Reporting Qualitative Research* (COREQ; Multimedia Appendix 1) [8]. Ethics approvals were obtained from Western Institutional Review Board 20 191 102 (Puyallup, Washington), and the Aga Khan University Nairobi Research Ethics Committee 2019/REC-02 (v2; Nairobi, Kenya).

Study Setting

The study was conducted at the Aga Khan University Hospital, Nairobi, a tertiary teaching and referral hospital with neonatal intensive care and high dependency units. The Aga Khan University Hospital is the busiest private hospital maternity unit in Nairobi, delivering approximately 4,500 neonates a year, and serves as a tertiary referral center for Kenya as well as the East Africa region. The neonatal high dependency unit has an 8-bed capacity and admits, on average, 5 to 10 neonates per week, with an approximate nurse-to-neonate ratio of 1:3. The ETNA project worked within the neonatal high-dependency unit and employed 2 research nurses to support the study.

Recruitment and Selection

A purposive study sample was drawn to include a wide variety of perspectives on the feasibility, usability, and acceptability of the 3 MCPM technologies. The sample consisted of health care administrators, including hospital leadership and administrative staff involved in the procurement of neonatal hospital equipment, HCPs who were direct users of the MCPM technologies (health care provider—direct [HCP-Ds]), indirect HCPs involved in neonatal care (HCP-Is), and caregivers. A sample size of 12 HCPs and 5 health care administrators was estimated to cover perspectives from the staffing positions available and selected from a predefined list of current hospital staff generated by the ETNA team. HCP-D were recruited from ETNA nursing staff. HCP-D was trained for the study and had experience working with the technologies, whereas HCP-I (facility-based neonatal consultants, pediatric residents, and nurses) were oriented to the technologies during the interviews. A sample size of 10 caregivers, including mothers and fathers

of neonates enrolled in the ETNA study, was estimated to reach data saturation because multiple technologies were used with each neonate during their hospital stay.

Study recruitment was publicized using flyers, and study participants were approached in person by a member of the qualitative study team, who were hired as part of the substudy and did not know the participants before the study. Interviewers first introduced themselves as members of the ETNA study team and explained the study in detail.

Data Collection

In-depth interviews with health care administrators, HCPs, and caregivers and direct observations were conducted between July and August 2020. A Kenyan research consultant (VN, PhD in sociology, female) and a research assistant (Diploma in health sciences, female) were hired by the ETNA substudy to collect data. The research assistant underwent a 3-day intensive training in qualitative research methods led by VN before conducting the interviews.

The semistructured interview guide and observation guide (Multimedia Appendices 2 and 3) were piloted within the Kenyan data collection team during training to refine the questions. Face-to-face interviews were conducted in a private place within the hospital after the study participants provided written informed consent. The 30- to 45-minute interview was conducted in English or Kiswahili, the major local language in Kenya, depending on participant preference. One participant opted for a mix of Kiswahili and English, whereas the rest of the participants opted for English. Observations were conducted after obtaining written informed consent from HCP-D and followed a structured guide covering preparation and initial technology application, ongoing monitoring or troubleshooting, and technology disconnect, removal, and cleaning. Interviews were audio-recorded with permission, and data collectors took field notes while conducting the interviews. No repeat interviews were conducted.

Data Analysis

Interviews were transcribed verbatim, translated into English as needed, and managed using NVivo 12 software (QSR International). We used a thematic approach to analyze the data following the methods described by Braun and Clarke to become familiar with the data, generating initial codes, collating identified codes into themes, and describing themes using illustrative quotes [9]. A coding framework was developed deductively from the study objectives to cover feasibility, usability, acceptability, and emergent themes from the transcripts. The coding framework was developed in consensus between the ETNA study team (ASG, MWK, VN, JR, DC, JC, and WMM), and VN conducted the primary coding with review by MWK (Multimedia Appendix 4). Confidentiality was maintained by limiting access of study materials to authorized personnel and ensuring that no identifying information was included in the analysis.

Results

Overview

Overall, the use of the relevant technologies was observed with 12 neonates, and observations took between 2 and 10 minutes per technology. In addition, 27 interviews were conducted, including 10 caregivers (9 mothers, 1 father), 2 HCP-D (study nurses), 10 HCP-I (4 medical doctors, 6 nurses), and 5 health care administrators (nurse managers, program administrators, and hospital unit supervisors). One HCP-I and no caregiver declined to participate. All health care administrators and HCPs had a postsecondary education. There were 2 HCPs with diplomas in nursing (1 HCP-D and 1 HCP-I), and all other health professionals had bachelor's or master's degrees. Health professionals had a median of 9 (<1-29) years of work experience in the medical field. In addition, all but 1 caregiver had a postsecondary education. The median age of caregivers was 33 (range 28-38) years, and they had a median of 2 (range 1-3) children. Caregivers were largely employed in professional occupations, including nursing, banking, human resource services, travel consultancy, business, sales, civil service, and farming.

Feasibility Factors for the Investigational Technologies

Health care administrators described challenges in staffing and maintenance of training in neonatal units as a key feasibility consideration for the development of neonatal MCPM technologies. A health care administrator described:

> *I am finding it difficult to get the expertise that we require because...we don't have many institutions who are training for critical care...neonatal nursing...[P]eople are learning on the job.*

Another health care administrator highlighted:

> *There has been a lot of turnover in the newborn unit. So...you need to now make sure that you are training...on a continuous basis. It is not just about the equipment; the staff also need to have a very good understanding of how that equipment function.*

Within the context of high staff turnover and on-the-job training, simple MCPM technologies were valued for the minimal training required and ease of application.

The minimal training required was a major facilitator reported for feasibility by the participants. Most HCPs and health care administrators (11/17, 65%) reported that the investigational technologies appeared to be easy to train for use and built on existing clinical skills. Referencing the EarlySense technology, an HCP-D nurse highlighted:

> *You only need very minimal training… just [place] it under the mattress and it monitors the baby, monitors the pressure. Very easy to use.*

An HCP-I nurse noted that the Sibel technology could be easily learned within a few hours mentored by a current user:

> *[it requires] like an on-job training, like maybe a few hours, because...it is not...totally new from what is being used.*

Feasibility challenges reported included the requirement of ancillary equipment, Wi-Fi requirements, and concerns about integration with existing facility equipment.

A minority of HCP and health care administrators expressed concerns about the requirements for external screens (2/17, 12%) and Wi-Fi (6/ 17, 35%). Equipment integration concerns were expressed particularly among health care administrators (3/5, 60%). A health care administrator said:

> *...we would want all the information in one place, and not this one here and the other on the other side...so that clinicians are not looking for information in two or three different places...*

Affordability has also been raised as an important issue for feasibility. An HCP-I nurse said of the EarlySense technology:

> *Number one thing will be the cost...If the cost is higher, then [the hospital administrators] will have to weigh which is a cheaper option that will give more or less the same results.*

Because the investigational MCPM technologies were perceived as simple, there was an expectation that costs would be affordable. A health care administrator said of the Sibel technology:

> *They should be about 10,000 shillings (approximately 90 USD) and not more than that. They are basic equipment.*

Usability Factors for the Investigational Technologies

Ease of use and efficiency of the technologies for neonatal care were major usability facilitators reported by most HCPs (9/12, 75%), health care administrators (4/5, 80%), and caregivers (7/10, 70%). An HCP-I nurse noted the EarlySense technology "is quite simple than our normal standard monitoring device here...it looks easier to use." Speaking about the Sibel technology, an HCP-D nurse said:

> *It even [has] more functions than our current cardiac monitor so that's a plus that we are having less manipulation to the baby in terms of attachment, but we are having much results. You can see more...heart rate, respirations, we can see movement, we can see temperature...*

Ease of use was also reflected in observations; trained HCP-D nurses were able to prepare and initiate the technologies, monitor, and disconnect smoothly without many errors or assistance from other HCPs. Caregivers shared that they found the investigational technologies easy to understand and memorable even as casual users while monitoring their neonate at the hospital. Regarding the EarlySense technology, a mother said:

> *At a glance, you're able to know all your readings...You're actually able to monitor at a glance; you don't need to worry.*

Another mother said of the Sibel technology:

> *.....on her iPad, I could see the oxygen [levels]. It was on the right levels.*

The potential for wireless features to improve work efficiency was another major usability factor reported by the participants. Approximately half of the caregivers, HCPs, and health care administrators (13/27, 48%) commented that the potential of the wireless or noncontact features of the investigational technologies to transmit information to an external screen and remotely monitor multiple neonates could increase the speed of HCP detection and reaction to changes in vital signs. An HCP-D nurse commented on the EarlySense technology:

> *The screen that you are using to display the results, you can put it at the nursing station...So you can monitor many babies at the same time. It will reduce workload...*

Speaking of the Sibel technology, a mother said:

> *You could be in a facility where babies are so many, so the service provider, they're overwhelmed. But if there are such devices that they're able to relay information faster, that means so many babies at least can be observed comfortably, so you save lives.*

Fewer attachments have also been reported to increase efficiency in care by reducing the need to disconnect and reconnect the neonate during HCP examinations and caregiving needs, such as breastfeeding. Speaking of the EarlySense technology, a health care administrator said:

> *...the coding is remote. It doesn't interfere with routine care...Like sometimes, I have to remove certain wires to be able to examine a baby properly. So, the fact that it leaves the baby unencumbered with all those things I think is a huge advantage*

However, with the EarlySense technology specifically, there were concerns from HCP and health care administrators (5/17, 29%) of monitoring during disruptions when the neonate was off the mattress during breastfeeding or otherwise being carried by caregivers.

Small size and portability were reported by some HCPs and health care administrators (8/17, 47%) as potential facilitators and challenges to usability. Although portability and convenience are linked, there was also concern about misplacement and theft because of their small size and portability. For example, a health care administrator said that it would be critical for the Sibel technology:

> *...to make sure that these things aren't lost by staff...We might buy them, but at the end of the year, they might all be lost. Because, you know something which is attached and something which is a little bit big might be better.*

Other usability challenges included concerns about infection control, shared by 41% (7/17) of the HCPs and health care administrators. In addition, 26% (7/27) of overall participants expressed concerns that equipment may be too large for preterm and low-birth-weight neonates. The plastic material of the Sibel technology was deemed easy to clean, but there was a preference for disposable items to streamline infection control processes at the hospital. Equipment that is too large for preterm and low-birth-weight neonates may lead to potentially poor application and inaccurate readings. For example, regarding

concerns that the sensors for the Sibel technology would not fit a preterm neonate, a health care administrator shared:

> *For the baby's chest, some of them like the preterms...I don't know whether it would be so big, and then if it is big, then it is not connecting well.*

Acceptability Factors for the Investigational Technologies

Perceptions of neonate comfort were a major acceptability facilitator reported by many of the HCPs (6/ 12, 50%), health care administrators (4/5, 80%), and caregivers (610, 60%). The investigational technologies were seen as more comfortable and did not interfere with the neonates' movements and sleep. Speaking about the EarlySense technology, one mother said:

> *It doesn't interfere in any way with the baby. The baby is sleeping; they can just sleep, you know?...It's painless while it's measuring.*

Another mother said, of the Sibel technology:

> *...the baby didn't seem uncomfortable...it didn't cause the baby any discomfort.*

Half of the caregivers interviewed also mentioned that the investigational technologies were simpler, less intimidating, and more acceptable than conventional monitoring technologies.

Concern about potential harm around electrical fields and wireless connectivity was a major acceptability challenge mentioned by caregivers (8/10, 80%) and HCPs (7/12, 58%). For example, as one mother said, about the EarlySense technology:

> *...okay, they're not using wires, so what are they using? Is there radiation, you know, that can harm my child?...of course, we asked about that, and we were told no, they're safe...The concerns...were put to rest.*

Speaking about the Sibel technology, an HCP-I nurse highlighted concerns shared by both caregivers and herself:

> *Now, you are not seeing any...wires moving from that device to...the screen next to the baby, so they [parents] want to know how that information is being passed...I am also wondering how it is working with that Bluetooth thing...so...personally I will go with the old version.*

Comparisons With the Reference Technology

A few HCPs and health care administrators (3/17, 18%) shared that in comparison with the investigational technologies, the complexity of the Masimo Rad-97 reference technology may require longer training. However, in contrast to the requirement of external screens or Wi-Fi with the investigational technologies, some HCPs and health care administrators shared that the reference technology is feasible within the Kenyan context because it is a stand-alone unit (3/17, 18%) and does not require Wi-Fi (2/17, 12%). For example, a health care administrator said:

> *...you don't necessarily need another device to monitor, unlike Sibel where you need a [tablet]...In terms of feasibility, I would go for the implementation of Rad-97 first...*

In addition, an HCP-I nurse said:

> *Aah, what I like about it is that...I don't think it requires those WiFi things...so it can be used anywhere, any part of the country.*

Of the 27 respondents, 4 (15%) mentioned that similar to the investigational technologies, the Masimo Rad-97 technology would be useful for care; 35% (6/17) of HCP and health care administrators shared that the Masimo Rad-97 technology seemed to have most of the features of the larger, wall-mounted conventional monitoring technology, but in a small and portable design.

In contrast to the investigational technologies, perceptions of neonate discomfort negatively impacted the acceptability of the reference technology, particularly with the nasal prong for capnography (12/ 27, 44%). Respondents (11/27, 41%) stated that wires and other attachments represent critical care and embody the seriousness of the health condition. A father shared:

> *Sometimes too many wires tend to shock...You might feel that the baby is in danger...Because the wires reflect the baby is, uh, is in dire need of help.*

The nasal prong was seen as part of oxygen delivery, which was especially stressful for caregivers with neonates previously in intensive care. A mother shared:

> *I freaked out because having been in the same situation for the past one week...the first question that came into my mind is the baby going to struggle again breathing using those tubing on the nose.*

An HCP-D nurse shared that caregivers were sometimes reluctant to accept the reference technology, as they perceived the nasal prong as invasive.

The facilitator of acceptability for the reference technology was brand familiarity, shared by HCPs (5/12, 42%) and health care administrators (3/ 5, 60%). An HCP-I physician described:

> *It is a device that has been used in the past, and its still being used all over the world. It's a no brainer. It's like going and asking someone "should you drive a Mercedes" it's a known brand.*

Feasibility, usability, and acceptability factors for the investigational and reference technologies included a myriad of facilitators and barriers (Table 1; Multimedia Appendices 5 and 6). Some factors have been reported to be potential facilitators and barriers.

Table 1. Feasibility, usability, and acceptability factors.

Factors	Investigational technologies		Reference technology	
	Facilitators	Barriers	Facilitators	Barriers
Feasibility	• Easy to train for use	• Requirement of ancillary equipment • Wireless connectivity requirements (Sibel Bluetooth or EarlySense Wi-Fi) • Integration capacities with existing equipment	• Stand-alone unit • Does not require Wi-Fi	• Longer training because of complexity
Usability	• Ease of use and useful for care • Wireless features improve work efficiency • Ability for infection control • Small size and portability	• Monitoring disruptions; such as when neonates are restless neonates or off mattress (EarlySense) • Need for appropriate preterm and low birth-weight sizing • Ability for infection control • Small size and portability	• Useful for care • Small size and portability	• Small size and portability
Acceptability	• Perceptions of neonate comfort • Simple and less intimidating	• Concerns about side effects from wireless connections	• Brand familiarity	• Perceptions of neonate discomfort because of nasal capnography • Wiring and tubing linked to critical care

Use Cases

HCPs and health care administrators shared that the investigational and reference technologies would be useful in different components of neonatal care at the hospital. As one health care administrator said, “I think in their own different capacity, they all have potential.”

Investigational technologies were especially recommended in the postnatal ward or nursery where healthy preterm and low-birth-weight neonates were being monitored. In these areas, there may be many neonates, largely under the care of their mothers and in stable health. Respondents suggested that the EarlySense technology would be useful “for babies who are being monitored [but] who are not so badly off” (HCP-I nurse), for “the postnatal babies...[where] there are many babies being continuously monitored” (HCP-D nurse), and for “a baby who we didn’t expect any sepsis or any challenges, and from this, we [would] be able to capture early signs of infection” (health care administrator). A health care administrator recommended the Sibel technology for the postnatal ward:

> *A mother who has delivered and has her baby needs to rest, and yet we have to monitor that baby. I would want that baby to be put on this. She can breastfeed and whatever she is doing, I can still be able to see the patterns and trends.*

The reference technology was described as more suitable for neonates requiring more critical care, where neonates may be largely under the care of an HCP rather than caregivers. “*Especially with capnography in place*,” an HCP-D nurse said that the reference technology is not appropriate “for the postnatal babies because it makes [parents] feel like their baby is very sick or maybe on oxygen.” She also said:

> *I don’t think it is appropriate for postnatal, the wiring and the limited space that is there...and...because the baby has to be unplugged from the wires for breastfeeding or bathing, so it is not exactly feasible where neonate is under almost complete care of the mother.*

However, she said that:

> *for babies in HDU or newborn ICU, it is very much feasible, as...it is familiar to what we are using.*

Discussion

Principal Findings

The purpose of this qualitative study was to assess the feasibility, usability, and acceptability of 2 noninvasive MCPM technologies for neonates in an African health care setting. Study participants reported that the investigational technologies were feasible and useful in the care of neonates at the Aga Khan University Hospital in Nairobi. Feasibility facilitators included simple training requirements, whereas infrastructural requirements such as Wi-Fi, external display screens, and limited integration with existing equipment were reported as potential barriers. Usability facilitators included ease of use and wireless features, and concerns of possible harm from wireless connections and mistrust of unfamiliar technologies emerged as potential barriers to acceptability. Appropriate sizing for preterm and low-birth-weight infants, portability, human resource requirements and training, and perceptions of wireless technologies were identified as key issues to consider during

the development and implementation of neonatal MCPM technologies.

Implications for Practice

Our experience with MCPM technologies highlights the potential of different technologies for different neonatal care settings. The EarlySense technology was recommended for the postnatal ward where neonates were largely in stable health conditions and there were more neonates than nurses who could regularly monitor. Because the EarlySense technology only monitored while the neonate was resting on the mattress, the Sibel technology may be more appropriate during kangaroo mother care when the neonate spends most of their time on the caregiver's chest. The investigational technologies' ease of use supported their function within less critical areas of neonatal care, where the neonate is largely under the care of family members. In contrast, the reference technology used in this study was valued as a more compact and portable version of the larger, wall-mounted existing monitoring systems in intensive care units. Contextually appropriate MCPM technologies are particularly needed for the management of clinically unstable neonates to support early and safe initiation of evidence-based interventions such as kangaroo mother care and to monitor emerging complications such as hypothermia during bubble continuous positive airway pressure for respiratory distress [10,11]. This is important because immediate kangaroo mother care of low-birth-weight infants in critical condition has been shown to reduce infant mortality rates compared with conventional kangaroo mother care initiated after stabilization [12].

Although wireless features of the investigational technologies supported usability and acceptability in certain dimensions, including the potential for remote monitoring, simple design, less interference with care, increased comfort, and concern for potential health risks with wireless connectivity emerged as an unexpected theme. A study evaluating the acceptability of a wireless fetal heart rate monitoring device among pregnant women in rural Uganda also reported concerns among mothers about possible negative effects of electromagnetic radiation [13]. An improved understanding of barriers to and enablers of innovative neonatal health technologies for resource-constrained settings is a recognized gap in the literature [3]. Two reviews of wearable continuous monitoring sensors for neonates compiled products and key features but did not investigate acceptability or implementation factors [14,15]. Concerns about potential side effects from wireless connections and electromagnetic fields emphasize the importance of caregiver engagement and the need to work with HCPs to address clients' mistrust of and fear of novel technologies. Caregivers expressed fear because of a lack of understanding of these technologies, but the fear appeared to be alleviated with HCP explanation for some.

Study findings such as identifying use case scenarios for different neonatal MCPM technologies and fears that wireless technologies may have adverse health effects highlight the importance of evaluating feasibility, usability, and acceptability during the development of medical technologies. Although medical technologies may demonstrate efficacy, their adoption, uptake, and use may be limited if implementation factors are not considered and incorporated during technology development. The potential impact of innovative neonatal MCPM technologies is substantial, particularly in resource-constrained settings. Frequently, there may be little to no neonatal continuous monitoring available in these settings, despite being routine in high-income settings for those who require it. This lack of monitoring may contribute to the higher rates of neonatal morbidity and mortality in resource-constrained settings [16-18]. An observational study at Kenyatta National Hospital in Nairobi reported that very few neonates had their vital signs recorded in the first hour of life, and more than half did not receive a temperature recording (54%), heart rate recording (56%), or respiratory rate recording (56%) on the first day of hospital admission [16]. Observations at 6 hospitals in Nairobi County found that missed vital sign monitoring and other nursing tasks were associated with nursing shortages and high patient workloads [17]. MCPM technologies are valuable for improving the quality of neonatal care by expanding nurses' capacities to monitor more neonates regularly and efficiently.

Strengths and Limitations

Of note, this qualitative study was conducted at a private, tertiary hospital where the study participants were highly educated, and almost all of the caregivers interviewed had university education and professional employment. In addition, limiting the generalizability of our study findings is that private and public hospitals in Kenya have dramatically different nursing workloads and infrastructure, with median ratios of 3 infants to 1 nurse at private hospitals around Nairobi and 19 infants to 1 nurse at public hospitals [17]. With a reliable back-up electrical system and maintenance team on staff at Aga Khan University Hospital, Nairobi, electrical outages, technology malfunction, and maintenance were not highlighted as feasibility concerns by our study participants. The feasibility of these investigational MCPM technologies for neonates has important implications for the sustainability and prevention of technology graveyards of nonfunctional or locally inappropriate technologies. Future research can explore whether feasibility, usability, and acceptability issues shift in a public hospital setting where resources may be more constrained. Another limitation of the study is that usability was not directly assessed among nontrained (HCP-I) users. The strengths of the study include the use of direct observations to support interview findings, as well as conducting in-depth interviews with caregivers, HCPs, and health care administrators to understand a diversity of perspectives.

Conclusions

MCPM for neonates is a critical component of comprehensive care that supports the effectiveness of other neonatal interventions. Our study examined the feasibility, usability, and acceptability of 2 investigational MCPM technologies for neonates compared with a reference MCPM technology and found that the different technologies fit different areas within the continuum of neonatal care at the hospital. Although each technology presented advantages suited for different neonatal care domains, challenges in maintaining training and ensuring

feasibility within resource-constrained health care settings warrant further research.

Acknowledgments

The authors are grateful to the ETNA (Evaluation of Technologies for Neonates in Africa) team for their support and to the health professionals and caregivers for sharing their thoughts and experiences with us. The authors would also like to thank Marianne Vidler for her insights on study design and the data collection tools as well as the research team who collected and managed the data without whom this study would not have been possible.

This trial was funded by the Bill & Melinda Gates Foundation (OPP12303136) and Save the Children Innovation Fund. Apart from the input provided for the trial design, funders had no role in data collection, analysis, interpretation, or writing of the report.

Authors' Contributions

ASG, JMA, and WMM conceptualized the study and components of the methodology with support from VN, JR, MC, BH, and RO. VN, JR, DC, and BH were responsible for data collection and project administration. MWK and VN performed the analyses. ASG and MWK wrote the first draft of the manuscript. All authors provided feedback and reviewed the manuscript.

Abstract

Background: Worldwide obesity rates have prompted 16 countries to enact policies to reduce children's exposure to unhealthy food marketing, but few policies address online advertising practices or protect adolescents from being targeted. Given adolescents spend so much time online, it is critical to understand how persuasive Instagram food advertisements (ads) are compared with traditional food ads. To strengthen online food marketing policies, more evidence is needed on whether social media ads are more persuasive than other types of ads in shaping adolescents' preferences.

Objective: This study examined whether adolescents could identify food companies' Instagram posts as ads, and the extent to which Instagram versus traditional food ads shape adolescents' preferences.

Methods: In Part 1, participants aged 13-17 years (N=832) viewed 8 pairs of ads and were asked to identify which ads originated from Instagram. One ad in each pair was selected from traditional sources (eg, print; online banner ad), and the other ad was selected from Instagram, but we removed the Instagram frame—which includes the logo, comments, and "likes." In Part 2, participants were randomized to rate food ads that ostensibly originated from (1) Instagram (ie, we photoshopped the Instagram frame onto ads); or (2) traditional sources. Unbeknownst to participants, half of the ads in their condition originated from Instagram and half originated from traditional sources.

Results: In Part 1, adolescents performed worse than chance when asked to identify Instagram ads (P<.001). In Part 2, there were no differences on 4 of 5 outcomes in the "labeled ad condition." In the "unlabeled ad condition," however, they preferred Instagram ads to traditional ads on 3 of 5 outcomes (ie, trendiness, P=.001; artistic appeal, P=.001; likeability, P=.001).

Conclusions: Adolescents incorrectly identified traditional ads as Instagram posts, suggesting the artistic appearance of social media ads may not be perceived as marketing. Further, the mere presence of Instagram features caused adolescents to rate food ads more positively than ads without Instagram features.

food marketing; traditional media; social media; adolescents; Instagram

Introduction

The high prevalence of childhood obesity persists in the United States, and the National Academy of Medicine identifies food marketing as a major contributing factor [1]. Despite both national and international efforts to restrict child-targeted food marketing, most policies do not protect adolescents aged 13-17 years, nor do they address social media advertising [2]. Yet adolescents spend an increasingly high number of hours online each day.

Recognizing social media's growing popularity, food companies have dramatically increased their advertising presence on social

media platforms in ways that appeal to young audiences. Coca-Cola, for example, dedicates 20% of their US $4 billion annual advertising budget to social media [3]. One descriptive study reported that 6.2 million adolescents followed a sample of 27 food and beverage brands on Instagram and Twitter [4]. This shift in marketing and exposure concerns public health experts [5] because studies have shown that food companies' official social media accounts promote mostly unhealthy products [6-8], and increase brand recognition among youth [9,10].

Adolescents' unique developmental stage may compound their vulnerability to social media food advertisements (ads). Social Norms Theory [11-13] suggests social media may capitalize on adolescents' exquisite sensitivity to peer behavior—"likes," for example, represent social norms that may signal to adolescents which social media accounts they should follow [14-16]. Experts have expressed concern that the ability to "like" posts also makes social media advertising uniquely interactive and may lead adolescents to perceive brands as friends more than companies [10]. Ads posted by companies may look similar to posts by friends because of context (ie, they appear interspersed with posts shared by friends) and content (ie, companies' posts mimic the aesthetic of everyday consumers' posts), and it is unclear whether these marketing strategies cloud adolescents' ability to identify company posts as advertising. A neuroimaging study showed heightened activity in the nucleus accumbens—a reward hub of the brain—among adolescents who viewed their own posts with high numbers of "likes" versus few "likes" [17]. Given the nucleus accumbens is more sensitive to reward among adolescents compared with adults and children [18], those findings reinforce adolescents' unique susceptibility to social media ads.

Despite the emerging research on adolescents' engagement with food marketing on social media, no studies have compared the power of unhealthy food ads on social media versus more traditional ads (eg, print ads; noninteractive website banner ads). It is not known whether adolescents are skilled at identifying social media ads. Besides, no studies have examined whether social media advertising is more powerful than traditional ads in its ability to affect adolescents' preferences. Finally, the combined effects of showing adolescents food ads and Instagram frames that include the Instagram logo, "likes," and comments have not been explored. Instagram frames that include the Instagram logo, "likes," and comments may have their own brand power and make ads highly appealing to adolescents.

The objective of this study is to address those gaps by examining whether adolescents could distinguish between food companies' Instagram ads and their more traditional ads, and the extent to which Instagram food ads generate more appeal compared with traditional ads. Given adolescents' frequent social media use [19], we hypothesized that participants would correctly identify Instagram ads, and that they would prefer Instagram ads more than traditional ads regardless of whether ads were photoshopped to appear as though they had originated from Instagram.

Methods

Study Population

We recruited 1044 adolescents aged 13-17 years who identified as either Black/African American or non-Latino White through Dynata, a firm that recruits research participants using online panels, digital networks, websites, SMS text messaging, and telephone alerts. The Institutional Review Board at New York University School of Medicine approved our study.

Of the 1044 adolescents who started the survey, 976 completed it, and 884 correctly answered our data integrity question (ie, "Type 'Facebook' in the box below."). A total of 52 adolescents identified as a race/ethnicity other than Black/African American or non-Latino White and were excluded from the analyses. We included only Black and non-Latino White adolescents in our sample because companies disproportionately target Black adolescents with their least healthy products [20,21], and White adolescents are featured in the majority of food ads [22]. Because of these differences in targeted marketing, we designed stimuli that featured either Black or non-Latino White individuals. Secondary analyses that examine a subset of racially targeted ads are under review elsewhere. Among the final sample (N=832), 387 (46.5%) adolescents identified as Black or African American and 445 (53.5%) adolescents identified as non-Latino White. Table 1 presents adolescents' self-reported demographic characteristics and social media usage.

Table 1. Demographic characteristics and social media usage of sample: January–June 2018.

Demographic characteristics	Total sample (N=832)	Part 2: Labeled advertisement condition (n=381)	Part 2: Unlabeled advertisement condition (n=451)
Age, years, mean, (SD)	14.73 (1.67)	14.75 (1.64)	14.71 (1.69)

Advertisement Development

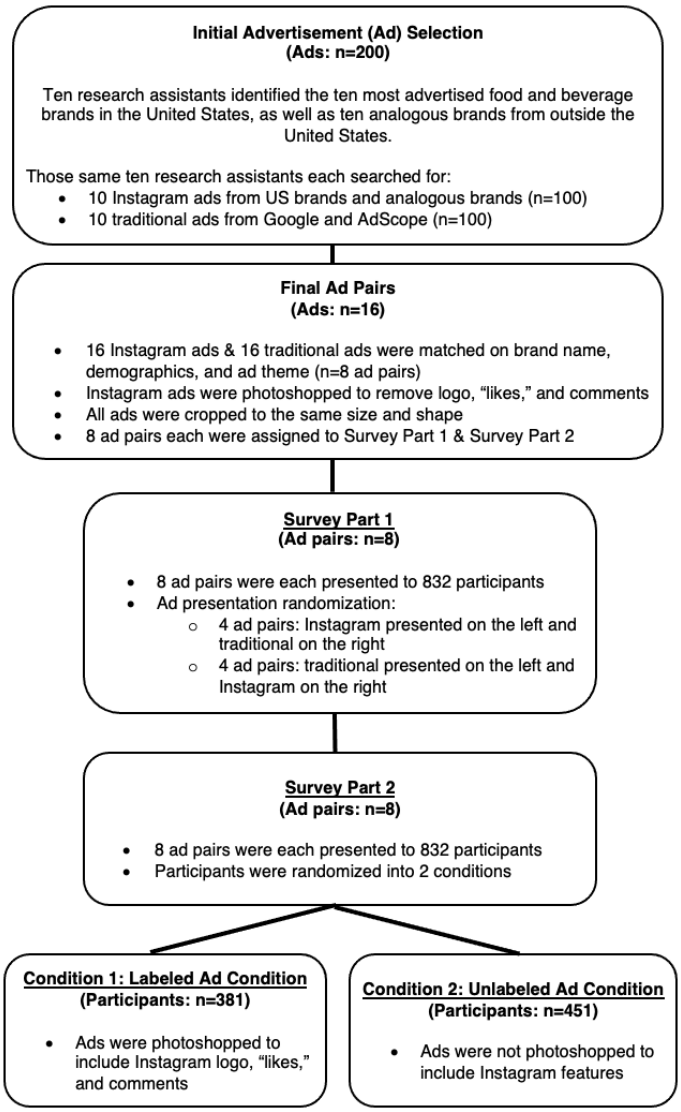
We identified the 10 most advertised food and beverage brands in the United States [23] and then identified 10 analogous brands originating outside of the United States (eg, Lay's Potato Chips from the United States vs. Walker's Crisps from the UK). We identified those analogous brands because consumers' familiarity with brands could potentially affect their survey responses [24]. We then aimed to select from those brands (1) 200 unhealthy food and beverage ads on Instagram; and (2) 200 traditional ads to serve as potential stimuli. To select the 200 Instagram ads for unhealthy food and beverages, we asked 10 research assistants to screen capture 10 Instagram ads from the official accounts of the most advertised brands and their analogous brands. Research assistants screen captured a random sample of 10 ads for unhealthy products from each brand (ie, 10 ads from 10 US brands + 10 ads from 10 analogous brands = 200 Instagram ads as potential stimuli). To select a random sample of 10 ads from each brand's Instagram account, research assistants were instructed to use a random number generator and then select the ad corresponding to the generated number by counting from the most recently posted ad. For example, if the number "10" was randomly generated, the research assistant would select the tenth most recent ad posted to the brand's Instagram feed. To identify traditional ads, we asked those same research assistants to capture 10 traditional ads for the same 10 most advertised and 10 analogous brands by searching on

Google and AdScope, a repository of all ads from television, print, radio, and the internet [25].

To assess the pairings of traditional and Instagram ads, we generated a codebook of ad themes using an iterative process. Researchers identified ad themes by assessing the ad image and text (eg, snowflakes or references to the cold for a "winter" theme). They then searched for traditional and Instagram ads with matching themes. In our first review of the matched ad pairs, we met 90% agreement. Discrepancies were resolved by consensus. The final ad themes included the following: features a human actor, features a nonhuman character, race of actor product visibility, product handling (eg, whether a person or character in the image holds the promoted product), seasonal (eg, fall, winter, spring, and summer themes), and number of actors or characters.

Researchers came to unanimous consensus on all matched pairs between traditional and Instagram ads based on demographic characteristics of the people in the ad and ad theme. We asked the researchers to identify 10 of the final 16 ad pairs from brands originating outside of the United States. By using ads from brands based in the United States we could evaluate reactions to ads that the participants would be most likely to see in their day-to-day life. By including some brands based outside of the United States, we could isolate reactions to the ad-specific effects of interest from potential confounding factors of preformed attitudes toward brands. As intended, this search process generated a final set of 32 unhealthy food and beverage ads, which included 16 ad pairs that were matched on brand name, demographics, and ad theme (Figure 1).

Figure 1. Advertisement development process and study procedure.



Survey Procedures

After parents provided informed consent, adolescents assented their participation and completed the online survey with a median completion time of 19 minutes. Qualtrics hosted the online survey. Data were collected in 2018 and analyzed in 2019.

In Part 1 of the survey, adolescents viewed 8 pairs of unhealthy food and beverage ads presented in random order (eg, a Starbucks magazine ad alongside a Starbucks Instagram ad). To remove cues indicating which ads originated from Instagram, we used Photoshop to compare advertising images with and without an "Instagram frame" which includes the Instagram

logo, "likes," and comments. We also cropped images to make ads the same shape because Instagram images are often square, which would have made it easier for adolescents to identify the Instagram ad. See Figure 2 for an example of our ad stimuli. We randomized the ad presentation so that half the pairs showed the Instagram ad on the left and the traditional ad on the right (Figure 1).

After viewing each pair, adolescents answered the following question, "Which of these photos do you think [brand name] would be most likely to post on their Instagram account?" See Figure 2 for an example of survey questions and images from Part 1.

Figure 2. Sample Question from Part 1: Identify the Instagram ad. In this question, the Instagram ad is on the right.

Adolescents were then randomly assigned to 1 of 2 conditions (Part 2) where ads ostensibly originated from (1) Instagram (ie, "labeled ad condition" in which advertising images have Instagram frames); or (2) traditional sources (ie, "unlabeled ad condition" in which advertising images do not have Instagram frames; Figure 1). Unbeknownst to participants, half of the ads in their condition originated from Instagram and half originated from traditional sources. Ads were presented in random order. The survey questions asked participants to rate the ad on how much they liked the image, trendiness, artistic appeal, how delicious they thought the featured product might be, and how likely they were to purchase the product (Table 2). We included the ratings of trendiness and artistic appeal because previous commentaries have noted that social media food ads are subtle and blend into the social media environment [10,26]. See Figures 3 and 4 for examples of survey questions and images from Part 2. Finally, participants responded to demographic questions. We included an attention check question (ie, "Type Facebook in the box") to ensure participants were carefully reading directions and questions. Those who did not type "Facebook" were excluded from analysis.

Table 2. Instagram and traditional advertisement ratings and differences by study condition, means, and SEs.

Participant advertisement ratings	Average rating of Instagram advertisement (SE)[a]	Average rating of traditional advertisement (SE)	Difference in ratings (SE)	*P* values[b]
Unlabeled advertisement condition, rating out of 0-100[c] (SE)				
How much do you like this image?	68.56 (0.93)	65.72 (0.93)	2.85 (0.49)	.001[d]
How artistic is this image?	68.83 (0.93)	66.86 (0.93)	1.97 (0.47)	.001[d]
How trendy is this image?	69.60 (0.90)	66.28 (0.90)	1.14 (0.54)	.001[d]
How delicious do you think this product is?	66.80 (0.94)	65.66 (0.94)	1.14 (0.54)	.07
How likely are you to purchase this product in the next 4 weeks?	56.25 (1.23)	55.27 (1.23)	0.97 (0.58)	.10
Labeled advertisement condition, rating out of 0-100[c] (SE)				
How much do you like this image?	67.43 (1.04)	67.11 (1.04)	0.32 (0.50)	>.99
How artistic is this image?	66.80 (1.07)	66.84 (1.07)	0.04 (0.50)	>.99
How trendy is this image?	68.16 (1.02)	66.92 (1.02)	1.24 (0.48)	.05[d]
How delicious do you think this product is?	66.62 (1.02)	67.51 (1.02)	0.88 (0.53)	.40
How likely are you to purchase this product in the next 4 weeks?	56.03 (1.38)	56.30 (1.38)	0.27 (0.60)	>.99

[a]SE: standard error.

[c]Ratings were based on a scale from 0 (not at all) to 100 (very much).

[d]Statistical significance ($P<.05$).

Figure 3. Sample images from "Labeled Ad Condition." The traditional ad (top) and the Instagram ad (bottom) both feature the Instagram panel.

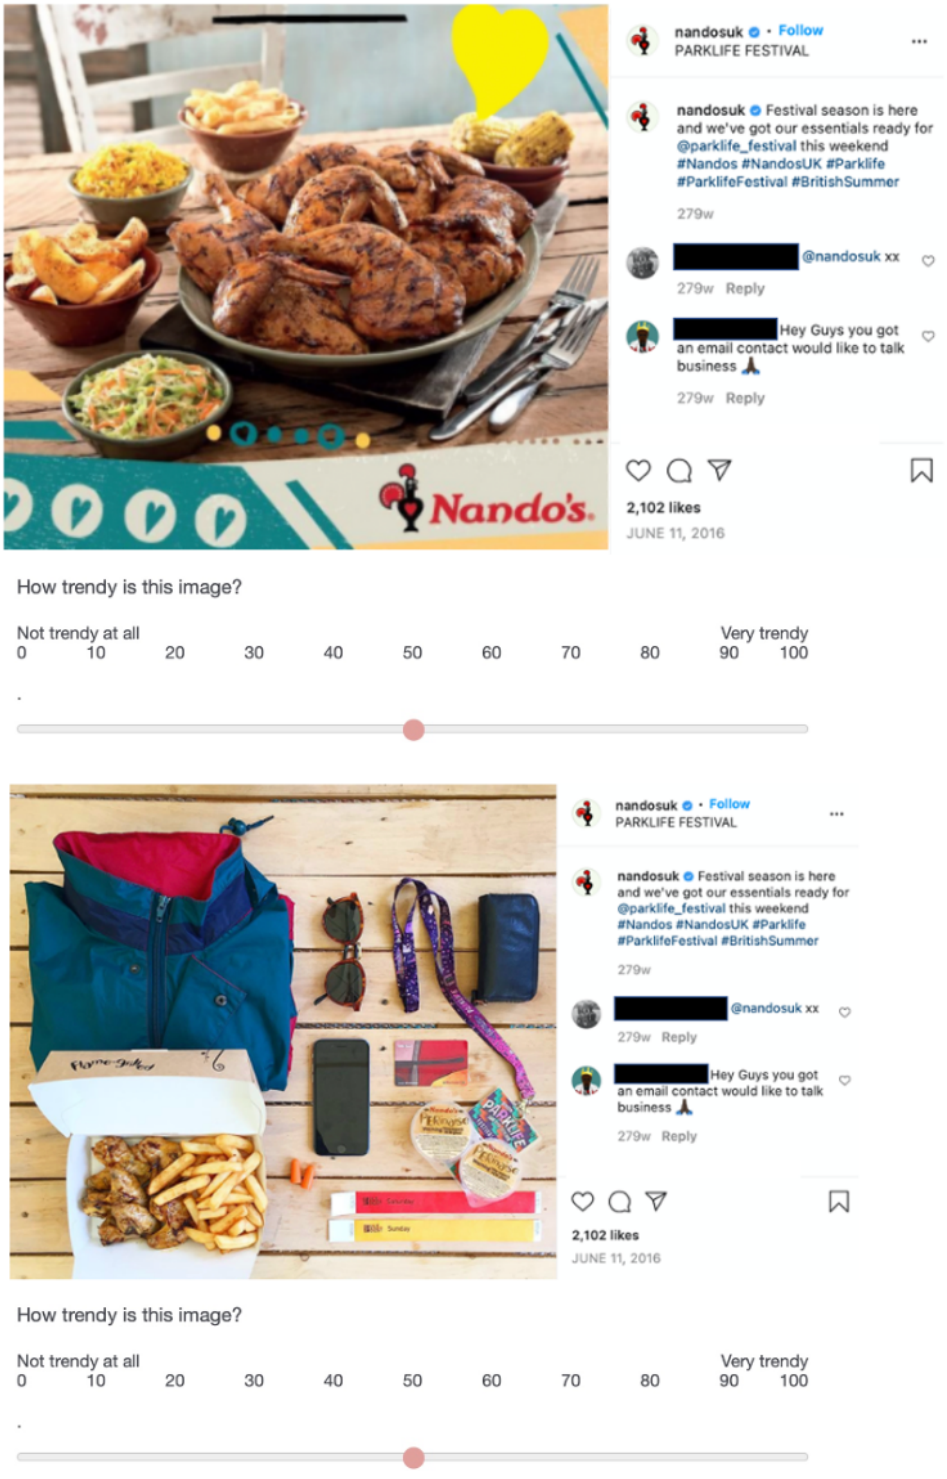

Figure 4. Sample images from "Unlabeled Ad Condition." The traditional ad (top) and the Instagram ad (bottom) do not feature the Instagram panel.

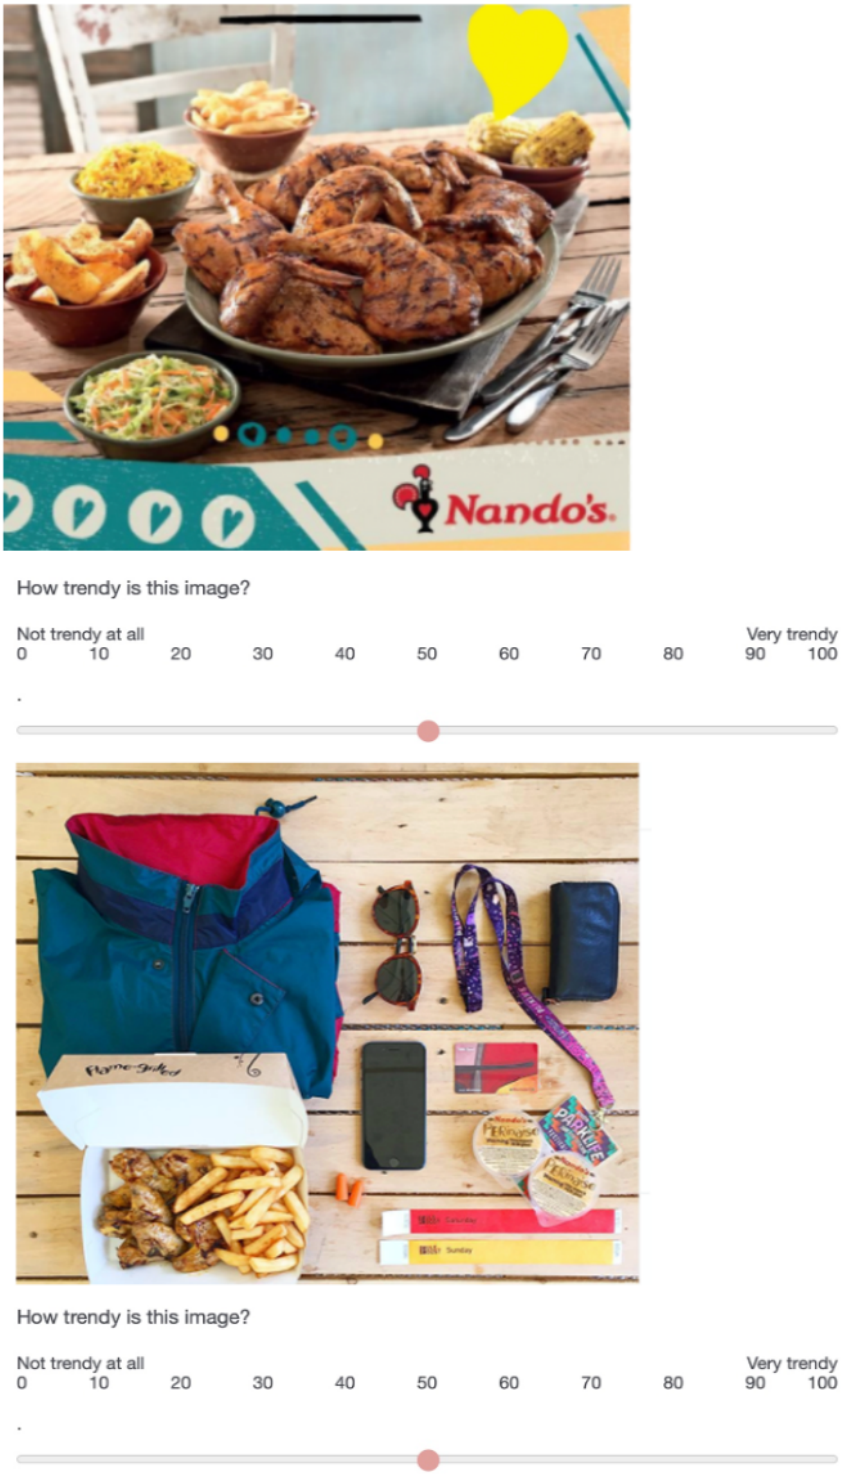

Statistical Analyses

Analyses were conducted in SAS 9.4 (SAS Institute). We used a score test to assess whether the proportion of correct responses was significantly different from 0.5, which is the percentage of correct responses we would expect if adolescents were guessing at random. We also used linear regression to compare adolescents' ad preferences between the unlabeled ad condition and the labeled ad condition. Ad preferences were scored from 0 to 100. Because each adolescent rated multiple ads, the model included a random effect for the participant to account for the repeated measures. Given adolescents spend approximately 7 hours per day using screens [27], it is critical to understand the extent to which heavy use of social media is associated with higher preferences for social media food ads compared with traditional food ads. To examine differences based on time spent on social media, we analyzed data according to time spent on social media. Specifically, analyses that adjusted for time spent

on social media used a median split at 3 hours, such that adolescents who reported spending more than 3 hours per day on social media were labeled "heavy social media users" and those who reported spending less than 3 hours per day on social media were labeled "light social media users." Analyses were then stratified by whether the ad had the "Instagram panel." We conducted chi-square tests and *t* tests to determine whether the randomization was successful and to verify that demographic characteristics did not differ between conditions. Because all tests were not significant, demographic characteristics were not included in the models. The Bonferroni–Holm procedure was used to correct for multiple comparisons.

Results

Part 1: Adolescents Were Asked to Identify Which Advertisements Originated from Instagram

Adolescents correctly identified the Instagram ad 39.1% of the time (z=17.293, P<.001). They correctly selected the Instagram ad significantly more often for international brands (42.8% of the time) than US brands (35.3% of the time; z=36.55, P<.001). We did not find a significant association between the likelihood of adolescents following the US brands on social media and their ability to accurately identify the Instagram ads for unhealthy food and beverages (z=.0022, P=.96), suggesting that the association was not confounded by brand familiarity.

In an analysis stratified by time spent using social media, we found that both light and heavy social media users performed worse than chance (z=15.79, P<.001 and z=8.4387, P<.001). However, heavy social media users correctly identified the Instagram ad more often (42.2%) than light users (36.3%; z=22.69, P<.001).

Part 2: Adolescents Rated Preferences for Instagram Advertisements and Traditional Advertisements

In the "unlabeled ad condition" where all ads for unhealthy products were presented without any Instagram features (Figure 4), analyses revealed adolescents reported higher preferences for Instagram ads than traditional ads on 3 of 5 measures after correcting for multiple comparisons (Table 2). Specifically, adolescents rated Instagram ads for unhealthy food and beverages as significantly trendier (P=.001) and more artistic (P=.001) than the traditional ads. They also reported liking the Instagram ads more than the traditional ads for unhealthy products (P=.001). There were no significant differences in how delicious they thought the featured products might be (P=.08) or how likely they would be to purchase them (P=.10).

Within the "labeled ad condition," we found significant differences on 1 of the 5 outcomes (Figure 3). Specifically, adolescents were more likely to rate the unhealthy food and beverage ads on Instagram as trendy compared with the traditional ads (P=.05), but they rated the ads similarly on the other 4 dimensions.

Heavy social media users responded more positively to social media ads for unhealthy food and beverages than light users across all 5 outcomes in both the "labeled ad condition" and the "unlabeled ad condition." In the " labeled ad condition," heavy social media users rated ads as significantly more artistic (9.46 points; standard error [SE] 2.02, P<.001), trendier (9.30 points; SE 1.93, P<.001), and delicious (7.69 points; SE 1.94, P<.001); they also reported liking ads more (9.37 points; SE 1.98, P<.001) and being more likely to purchase the featured products (15.84 points; SE 2.57, P<.001). In the "unlabeled ad condition," heavy social media users rated unhealthy food and beverage ads as more artistic (8.01 points; SE 1.76, P<.001), trendy (8.20 points; SE 1.70, P<.001), and delicious (7.92 points; SE 1.77, P<.001). They also reported liking them more (7.73 points; SE 1.76, P<.001) and being more likely to purchase the products pictured (13.68 points; SE 2.31, P<.001).

Discussion

Principal Findings

Our findings demonstrate that Instagram food ads were highly appealing to adolescents relative to traditional food ads. This is concerning given adolescents spend 7 hours online each day [27], and companies now spend US $41.5 billion on social media marketing each year [28]. Coca-Cola alone spends US $800 million—20% of their US $4 billion budget—on social media marketing [3], suggesting that companies may be increasingly able to place more ads in front of adolescents in digital spaces. Adolescents incorrectly identified traditional ads as Instagram ads, consistently, suggesting that the artistic quality of Instagram ads may not be perceived as marketing. The subtlety of these Instagram ads may create a public health challenge because adolescents might be more vulnerable to the persuasive influence of these visually artistic and entertaining ads. Additionally, when rating unlabeled, unhealthy food and beverage ads in Part 2, adolescents reported higher preferences for Instagram ads compared with traditional ads on 3 of 5 outcomes. This finding suggests that there is something uniquely appealing about the visual appearance of Instagram ads compared with traditional ads that piques adolescents' interests. But, when we photoshopped the Instagram frame onto those same ads, adolescents preferred the Instagram ads on just 1 of 5 outcomes. This suggests that the "Instagram frame" exerts a powerful influence on adolescents' perceptions by equalizing the appeal of traditional and Instagram ads for unhealthy products. In 2019, 2 bipartisan US Senators proposed expanding the Children's Online Privacy and Protection Act to reduce companies' ability to target youth in online advertising—their proposal would also extend the protected age range to include adolescents aged 13-16 years [29]. Providing policy protections for adolescents in digital spaces is critical given Instagram food ads are highly appealing to adolescents compared with traditional ads.

Contrary to our hypothesis that adolescents would be skilled at identifying which of 2 ads originated from Instagram in Part 1, adolescents performed significantly worse than chance by incorrectly choosing the traditional ad. One possibility is that adolescents could not discern between ads that originate on Instagram and traditional outlets—but adolescents' responses were worse than 50-50 chance, meaning they *consistently* thought the traditional ad was an Instagram ad. One explanation for the recurring misattribution is that companies mimic social media trends that are highly appealing to adolescents (eg, photo

filters or aerial photos of foods arranged in artistic ways), and such mimicry is not readily perceived as marketing [30-32]. These findings support that ads promoted on Instagram are highly appealing to adolescents compared with ads presented in a more traditional form.

The findings that "heavy users" reported higher ad preferences across all outcomes—and were more likely to "guess correctly" in Part 1 relative to "light users"—may be concerning because of the potential additive effect of social media: when users "like" posts, Instagram's algorithms place similar posts in their feed, thereby increasing ad exposure [33]. It is possible, however, that "heavy users" merely have more Instagram fluency, which may have accounted for their ability to correctly identify the Instagram ads. And it is possible that their heavy use of media makes them more inclined to like any type of image that stems from Instagram or other outlets.

This study contributes to the literature on food marketing in several ways. It is the first study, to our knowledge, to compare unhealthy food ads on social media with traditional ads. The power of the Instagram "halo" is concerning given adolescents' exposure to food ads on social media—one study found that 72% (n=101) of adolescents were exposed to social media food ads during a 5-minute data collection period [34], and another survey of 1564 adolescents in the United States found that 75% of adolescents followed, "liked," or shared food and beverage brands on social media [35]. This "halo" effect has also been shown to impact children and adolescents' eating behaviors. In a laboratory study, children who viewed influencers holding unhealthy snacks ate significantly more food than children who saw influencers holding nonfood products [36]. Another laboratory study randomized 132 adolescents aged 13-16 years to view a social media influencer who promoted unhealthy food, vegetables, or a nonfood item and found that adolescents exposed to the healthy food posts did not consume more vegetables [37]. Finally, one study of 72 adolescents (mean age 13 years) found that adolescents who viewed unhealthy food brand posts were more willing to share the post and report a positive attitude toward the product compared with adolescents who viewed healthy foods [38]. But one limitation of existing social media food ad studies is the absence of nonsocial media ads. Our study, therefore, builds upon previous research by demonstrating that the mere presence of the Instagram logo, "likes," and comments causes adolescents to rate ads more favorably than adolescents who see the same ads without those Instagram features.

Limitations

This study has several limitations. We did not ask participants about their rationale for choosing the traditional ad or the Instagram ad in Part 1, and additional research is needed to determine whether differences between heavy and light users' ratings translate into increased susceptibility to advertising. We did not collect data on self-reported height and weight, and it is possible that BMI could moderate the observed effects [39]. But studies suggest that BMI does not always predict higher preferences for ads [40,41]. Our study may not generalize to all adolescents given this was not a nationally representative sample. Despite these limitations, our study has several strengths. The randomized design and the within-subjects comparisons provide clear evidence of preferences for unhealthy food and beverage ads on Instagram relative to traditional ads. Further, "likes" are an ecologically valid signal of preferences, as most adolescents use social media regularly and are familiar with "liking" social media content [42]. Future research should examine how social media food ads affect food purchases.

Conclusion

This study provides the first evidence regarding adolescents' preferences for unhealthy food and beverage ads on social media relative to traditional food ads, sheds light on potential mechanisms that influence adolescents' behavior on social media, and can inform the extent to which self-regulatory food marketing pledges and food marketing policies should expand to include social media–based food marketing.

Abstract

Background: Internet access is increasingly critical for adolescents with regard to obtaining health information and resources, participating in web-based health promotion, and communicating with health practitioners. However, past work demonstrates that access is not uniform among youth in the United States, with lower access found among groups with higher health-related needs. Population-level data yield important insights about access and internet use in the United States.

Objective: The aim of this study is to examine internet access and mode of access by social class and race and ethnicity among youth (aged 14-17 years) in the United States.

Methods: Using the Current Population Survey, we examined internet access, cell phone or smartphone access, and modes of connecting to the internet for adolescents in 2015 (unweighted N=6950; expanded weights N=17,103,547) and 2017 (unweighted N=6761; expanded weights N=17,379,728).

Results: Internet access increased from 2015 to 2017, but socioeconomic status (SES) and racial and ethnic disparities remained. In 2017, the greatest disparities were found for youth in low-income households (no home access=23%) and for Black youth (no home access=18%) and Hispanic youth (no home access=14%). Low-income Black and Hispanic youth were the most likely to lack home internet access (no home access, low SES Black youth=29%; low SES Hispanic youth=21%). The mode of access (eg, from home and smartphone) and smartphone-only analyses also revealed disparities.

Conclusions: Without internet access, web-based dissemination of information, health promotion, and health care will not reach a significant segment of youth. Currently, SES and racial and ethnic disparities in access prolong health inequalities. Moreover, the economic impact of COVID-19 on Black, Hispanic, and low-income communities may lead to losses in internet access for youth that will further exacerbate disparities.

internet access; smartphone use; Black youth; Hispanic youth; low-income youth; disparities; mobile phone

Introduction

Access to the internet is increasingly critical for adolescents with regard to health, employment, and education [1-7]. Furthermore, the COVID-19 pandemic has highlighted the fundamental importance of web-based access when in-person channels of communication are blocked [2,8]. Youth may use the internet to find health-related information, find resources,

or participate in web-based interventions addressing a variety of physical and mental health topics [3,9-11] and for communicating with health providers [12,13]. Given that health-related conditions (eg, obesity, diabetes, and sexually transmitted infections) disproportionately impact low-income and racial and ethnic minority youth [14-16], access may be particularly important for these groups. Those with intermittent, limited, or no access to the internet will be disadvantaged because their ability to benefit from web-based health-related resources and programs, job searches, and educational activities will be lower than among those who have stable internet access [17-21].

Rapid increases in internet access have been attained over the past decade; however, US national household data from the American Community Survey (ACS) and the Current Population Survey (CPS) have demonstrated that we have yet to achieve the goal of universal access to the internet [22]. Furthermore, they also document continued disparities in access for Black and Hispanic people, low-income households, and those in rural areas [23]. Although the CPS and ACS found that internet access is higher in households with members ≤18 years of age, published analyses of national probability household surveys infrequently focus on internet access for adolescents.

Valuable data on internet access among adolescents can be obtained from probability-based national surveys conducted by the US Census, including the CPS. Prior analyses of the CPS (2012 data) showed that youth aged 14-17 years living in low-income households had lower internet access than youth in moderate- and high-income households (household income <US $25,000=63%, US $25,000-$49,999=80%, and ≥US $50,000=95%) [4]. In addition, Black and Hispanic youth had lower in-home access than Asian and White youth (White=89%, Black=73%, Asian=93%, and Hispanic=76%). This research, which focused primarily on Black youth, also revealed disparities within racial and ethnic groups. That is, Black youth living in low-income households had lower access than Black youth living in households with middle or high incomes (household income <US $25,000=52%, US $25,000-$49,999=77%, and ≥US $50,000=93%) [4]. Cell phone access was lowest among both low- and high-income Black youth. Furthermore, Black youth have limited access to the internet in the community (schools=60%, libraries=27%, and community centers=5%), highlighting the importance of home access [4]. Given the broadscale uptick in internet access observed in the population at large, we anticipate that youth access will also have increased in recent years.

Other national studies on youth suggest substantial increases in access over time and a more even distribution of internet access across subgroups of youth [1,24,25]. A recent Pew Research Center report showed nearly universal internet access among youth in the United States (99%), with 95% reporting access to a smartphone (White=94%, Black=94%, and Hispanic=95%). Furthermore, relatively small differences in access by household income were reported (<US $30,000=93%, US $30,000-$74,999=93%, and ≥US $75,000=97%) [1]. However, these point estimates may conceal true differences. When CIs are taken into consideration, the Pew Research Center study shows that access for Black youth may range from 82.1% to 100%, and for Hispanic youth, the estimated range is 85.5%-100% (ie, margin of error by race and ethnicity: White=–7.2 to +7.2 points, Black=–11.9 to +11.9 points, and Hispanic=–9.5 to + 9.5 points). Similarly, CIs for income categories are wide (ie, margin of error by income: <US $30,000=–9.6 to +9.6 points, US $30,000-$74,999=–8.3 to +8.3 points, and ≥US $75,000=–8.1 to +8.1 points), suggesting that access by income may also be more variable. In light of this, it is critical that other sources, such as census data (eg, CPS and population studies with reduced error) are used to provide a sharper picture of access [22].

This research examines changes in access and use of the internet among those aged 14-17 years using the 2015 and 2017 CPS. We focus specifically on 2 racial and ethnic groups that have previously had lower access, Black and Hispanic youth, to determine whether disparities in access for racial and ethnic minorities and low-income youth have decreased over time. In light of recent research on adults, which suggests that the number of smartphone-only internet users in the United States is increasing [26], we also examined smartphone-only use among youth.

Methods

Data Source: The CPS

The CPS periodically collects data on computer and internet use, which provides national-level estimates of these topics. This household probability study conducted by the US Census Bureau is the primary source of labor force statistics [27,28]. Data for this study were obtained from the CPS Computer and Internet Use supplement conducted in July 2015 and November 2017. The supplement is sponsored by the National Telecommunications and Information Administration.

We used the 2 most recent surveys for which data are available to examine internet use inside and outside the home and additional modes (eg, devices) used to access the internet. Given our focus on youth, we limited our examination to household members aged 14-17 years in 2015 (total sample unweighted: N=6950; Black: n=917; Hispanic: n=1412) and 2017 (total sample unweighted: N=6761; Black: n=800; Hispanic: n=1377). This age group represents minors most likely to be in high school and living at home and corresponds to the age range examined in prior analyses of CPS 2012 data [4].

Measures and Analyses

All analyses were conducted for a subsample of the CPS representing youth aged 14-17 years. Data on youth were collected from an adolescent aged ≥15 years or from a proxy. We examined four primary questions (yes or no responses) that were assessed in 2015 and 2017. Three items were identical in both waves: “Do you/Does anyone in this household, including you, use the internet at home?” “Who uses the internet at home?” “Who uses a cellular phone or smartphone?” The item regarding smartphone use was asked slightly differently across the two waves (2015: “Do you/Does anyone in this household use a cellular phone or smartphone?” 2017: “What about a smartphone or a cell phone that connects to the internet? Do you/Does anyone in this household use a smartphone?”). In

addition, we constructed a variable to identify smartphone-only use, which was defined as accessing the internet from smartphone but not accessing the internet from home.

Analyses were conducted for all racial and ethnic groups, followed by analyses for Black and Hispanic youth separately. Cross tabulations are weighted using the final person weight [29]. Data analyses were generated using SAS software, version 9.3 of the SAS System (SAS Institute Inc; SAS and all other SAS Institute Inc product or service names are registered trademarks or trademarks of SAS Institute Inc). Standard survey weights adjusted with expansion weights provide estimates of the size of the population to which data are generalized (expanded weights for total sample: N=17,103,547 [2015] and 17,379,728 [2017]; Black: N=2,626,139 [2015] and 2,560,101 [2017]; Hispanic: N=3,867,713 [2015] and 3,981,899 [2017]). Owing to the population sizes, the CIs around the point estimates are very tight (ie, for proportions, –1% to +1% on either side) and can be interpreted as population parameters. For illustration purposes, we calculated the 95% CI for access by income for Black households with those aged 14-17 years and found that the CIs for all 3 categories of income were less than 1% (eg, <US $25,000=27.37% (95% CI 27.32-27.42), US $25,000-$50,000=27.7% (95% CI 27.65-27.67), and >US $50,000=44.93% (95% CI 44.87-44.99). Finally, we do not conduct statistical hypothesis testing for differences between groups because very large population sizes will invariably produce statistically significant differences [30-32].

Results

Overview

The results examine 2 major elements: internet access and the mode of internet access. To report on internet access, we examined the proportion of youth residing in households that have internet connection and the proportion of youth residing in households in which an adolescent, aged 14-17 years, has a cell phone or smartphone. The mode of internet access is reflected in data on (1) the proportion of adolescents accessing the internet through home internet connections, (2) cell phone or smartphone internet connections, and (3) those who have accessed the internet only through smartphones (ie, smartphone only). We examined internet access and mode of internet access for 2015 and 2017 with a focus on racial and ethnic minority and social class differences for the population as a whole and social class differences within Black and Hispanic populations.

Table 1 presents the percentage of those aged 14-17 years (1) living in a household with internet, (2) who have a cell phone or smartphone, and (3) with modes of accessing the internet (eg, home and smartphone) for 2015 and 2017 by racial and ethnic group and household income for the total population of households with an adolescent resident. Table 2 presents data separately by household income for Black and Hispanic youth, the 2 racial and ethnic groups that evidence the lowest access. In the text, we highlight the disparities in access and use by discussing the proportion of youth who lack access overall and through specific modalities (Figures 1-3 present data on lack of access; parallel data on modalities are not included in figures). Our disparity analysis assumes the ideal goal of universal internet access (ie, 100%).

Table 1. Reported internet use in the United States: youth aged 14-17 years by selected characteristics (Current Population Survey 2015 and 2017)[a].

Characteristic	Individual lives in household with internet use[b], n (%)		Individual uses a cell phone or smartphone, n (%)		Mode of internet access, n (%)			
	Year, 2015	Year, 2017	Year, 2015	Year, 2017	Home		Smartphone

[b]At least one member of the individual's household reported using the internet from home, even if that individual did not report use themselves.

[c]Data collected from respondents aged 14-17 years. Standard survey weights were adjusted with expansion weights to provide an estimate of the size of the population to which the data are generalized. Black: expanded weights, N=2,626,139 (2015) and N=2,560,101 (2017). Unweighted N=917 (2015) and N=800 (2017). Hispanic: expanded weights N=3,867,713 (2015) and N=3,981,899 (2017). Unweighted N=1412 (2015) and N=1377 (2017).

Disparities in Internet and Cell Phone or Smartphone Access 2015-2017

Youth Access: Population Profile

In 2015, no group had 100% access, and racial, ethnic, and income disparities were evident (Figures 1 and 2). Up to one-fourth of youth lived in households without internet access; Black and Hispanic youth evidenced the greatest disparities. Overall, low-income youth were most likely to have no home internet access. Similarly, more Black and Hispanic youth and youth in middle-income households reported not using cell phones or smartphones. In 2017, there continued to be disparities despite gains in household internet access from 2015 to 2017 (Table 1). Although disparities by income and across racial and ethnic groups decreased in 2017 (Figures 1 and 2), low-income and Black and Hispanic youth continued to lag behind other groups. In some groups, fewer youth reported having cell phones or smartphones in 2017, revealing small increases in disparities overall from 2015 to 2017. Racial and ethnic disparities in cell phone or smartphone use in 2017 remained (Figure 1).

Figure 1. Disparities in access by race and ethnicity 2015-2017. The figure shows the percentage of youth (aged 14-17 years) who do not have access; household internet: internet access in the home; cell phone/smartphone: has cell phone or smartphone.

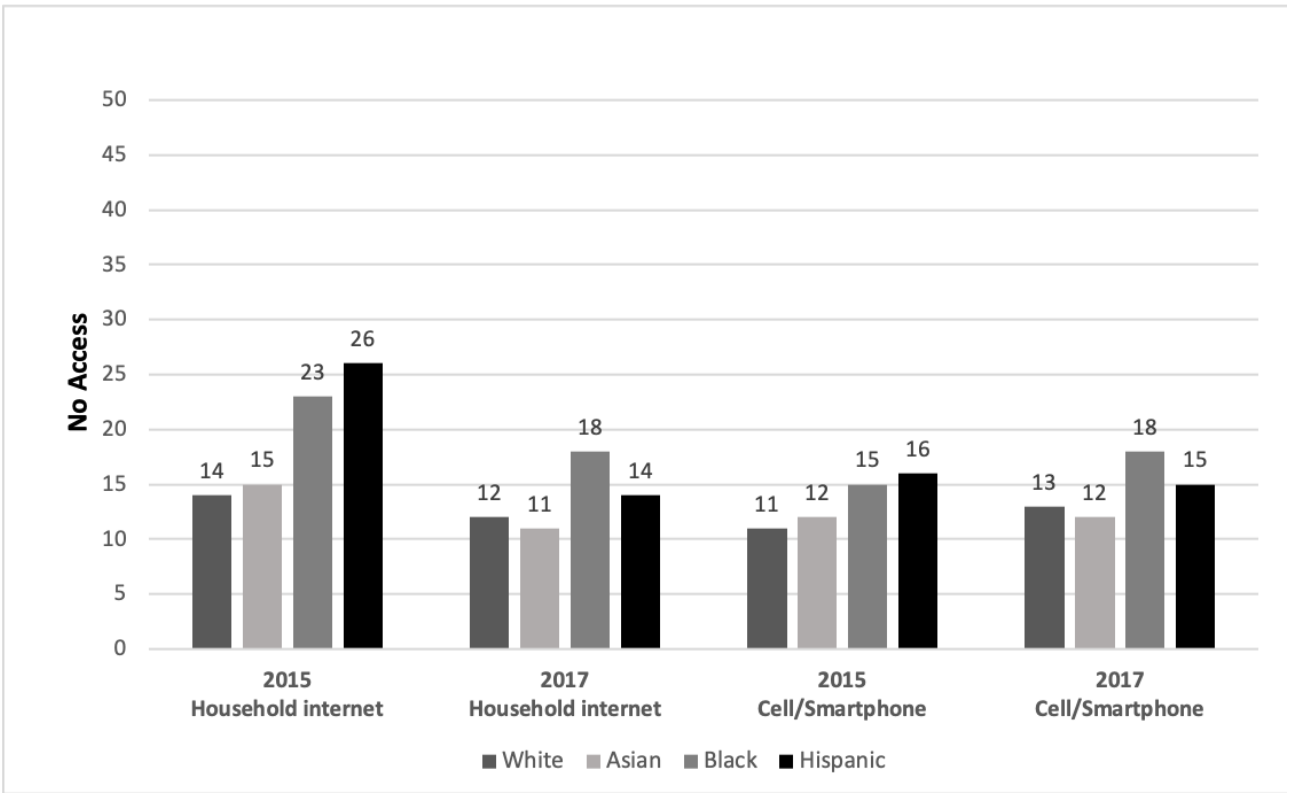

Figure 2. Disparities in access by income 2015-2017. The figure shows the percentage of youth (aged 14-17 years) who do not have access; household internet: internet access in the home; cell phone/smartphone: has cell phone or smartphone.

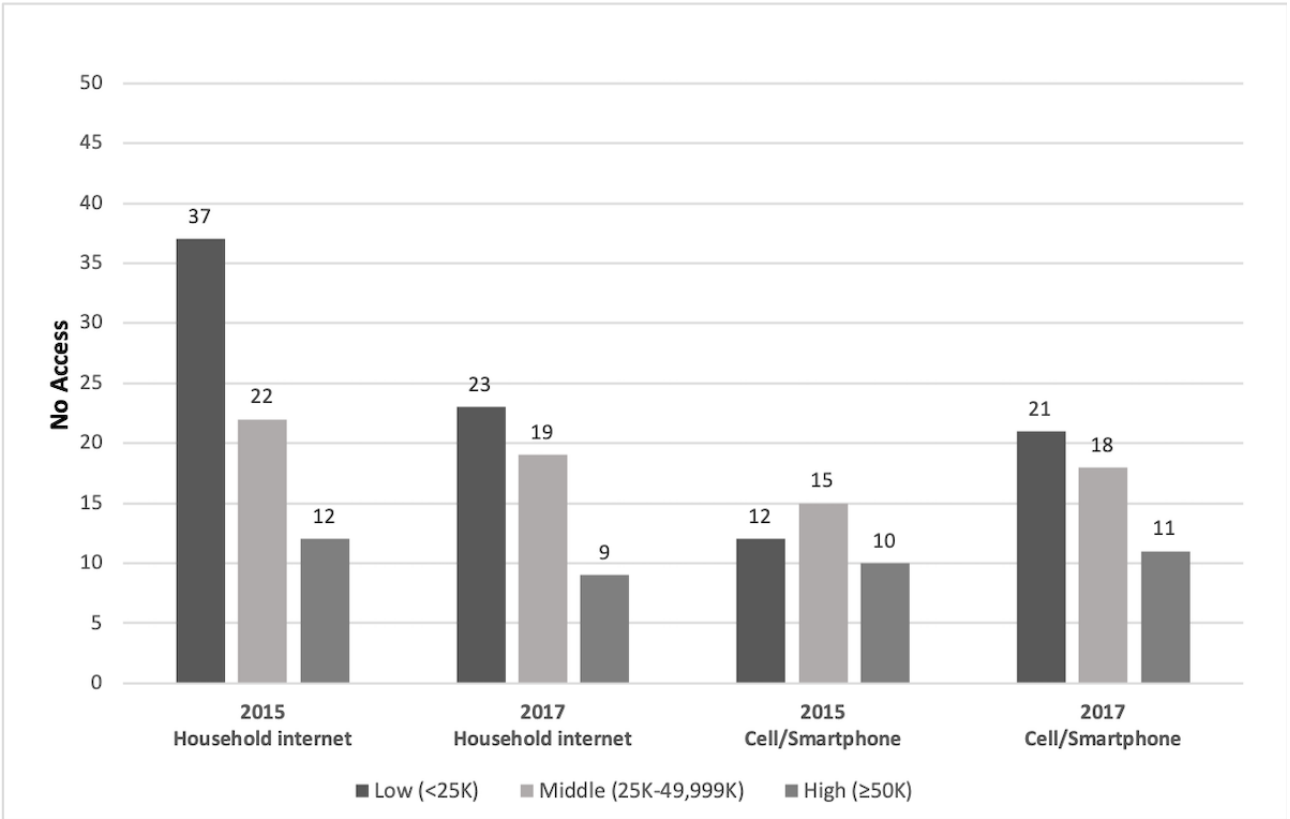
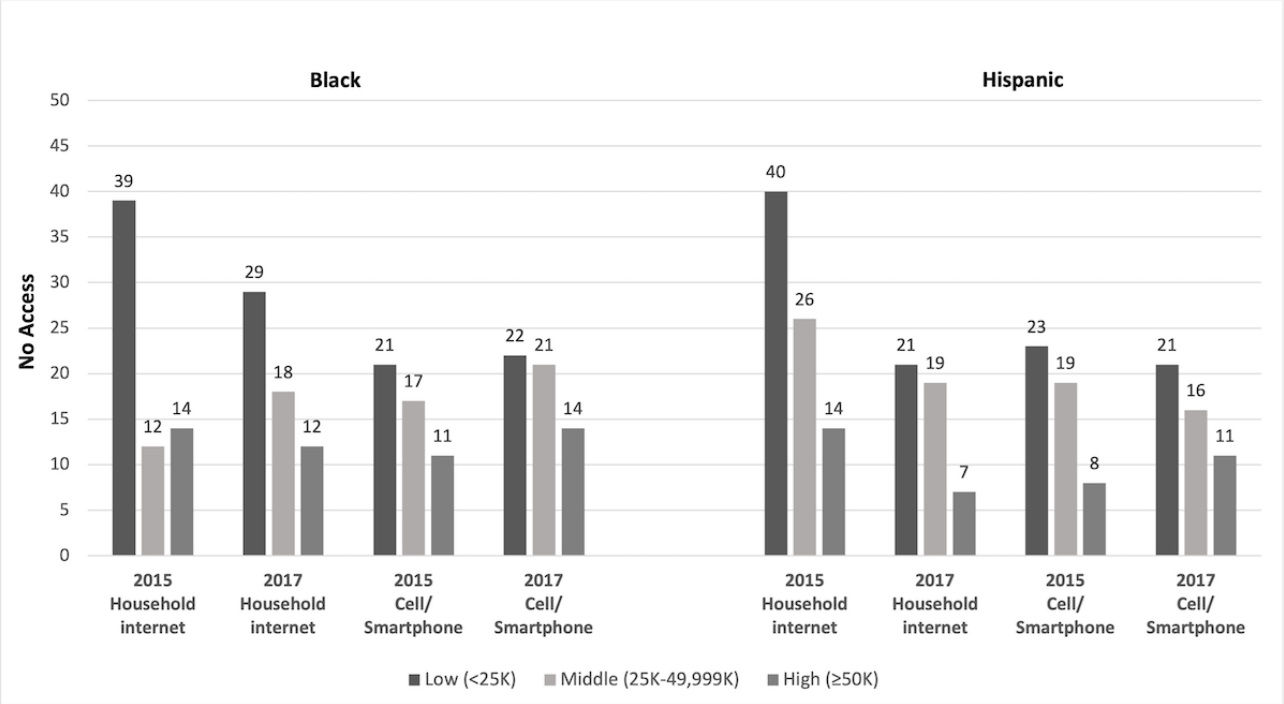


Youth Access: Disparities Among Black and Hispanic Youth

Socioeconomic status differences were evident among Black and Hispanic youth in 2015 (Figure 3). Nearly 3 times as many low-income compared with high-income Black and Hispanic youth lacked home access to the internet in 2015. Approximately 40% of low-income Black and Hispanic youth did not have home internet access. Cell phone and smartphone use followed a similar pattern, with greater disparities for low-income youth. In 2017, Black and Hispanic youth in the lowest-income households continued to evidence the greatest disparities. A total of 29% and 21% of low-income Black and Hispanic youth, respectively, lacked home access. In contrast, 12% and 7% of high-income Black and Hispanic youth, respectively, lacked access. Cell phone and smartphone use followed similar patterns (Figure 3).

Figure 3. Disparities in access by income among Black and Hispanic youth. The figure shows the percentage of youth (aged 14-17 years) who do not have access; household internet: internet access in the home; cell phone/smartphone: has cell phone or smartphone.



Mode of Internet Access 2015-2017

Youth's Mode of Access: Population Profile

We examined modes of youth use for connecting to the internet, including accessing the internet from home or from a smartphone (Table 1). In 2015, more than 20% of youth did not access the internet from home, and at least 30% did not access the internet from a smartphone; Black and Hispanic youth were less likely than other groups to access from either mode. Overall, youth in low-income households were least likely to access the internet from home or from a smartphone in 2015; gaps between the lowest and highest income households were substantial. In 2017, a large proportion of youth still did not access the internet from home. Some racial and ethnic disparities observed in 2015 were reduced because more Hispanic youth reported accessing the internet from home. Disparities in the use of smartphones to access the internet also remained in 2017. Overall, nearly one-third of the youth did not access the internet from a smartphone (population average=33%). An income gap in accessing the internet from home continued to exist in 2017, although a substantial increase in access among low-income households narrowed the gap. Surprisingly, there were only modest changes in accessing the internet from smartphones between 2015 and 2017, with lower use reported overall. Youth in low-income households continue to be the most likely to not access the internet from a smartphone.

Mode of Access: Disparities Among Black and Hispanic Youth

Table 2 includes the mode of access data for Black and Hispanic youth. In 2015, Black and Hispanic youth in the lowest-income households were substantially more likely than those in households with higher income to lack access to the internet from home. Strikingly, about half of low-income Black and Hispanic youth did not access the internet from home or from a smartphone. Income disparities in access modality decreased from 2015 to 2017, with more low-income Black and Hispanic youth reporting access to the internet from home or smartphones in 2017. Despite this change, the disparity between low- and upper-income brackets continues to be evident in 2017. More specifically, 39% and 32% of low-income Black and Hispanic youth, respectively, did not access the internet from home in 2017. Similarly, 43% and 46% of low-income Black and Hispanic youth, respectively, did not access the internet from a smartphone in 2017.

Mode of Access: Smartphone Only

We examined whether the youth accessed the internet *only* from a smartphone for both time points (eg, smartphone-only users; data not presented). In 2015, nearly 10% of the youth were

smartphone-only users, with Hispanic youth having the largest percentage with smartphone-only access (White=5%, Asian=7%, Black=8%, and Hispanic=9%). In addition, youth in low-income households were the most likely to have only smartphone access (12%); this was also true among Black and Hispanic youth. In 2017, there was a small reduction in reports of smartphone-only access; Hispanic youth were again the most likely to report only smartphone access (White=3%, Asian=3%, Black=3%, and Hispanic=5%). Youth in low-income households continued to be the most likely to have smartphone-only access in 2017 (6%). Among Blacks, low-income youth were more likely to report smartphone-only access in 2017, whereas among Hispanics, youth in middle-income households were the most likely to report smartphone-only use.

Discussion

Principal Findings

Using the CPS, we found that internet access has not reached universal levels, despite the critical role that the internet plays in connecting youth to health information, interventions, and providers. On a positive note, we observed a reduction in disparities from 2015 to 2017, with the largest gains typically found among the racial, ethnic, and income groups that lagged behind. Despite these gains, Hispanic and Black youth continue to have lower levels of household access. Regardless of racial or ethnic group membership, youth in low-income households remain at a disadvantage. Even with recent gains, nearly 30% of low-income Black youth and over 20% of low-income Hispanic youth aged 14-17 years did not have home internet access in 2017. Thus, disparities in access found at earlier time points [4,35,36] have not been eliminated, and these will continue to impact youths' ability to benefit from web-based health-related resources.

With increasing reliance on the internet for information and for a host of health and educational services, youth without home internet access are at a disadvantage [37]. Although smartphones can also be used to access the internet, and indeed many youth use smartphones, there are recognized limits to having *only* smartphone internet access [24,38]. Our finding that in 2017, 3%-5% of youth accessed the internet only from smartphones, suggests that some youth will experience challenges (eg, with connectivity and poor audio and video) [17,24,38]. The disadvantages of smartphone-only access will have a greater impact on Black and Hispanic youth living in low- and middle-income households. Similarly, research by the National Center for Educational Statistics found that 6% of children aged 3-18 years had smartphone-only access to the internet, a situation that was more common among Black, Hispanic, and low-income children [39]. In addition to challenges with connectivity, the demands of video connection (eg, telehealth visit and educational interactions) create disadvantages for those who rely only on smartphones for accessing the internet. Furthermore, even when the internet is available on a computer or smartphone, other limitations exist, such as digital literacy (eg, ability to download and install), limited internet speed that can impede using video, and incompatibility of the recipient's devices with the platform on which the health care is being delivered [8,21,40]. Thus, although this study's findings provide information on access and internet use in the home and via smartphone, there are additional factors that influence whether one can effectively participate in health programs or health care via the internet.

Our findings reinforce the importance of income. At both the population level and within racial and ethnic groups (ie, Black and Hispanic youth), we consistently found disparities in access for youth in low-income households. As the effects of unemployment because of the COVID-19 pandemic continue to unfold, an increasing number of households will make decisions about what is affordable. Without public and private efforts to boost internet access [41,42], more low-income households may lose this important service. Given the scope of the impact of COVID-19 on Black and Hispanic communities [43,44], gains in access between 2015 and 2017, especially among low-income households, are at risk.

Home access may have advantages over community access (eg, school and library) for youth seeking health-related information or assistance on sensitive topics (eg, sexual health and mental health; see the study by Smith-East [17]). For example, with rare exceptions, sexual content is blocked on school computers (see the study by Dolcini et al [4]), and community sites may not offer adequate privacy for health consultations [17]. Regardless of these limitations, community internet access follows similar patterns as home access, such that low-income youth have lower access than high-income youth [4]. Community closures because of COVID-19 will have further reduced access because schools, libraries, and community centers were closed for extended periods in many communities.

Although some prior research is viewed as providing evidence of nearly universal access to the internet for youth in the United States (eg, the study by Anderson and Jiang [1]), this study suggests a different reality. Our findings show continued disparities in internet access that are in alignment with other published work using population-level data (eg, ACS and the CPS) [22,23]. The perceived discrepancies in findings across studies may be explained by large margins of error for data on Black and Hispanic youth in studies that include relatively small numbers of these subpopulations. In fact, our findings with respect to household internet access for Black and Hispanic youth roughly correspond to the lower ranges of access identified by Anderson and Jiang [1] (ie, when the margin of error is taken into account). This study underscores the importance of large population-based surveys, which produce estimates with narrow CIs that avoid camouflaging population disparities. We recommend that surveys provide CIs along with point estimates to allow for cross-survey comparisons.

Strengths and Limitations

This study has several limitations. First, the rates of internet access and use may have changed since 2017. On the basis of past trends, we anticipate that disparities by racial and ethnic groups and income would continue [4,35,36]. In addition, the 2020 recession may reverse prior gains in access. Second, we were unable to examine regional differences because the CPS was not designed to examine patterns at that level; other studies provide evidence of regional disparities in access [22]. Third,

the CPS questions on internet use were updated in 2015 and one item used in this study differed between 2015 and 2017. Wording changes in items can influence responses, especially those related to smartphone use [45]. Wording changes in the item on smartphone use could have contributed to the finding showing lower use in 2017; responses to the 2015 item could have included cell phones without capacity to connect to the internet. Despite item changes, patterns observed in 2012 and in later waves of CPS were similar and broadly aligned with patterns observed in the ACS. Finally, CPS data rely on interviews with adolescents and proxies. The survey literature provides a good case for accepting proxy reports in large surveys [46-50]. Agreement between a proxy and the primary respondent is high when questions are general, observable, and use a yes/no format [49]. Fulton et al [46] demonstrated strong agreement for items in the CPS that assess computer and internet use, and laboratory studies show reliability above 90% for general items [49,50]. As noted earlier, the limitations of this study are balanced by the advantages of using population-level data sets, especially when examining racial and ethnic minority populations.

Conclusions

Despite continued calls for universal access to the internet and the recent proposition that broadband internet access is a social determinant of health [51], this study, along with other sources [52], reveals continued disparities in access and use among youth in the United States. A variety of approaches, including private-public collaborations, increasing community *hot spots*, government sponsored expansion of broadband to rural communities, and public access broadband have potential to increase internet access of youth in the United States [37,53-55]. Along with efforts to make the internet more available to all youths to ensure access to important health resources, continued monitoring of internet access among youth using population-level data is warranted.

Acknowledgments

This research was supported by the National Institutes of Mental Health (MH120512, principal investigator: MMD). We thank the Bureau of the US Census for making the Current Population Survey data available. We thank Marissa Lovell (Master of Public Health) and Ashley Schuyler (Master of Public Health) for assistance in manuscript preparation.

Abstract

Background: As the world is becoming increasingly connected by the World Wide Web, the internet is becoming the main source of health information. With the novel COVID-19 pandemic, ubiquitous use of the internet has changed the daily lives of individuals, from working from home to seeking and meeting with health care providers through web-based sites. Such heavy reliance on internet-based technologies raises concerns regarding the accessibility of the internet for minority populations who are likely to already face barriers when seeking health information.

Objective: This study aims to examine the level of technology access and common modes of technology used by Korean American women and to investigate how key psychosocial determinants of health such as age, education, English proficiency, and health literacy are correlated with sources of health information used by Korean American women and by their use of the internet.

Methods: We used data from a subsample of Korean American women (N=157) who participated in a community-based randomized trial designed to test a health literacy–focused cancer screening intervention. In addition to descriptive statistics to summarize Korean American women's internet access and common modes of technology use, we conducted backward stepwise logistic regression analyses to substantiate the association between the psychosocial determinants of health and internet use.

Results: Approximately two-thirds (103/157, 65.6%) of the sample had access to the internet, and nearly all had access to a mobile phone. The internet was the most commonly used channel to obtain health information 63% (99/157), and 70% (110/157) of the sample used text messaging. Nevertheless, only approximately 38.8% (40/103) of the sample were very confident in using the internet, and only 29.9% (47/157) were very confident in using text messaging. Multivariate analyses revealed that older age (>50 years) was associated with 79% lower odds of using the internet to seek health information (adjusted odds ratio [AOR] 0.21, 95% CI 0.10-0.46). The higher health literacy group (19+ on Rapid Estimate of Adult Literacy in Medicine) had 56% lower odds of using the internet to acquire health information (AOR 0.44, 95% CI 1.13-11.18). Higher education (college+) was associated with both internet use (AOR 4.42, 95% CI 1.88-9.21) and text messaging (AOR 3.42, 95% CI 1.55-7.54). Finally, English proficiency was associated with text messaging (AOR 4.20, 95% CI 1.44-12.24).

Conclusions: The differences in modes of technology access, use, and confidence by some of the key psychosocial determinants, as observed in our study sample, have important implications when health care teams develop dissemination plans.

technology use; internet; text messaging; health literacy; English proficiency; immigrant; health disparities; Korean American; women; mobile phone

Introduction

Background

The internet is a unique technology that is constantly developing and encompasses various forms of technologies, such as social media, e-communications, e-commerce, telecommunications, and telehealth. The internet is currently used as a platform that connects people, stores and shares information, and virtually provides health services [1]. Especially during the COVID-19 pandemic, with the suspension of many face-to-face medical and health care services, telehealth and telecommunication have been widely used to offset the loss of manpower within face-to-face medical services [2]. Furthermore, many forms of internet-based health technologies ease the daily lives of Americans by providing ways to self-manage their illnesses and conditions such as diabetes, physical activity, diet, weight loss, heart failure, and more [3]. These daily health technologies use combinations of already existing technologies that are updated with the current technology. For example, sphygmomanometer, weight scale, electrocardiogram recorder, and smartphone apps are combined to monitor heart failure with cost-saving benefits compared with telephone-based monitoring [4].

Despite the proven benefits and rapidly increasing, ubiquitous use of the internet and internet-based health technologies for all Americans, this rapid incline is exposing the health disparities and digital divide in underserved populations: racial and ethnic minorities, older adults, rural populations, lower-income groups, and populations with a lower educational background [5,6]. These underserved populations are more likely to have lower health literacy levels, lack health care coverage, lack provider availability, experience lower quality of care, and are more likely to face discrimination in general and in health care [7]. They are also less likely to have adequate internet connectivity and are less likely to use the internet to seek health information [5,8].

Asian racial or ethnic minorities are rapidly growing in the United States: 72% growth between 2000 and 2015 compared with 60% in Hispanic racial or ethnic minority populations and are currently projected to be the largest immigrant racial or ethnic group by 2055, accounting for 38% of the immigrant population [9]. Overall, 97% of English-speaking Asian Americans are estimated to use the internet compared with 85% of non-Hispanic Whites, 81% of Hispanics, and 78% of non-Hispanic Blacks [10]. However, the healthier and more affluent Asian American subgroups tend to be overrepresented in these reports. This tends to overcast the underserved Asian American subgroups: non–English-speaking, lower socioeconomic status, elderly, disabled, and unauthorized immigrant subgroups comprise more than 50 ethnic and 100 language groups [11]. Some of these smaller Asian ethnic and language groups live in poverty rates that are three times higher than the US average of 10.5%, such as Hmong (28.3%), Bhutanese (33.3%), and Burmese (35%) [9,12]. In addition, some subgroups, such as Koreans, culturally do not express their hardships or deficiencies to the public because they do not want to show their weakness—financially or socially [9].

According to the 2019 American Community Survey, Korean Americans are the fifth largest Asian population and represent one of the fastest growing ethnic groups in the United States [13]; 59% of Korean Americans are first-generation immigrants, significantly higher than the 14% immigrant share among general Americans [14]. Research has revealed health disparities in the Korean American population. For example, Korean American women are 1.5 times more likely to die from cervical cancer than non-Hispanic White women, yet are nearly 20% less likely to receive triennial Papanicolaou tests [15,16]. Korean Americans are also more susceptible to acquiring hepatitis B virus than White Americans by 10-fold because of significant language barriers, limited health knowledge, financial issues, and poor access to care [17].

With their well-documented benefits, internet-based health technologies provide an opportunity to eliminate the health disparities experienced by traditionally underserved populations with limited resources and limited English proficiency, such as Korean Americans [5]. However, information addressing technology access and the use of the internet among Korean Americans is currently scarce. As health care professionals are rapidly adapting and expanding the use of the internet and technology, a better understanding of how Korean American women use the internet may help researchers and clinicians to implement and disseminate health programs to address health disparities in Korean American populations.

Objective

The purpose of this study was to understand the internet use among Korean American women. Specifically, we examined the level of internet access and the common modes of technology used by the target group of Korean American women. We also investigated how key social determinants of health, such as age, education, English proficiency, and health literacy, are associated with Korean American women's use of internet technology.

Methods

Study Design and Sample

This study used data obtained from a sample of Korean American women who participated in a community-based, cluster randomized controlled trial that was designed to test the efficacy of a community health worker–led health literacy–focused intervention program, including mammograms and Papanicolaou test screening, among Korean American women. Details regarding the study design and outcomes have been published elsewhere (NCT00857636) [18]. Briefly, trained community health workers from 23 ethnic churches (intervention=11 and waitlist control=12) in the Maryland-Washington metropolitan area recruited the study sample. Sample inclusion criteria included Korean American women aged 21-65 years who were overdue for either a mammogram (for women aged ≥40 years) or Papanicolaou tests. Those with an acute or terminal condition (eg, cancer diagnosis or life expectancy of <6 months), psychiatric diagnosis, or other conditions that precluded participation in the study activities were excluded. A total of 560 eligible women were recruited and enrolled in the study (intervention, n=278; control, n=282)

and completed the baseline assessment. Follow-up data were collected at 3 and 6 months from the start of the intervention. At 6-month follow-up, 527 women participated in the final data collection (intervention, n=261; control, n=266). For the women participating only in the intervention, a brief phone survey was conducted 1 year after the final data collection between 2013 and 2017. The main goal of this 1-year postsurvey was to examine the long-term effects of the study intervention on cancer screening behaviors and the intervention of women's dissemination of cancer screening knowledge to neighbors in the community (Multimedia Appendix 1). The postsurvey also included questions about access to and use of the internet. A total of 157 intervention women participated in the 1-year postsurvey (response rate=60%). For this analysis, we combined baseline data for key sociodemographic and 1-year postsurvey data for internet use.

Procedures and Measures

All study procedures were approved by the Johns Hopkins Medicine Institutional Review Board. The baseline questionnaire was administered face-to-face by trained bilingual research staff to assess participant characteristics. The baseline questionnaire included sociodemographic questions such as age in years, educational level, income comfortability, marital status, health insurance, and English proficiency. In addition, health literacy was measured using the Rapid Estimate of Adult Literacy in Medicine (REALM), a well-validated 66-item screening instrument that assesses an adult's ability to read common medical words and lay terms for body parts and illnesses [19]. Each correctly pronounced word was coded as *1*, with a total score ranging from 0 to 66. The REALM has been significantly correlated with other standardized reading tests. The REALM was validated in a Korean sample [20].

The 1-year postsurvey was completed through phone interviews by trained bilingual research assistants. Trained bilingual research assistants called the study participants in the intervention group who agreed to participate in a follow-up survey. Part of the postsurvey asked questions about the main sources of health information (eg, internet, television [TV], radio, newspaper, book, or magazine) and access to the internet (with access location) and mobile phones. For those who reported the internet as the main source of health information, additional questions were asked about the frequency of internet use and types of health information sought. Similarly, for those who reported having access to mobile phones, the frequency of use of text messaging was asked. Finally, the level of confidence in using the internet and text messaging was assessed for those who indicated access to these technologies. Each phone interview lasted, on average, approximately 10 minutes.

Data Analysis

We used descriptive statistics such as means, SDs, frequencies, and percentages to summarize the sample characteristics. We conducted a series of backward stepwise logistic regression analyses to examine the association between the key social determinants of health (age, education, English proficiency, and health literacy), sources of health information, use of internet technology, and confidence in using technologies. Age, education, and English proficiency were categorized as young and old (<50 years vs ≥50), low and high education (less than college vs college or more), and limited and proficient English (none, little, and well vs fluent). More than 80% of the analysis sample scored zero on the REALM; hence, instead of using the suggested cutoff of 60 to represent adequate health literacy (ie, high school reading level), we used a cutoff of 18 to categorize the sample as low versus high health literacy groups. The cutoff of 18 on the REALM indicates a reading level of third grade and below, where people will not be able to read most low-literacy materials and may require repetitive oral instructions or written materials composed of illustrations or audiotapes or videotapes [19]. All statistical significance was set at $P<.05$.

Results

Sample Characteristics

Table 1 summarizes the sample characteristics. The analysis sample was mostly middle-aged (mean age 46.3, SD 8.2 years) and married (133/157, 84.7%) women. More than half (100/157, 63.7%) received college or more education, but only 1 in 5 (33/157, 21%) said they felt comfortable with their income level. Slightly more than one-third (55/157, 35%) of study participants indicated at baseline that they had health insurance and a primary care provider (53/157, 33.7%). The majority of the sample had limited English proficiency; only 12.1% (19/157) reported being fluent in English. Similarly, more than three-fourths (134/157, 85.4%) scored ≤18 on the REALM, indicating a reading level of third grade or lower.

Table 1. Sample characteristics (N=157).

Characteristics	Values
Age (years; range 24-64), mean (SD)	46.3 (8.2)
<50, n (%)	96 (61.1)
≥50, n (%)	61 (38.9)
Married, n (%)	133 (84.7)
Education (years; range 8-22), mean (SD)	14.7 (2.5)
Less than college (12 years), n (%)	57 (36.4)
College and more (13 years), n (%)	100 (63.7)
Income comfortability, n (%)	
Difficult and very difficult	69 (43.9)
Okay	55 (35.0)
Comfortable and very comfortable	33 (21.0)
Have health insurance, n (%)	55 (35.0)
Have primary care provider, n (%)	53 (33.8)
English proficiency, n (%)	
None, little and well	138 (87.9)
Fluent	19 (12.1)
Health literacy (range 0-66), mean (SD)	7.0 (17.0)
Third grade reading level or less, n (%)	134 (85.4)
More than third grade reading level, n (%)	23 (14.6)

Technology Accessibility, Usability, and Confidence

Table 2 shows the technology accessibility, usability, and confidence of Korean American women. The most commonly used method for obtaining health information was the internet (99/157, 63%). Of those who indicated the internet as the main source of health information, the main types of health information they searched for were disease (64/99, 65%), followed by alternative medicine (26/99, 26%) and health supplements (21/99, 21%); the majority (65/99, 66%) indicated that they searched on average 1-2 times or less per month. Approximately two-thirds (103/157, 65.6%) of the study sample indicated that they had access to the internet; most of them (101/103, 98.1%) had internet access at home. In addition, nearly all (153/157, 97.5%) participants reported that they had access to a mobile phone; 70.1% (110/157) used text messaging. Nevertheless, only 39% (40/103) were very confident in using the internet; 30% (47/157) were very confident in using text messaging.

Table 2. Accessibility and use of technology (N=157).

Characteristics	Values, n (%)

[a]Multiple choice.

[b]Women who used the internet to obtain health information only (n=99).

[c]Women who had access to the internet only (n=103).

Relationship Among Social Determinants of Health, Sources of Health Information, Technology Use, and Confidence

Multivariate analyses revealed that older age was associated with approximately 79% lower odds of using the internet as the main source of health information (adjusted odds ratio [AOR] 0.213, 95% CI 0.100-0.455) but had at least 2.4 times higher odds of using print media (eg, books and magazines) to obtain health information (AOR 2.403, 95% CI 1.166-4.950). The high health literacy group had 56% lower odds (AOR 0.440, 95% CI 1.134-11.182) of using the internet to acquire health information but more than 1.5 times higher odds (AOR 1.535, 95% CI 1.004-6.400) of using TV and radio. When these variables were examined compared with technology use and confidence, educational level was significantly associated with both internet use (AOR 4.419, 95% CI 1.870-9.205) and text messaging (AOR 3.417, 95% CI 1.549-7.540), with high education favoring the use of both technologies. Although no variables were associated with confidence in using the internet, English proficiency was associated with more than four times higher odds of confidence in using text messaging (AOR 4.198, 95% CI 1.439-12.244; Table 3).

Table 3. Multiple logistic regression analysis to explain sources of health information, technology use, and confidence[a].

Outcome	Social determinants of health, adjusted odds ratio (95% CI)			
	Age	English proficiency	Education	Health literacy
Main source of health information				
Internet	0.213 (0.100-0.455)	N/A[b]	N/A	0.440 (1.134-11.182)
Print	2.403 (1.166-4.950)	N/A	N/A	N/A
Television and radio	N/A	N/A	N/A	1.535 (1.004-6.400)
Use of technology				
Internet	N/A	N/A	4.419 (1.870-9.205)	N/A
Text messaging	N/A	N/A	3.417 (1.549-7.540)	N/A
Confidence in using technology				
Internet	N/A	4.198 (1.439-12.244)	N/A	N/A
Text messaging	N/A	N/A	N/A	N/A

[a]Variables were added if the *P* value was less than .05. The adjusted odds ratio (95% CI) is displayed. The different groups were as follows: younger age (<50 years), limited English proficiency (less than fluent English), low education (less than college), and low health literacy (≤18 on the Rapid Estimate of Adult Literacy in Medicine).

[b]N/A: not applicable.

Discussion

Principal Findings

We found that only approximately two-thirds of our study sample had internet access. However, the internet was the most popular source of health information used by Korean American women in this study. We also found that although nearly all study participants (153/157, 97.4%) had access to a mobile phone, slightly more than two-thirds (110/157, 70%) of them used text messaging. The Korean American women in the study had overall low levels of confidence in using the internet and text messaging. Older women, lower education, and limited English proficiency were associated with less use of these technologies. This is one of the first studies to comprehensively examine the common modes of technology and to investigate how key social determinants of health are associated with technology use in one of the fastest growing yet understudied ethnic groups in the nation (ie, Korean American) [21].

The level of home-based internet access among our study sample of Korean American women was comparable with that in Black populations (66%) but lower than that in the general US population (73%) or White populations (79%) and higher than that in Hispanic (61%) populations [5]. Relying on the internet to seek health information may have been due in part to the finding that Korean Americans represent one of the most uninsured ethnic groups in the nation. For example, in a survey of 498 patients from primary care clinics mainly serving Hispanic and Black patients, Gutierrez et al [21] revealed that the primary source of health information most commonly reported was their health care professionals, followed by various forms of media, such as news, radio, or books. The internet was used less frequently (<25%). In our study sample, only approximately one-third of women had health insurance (35%) and reported having a primary care provider (34%). For individuals with limited access to care, the internet may serve as a key resource for health information. As the internet plays an increasingly important role in health information access, it is important to identify strategies to promote and control the quality of health information posted on the internet. For example, a recent systematic review yielded three criteria that are most important in evaluating web-based health information: trustworthiness, expertise, and objectivity [22]. These indicators can be used to guide those who develop web-based health information.

Age was significantly associated with the sources of health information used by Korean American women in this study. Specifically, older age (≥50 years) was associated with an

approximately 80% lower likelihood of using the internet but more than two times higher likelihood of using print media as the main source of health information. Using data from the 2011-2014 Health Information National Trends Survey (58% female and 70% White with mean age 54 years), Jacobs et al [23] reported that younger US populations were more likely to use web-based sources to seek health information compared with older populations. In this study, the older population with less internet proficiency was more likely to use health care professionals as a source of health information [23]. Taken together, our findings suggest the importance of satisfying health information-seeking behavior with appropriate dissemination approaches based on the characteristics of the target population.

Korean American women with higher education (college or more) were four times more likely to use the internet and three times more likely to use text messaging than women with less than a college-level education. The ability to use the internet and text messaging may be attributable to multiple factors such as generation gaps (eg, younger generations being exposed to digital technologies early on in their life), regularized use, and required higher reading levels for many publicly available websites. In particular, people with higher education are more likely to be easily adapted to use new technologies [24,25]. Korean American women with higher education might have learned to use the internet to seek information during years of education and used text messaging for social interactions and group projects. The national guideline states that health information on public websites should be written at a lower than eighth grade reading level [26,27]. Nevertheless, evidence suggests that the health information found on the web is above a grade 10 level or even 12th [28,29]. Most Korean American women in our study had an average reading level of third grade and lower on REALM, indicating a significant barrier to finding adequate health information on the web. Future efforts should focus on the development of plain language health information that is accessible and understandable to wider audiences, including recent immigrants with limited health literacy, such as Korean Americans.

We found that high health literacy was associated with a lower likelihood of using the internet but a higher likelihood of using TV and radio as the main source of health information. This finding conflicts with a study (N=498, 62% Hispanic) in which patients with limited health literacy had lower odds of seeking health information on the web after controlling for age, sex, and race and ethnicity [21]. It may be that Korean American women might have lacked the necessary skills to use health information on the internet. Overall, our study sample had very low health literacy, with 85% of participants being lower than the third-grade level. In addition, nearly 9 of 10 women (88%) had limited English proficiency, a risk factor for low health literacy [30]. In fact, confidence in using the internet was more than four times higher among women with higher English proficiency in the study. The US Department of Health and Human Services' Healthy People 2020 published a report that states an upward trend of access to the internet in the general population, from 69% in 2007 to 81% in 2017 [31]. However, the proportion of web-based health information seekers who report that they can easily access health information decreased from 41% in 2008 to 38% in 2017 [31]. The findings suggest that having access to the internet does not necessarily mean that health information seekers have the skills and resources to adequately use the information obtained from the internet [32]. To collectively provide a wide range of health information to the general public, health information published on the web not only needs to be accurate and reliable in English and Spanish but also lower-grade English reading levels and diverse languages. As the US is projected to be a *minority-majority* country as early as 2045, it is particularly important to provide lower English reading levels and accurately translate health information [33].

Despite nearly every woman in our sample indicating access to a mobile phone, only 70% of those reported ever using text messaging, and only 30% were very confident. More than 9 of 10 (97%) US adults use text messaging as the most frequently and widely used feature of smartphones [34]. Text messaging is an increasingly popular way of getting connected to the health care system for appointment alerts, information sharing, and methods for quick communication to question and answer between health care providers and patients. As studies show higher efficiency and result through text messaging for health care [35,36], it is important to understand the reasons why Korean American women face difficulties in using text messaging features. Ladley et al [37] found that the use of text messaging to disseminate health information to infant caregivers with low health literacy improved information retention and resulted in fewer visits to the emergency department during the first year. The use of text messaging also benefits health care providers, as it offers advantages such as time management [38]. Active smartphone use may be a gateway for telehealth communications and web-based patient portals such as MyChart, which provide reliable sources of health information. Currently, digital technology health resources are primarily used by the highly educated White population and are often out of reach for those with less than high school education and lower English proficiency [39,40]. These underserved populations are likely to face barriers in accessing health care similar to MyChart because of external factors such as low health literacy and low technology proficiency or lack of access to the internet or devices to access web-based patient portals [40,41]. According to a recent review of technology use among underserved populations, having a proxy person to provide support helped to increase health technology uptake [32]. Future research should explore whether and how the availability of social resources to impart knowledge and skills can serve as a facilitator of digital technology use for health information in underserved populations.

Limitations

Our study limitations include a lack of generalizability of the study findings beyond the targeted sample. Women in the study were recruited from ethnic churches in one geographical area (Maryland-Washington metropolitan area). People in urban areas have more access to the internet than those in rural areas (97% vs 65%) [42]. Nevertheless, most Korean Americans reside in metropolitan areas (eg, Los Angeles, New York, and Washington, DC) [43]. In addition, we did not specify the use of social media as part of the postintervention survey, mainly focusing on some of the most common sources of information

used in our study sample. However, the literature indicates that certain cultural and age groups (eg, Hispanic women aged between 45 and 55 years) use social media frequently, especially when a message is centered on familism [44]. This was a secondary analysis of data that were already collected for its parent study and were pulled only from the intervention group of its parent study sample. For the purposes of the parent study, participants completed a sociodemographic survey about 1.5 years before the internet use survey. However, we do not believe that any significant change might have occurred in the psychosocial determinants of health we examined (ie, age, education, English proficiency, and health literacy) in relation to technology use.

Conclusions

As the use of digital technology is ubiquitous in our daily lives with better health outcomes, it is important to allow all populations to use these technological advances to narrow the gap between health inequality. Although working with ethnic minority populations, particularly recent immigrants, it is important to understand the role of social determinants of health in relation to the types of technologies being used, how they are used, and their level of confidence in using the technologies. Such specific information may help provide effective strategies for optimal health information dissemination to engage underserved populations, such as Korean American women. Future research should address barriers to and facilitators of using digital technologies, health information, and health care. In addition, given that people with limited access to health care, such as Korean Americans, are not likely to obtain health information from a health provider, diverse health information dissemination strategies beyond web-based information (eg, using friends and family as main sources of health information) should be considered and tested for its efficacy [45]. The Plain Writing Act of 2010 stipulates that the government-issued documents to the public be written clearly with the audiences' recommended reading level [46,47]. This act can be expanded to not only federally supported agencies but also all agencies subsidized by federal and state governments and include set guidelines of all documents disseminated be written with a readability score of eighth grade and lower in accordance with the National Institute of Health and American Medical Association's readability recommendations [48,49]. The rapid evolution of technology from word of mouth to telephones, radio, and TV and then to the internet and smartphones are differentiating the methods of obtaining health information and health care seeking behavior. The differences in the modes of obtaining health information in younger and older persons, as observed in our study sample, have important implications when health care teams develop dissemination plans. Having multiple modes such as paper, text message, and web-based along with dissemination with respect to age groups may lead to more successful health information delivery.

Acknowledgments

This study was supported, in part, by a grant from the National Cancer Institute (R01CA129060). Additional funding was received from the National Center for Advancing Translational Sciences (UL1TR003098), the National Institute of Nursing Research (P30NR018093), and the National Institute on Aging (R01AG062649). The funding sources had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and the decision to submit the manuscript for publication. The authors are grateful to all Korean American women and community health workers who participated in this study and to the research staff for their assistance with data collection.

Authors' Contributions

All authors approved the final version of the manuscript. HRH originated the study and led to writing. SC and YJL contributed to the development of the study concept and design. SC, YJL, and HRH contributed to the analysis and interpretation of the data. SC drafted the manuscript, and all authors contributed to the critical revision of the manuscript. HRH also supervised the study.

Conflicts of Interest

None declared.

Abstract

Background: Wearable devices have been widely used in clinical studies to study daily activity patterns, but the analysis remains a major obstacle for researchers.

Objective: This study proposes a novel method to characterize sleep-activity rhythms using actigraphy and further use it to describe early childhood daily rhythm formation and examine its association with physical development.

Methods: We developed a machine learning–based Penalized Multiband Learning (PML) algorithm to sequentially infer dominant periodicities based on the Fast Fourier Transform (FFT) algorithm and further characterize daily rhythms. We implemented and applied the algorithm to Actiwatch data collected from a cohort of 262 healthy infants at ages 6, 12, 18, and 24 months, with 159, 101, 111, and 141 participants at each time point, respectively. Autocorrelation analysis and Fisher test in harmonic analysis with Bonferroni correction were applied for comparison with the PML. The association between activity rhythm features and early childhood motor development, assessed using the Peabody Developmental Motor Scales-Second Edition (PDMS-2), was studied through linear regression analysis.

Results: The PML results showed that 1-day periodicity was most dominant at 6 and 12 months, whereas one-day, one-third–day, and half-day periodicities were most dominant at 18 and 24 months. These periodicities were all significant in the Fisher test, with one-fourth–day periodicity also significant at 12 months. Autocorrelation effectively detected 1-day periodicity but not the other periodicities. At 6 months, PDMS-2 was associated with the assessment seasons. At 12 months, PDMS-2 was associated with the assessment seasons and FFT signals at one-third–day periodicity (P<.001) and half-day periodicity (P=.04), respectively. In particular, the subcategories of stationary, locomotion, and gross motor were associated with the FFT signals at one-third–day periodicity (P<.001).

Conclusions: The proposed PML algorithm can effectively conduct circadian rhythm analysis using time-series wearable device data. The application of the method effectively characterized sleep-wake rhythm development and identified the association between daily rhythm formation and motor development during early childhood.

wearable device; actigraphy; circadian rhythm; physical activity; early childhood development

Introduction

Background

Wearable devices have been increasingly used in research recently because they can provide continuous objective monitoring of activities and vital signs data such as body temperature and pulse rates [1-3]. In sleep and activity studies, researchers have focused on the actigraphy data generated from wearable devices to study sleep and activity patterns as an alternative to sleep diaries and polysomnography [1,4]. The device usually uses an accelerometer that monitors acceleration in one or more directions, and this wristwatch-like device is often worn on the wrist to record activity continuously for several days. Either the raw data or the transformed activity count data can be used to study sleep-wake patterns and screen sleep disorders [4,5]. Actigraphy not only avoids the subjectivity and bias issues with sleep diaries but also overcomes the drawbacks of polysomnography, such as high costs, in-laboratory setting, intrusive measures, and difficulty in long-term monitoring.

Continuous objective monitoring using wearable devices provides researchers with the opportunity to conduct circadian rhythm studies. Circadian rhythms are endogenous and entrainable biological processes that follow a period of approximately 24 hours, and many physiological phenomena such as sleep-wake patterns, body temperature, and hormone levels exhibit circadian rhythms. For humans, most circadian rhythms are under the control of the pacemaker located in the suprachiasmatic nuclei in the anterior hypothalamus of the central nervous system, and suprachiasmatic nuclei accept environmental information such as the light and dark cycle to adjust the 24-hour cycle [6]. However, 24-hour human circadian rhythms are not mature at birth, when the predominant rhythm is ultradian, and the circadian rhythms of sleep-wake cycles and body temperature gradually develop during the first year after birth [6-9]. Many studies have investigated how circadian rhythms develop through childhood into adolescence and adulthood and how they are related to health issues such as sleep problems, mental problems, and disease risks, to name a few [8,10-14]. It is noteworthy that the development of circadian rhythms during early childhood is associated with disease risk factors and can affect both childhood and adult life [8]. Therefore, it is important to conduct circadian rhythm studies to gain a thorough understanding of the formation and consolidation of daily activity rhythms during early development as well as the association between the changes in daily rhythms and health conditions.

Actigraphy data generated from wearable devices have been validated to provide reliable information on sleep and circadian rhythms [15]. However, the analysis of time-series data from actigraphy remains a major obstacle for researchers. Current major statistical methods are either parametric, based on cosinor analysis, or nonparametric [16-21]. These methods do not specifically focus on periodic information and are not specifically suitable for populations whose sleep-wake rhythms are not sinusoidal, such as patients with Circadian Rhythm Sleep Disorder, or not mature, such as young infants and toddlers [6-10,12]. Therefore, traditional approaches targeting normal daily rhythms might not work because detailed activity rhythms cannot be captured. There is a need to develop an appropriate methodology to extract periodic information and study detailed circadian patterns of all populations to better characterize daily rhythms.

Objective

In this paper, we propose a Penalized Multiband Learning (PML) approach that can complement current methods to characterize daily rhythms based on periodic information in time-series wearable device data. PML extracts periodic information using the Fast Fourier Transform (FFT) algorithm and then performs penalized selection based on regularization, a classic approach used in machine learning, to identify dominant periodicities and further characterize daily rhythms [22,23]. In this paper, we first present the proposed PML approach in detail and discuss its usefulness and advantages compared with other methods. Subsequently, we present an application of the method to early childhood wearable device activity data, in which we characterize the formation and consolidation of sleep-activity rhythms and further study its association with physical development during early childhood.

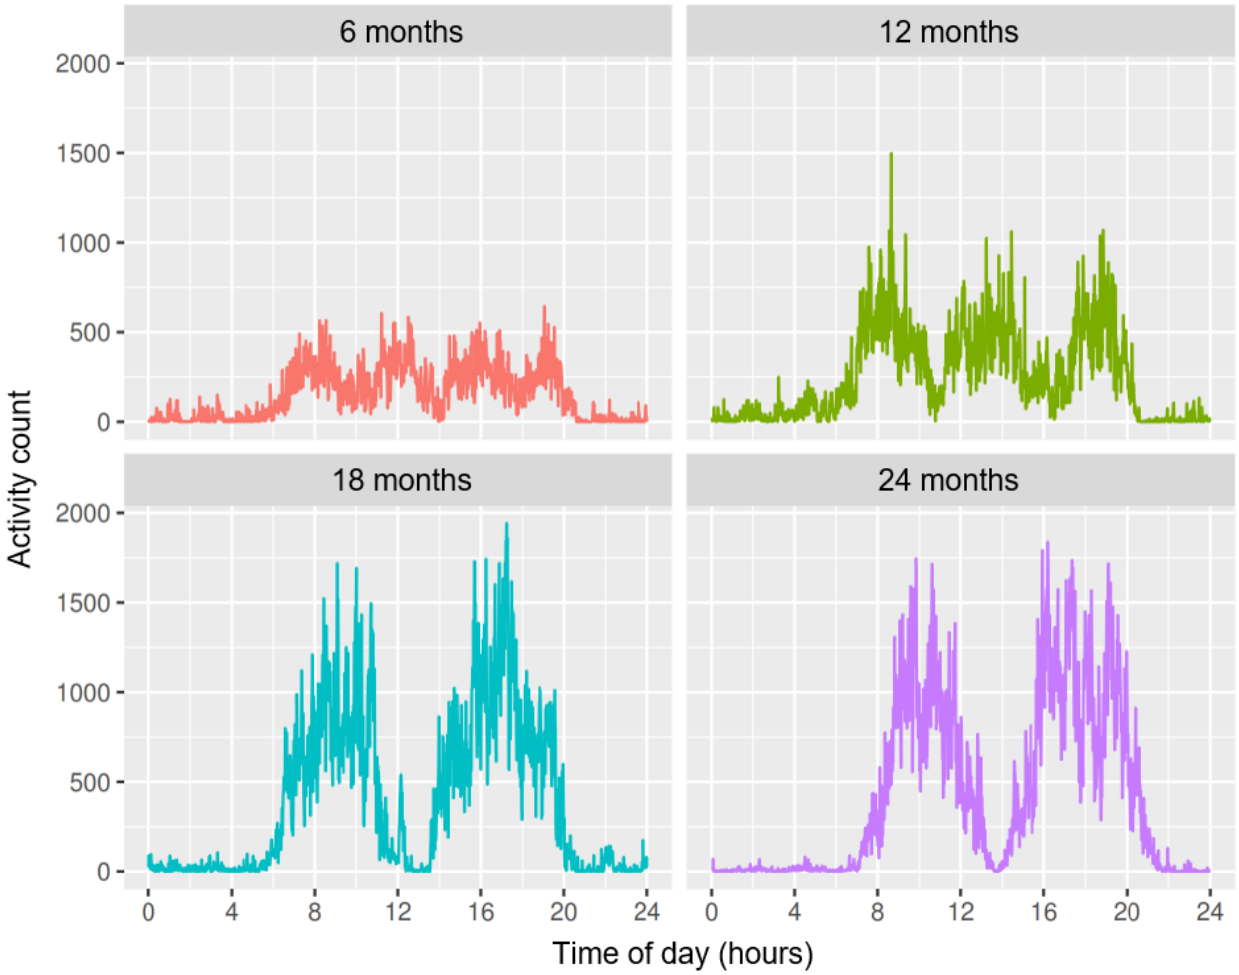
Methods

Data

The study participants were 262 healthy newborns recruited in 2012-2013 by the Shanghai Children's Medical Center, Shanghai, China. Actiwatch data were collected at ages 6, 12, 18, and 24 months, with 159, 101, 111, and 141 participants at each time point, respectively; not all participants from the cohort participated each time. The infants and toddlers were required to wear Actiwatch 2 (Philips Respironics Mini-Mitter) on the ankle for 7 consecutive days. Wearing such devices on the ankle is commonly recommended for young infants or toddlers [24]. The Actiwatch 2 uses a piezoelectric sensor to detect accelerations between 0.5 and 2.0 g with a frequency response range between 0.35 and 7.5 Hz, and activity counts summarize the accelerations over each epoch. The data output format for Actiwatch 2 was configured to be the activity count per 1-minute epoch. On the basis of sleep diaries and activity plots for each individual, the days showing nonwear periods with straight lines of zero activity counts were removed. Nonwear periods can be differentiated from sedentary behaviors or sleep because the former gives almost all zero activity counts, whereas the latter gives nonzero activity counts every now and then. Figure 1 shows the activity plots for participant ID 17, and it can be seen that at 6 months, low and high activities were intermittent during the day, suggesting multiple daytime naps, whereas near-zero activity levels at night suggest long nighttime sleep. At 12 months, 3 activity peaks, one morning nap, and one afternoon nap can be identified. At 18 and 24 months, 2 activity peaks

formed and stabilized, showing only one afternoon nap. The daily activity rhythm developed and stabilized as the infant grew. In addition to Actiwatch data, demographic information and family information were collected at baseline, such as child's sex, child's date of birth, parents' age, child's birth weight and body length, parents' height and weight, parents' educational levels and working status, and family income. The Peabody Developmental Motor Scales-Second Edition (PDMS-2) was used to assess early childhood physical development at 6, 12, 18, and 24 months [25]. The institutional review board of the Shanghai Children's Medical Center, Shanghai Jiao Tong University, approved the study (approval number: SCMCIRB-2012033). The parents of the children who participated in the study provided written informed consent.

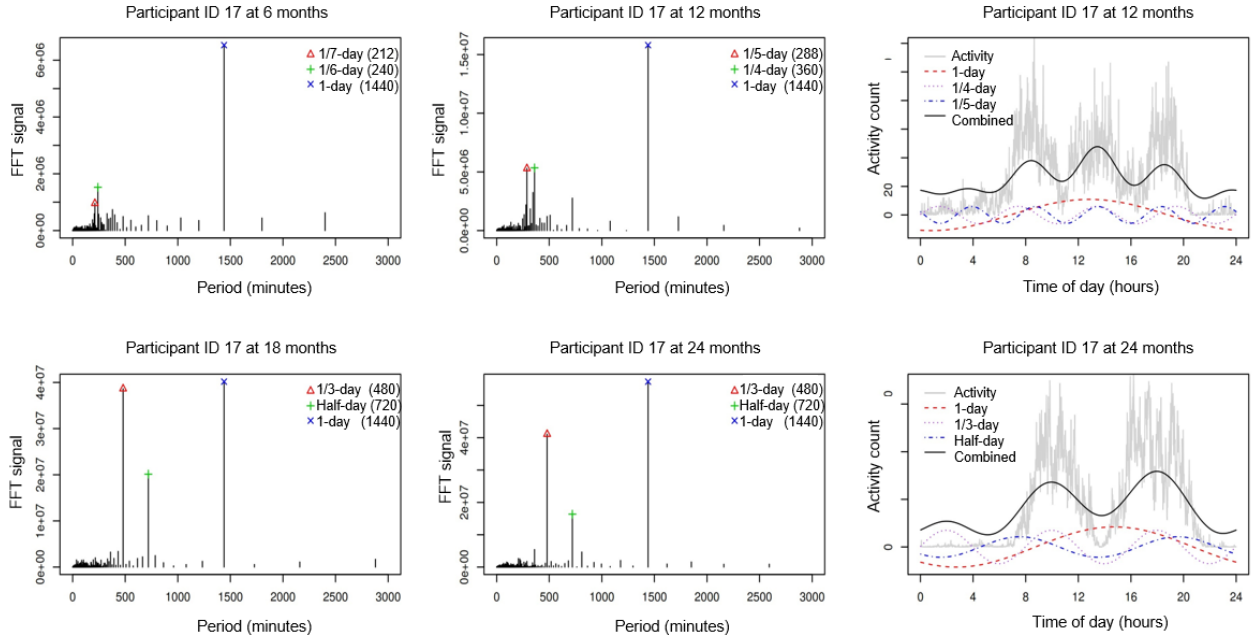
Figure 1. The activity plots for participant ID 17 at 6, 12, 18, and 24 months, with activity counts averaged across 7 days at each time point.



FFT Algorithm

To describe the consolidation of sleep-activity rhythms during early childhood, we used periodic information to characterize the daily rhythms. Specifically, we used the FFT algorithm to convert time domain signals into a frequency domain spectrum to extract periodic information. We analyzed the original data to allow for non–24-hour sleep-wake rhythm detection. Figure 2 shows the FFT results for participant ID 17 at each age. The 1-day periodicity was the most dominant at all time points. The one-fifth–day and one-fourth–day periodicities can be identified at 12 months. The half-day and one-third–day periodicities did not become dominant until 18 and 24 months. It is noteworthy that each periodicity is not interpreted alone; rather, the periodicities are combined to understand the overall pattern. As suggested in the 2 right panels of Figure 2, the combined one-fifth–day and one-fourth–day periodicities form a three-peak, two-nap pattern at 12 months. Similarly, the combined half-day and one-third–day periodicities exhibited a two-peak, one-nap pattern at 18 and 24 months. Therefore, the combination of dominant periodicities can be used to capture the main sleep-activity patterns at each age and describe the gradual consolidation of daily rhythms in early childhood development.

Figure 2. Four panels on the left: Fast Fourier Transform results for participant ID 17 at 6, 12, 18, and 24 months. Two panels on the right: top three periodicities and the combined periodicities plotted on 1-day observation for participant ID 17 at 12 and 24 months. FFT: Fast Fourier Transform.



Identification of Dominant Periodicities

The PML algorithm is as follows: let matrix $X \in R^{n \times p}$ denote the FFT results, where denotes the number of individual observations and denotes the number of periodicities from FFT. Specifically, $X = (x_1,x_2,...,x_p)$, where x_j is the vector of length n for the jth periodicity.

Let Θ be the diagonal matrix selecting columns from X such that  and $0 \leq \theta_{j,j} \leq 1$, $j=1,...,p$:

Θ identifies columns of dominant periodicities from X in such a way that dominant periodicities corresponding to nonzero $\theta_{j,j}$'s are selected. We minimized the squared Frobenius norm  , which is the sum of the squared elements of the matrix. Using the properties of the Frobenius norm, we obtained the following:

As X^TX is fixed, it is equivalent to minimize as follows:

To estimate Θ and identify dominant periodicities, we used a penalized selection method similar to Lasso, a widely used method in shrinkage and selection of a subset of features in regression models and machine learning approaches [23]. In regression analysis, the Lasso penalty is most effective in selecting a few important features while suppressing the regression coefficients of other nonselected features to 0 [23]. In our case, the Lasso penalty served to select a few dominant periodicities through diagonal elements of Θ instead of regression coefficients. Furthermore, we added an elastic net–like penalty term to the Frobenius norm, namely a combination of L1 and L2 norms [22]:

where λ is the turning parameter and α controls the balance between the L1 and L2 norms. Note that $\theta_{j,j}$'s is nonnegative; thus, we do not need to take the absolute value for the L1 norm. By setting λ large enough, all diagonal elements of Θ, namely all $\theta_{j,j}$'s are suppressed to zero, and no periodicities are selected. As λ decreases, some $\theta_{j,j}$'s become nonzero, and they correspond to the most dominant periodicities that are selected sequentially according to their dominance.

To minimize $g(\theta)$, we took the partial derivative of $g(\theta)$ with respect to each  $= -2||x_k||^2 + 2\theta_{k,k}||x_k||^2 + (1\text{-}a)\lambda\theta_{k,k} + a\lambda$,which is convex and subject to the constraint $0 \leq \theta_{k,k} \leq 1$. Thus, we have the following:

If we only have the L1 penalty, then $\alpha=1$ and  . In our case, we used the Lasso L1 penalty alone and trained λ because we wanted to select the most important periodicities while suppressing other periodicities to 0. However, we still kept the L2 norm in the original model as an option because it might be helpful in future tasks such as prediction, classification, and reconstruction of curves.

We used the mean squared error (MSE), which is equivalent to the squared Frobenius norm  , as the criterion for choosing λ and the number of nonzero $\theta_{j,j}$'s (the number of dominant periodicities selected), as well as to evaluate the variability that was not explained by the selected periodicities. We did not

choose cross-validation because the results showed that the test data set error curve was monotonous. We trained λ from  to 0 because λ =  suppresses all $\theta_{j,j}$'s to and λ=0 gives no penalty. By decreasing λ, we identified dominant periodicities sequentially and characterized the daily sleep-activity rhythm at each age. An R package named PML was developed [26] for the implementation of the PML algorithm [27].

Comparison With Other Methods

To rigorously conduct statistical tests and select significant periodicities, we applied the Fisher test in harmonic analysis [28]. It is a sequential test for ordered statistics, and periodicities are first ordered and then tested for significance. If one periodicity is statistically significant, the next one will be tested further. Otherwise, the sequential test will be stopped. At each step, the critical value at which to declare statistical significance was different. In some studies, the method may not be implemented correctly; therefore, we included the sequential test in the R package for easy implementation. As we performed multiple testing, Bonferroni correction was used to adjust the *P* values. If we conduct the tests at significance level α, we reject the null hypothesis if *P* value≤α/*p*, where *p* is the number of periodicities, and conclude that the periodicity is significant.

To evaluate the effectiveness of the PML algorithm, we compared it with the autocorrelation of the standard approach. The autocorrelation r_k is calculated between activity measurements with a time lag *k*, and the coefficient r_{24} denoting a 24-hour time lag is of primary interest in circadian studies [29]. r_k ranges between –1 and 1, and a *k*-hour periodic pattern can show a higher value of the correlation coefficient r_k. In the plot of r_k against the time lag *k*, a peak around *k*=24 can be observed when there is a dominant circadian pattern of 24-hour periodicity. We plotted autocorrelation against the time lag to compare the autocorrelation method with our algorithm.

Association Between Daily Rhythms and Motor Development

Next, we conducted linear regression analysis to study the association between the consolidation of daily activity rhythms and early childhood physical development. PDMS-2 is considered an early childhood developmental assessment tool, and the score is used as the outcome. If the PDMS-2 total motor standard scores are found to be associated with daily rhythm features, the standard scores for the subtests, including stationary, locomotor, object manipulation, grasping, and visual-motor integration as well as gross motor and fine motor, are used as the outcome to examine which specific subcategory is associated. Gross motor represents the overall performance on stationary, locomotion, and reflexes (6 months) or object manipulation (12, 18, and 24 months) for infants, and fine motor represents the overall performance on grasping and visual-motor integration.

The FFT signals at dominant periodicities identified by the PML were used as daily rhythm features and considered covariates in the model. In addition to periodic features, demographic information and family information as potential confounders were also considered in the model. Backward selection was used in the model-fitting process. Although some variable (denoted as variable A here) may seem to be statistically significant in the complete model, after removal of insignificant variables in the variable selection process, variable A may become insignificant. In such cases, variable A is removed in the final model to achieve parsimony.

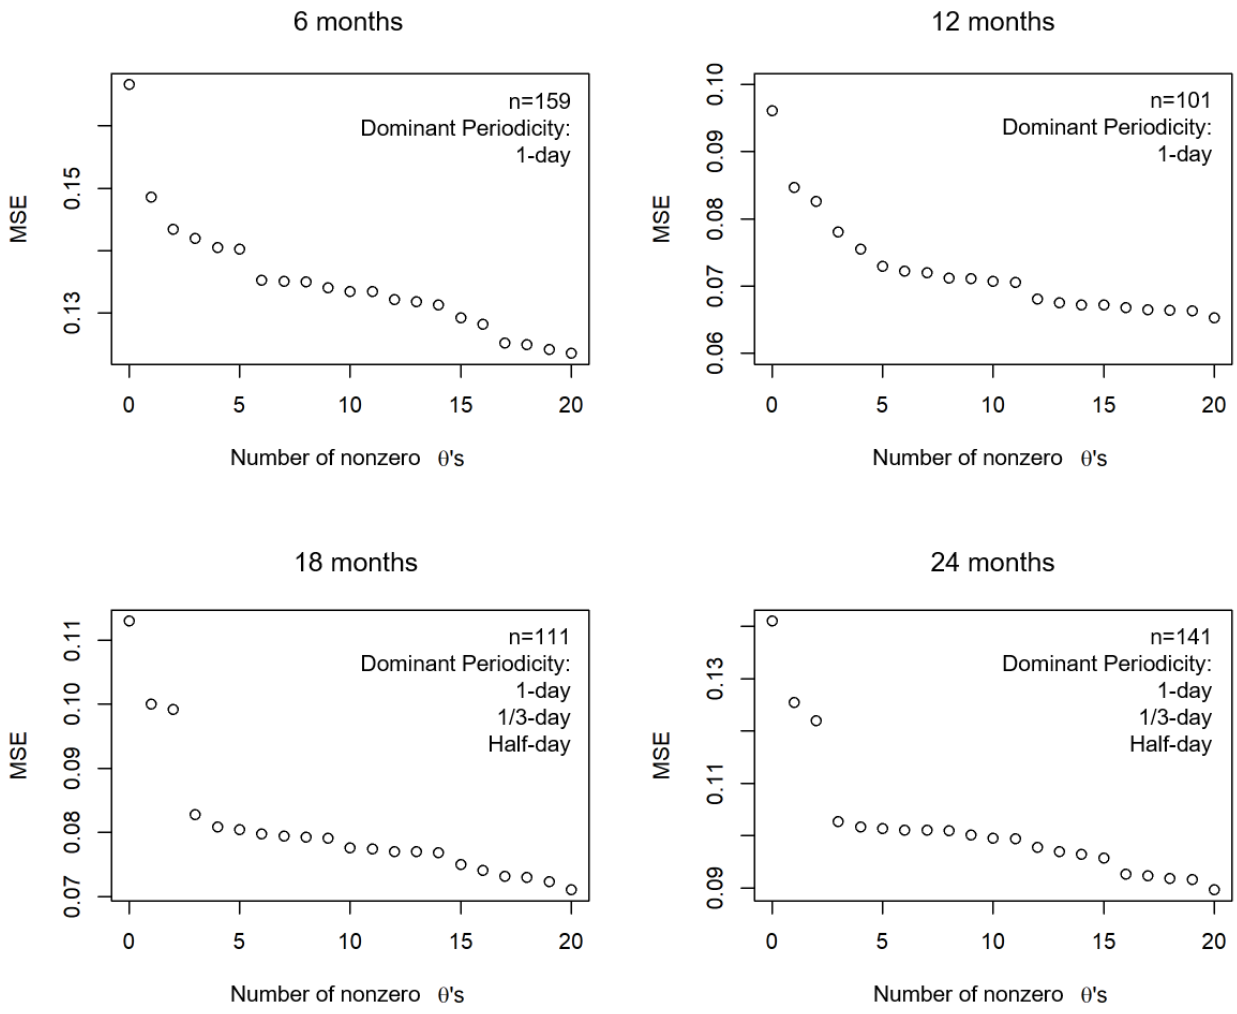
Linear regression analysis was conducted at 6, 12, 18, and 24 months to study the association between daily rhythms and motor development. For the final model comparison, r^2, which measures the proportion of variance in the outcome explained by the model, and the adjusted r^2, which modifies r^2 based on the number of predictor variables, were also calculated. All statistical analyses were conducted using R version 3.3.2 (R Foundation for Statistical Computing).

Results

Identification of Dominant Periodicities

As shown in Figure 3, at each age, we plotted the MSE against the number of nonzero θ's. Specifically, we plotted only the points where the number of nonzero θ's (periodicities selected) increased as the penalty term λ decreased. For 6 months and 12 months, the first harmonic at 1-day periodicity is the most dominant because we can observe a large dip in the MSE when the first periodicity is selected, whereas the periodicities that are further selected do not cause the same level of decrease. For 18 and 24 months, the first three periodicities of 1 day, one-third day, and half day are the most dominant, and selecting the first three can lead to a relatively large decrease in the MSE. The results indicate that during the first year, only one-day periodicity was formed and stabilized in the infant population. The sleep-activity rhythm did not stabilize until 18 months, showing the pattern of 1 nighttime sleep, 1 daytime nap, and 2 daytime activity peaks.

Figure 3. Mean squared error plotted against the number of nonzero θ's as the penalty term λ decreased at 6, 12, 18, and 24 months. MSE: mean squared error.



The Fisher tests yielded similar results. As shown in Table 1, only 1-day periodicity was significant at 6 months ($P<10^{-5}$) because for infants at this stage, sleep-activity patterns have already adjusted to a 24-hour cycle. However, daytime activities have not yet been stabilized and variations exist across days. At 12 months, the 4 periodicities were significant ($P<10^{-5}$). This is because infants' sleep-activity patterns start to stabilize, but there are variations across individuals: some take one nap in the afternoon, whereas others take two naps, one in the morning and one in the afternoon. The one-nap pattern can be captured by the one-third–day periodicity, whereas the two-nap pattern can be captured by the one-fourth–day periodicity, as shown in Figure 2. Furthermore, at 18 and 24 months, three periodicities were significant ($P<10^{-5}$): 1 day, half day, and one-third day, indicating the final consolidation of daily sleep-activity rhythms with only one daytime nap in the afternoon. In addition, the proportions of variance explained by the half day and one-third day periodicities at 18 months and 24 months were approximately the same, both higher than those at 12 months.

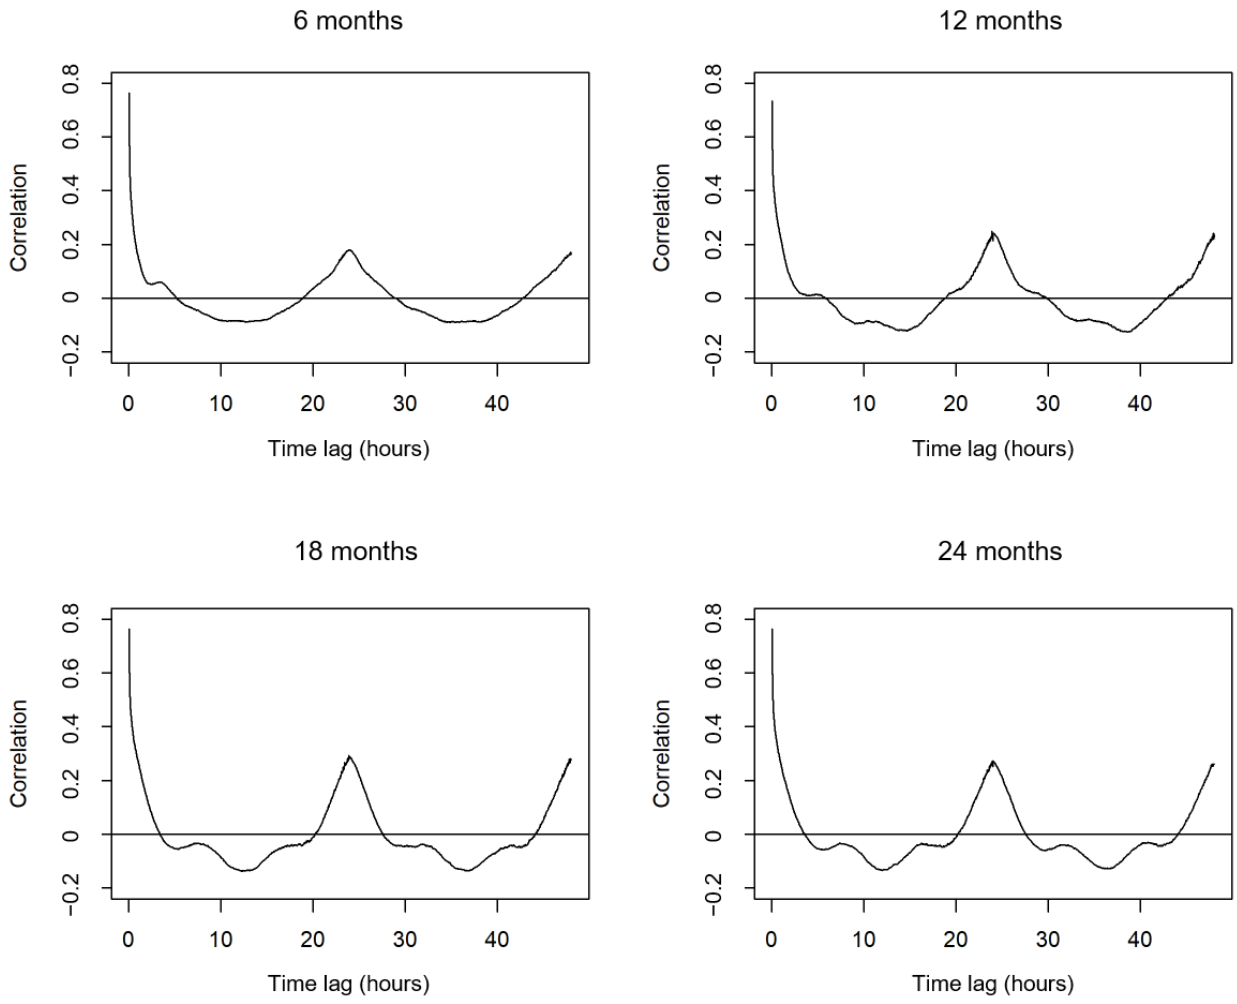
Table 1. Significant periodicities at 6, 12, 18, and 24 months, with the corresponding proportions of variances among all Fast Fourier Transform signals and *P* values.

Age (months)	Proportions of variance	Period		*P* value
		Minutes	Days	
6	0.0110	1440	One	6.59×10^{-8}
12	0.0120	1440	One	1.75×10^{-8}
12	0.0068	720	Half	3.75×10^{-7}
12	0.0056	360	One-fourth	2.82×10^{-7}
12	0.0045	480	One-third	6.49×10^{-6}
18	0.0130	1440	One	1.46×10^{-9}
18	0.0085	480	One-third	1.87×10^{-10}
18	0.0083	720	Half	5.02×10^{-15}
24	0.0130	1440	One	1.97×10^{-9}
24	0.0086	480	One-third	1.17×10^{-10}
24	0.0080	720	Half	3.78×10^{-14}

Comparison With Autocorrelation

To compare the PML algorithm with autocorrelation, the plot of correlation estimates against time lags is shown in Figure 4. The circadian rhythm at 24 hours can be observed at all time points because the peaks of estimated correlation are at time lags between 23.8 hours and 24.3 hours. We can also observe some local maximal correlation estimates at other time lags: 3.3 hours at 6 months, 4.7 and 10.7 hours at 12 months, 7.5 hours at 18 months, and 7.5 and 16.3 hours at 24 months. Although 3.3 hours at 6 months may seem reasonable because of the infant feeding schedule, other cycles are difficult to explain [30,31]. Autocorrelation estimates can be biased because of the presence of multiple periodicities, and researchers generally use these estimates to verify the most dominant periodicity such as 24 hours. Thus, from the autocorrelation plots, the most dominant 24-hour rhythm that yields the global maximal correlation estimate can be identified at each age, and this dominant periodicity was also identified by PML.

Figure 4. Estimated autocorrelation against time lags at 6, 12, 18, and 24 months.



Association Between Daily Rhythms and Motor Development

The summary of the PDMS-2 standard scores for each category is presented in Table 2.

As shown in Table 3, at 6 months, the PDMS-2 total motor scores were found to be associated with the assessment seasons (P<.001). Infants receiving the PDMS-2 assessment in winter and spring tended to have lower PDMS-2 total motor scores than those assessed in summer and autumn. At 12 months, the PDMS-2 total motor scores were associated with both seasons and FFT signals: infants assessed in summer tended to have higher PDMS-2 total motor scores, and infants with higher FFT signals detected at one-third–day and half-day periodicities also tended to have higher PDMS-2 total motor scores (P<.001 and P=.04, respectively). r^2 was 0.25, and the adjusted r^2 was 0.21. At 18 and 24 months, no association was identified between the PDMS-2 total motor scores and any other variables.

Table 2. The PDMS-2[a] standard scores for the subtests, gross motor, fine motor, and total motor.

PDMS-2 category	Standard scores, mean (SD)			
	6 months (n=246)	12 months (n=225)	18 months (n=192)	24 months (n=170)
Reflexes	10.56 (1.02)	—[b]	—	—
Stationary	9.67 (1.44)	9.48 (1.00)	9.94 (0.36)	9.03 (1.38)
Locomotor	10.09 (1.08)	8.82 (1.76)	9.26 (1.24)	8.61 (1.70)
Object manipulation	—	9.92 (0.78)	9.49 (1.16)	8.74 (1.33)
Grasping	10.69 (1.02)	11.08 (1.44)	9.55 (0.78)	9.99 (0.98)
Visual-motor integration	11.19 (1.20)	10.69 (1.13)	11.04 (1.74)	9.79 (1.74)
Gross motor	30.34 (2.72)	28.25 (2.65)	28.63 (2.21)	26.16 (3.17)
Fine motor	21.86 (2.02)	21.83 (2.17)	20.67 (1.93)	19.80 (2.22)
Total	52.24 (4.18)	50.23 (5.05)	49.43 (3.19)	45.98 (4.69)

[a]PDMS-2: Peabody Developmental Motor Scales-Second Edition.

[b]Reflexes is only for 6-month infants, and object manipulation is only for 12-, 18-, and 24-month infants.

Table 3. Linear regression analysis of Peabody Developmental Motor Scales-Second Edition total motor standard scores by season and Fast Fourier Transform signals at 6 months and 12 months, respectively.

Time and variable	Estimate (SE)	*t* test (*df*)	*P* value
6 months			
(intercept)	50.10 (0.56)	89.52 (155)	<.001
spring	0.48 (0.85)	0.56 (155)	.58
summer	4.48 (0.82)	5.43 (155)	<.001
autumn	4.06 (0.89)	4.54 (155)	<.001
12 months			
(intercept)	45.52 (1.29)	35.25 (96)	<.001
summer	1.66 (1.58)	1.05 (96)	.30
half day[a]	0.19 (0.09)	2.10 (96)	.04
one-third day[a]	0.31 (0.09)	3.55 (96)	<.001
summer: one-third day[a]	-0.48 (0.16)	−3.00 (96)	.004

[a]The Fast Fourier Transform signals were multiplied by 10,000 in regression models, so that the estimated effect sizes were for every 10,000-unit increase in the Fast Fourier Transform signals.

As PDMS-2 total motor scores are associated with FFT signals at 12 months, further linear regression between each subtest score and FFT signal was also examined. As shown in Table 4, subtests for stationary and locomotion as well as gross motor and fine motor were found to be associated with the one-third–day periodicity. The gross motor represents the overall performance on the three subtests of stationary, locomotion, and object manipulation for infants at 12 months, and because the association of FFT signals at one-third–day periodicity with stationary and locomotion subtests is strong, it is expected that the association of FFT signals at one-third–day periodicity with gross motor is also strong. r^2 and the adjusted r^2 were 0.05 and 0.04 for the stationary model, 0.23 and 0.20 for the locomotion model, 0.21 and 0.17 for the gross motor model, and 0.15 and 0.11 for the fine motor model, respectively.

Table 4. Linear regression analysis of Peabody Developmental Motor Scales-Second Edition standard scores by season and Fast Fourier Transform signals at 12 months: stationary and locomotion subtests and gross motor and fine motor as the outcome, respectively.

Category and variable[a]	Estimate (SE)	*t* test (*df*)	*P* value
Stationary

Discussion

Method Evaluation

The PML approach is very effective in studying daily activity rhythms among infants and toddlers. At 6 and 12 months, the dominant 1-day periodicity suggests the formation of the 24-hour cycle. At 18 and 24 months, the combination of the dominant 1-day, one-third–day, and half-day periodicities forms a consolidated daily activity pattern with 2 activity peaks during the day and 1 afternoon nap. PML not only effectively identified population-level dominant periodicities, but also characterized sleep-activity patterns without complex functional analysis. PML can complement current methods for circadian rhythm analysis and is especially useful for populations whose daily rhythm patterns are nonsinusoidal and irregular. On the other hand, because PML is applicable to time-series data with a nature similar to that of actigraphy, the application of PML can be extended to other types of circadian rhythm studies using information such as body temperature and hormone data to study and characterize daily rhythms effectively.

Comparison With Other Methods

In comparison, the Fisher test in harmonic analysis tends to identify many significant periodicities unless a stringent threshold is used for statistical significance. In this study, we used the Bonferroni correction to adjust for multiple testing and used a significance level of 10^{-5} to select the periodicities, even though we did not conduct as many statistical tests simultaneously. In sequential testing procedures, as was the case in our study, people often use less-conservative multiple testing correction methods such as the Benjamini-Hochberg procedure [32]. We chose the most stringent threshold to avoid selecting too many periodicities that are not helpful in characterizing daily activity patterns at each age.

We also compared our PML algorithm with the standard approach autocorrelation. Plots of correlation estimates against time lags are useful for identifying the correlation peak at 24 hours but not for shorter periods of rhythmicity. This is because the estimation of correlation can be biased because of the presence of multiple periodic rhythms, and the identification of multiple periodicities by simple calculation of autocorrelation may not be accurate. Therefore, the standard approach using autocorrelation is effective in confirming the most dominant 24-hour periodicity but is not as effective in identifying other periodicities, which the PML algorithm can achieve.

Other standard approaches such as periodograms and cosinor analysis were not used in this study because there are, in fact,

connections between PML and the two methods. It is important to point out their connections as well as differences. Among periodograms, the Fourier, Enright, and Lomb-Scargle periodograms are commonly used [18]. Both our PML algorithm and the Fourier periodogram use Fourier analysis to identify dominant periodicities, but the PML algorithm uses a shrinkage method in machine learning to identify dominant patterns in the population, whereas Fourier periodograms are focused on individuals to manually identify dominant periodicities based on individual plots. The Enright periodogram, although suitable for equidistant activity measurements in our scenario, may not be applicable here because it requires ≥10 days of data [18]. In addition, the estimation method only holds when there is one periodic component, but in our case, the presence of multiple periodic components may have attenuated the results [18]. The Lomb-Scargle periodogram is a modification of Fourier analysis to accommodate unevenly spaced data or missing data. As our data do not have this issue, the Lomb-Scargle periodogram is equivalent to the Fourier periodogram in our case. Compared with the PML algorithm, the Fourier periodogram involves more manual work to generate periodograms for each individual and visually identify dominant periodicities, whereas PML is more automated and more effective in studying the population as a whole and further identifying the periodicities that are characteristic of the population. In addition, researchers often use periodograms to validate the most dominant periodicity such as 24 hours but do not specifically examine information on secondary dominant periodicities or use periodic curves to reconstruct or approximate activity patterns, even though the connection between dominant frequencies or periodicities and functional curves can be made and the periodic information can be fully used. Therefore, the PML algorithm makes full use of the information from more than one dominant periodicity and links the FFT results in the frequency domain with their corresponding cosine curves to effectively characterize activity patterns.

For cosinor analysis, one may recall that the FFT results consist of real parts and imaginary parts that correspond to cosine curves and sine curves, respectively; thus, FFT is equivalent to fitting the cosine model. We fitted cosine models to the activity data with 1 to 3 cosine curves at dominant periodicities identified by the PML algorithm. Even though the estimated amplitudes for the cosine curves are different from the amplitudes in the FFT results, the Pearson correlation between the cosine coefficients and the FFT signals of the same periodicity is 1, indicating equivalence. Although the final results are equivalent, the procedures are different. For cosinor analysis, if prior knowledge is available, simple least squares methods can be used to fit the model [33]. However, if there is no prior knowledge of periodic information, the least squares method cannot be used because the dominant periodicity needs to be estimated first, and the cosinor model can no longer be linearized in its parameters. One has to either start from an initial guess and use iterative procedures to minimize the residual sum of squares or use simulated annealing alternatively to fit the model, the process of which can be exhaustive [34-36]. In comparison, without prior knowledge of the dominant periods, the PML algorithm based on shrinkage in machine learning is still easy to implement without computational burden in extracting periodic information, and the results are as effective as the cosinor model to characterize daily activity patterns using cosine curves.

In summary, the proposed PML algorithm is effective in extracting periodic information, identifying dominant periodicities, and characterizing activity patterns. In the presence of multiple periodicities, PML does not have the estimation problem that autocorrelation encounters. To identify dominant periodicities, PML uses shrinkage in machine learning methods that can help researchers avoid manual work in periodograms, which require individual plots and visual identification. PML can also characterize activity patterns by making full use of the cosine curves represented by FFT signals and avoiding the computationally intensive process of choosing and fitting cosinor models when prior knowledge of the dominant periodicities is not available.

Sleep-Activity Rhythm Characterization

Our study confirms previous findings that infants already form 24-hour sleep-wake cycles at 6 months due to entrainment by cyclical changes in the environment, whether it is due to light-dark cycles or maternal rest-activity cycles [6,9,10,37,38]. It is noteworthy that although 24-hour cycles are formed, sleep-activity patterns over the 24-hour period are not stabilized: infants often take multiple naps at different times of the day, and their daily activity patterns vary across days and across individuals.

Our study indicates that from 6 months to 12 months, the infant sleep-activity pattern gradually develops: some infants take only 1 afternoon nap, whereas others take two naps: one in the morning and one in the afternoon. Strong FFT signals at one-third–day periodicity capture two-peak, one-nap activity patterns, whereas strong FFT signals at one-fourth–day periodicity capture three-peak, two-nap patterns. The results are in line with those of previous sleep studies which indicated that the duration of nighttime sleep gradually lengthens and sleep patterns become increasingly consolidated during the first year after birth [12,39].

Although the timing for the stabilization of infant sleep-activity patterns varies across individuals, by the time infants reach the age of 18 months, their daily activity patterns have consolidated into a predominant nighttime pattern with 1 afternoon nap only, which can be obtained by combining the 3 dominant periodicities at 1 day, half day, and one-third day. The consolidation of sleep-activity patterns is confirmed by increased FFT signals at half-day and one-third–day periodicities and decreased FFT signals at other periodicities compared with previous ages. The results for 24 months remained the same as those at 18 months, showing no changes and confirming further that sleep-activity patterns are consolidated by 18 months and are stable from that age onward.

In our study, the 3-hour periodicity, normally for feeding behaviors, was not detected, and there might be 2 reasons for this. First, in the feeding guidelines for infants, the feeding of infants aged 6-8 months is advised to be 5-6 times in 24 hours, less frequent than the 3-hour (8 times) schedule, and it is advised that infants aged 12-24 months should have 3 meals with family

and have additional snacks 2-3 times [30,31]. Infants aged below 6 months may have a more frequent feeding schedule, but our activity data were collected at 6 months or later. Second, there might be desynchronization between the feeding schedules and activity patterns. Although infants aged 6 months might be fed 5-6 times per day, they do not nap or sleep 5-6 times within the same time frame. We referred to the sleep diaries recorded by the parents as a reference for napping information. Most infants aged 6 months have 1 to 2 naps in the morning and 1 nap in the afternoon. Infants aged 12 months generally have 1 or no naps in the morning and 1 nap in the afternoon. Most infants aged 18 months and 24 months have 1 nap in the afternoon. Therefore, sleep-activity patterns are desynchronized with feeding schedules because feeding behaviors might not dominate infant sleep-activity patterns at this age. For the aforementioned reasons, feeding cycles such as 3-hour periodicity were not detected in our data.

Association Between Daily Rhythms and Early Childhood Development

Using FFT signals at dominant periodicities identified by PML, we were able to find an association between the consolidation of sleep-activity rhythms and early childhood motor development. At 6 months, the association between PDMS-2 total motor scores and assessment seasons may be explained by the different number of layers of clothing worn by infants in different seasons. In winter, infants are likely to wear many layers of clothing, which may restrict their behaviors and result in suboptimal performance compared with infants wearing light clothes and taking the PDMS-2 assessment in summer. As a result, infants aged 6 months who were assessed in summer and autumn obtained relatively higher PDMS-2 scores than infants assessed in winter and spring.

At 12 months, after controlling for the assessment seasons, stronger FFT signals at half-day and one-third–day periodicities were generally associated with higher PDMS-2 scores. The period of 12 months is critical for sleep-activity rhythm consolidation, which was captured by the growing FFT signals at half-day and one-third–day periodicities. It is noteworthy that all the infants at this age had strong FFT signals at 1-day periodicity, indicating that they exhibited 1-day periodicity in their sleep-activity patterns and that their 24-hour periodic activity patterns tended to be stabilized. As a result, there was not much variation in the strength of 1-day periodicity, which might not explain much of the variability in the PDMS-2 scores among individuals. In comparison, the activity pattern over the 24-hour period was not consolidated, and the activity pattern could be characterized by the one-third–day and half-day periodicities. The larger variability in the strength of one-third–day and half-day periodicities can describe the degree to which the daily sleep-activity pattern is consolidated, which is further associated with child development as evaluated by the PDMS-2 scores. The infants with a more consolidated activity pattern tended to have better motor development evaluations. In addition, activity rhythm consolidation is strongly associated with the subcategories of locomotion and stationary, which belong to the gross motor and measure how the large muscle system is used to move from place to place or assume a stable posture when not moving. Therefore, we obtained new insights into early childhood development that the degree to which the sleep-activity pattern is consolidated at 12 months is associated with infant motor development and with large muscle system development in particular.

At 18 and 24 months, the PDMS-2 scores were not associated with the season, FFT signals, or any other variables in our data set. Most of the toddlers had stabilized daily activity patterns with strong periodic rhythmicity at this age. FFT signals as characteristics of sleep-activity rhythms were no longer associated with the PDMS-2 scores, and this is likely because the critical age at which the daily activity rhythm stabilizes had passed.

Limitations and Future Work

One limitation of our study is that we collected Actiwatch data every 6 months, and thus we were not able to capture more detailed monthly changes over the period. Future work may collect Actiwatch data in a more frequent manner, such as every 3 months or every month, to capture gradual changes in the sleep-activity rhythm during early childhood. For infants aged ≤6 months, more frequent observations can also allow us to observe how the predominant rhythm of infants changes from ultradian to circadian by adjusting to the 24-hour cycle in the environment. Another limitation of this study is that although we identified the association of sleep-activity daily rhythm consolidation with early childhood motor development and with large muscle system development in particular, the mechanism behind this association is not clear. Future work should investigate how daily rhythm consolidation and motor development interrelate and contribute to early childhood development.

Conclusions

In summary, the proposed PML algorithm provides a new method for circadian rhythm analysis and is particularly useful for studying populations whose daily patterns are not regular. In addition, the PML algorithm is applicable to other types of wearable device data in the format of a time series with a nature similar to that of actigraphy; therefore, it can be extended to other types of circadian studies using information such as body temperature, heart rate, and hormone data. Therefore, the PML algorithm can be widely applied to other wearable device studies to help characterize periodic information. Using the proposed method, our study provides novel insights into sleep-activity rhythm development in early childhood. First, in our study, the critical period for the consolidation of sleep-activity rhythms was between 6 and 18 months. This is because at 6 months, 24-hour sleep-wake cycles are formed, but their daily activity patterns are not stabilized, and by the time toddlers reach the age of 18 months, their sleep-activity patterns have consolidated into a fixed pattern with 2 activity peaks and 1 afternoon nap. The period between 6 and 18 months is critical for early childhood sleep-activity rhythm development and consolidation. Second, we identified the association between the consolidation of daily rhythms and early childhood motor development and large muscle system development in particular. This association has not been identified in previous studies. Infants with more consolidated circadian rhythms tend to have better motor development assessments. Although the mechanism is not clear,

maintaining a regular and stable sleep-activity pattern and maintaining a healthy circadian system are important for healthy physical development in early childhood.

Abstract

Background: Hyperinsulinism (HI) due to excess and dysregulated insulin secretion is the most common cause of severe and recurrent hypoglycemia in childhood. High cerebral glucose use in the early hours results in a high risk of hypoglycemia in people with diabetes and carries a significant risk of brain injury. Prevention of hypoglycemia is the cornerstone of the management of HI, but the risk of hypoglycemia at night or the timing of hypoglycemia in children with HI has not been studied; thus, the digital phenotype remains incomplete and management suboptimal.

Objective: This study aims to quantify the timing of hypoglycemia in patients with HI to describe glycemic variability and to extend the digital phenotype. This will facilitate future work using computational modeling to enable behavior change and reduce exposure of patients with HI to injurious hypoglycemic events.

Methods: Patients underwent continuous glucose monitoring (CGM) with a Dexcom G4 or G6 CGM device as part of their clinical assessment for either HI (N=23) or idiopathic ketotic hypoglycemia (IKH; N=24). The CGM data were analyzed for temporal trends. Hypoglycemia was defined as glucose levels <3.5 mmol/L.

Results: A total of 449 hypoglycemic events totaling 15,610 minutes were captured over 237 days from 47 patients (29 males; mean age 70 months, SD 53). The mean length of hypoglycemic events was 35 minutes. There was a clear tendency for hypoglycemia in the early hours (3-7 AM), particularly for patients with HI older than 10 months who experienced hypoglycemia 7.6% (1480/19,370 minutes) of time in this period compared with 2.6% (2405/92,840 minutes) of time outside this period (P<.001). This tendency was less pronounced in patients with HI who were younger than 10 months, patients with a negative genetic test result, and patients with IKH. Despite real-time CGM, there were 42 hypoglycemic events from 13 separate patients with HI lasting >30 minutes.

Conclusions: This is the first study to have taken the first step in extending the digital phenotype of HI by describing the glycemic trends and identifying the timing of hypoglycemia measured by CGM. We have identified the early hours as a time of high hypoglycemia risk for patients with HI and demonstrated that simple provision of CGM data to patients is not sufficient to eliminate hypoglycemia. Future work in HI should concentrate on the early hours as a period of high risk for hypoglycemia and must target personalized hypoglycemia predictions. Focus must move to the human-computer interaction as an aspect of the digital phenotype that is susceptible to change rather than simple mathematical modeling to produce small improvements in hypoglycemia prediction accuracy.

hyperinsulinism; continuous glucose monitoring; digital phenotype; hypoglycemia; nocturnal hypoglycemia

Introduction

Background

Hyperinsulinism (HI) is a diverse collection of disorders united by the pathology of inappropriate insulin secretion causing hyperinsulinemic hypoglycemia with simultaneous suppression of alternative fuel sources. It has an estimated incidence of 1:28,000 in the United Kingdom [1] and is the most common cause of severe and recurrent hypoglycemia in childhood. This recurrent hypoglycemia, with the corresponding suppression of ketones as an alternative fuel source, results in brain damage in an unacceptably high proportion of cases, up to 48% [2]. The risk of brain damage is independent of the chronicity of the disease [3], as damage often occurs early in life when the neonatal brain is highly susceptible to such insults [4,5].

Significant progress in the understanding of the underlying pathophysiology of HI has been made since its first detailed description in 1953 [6]. Increased knowledge of changes at the organic [7], cellular [8], and genetic [9,10] levels has led to improvements in the care of these patients, and recent studies even suggest a lowering of the subsequent rate of brain injury [11]. As first suggested by Richard Dawkins in 1976, there is an “extended phenotype” of all conditions, not just limited to observable physical traits or cellular changes [12]. The most recent extension of this is that of a digital phenotype, encompassing aspects of patients’ behaviors related to and measured by technology [13]. The digital phenotype includes everything from interactions with others on social media to digitally collected location data and continuously measured physiological parameters, such as glucose levels and heart rate. These measures sit alongside the traditional characterization of diseases to form a more comprehensive picture and facilitate a more nuanced approach to management. Current management of HI is complex, balancing the risks and benefits of a limited repertoire of medications, all of which have a small therapeutic window and significant side effect profiles [14]. Because of the dysregulated secretion of insulin in these patients, hypoglycemic events are often very difficult to predict. The standard of care for home monitoring of hypoglycemia is intermittent fingerpick testing for blood glucose. However, patients rarely achieve more than three to four such measurements per day and this infrequent testing strategy risks missing hypoglycemia between tests, particularly overnight [15]. This practice also offers little in the way of disease characterization and does very little to extend the phenotype or the scientific understanding of HI.

In recent years, continuous glucose monitoring (CGM) has emerged as an alternative, offering insight into glucose trends. CGM measures subcutaneous glucose at frequent intervals over extended periods (7-10 days) to provide glycemic phenotypes in patients with hypoglycemia and diabetes and contributes to the digital phenotype [16]. The application of CGM may not yet be readily applicable in patients with HI as a reliable means of hypoglycemia detection or prediction [17]. However, as CGM is a passive form of monitoring, it can record data at a high granularity with very minimal response burden on users [18]; therefore, it has the potential to collect detailed glycemic data while being acceptable to patients on a long-term basis. There have been a limited number of studies describing the utility of CGM in patients with HI [19-22], and none have described the timing of hypoglycemia events or glycemic trends.

There is good empirical evidence [23] to suggest that hypoglycemic events may not be evenly distributed throughout the day and that the risk of hypoglycemia may be disproportionately higher during periods of reduced food intake. In all but the youngest children, each day is divided into two distinct phases, one of activity and eating and the other of fasting and rest [23]. It is well established that hormones such as cortisol vary throughout the day, with peak levels varying in relation to the time of sunrise [24]. Glucose homeostasis also varies with the time of day [25], but this variability is not likely to be directly related to cortisol [26,27]. Rather, there is likely a direct circadian control involving the suprachiasmatic nucleus in the hypothalamus [28,29] and peripheral clock-gene–regulated components in the pancreas [23].

Before waking, early morning is a high-risk period for hypoglycemia, as glucose use is at its highest [23]. Normally, this is counteracted by a high rate of gluconeogenesis [23]; however, in patients with HI, this is suppressed owing to inappropriate secretion of insulin, resulting in an imbalance of glucose homeostasis weighted toward hypoglycemia [30]. The high risk in early morning is exacerbated by the time-independent, high-glucose requirement of the brain during late sleep [31].

Despite over 30 years of investigation into nocturnal hypoglycemia in children with diabetes [32], the estimated incidence remains as high as 68% [33]. More than half of all severe hypoglycemic events occur overnight [34], and up to 18% of deaths in younger patients with diabetes are attributed to nocturnal hypoglycemia [35].

The potential for CGM data to contribute to the digital phenotype of HI has not yet been investigated. Despite the physiological and empirical evidence from healthy participants and participants with diabetes regarding the risks of nocturnal hypoglycemia, no study has investigated the timing of hypoglycemic events in children with HI. It is important to identify periods of greater risk of hypoglycemia to design targeted detection, prediction, and prevention strategies, as traditional medical management techniques do not allow for this. Hall et al [36], Colas et al [37], and Lunt et al [38] used CGM as a short-term phenotyping tool to better understand patient profiles and categorize risks. Larkin et al [39] detailed their intention to use CGM as part of a long-term phenotyping tool on a large scale to provide personalized insights into disease.

Digital phenotyping allows for two important changes in disease management. First, the detailed analysis of CGM data provides an extension of the digital phenotype for both the disease and

the individual and allows for the targeting of interventions to times when they will achieve the optimum effect. Second, patients and parents are not passive bystanders in the management of HI, and an analysis of how they interact with and respond to the technology further extends the digital phenotype [40], as well as enabling and enhancing behavior change [41]. Knowledge of an extended digital phenotype will not, in and of itself, improve outcomes but does improve understanding of how future interventions can be adapted to achieve the most significant and lasting behavior change [42].

Objective

In this study, we take the first step in extending the digital phenotype of HI by describing glycemic trends and identifying the timing of hypoglycemia measured by CGM. The following findings provide a basis for future work concentrating on using the newly extended digital phenotype with human-computer interactions and ultimately altering care behaviors of parents to reduce the incidence of damaging hypoglycemia. Our original code is provided as an appendix (Multimedia Appendix 1) and is freely available on GitHub [43].

Methods

Recruitment

Patients were recruited between July 2017 and October 2020. Three distinct groups of patients were enrolled in the study: (1) those with a diagnosis of HI who were in hospital for acute management (n=6), (2) those in an outpatient setting with a diagnosis of HI and for whom glycemic control was suboptimal (n=17), and (3) those with a diagnosis of idiopathic ketotic hypoglycemia (IKH) for whom glycemic control was unstable (n=24). The IKH group was selected to investigate CGM profiles in an alternative clinical model of hypoglycemia that does not involve excess insulin secretion. All patients underwent CGM with the primary intention of better understanding their glucose control for clinical purposes. All patients were approached by the research team to seek consent to use anonymized CGM data for research purposes, as per a local research ethics protocol (REC/H1010/88).

Within the HI group, further subcategorization was done as either diffuse or focal disease [44]. Focal HI is characterized by the formation of a focal lesion within the pancreas comprising hyperfunctioning islets and is potentially curative by focal lesionectomy. Diffuse HI implies some specific histopathological features but practically implies nonfocal HI in which medical therapy should be prioritized over surgery when possible.

Patient recruitment to the study was based on a pragmatic design in the absence of previous studies to determine sample size in a rare disease. Previous studies investigating CGM in patients with HI recruited 11 to 15 patients [19,21]. We recruited all patients undergoing CGM for clinical reasons over a 3-year period.

Data collection

Patients undergoing inpatient monitoring had their CGM device (Dexcom G4 or G6 depending on the date) attached between 1 and 5 days before pancreatic surgery (lesionectomy or subtotal pancreatectomy) and removed after plasma glucose levels stabilized, reducing the need for frequent monitoring. All other patients were brought to the Royal Manchester Children's hospital to have their CGM device attached by a specialist nurse, after which they returned home for the remainder of the monitoring period. The patients returned CGM devices to the department at the end of the monitoring period. CGM devices were always inserted in the daytime to ensure that full calibration had occurred before the evening and data collected overnight were reliable. Data were collected for between 4 and 10 days from each patient.

For patients who underwent a controlled fast in hospital (n=0 for HI, n=2 for IKH) during CGM, data during the fasting period were deleted from the analysis and the only data used were those acquired from home monitoring after discharge from hospital. Dexcom G4 devices were used from the beginning of the study period until March 2019, from which point all patients were monitored using a Dexcom G6 device. All devices were unblinded so that parents and staff could see glucose values in real time and alarms would sound if glucose levels dropped (or was predicted to drop) below 3.5 mmol/L for those with HI and 3.3 mmol/L for those with IKH (as per lowest allowable device settings). The fall rate and urgent low soon alarms were set to *on* when the device was given to the patient. Patient modifications of the alarms were not routinely investigated.

Data Analysis

Hypoglycemia was defined as any glucose value <3.5 mmol/L (63 mg/dL) as a safe cutoff used by most specialized centers for the everyday management of HI [14]. Dexcom CGM devices report a glucose value every 5 minutes, and therefore, hypoglycemia events were measured at 5-minute intervals with a minimum duration of 5 minutes. The term *early hours* is used throughout the manuscript to refer to the period 3 AM to 7 AM.

Data were downloaded from CGM devices to Dexcom CLARITY database and raw data were downloaded for analysis using Python 3.8. We analyzed the total number of hypoglycemia events by start time irrespective of length and separately the total amount of time spent in hypoglycemia within each hour period.

As data were not normally distributed, nonparametric tests (Mann–Whitney *U*) were used to assess for differences between continuous variables. Chi-square tests were used to assess differences in proportions or percentages between the groups. The results provided are raw test statistics and associated *P* values.

Glucose testing using alternative methods (plasma glucose measured by point-of-care testing or handheld home glucose monitoring) was not routinely performed alongside CGM because assessment of CGM accuracy was not the intention or focus of this study. Correlations between CGM-derived subcutaneous glucose and plasma glucose have been previously reported in patients with HI [19,21].

Results

Overview

Baseline data showed a male predominance (29 males, 18 females) and mean age in months at the time of CGM was higher in those with IKH than in those with HI (82, SD 43 vs 57, SD 61; *P*=.03), as expected, given that HI is prevalent at a younger age than IKH. At the time of CGM testing, the mean time in months from diagnosis did not differ significantly between those with IKH and HI (33, SD 34 vs 49, SD 53; *P*=.43) (Table 1). A total of 28 patients underwent monitoring with a Dexcom G4 device and 19 with a Dexcom G6.

Table 1. Demographics of hyperinsulinism and idiopathic ketotic hypoglycemia groups.

Demographics	Hyperinsulinism (N=23)	IKH[a] (N=24)	*P* value[b]
Male, n (%)	17 (74)	12 (50)	.09
Female, n (%)	6 (26)	12 (50)	N/A[c]
Age (months), mean (SD)	57 (60)	82 (43)	.03
Time since diagnosis (months), mean (SD)	49 (52)	33 (44)	.43

[a]IKH: idiopathic ketotic hypoglycemia.

[b]*P* value for difference between groups calculated via chi square test for sex and Mann–Whitney *U* test for continuous values.

[c]N/A: not applicable.

Demographic data demonstrate that the only difference between groups at baseline was that patients with IKH had a higher mean age at time of CGM.

A total of 449 hypoglycemic events (189 in HI and 260 in IKH) were captured over 237 days. The time spent in hypoglycemia was 15,610 out of a total of 342,355 minutes (4.6%). The mean duration of hypoglycemic events was 35 (SD 57) minutes and was longer in those with IKH than in those with HI (40 vs 28). Mean lowest glucose per hypoglycemia event was 3.1 (SD 0.37) mmol/L. The mean number of hypoglycemic events per patient was 9.5 (SD 9.6) with a positive skew to the distribution (Figure 1), illustrating the small number of patients with a very large number of hypoglycemic events. In patients with HI, there were 42 hypoglycemia events lasting more than 30 minutes from 13 separate patients. The mean duration of such prolonged hypoglycemia events was 79 (SD 72) minutes, with a mean lowest glucose of 2.8 mmol/L. The characteristics of patients with HI are shown in Table 2.

Figure 1. Frequency plot of number of hypoglycemia events (hypos) per patient. This plot demonstrates the positive skew to the distribution of hypoglycemic events. Mean number of hypoglycemia events was 9.5 per patient, and median was 6.0 with 6 patients having no episodes of hypoglycemia and 1 patient having more than 30 separate hypoglycemic events. The majority of patients had 5 to 20 hypoglycemic events.

[d]Subtotal: subtotal pancreatectomy.

Timings of Hypoglycemia in Patients With HI

Figure 2 presents the number of hypoglycemic events by start time in patients with HI (n=23). This does not account for the duration of hypoglycemia episodes and is only representative of the hour in which the event started. There was a higher risk of a hypoglycemia event beginning in the later part of the night/early morning compared with the rest of the day. Figure 3 illustrates the percentage of time spent in hypoglycemia by patients with HI within each hour of the day. There was an increase in the prevalence of hypoglycemia in the early hours (3 AM-7AM), 6.4% (1665/25,875 minutes) of this time hypoglycemic compared with only 2.9% (3585/123,490 minutes) of time outside this period (χ^2_1=98.4, P<.001). This represents a doubling of risk during this period. Although the frequency of hypoglycemia was greater in the early hours, the mean duration (minutes) of individual hypoglycemic episodes in this period was the same as the rest of the day (28.2 minutes vs 28.1 minutes, P=.99).

Figure 2. Number of hypoglycemic events (hypos) plotted by start time in patients with HI. The X-axis represents hours of each 24 hour period. Bars represent the number of hypoglycemic events starting at any particular point in the day but do not indicate the duration of each episode. What is demonstrated is the increased number of hypoglycemic episodes starting in the later hours of the night and early morning (black) compared with the rest of the day (grey). HI: hyperinsulinism.

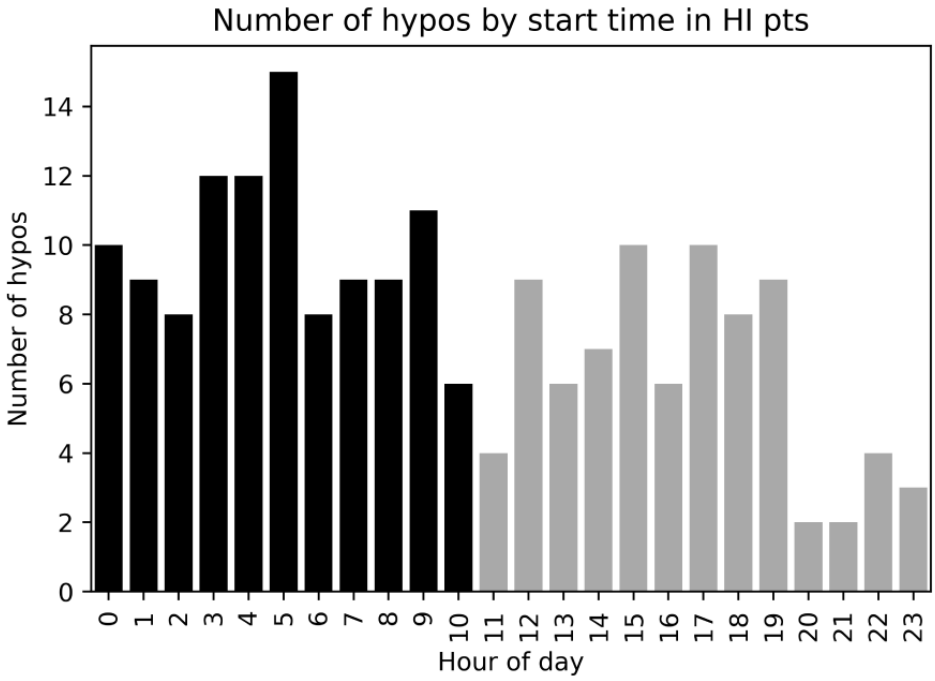

Figure 3. Percentage time spent in hypoglycemia by hour of the day in patients with HI.There is a clear period of high risk for hypoglycemia between 3 AM and 7 AM (dark blue) which represents the early hours. There are also three distinct spikes of increased hypoglycemia prevalence at 9 AM, 3 PM and 7 PM (orange), which may represent postprandial hypoglycemia. HI: hyperinsulinism.

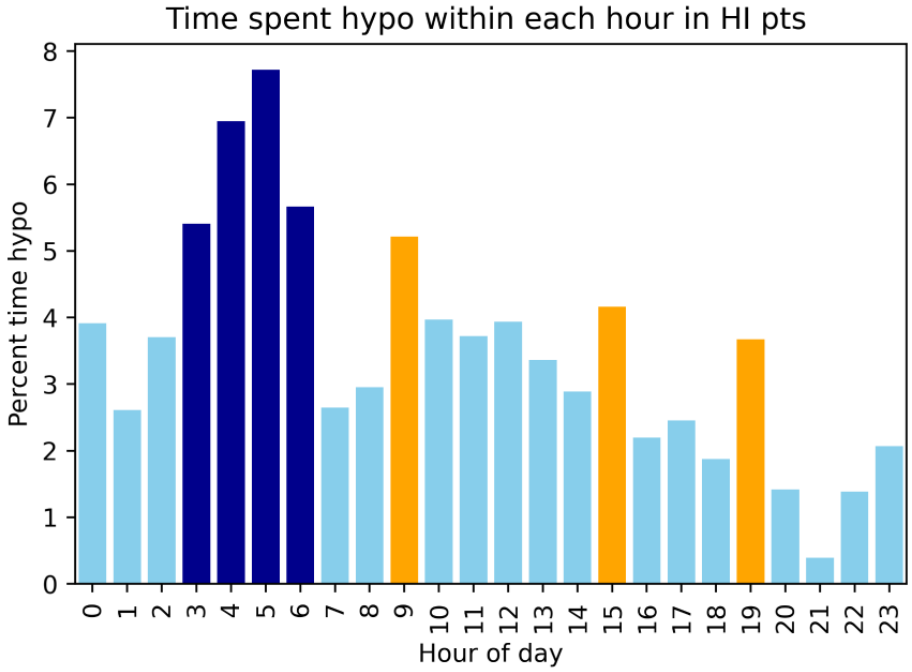

The other periods of increased risk were the separate hours of 9 AM, 3 PM, and 7 PM, within which there was a higher proportion of minutes spent hypoglycemic than the rest of the daytime/evening (7 AM to midnight), that is 5.2% (320/6140 minutes), 4.2% (250/6015 minutes), and 3.7% (230/6265 minutes), respectively, versus 2.8% (2915/103,910 minutes; P<.001).

Subgroup Analysis of Patients With HI

Analysis of time spent in hypoglycemia by patients with HI above (n=16) and below (n=7) the age of 10 months (ie, the age at which a weaning diet with solid food is well established) demonstrated that the risk of early hours of hypoglycemia was even more pronounced in the group above the age of 10 months (Figure 4). Within the early hours, 7.6% (1480/19,370 minutes)

of the time was hypoglycemic compared with 2.6% (2405/92,840 minutes) of time outside of this period (χ^2_1=146.4, *P*<.001), indicating an almost trebling risk of hypoglycemia. In the group below the age of 10 months, no obvious patterns of hypoglycemia were visible with risk of hypoglycemia distributed randomly throughout the day, except for an unexplained peak of risk at 7 PM (Figure 5).

Figure 4. Percentage time spent hypoglycemic by hour of the day in patients with HI > 10 months of age. Analysis of timings of hypoglycemia in this subgroup show a greater tendency to early hours hypoglycemia between the hours of 3 AM and 7 PM (dark blue) with a persistence of spikes in hypoglycemia risk at 9 AM and 3 PM (orange). No spike is observed at 7 PM in contrast to the analysis for all ages. HI: hyperinsulinism.

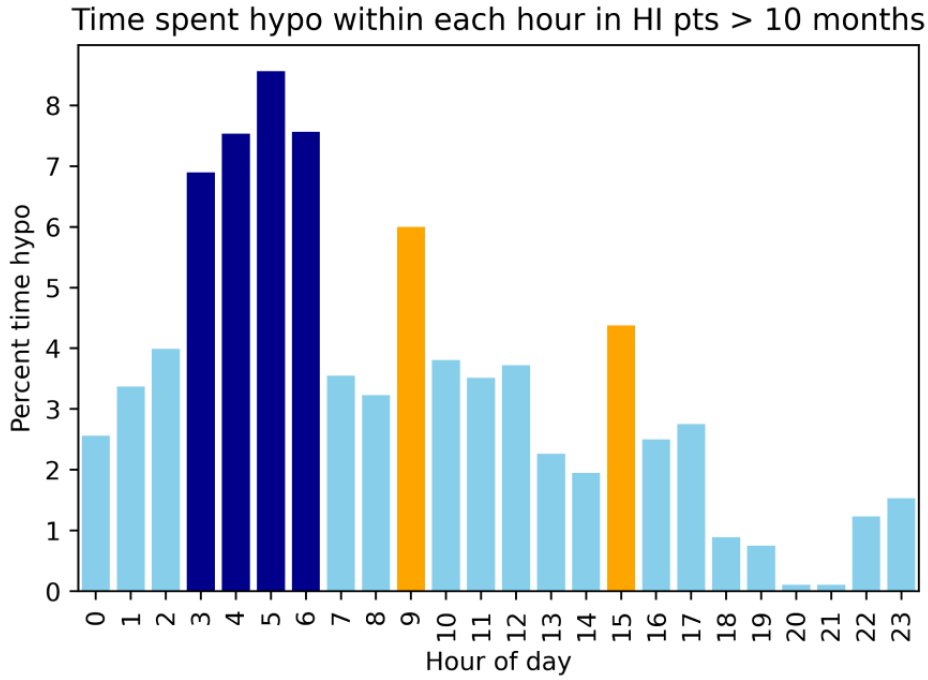

Figure 5. Percentage time spent hypoglycemic by hour of the day in patients with HI < 10 months of age. Analysis of timings of hypoglycemia in this subgroup are limited by numbers but clearly show a very different pattern of hypoglycemia compared with the group > 10 months of age. There is no obvious pattern of hypoglycemia and no obvious periods of higher risk. HI: hyperinsulinism.

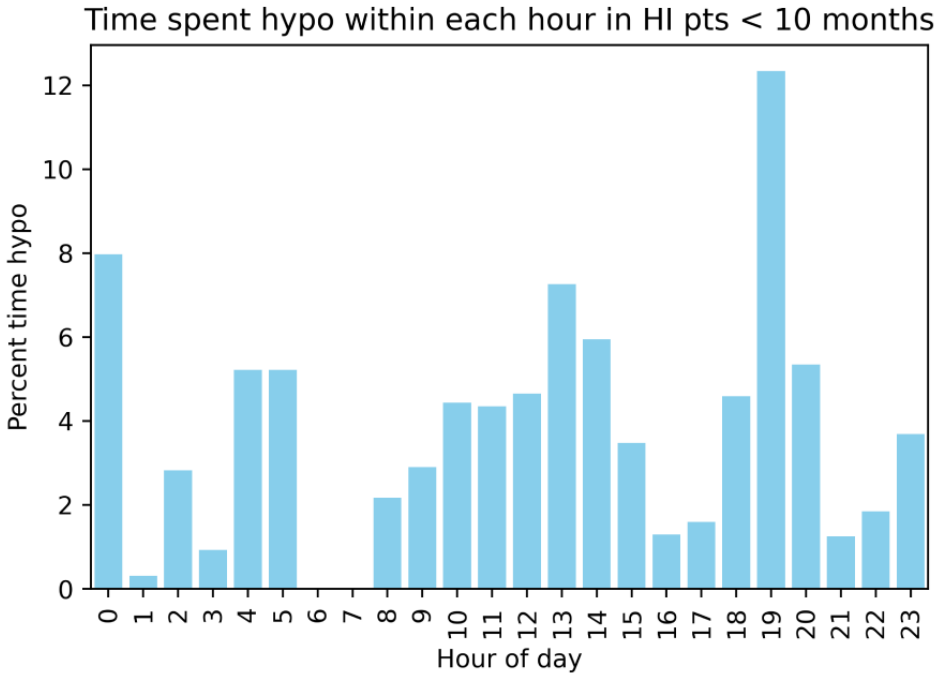

Further comparisons were performed between the following HI subgroups: mutation-positive versus mutation-negative and medication versus off-medication. The results are summarized in Table 3 and reported in more detail (along with Figures S1-S4) in Multimedia Appendix 2: further HI subgroup comparisons.

Table 3. Comparisons of timings of hypoglycemia between hyperinsulinism (HI) subgroups.[a]

	Time hypoglycemic in early hours (minutes)		Time hypoglycemic outside early hours (minutes)		Minutes hypo contained in early hours (expected 16.7%; minutes)		Period of risk (compared with all HI)
	Total, N	Value, n (%)	Total, N	Value, n (%)	Total, N	Value, n (%)	
All HI	25,875	1665 (6.43)	123,490	3585 (2.9)	5250	1665 (31.71)	Early hours
Age (months), mean (SD)							
>10	19,370	1480 (7.64)	92,840	2405 (2.59)	3885	1480 (38.09)	Early hours ++[b]
<10	6505	185 (2.84)	37,150	1365 (3.85)	1365	185 (13.55)	Evenly distributed
HI causing mutation							
Positive	17,005	1135 (6.67)	81,810	2290 (2.79)	3425	1135 (33.14)	Early hours +[c]
Negative	8870	530 (5.98)	41,680	1295 (3.11)	1825	530 (29.04)	Early hours –[d]
Medication							
On	14,415	790 (5.48)	69,485	2395 (3.45)	3185	790 (24.8)	Early Hours ––[e]
Off	11,460	875 (7.64)	54,005	1190 (2.2)	2065	875 (42.37)	Early Hours ++

[a]Detailed is the difference in percentage time hypoglycemic in the early hours (3 AM-7 AM). Also reported is the percentage of all hypoglycemia minutes spent in the early hours as a comparison to the expected 16.7% that would be seen if hypoglycemia was distributed evenly. The table demonstrates an exaggerated tendency to hypoglycemia at early hours in those above the age of 10 months, off medication, and with a known hyperinsulinism causing mutation.

[b]++ is used to denote a very strong tendency to early hours hypoglycemia.

[c]+ is used to denote a strong tendency to early hours hypoglycemia.

[d]– is used to denote a relatively weak tendency to early hours hypoglycemia.

[e]–– is used to denote a weak tendency to early hours hypoglycemia.

Timings of Hypoglycemia in Those With IKH

The timing of hypoglycemia in patients with IKH showed a more evenly distributed pattern than in those with HI. The number of hypoglycemic episodes starting overnight was slightly higher than that during the day (Figure 6), but not as markedly as in the patients with HI. Total minutes spent hypoglycemic were also more evenly distributed throughout the day in patients with IKH than in those with HI (Figure 7). There was no clear period of higher than average risk of hypoglycemia; rather, a period of relatively low risk was observed in the evening and early night (6 PM-1 AM). Within this period, the risk of hypoglycemia was 2.8% (1575/57,195 minutes) compared with 6.5% (8785/135,805 minutes) outside of this period (X^2_1=132.2, P<.001).

Subgroup analysis of patients with IKH was not performed, as no patients within this group were below the age of 10 months and this group was primarily analyzed as a comparison group for those with HI.

Figure 6. Number of hypoglycemic events (hypos) plotted by hour of the day in patients with IKH. This demonstrates the risk of a hypoglycemic event starting at any particular point in the day but does not account for the length of this episode. An increased number of hypoglycemic episodes starting in the later hours of the night and early morning (dark blue) is observed, compared with the rest of the day (light blue). This, however, is less pronounced than in those patients with HI. HI: hyperinsulinism; IKH: idiopathic ketotic hypoglycemia.

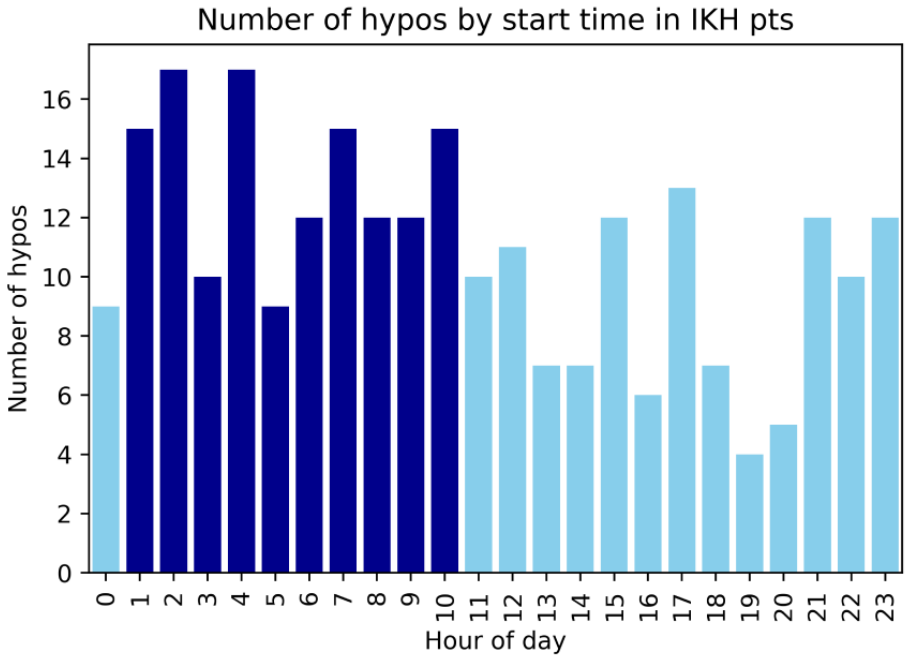

Figure 7. Percentage time hypoglycemic by hour of the day in patients with IKH. There is no period of particularly high risk as seen in patients with HI. In contrast, a short period of lower than average risk in the evening and early night (green) can be observed. HI: hyperinsulinism; IKH: idiopathic ketotic hypoglycemia.

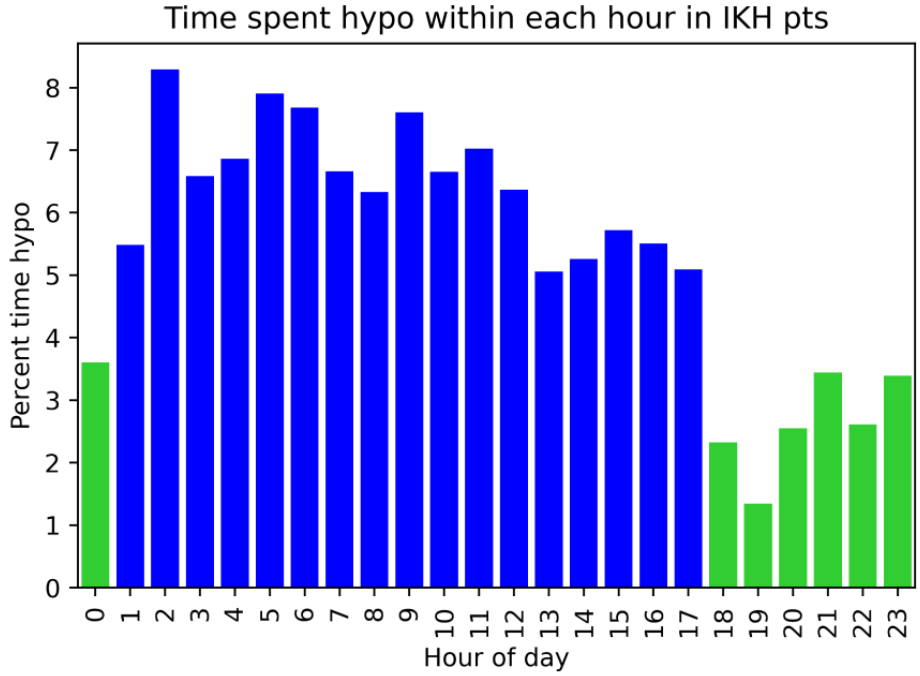

Altering Thresholds for Hypoglycemia

As the definition of hypoglycemia differs between countries, regions, and even hospital departments, we performed further analysis by altering the threshold for hypoglycemia. The cutoffs of 3.9 mmol/L, 3.5 mmol/L, and 3.0 mmol/L were chosen as commonly used definitions for hypoglycemia in children [44,45]. Further analysis of values below this were deemed unlikely to be meaningful as they are rare events, and the Dexcom CGM devices only measure glucose down to 2.2 mmol/L, below which values are reported as *Low*.

Data for HI patients above the age of 10 months were compared with those of patients with IKH, as these 2 groups were more comparable in terms of age. As hypoglycemia threshold was reduced from 3.9 mmol/L to 3.5 mmol/L and then 3.0 mmol/L,

the tendency to hypoglycemia during early hours was emphasized in patients with HI. In patients with HI, the early hours contained 41% of all minutes (63/152 minutes) spent with a glucose level <3.0 mmol/L despite this period representing only 16.7% of the 24-hour period. A similar trend began to emerge in patients with IKH when the hypoglycemia threshold was reduced, and the proportion of all minutes spent hypoglycemic that lay within the early hours increased from 21% (842/3998 minutes) to 27% (157/577 minutes). Figures S5 and S6 provide a visualisation of this change and are provided in Multimedia Appendix 3.

Discussion

Principal Findings

We have provided a novel analysis of the timing of hypoglycemic events in patients with HI using CGM data. Our data provide new and clinically useful information to extend the digital phenotype of HI. This aspect of the newly described digital phenotype demonstrates a tendency for hypoglycemia during the early hours (3 AM-7 AM) where the risk is 2 to 3 times higher than that at other times of the day. The relative risk of nocturnal hypoglycemia compared with daytime hypoglycemia was greater in patients with HI than in those with IKH. This risk is greater still in patients with HI above the age of 10 months, those with genetic mutations, and those off medication.

A strength of this study is the novel examination of a glycemic phenotype using CGM in patients with HI while using an alternative model of hypoglycemia in children with IKH as a contrasting paradigm, demonstrating the specificity of glycemic profiles within each condition's digital phenotype. Although home blood glucose monitoring remains the standard of care for monitoring in patients with HI, we have used high-granularity glucose data to expand the phenotype of HI and highlight an important role for CGM, that is, describing nocturnal glycemic status in real time with high ecological validity. Alternative strategies to identify periods of hypoglycemia on the basis of parent interviews would be open to recall bias and unable to identify unexpected hypoglycemia, as self-monitoring of blood glucose is rarely performed overnight. With increasing refinements in CGM technology and the increasing popularity of the use of CGM in children with hypoglycemia, our study highlights the need for a targeted application of CGM. Although previous studies have used simplistic correlation methods to test the accuracy of CGM in the detection of hypoglycemia vis-à-vis home blood glucose monitoring, our study has investigated a deeper phenotype with significant clinical impact.

Our study is exploratory, as a similar analysis of CGM data has never been attempted. Therefore, it is not possible to validate the strength of our observations, except that the glycemic phenotype is replicable across the whole group with HI, in contrast to an alternative model of hypoglycemia in IKH. The number of patients with HI was large for a rare disease, and the total number of measurements in the data set adds strength to the rigor of the study.

It is not possible to investigate the cause of early hours hypoglycemia from the design of our study, nor was this the intended purpose. We speculate that the unavailability of carbohydrates due to the nocturnal fasting period, high glucose demand in the brain at this time [23,31], and the suppression of counter-regulatory gluconeogenesis in patients with HI [30] could be the probable causes. The latter view is supported by the observation of a reduced tendency to early hours hypoglycemia in patients with IKH and an increased tendency in those positive for genetic mutations known to cause HI. Patients with IKH do not have underlying metabolic disturbances and are therefore capable of mounting adequate counter-regulatory responses. In contrast, those positive for HI mutations tend to have more severe disease [11] and less ability to mount counter-regulatory responses. Further investigation of the metabolic and counter-regulatory hormonal milieu in patients with HI may be required to refine specific causation. It is not clear why patients negative for mutations had a relatively high incidence of hypoglycemia between 9 PM and 1 AM, and further work will be required to investigate this apparent trend.

We observed a tendency for early hours hypoglycemia in patients with HI above the age of 10 months (Figure 4); this may be explained by older children sleeping longer and requiring less frequent feeds through the night. We did not record sleep-wake cycles in our study to confirm or refute this possibility. However, children below the age of 10 months were also more likely to be inpatients during the period of monitoring, and the lack of early hours hypoglycemia tendency may reflect 24-hour nursing care and a reduction in ecological validity. The reason for the significant increase in time spent in hypoglycemia between 7 PM and 8 PM is unclear and may reflect the small number of patients from whom this sample was taken. Further data are required to validate or refute this finding.

Patients with HI who were no longer receiving HI medications showed a clear tendency toward hypoglycemia during early hours seen in other groups. This response was not observed in patients receiving medications for HI (diazoxide or octreotide). This may reflect the efficacy of HI medications in preventing nocturnal hypoglycemia but may also be simply reflective of the much higher median age in the off-treatment group and the subsequent effects described above. Because this study was completed, it was not possible to assess the relative impacts of age and medication on the timing of hypoglycemia in patients with HI, and further work is required.

Tendency to hypoglycemia was shown to reduce throughout the day in patients with HI, but with small increase in risk at 9 AM, 3 PM, and 7 PM (Figure 3). These periods of increased risk are likely to correlate with postmeal times in those having three meals a day, suggesting possible postprandial hypoglycemia secondary to the hyperinsulinemic response to food sometimes observed in patients with HI [46]. This trend was not observed in patients with IKH who had fasting rather than postprandial hypoglycemia. This was not observed in patients with HI below the age of 10 months who would have been receiving a high proportion of caloric intake as milk feeds distributed more frequently throughout the day and night.

As hypoglycemia thresholds were reduced from 3.9 mmol/L to 3.5 mmol/L and 3.0 mmol/L, the number of hypoglycemic events and total minutes spent hypoglycemic also reduced significantly, as reflected in the differing Y axes in Figures S5 and S6 (Multimedia Appendix 3). This is unsurprising, as patients with HI are told to maintain glucose levels >3.5 mmol/L and those with IKH >3.0 mmol/L. Reducing the hypoglycemia threshold emphasized the tendency for early hours hypoglycemia in those with HI and allowed it to become apparent in those with IKH. These likely better reflect the true hypoglycemic events that would be acted on by parents.

There were 42 hypoglycemia events lasting more than 30 minutes in patients with HI despite them wearing an unblinded CGM device programmed to alarm at glucose levels <3.5 mmol/L and parents being aware of the importance of keeping glucose levels ≥3.5 mmol/L at all times. This high prevalence of prolonged and potentially dangerous hypoglycemia events may reflect CGM inaccuracy, and these events may represent false positives not acted on by parents. However, this is unlikely to explain all the prolonged hypoglycemic events.

Although CGM provides vital information, the volume of data provided by continuous monitoring such as CGM can be overwhelming for both health care professionals and patients [47], and simple detection and reporting of glucose values will not be sufficient to eliminate all hypoglycemia. It is well recognized that alarm fatigue is a significant problem [48] and that only 37% of parents will wake to hypoglycemia alarms that sound overnight [49]. Other behavioral explanations are possible, including voluntary alarm switching off and leaving the receiver out of earshot. The engagement of parents with the CGM device and their behaviors in response to data provided comprise a vital extension of the digital phenotype of HI [40,42].

Future work must further evaluate this aspect of the digital phenotype of HI to better understand not only the underlying pathophysiology but also the human in the loop. Simple mathematical modeling to generate ever better glycemic predictions is unable to eradicate hypoglycemic events in the real world if it does not factor in how human behaviors change in response to the data.

Conclusion

We provide the first analysis of the timing of hypoglycemia in patients with hypoglycemia due to HI using CGM data and, in doing so, expand the digital phenotype. In contrast to the phenotype of hypoglycemia in children with IKH, a clear period of high risk for hypoglycemia was observed in patients with HI in the early hours (3 AM-7 AM). Such early hours hypoglycemia was particularly frequent in those with genetic mutations known to cause HI and in children older than 10 months. Despite the unblinded state-of-the-art technology, prolonged and potentially harmful hypoglycemic events were detected in patients with HI. Hypoglycemia during early hours poses a high risk for neuroglycopenic brain injury, and behavioral aspects of the digital phenotype in HI must be evaluated so that interventions can be designed to maximize effect.

Abstract

Background: The provision of reliable patient education is essential for shared decision-making. However, many clinicians are reluctant to use commonly available resources, as they are generic and may contain information of insufficient quality. Clinician-created educational materials, accessed during the waiting time prior to consultation, can potentially benefit clinical practice if developed in a time- and resource-efficient manner.

Objective: The aim of this study is to evaluate the utility of educational videos in improving patient decision-making, as well as consultation satisfaction and anxiety, within the outpatient management of chronic disease (represented by atrial fibrillation). The approach involves clinicians creating audiovisual patient education in a time- and resource-efficient manner for opportunistic delivery, using mobile smart devices with internet access, during waiting time before consultation.

Methods: We implemented this educational approach in outpatient clinics and collected patient responses through an electronic survey. The educational module was a web-based combination of 4 short videos viewed sequentially, followed by a patient experience survey using 5-point Likert scales and 0-100 visual analogue scales. The clinician developed the audiovisual module over a 2-day span while performing usual clinical tasks, using existing hardware and software resources (laptop and tablet). Patients presenting for the outpatient management of atrial fibrillation accessed the module during waiting time before their consultation using either a URL or Quick Response (QR) code on a provided tablet or their own mobile smart devices. The primary outcome of the study was the module's utility in improving patient decision-making ability, as measured on a 0-100 visual analogue scale. Secondary outcomes were the level of patient satisfaction with the videos, measured with 5-point Likert scales, in addition to the patient's value for clinician narration and the module's utility in improving anxiety and long-term treatment adherence, as represented on 0-100 visual analogue scales.

Results: This study enrolled 116 patients presenting for the outpatient management of atrial fibrillation. The proportion of responses that were "very satisfied" with the educational video content across the 4 videos ranged from 93% (86/92) to 96.3% (104/108) and this was between 98% (90/92) and 99.1% (107/108) for "satisfied" or "very satisfied." There were no reports of dissatisfaction for the first 3 videos, and only 1% (1/92) of responders reported dissatisfaction for the fourth video. The median reported scores (on 0-100 visual analogue scales) were 90 (IQR 82.5-97) for improving patient decision-making, 89 (IQR 81-95) for reducing consultation anxiety, 90 (IQR 81-97) for improving treatment adherence, and 82 (IQR 70-90) for the clinician's narration adding benefit to the patient experience.

Conclusions: Clinician-created educational videos for chronic disease management resulted in improvements in patient-reported informed decision-making ability and expected long-term treatment adherence, as well as anxiety reduction. This form of patient

education was also time efficient as it used the sunk time cost of waiting time to provide education without requiring additional clinician input.

Introduction

Chronic disease is the leading cause of disease burden and mortality worldwide, with increasing prevalence due to an aging global population [1]. Cardiovascular disease is one of the major categories of chronic disease, and atrial fibrillation (AF) is widely recognized as one of the most common chronic conditions [2].

Ongoing outpatient consultations are an essential component of chronic disease management [3], and one strategy that could have considerable utility in this setting is that of "shared decision-making" [4]. Shared decision-making involves bidirectional information exchange within the clinician-patient relationship before making management decisions [5], and can optimize the practice of evidence-based medicine [6]. Patients are informed and care is patient-centered as the patient is empowered to communicate their personal values and management preferences for the clinician to individualize suggested management options [7]. A patient's level of involvement in shared decision-making is influenced by their level of health literacy [8], and accordingly educational decision aids are facilitative [9]. Decision aids have shown potential benefit [10] when implemented while patients are waiting for the consultation [11].

Audiovisual education aids, including videos, can be an effective method of improving patient health literacy [10,12,13]. However, clinicians may be reluctant to use those that are commonly available (eg, those publicly available on health care websites or YouTube) if they are generic or contain information of insufficient accuracy, quality, or currency [14]. Patient care may benefit from clinicians creating their own audiovisual content and delivering it to their patients within the clinical setting.

Based on findings from the prior literature [15], we hypothesized that clinician-created audiovisual content could be created with limited resources and would be acceptable and improve the ability of patients to contribute to the decision-making process. Integral to this is understanding effects of the intervention on anxiety around consultation ("white coat" effects) [16] and potential long-term compliance to formulated management plans [17]. We aimed to evaluate this approach within outpatient management of chronic disease (represented by AF in this instance [2]), whereby clinicians create audiovisual patient education in a time- and resource-efficient manner for opportunistic delivery, using mobile smart devices with internet access, during waiting time before consultation. Specifically, we aimed to assess the following: patient satisfaction with the individual videos and the approach overall, patient response to clinician narration within the content, and the patient-perceived effect of the approach on patient decision-making, patient anxiety around consultation, and potential long-term treatment adherence.

Methods

Study Design

We conducted a prospective, nonrandomized, observational study of 116 patients presenting specifically for the outpatient management of AF. Patients provided informed consent through a validated electronic form before commencing the audiovisual module on a smart device. Ethical approval for the study was obtained from the Western Sydney Local Health Network Human Research Ethics Committee (item number 2011–18).

Setting and Participants

Consecutive patients presenting for outpatient management of AF were prospectively recruited at a specialist outpatient clinic within a large university teaching hospital in Sydney, Australia. The site was within a public metropolitan hospital that serves patients of the Western Sydney Local Health District. As of 2018, the district provides AUD $1.8 billion (US $1.3 billion) in public health care to over 120 suburbs consisting of a demographically diverse population; approximately 50% of the residents have chronic conditions [18]. Potential participants were identified by study personnel via screening of the specialist outpatient clinic lists.

Patients were eligible for inclusion if they had presented to the specialist outpatient clinic specifically for consultation for the management of AF, and were English speaking, willing and able to use smart devices, and could provide informed consent. Patients were excluded if they were unable to speak English, refused consent, or had visual impairment or any other factor that prevented them from using the provided tablet (eg, rheumatoid arthritis). All prospective patients who met the inclusion criteria were enrolled in the study.

Development of the Audiovisual Module

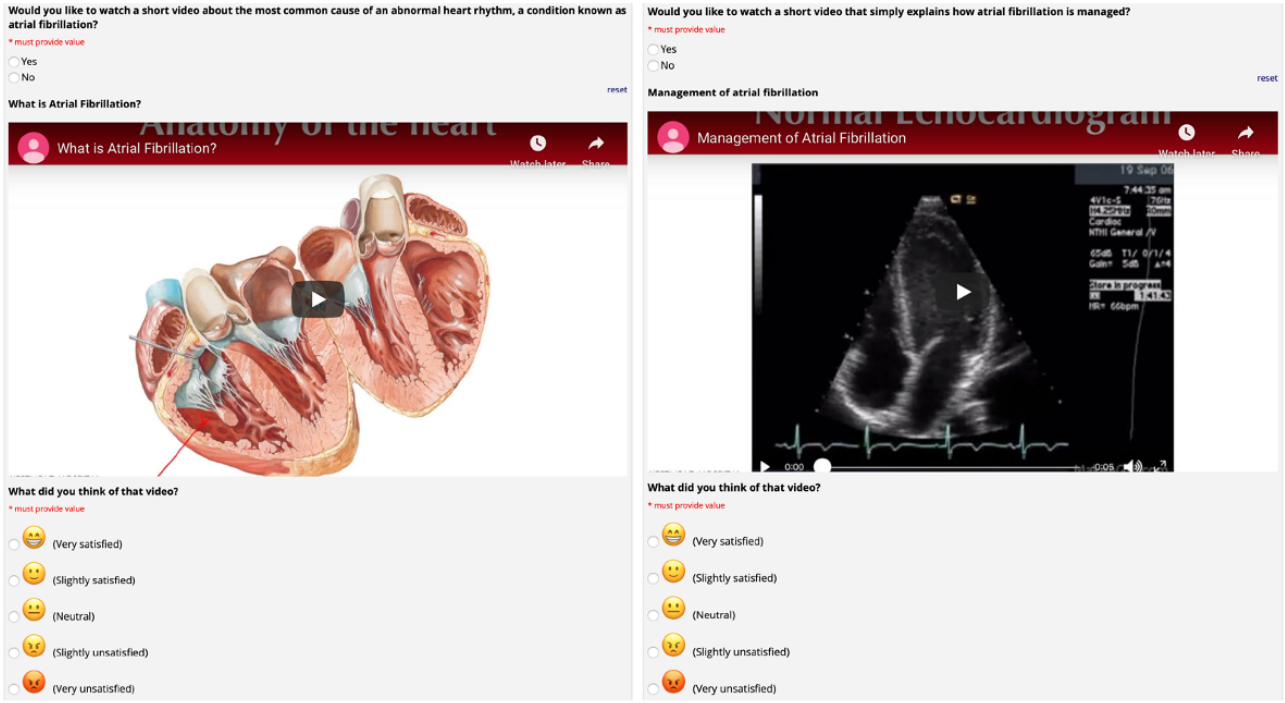
The educational audiovisual module was designed to be a web-based combination of 4 short videos (privately hosted on YouTube) to be viewed sequentially, accompanied by questions gauging patient experience. The module was consolidated using Research Electronic Data Capture (REDCap) [19]. Data from the module were collected and coded on REDCap via a secure database.

The audiovisual module sought to provide a baseline level of disease-specific health literacy to patients that supplemented information provision and improved shared decision-making

in the subsequent outpatient consultation. For this study, two of the authors (AT and JGK) consulted the latest guidelines and peer-reviewed literature, and decided on an up-to-date, reliable, yet simple syllabus covering the fundamental concepts of the pathophysiology, clinical presentation, diagnosis, and management of AF. For this, we searched for studies of any design, in any setting, within Scopus using the search term "atrial fibrillation" in all fields. To ensure that the most prominent recent AF literature was reviewed, the search was date restricted from January 2016 to December 2018, and the 46,393 resultant records were sorted in order of total number of citations. From the prominent recent AF literature that was reviewed, the two most cited guidance statements specifically relevant to the management of AF [20,21] were discussed by two authors (AT and JGK) and concepts and the syllabus outline were subsequently formulated by consensus. The resultant module contained four succinct videos encompassing the following topics: (1) "What is AF?" (2) "AF Management," (3) "Stroke risk and anticoagulation," and (4) "Lifestyle modification."

For the measurement of outcomes, we used Likert scales and visual analogue scales, which have both demonstrated reliability and validity as health measurement tools [22]. The level of patient satisfaction for each individual video and satisfaction with the videos overall were recorded on 5-point Likert scales [23]. Further, 0-100 visual analogue scales were used to gauge the patient's response to clinician narration, as well as the module's patient-perceived utility in improving patient decision-making, anxiety around consultation, and potential long-term treatment adherence. The visual analogue scales and Likert scales were created and combined with the 4 videos for the audiovisual module using REDCap (Figure 1).

Figure 1. A sample of the web-based audiovisual educational module consolidated using REDCap.

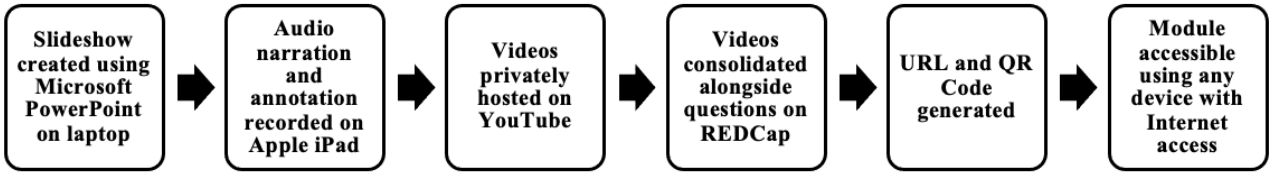


After the simple syllabus was formulated, the clinician (AT) developed the audiovisual module over a 2-day span between clinical commitments and within normal working hours (approximately 3 hours total). No disruption to regular clinical duties was experienced. The only material resources used in the process were that of a laptop containing Microsoft PowerPoint (Microsoft Corp) and an Apple iPad (Apple Inc), both of which were already owned by the clinician, thus not incurring any additional financial costs.

To make the 4 educational videos within the module, the clinician created 4 brief slideshows using PowerPoint on a laptop, then recorded audio narration simultaneously to annotate the slideshows using the Apple iPad using the Screen Recording function available by default on iOS 13 or later (Figure 2). The latter was done in a single take; on average, it took the clinician 3 minutes and 42 seconds to record the audio narration and annotation that complemented the slideshows within each individual video. The videos were subsequently privately hosted on YouTube in order to be consolidated alongside the patient experience survey on REDCap. This ensured that no advertising material was delivered with the videos by the YouTube website. REDCap then generated a URL, also known as a web address, and a Quick Response (QR) code, both of which enabled access to the educational module using any device with internet access.

All information provided within the module was only included following brief inspection of the latest peer-reviewed literature on the associated topics by the clinician to update existing knowledge. Further, the module was recorded in English with language and readability aimed below an eighth grade level to enhance accessibility for the general adult population [24]. The audiovisual module, along with all included images and visual media, was consolidated solely for private use limited to the duration of the study. It was not marketed or sold for commercial purposes.

Figure 2. Technique for audiovisual module creation by a clinician.



Delivery During Waiting Time

To minimize potential bias attributable to the halo effect [25], patients were approached by members of staff in the specialist clinic other than the clinician who created the educational videos. Following informed consent, patients completed the audiovisual educational module during the otherwise nonclinically utilized waiting time before their consultation for AF. Patients accessed the web-based module through either the URL or QR code generated by REDCap. This was done using either a tablet that was already owned by the treating specialist in the clinic or mobile smart devices that the patients already owned.

The entire audiovisual module was designed to take a maximum of 20 minutes for the patient to complete, so as to comfortably be completed during the expected waiting time before outpatient consultation [26]. Further, the cumulative duration of all four videos totaled 14 minutes and 46 seconds, so as to maximize concentration and minimize the chances of attention decline [27].

Data Elements

The primary outcome of the study was the audiovisual educational module's utility in improving patient decision-making ability during the subsequent outpatient consultation [17], which was measured in an anonymous manner using a 0-100 visual analogue scale. The secondary outcomes were the level of patient satisfaction for each video and satisfaction with the videos overall (both measured using 5-point Likert scales), as well as the patient's value for clinician narration, and the module's patient-perceived utility in improving anxiety around consultation and potential long-term treatment adherence (all measured using 0-100 visual analogue scales in an anonymous manner). Data were extracted by two authors (JGK and AT) from the secure REDCap database as a CSV file.

Statistical Analysis

Data were assessed in Python (open source, Python Software Foundation) using the Pandas library (version 1.0.4, open source, PyData), with results reported using medians and interquartile ranges. Figures were prepared using the Plotly (version 4.8.1) library. Friedman test and post hoc analysis were performed using Statsmodels (version 0.10.2, open source) as the data were not normally distributed, with repeated observations on the same individuals.

Results

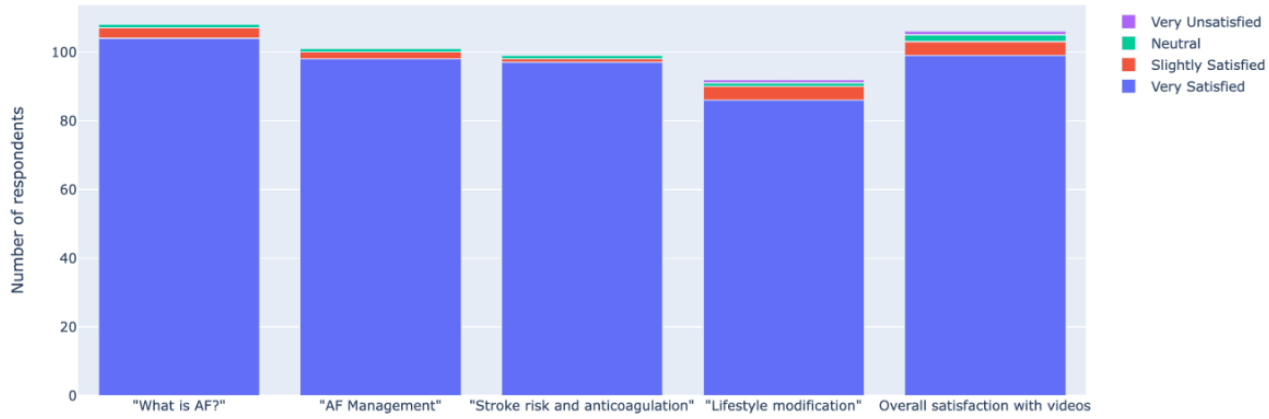
Overview

Between January 2019 and August 2019, all 116 prospective patients who met the aforementioned inclusion criteria were enrolled in the study. Response rates for the 5-point Likert scales progressively decreased with each successive video, with 93.1% (108/116) of the total cohort conveying their level of satisfaction with the first video ("What is AF?"), 87.1% (101/116) for the second ("AF Management"), 85.3% (99/116) for the third ("Stroke risk and anticoagulation"), and 79.3% (92/116) for the fourth ("Lifestyle modification"). In addition, 85.3% (99/116) of the total cohort reported the effect of the audiovisual module on consultation anxiety, decision-making ability, and likelihood of potential treatment adherence through the 0-100 visual analogue scales, with 84.5% (98/116) reporting the importance of clinician narration.

Likert Scales

The proportion of participants that were "very satisfied" with the educational video content ranged from 93% (86/92) to 96.3% (104/108) for the individual videos. In the final 5-point Likert scale assessing overall satisfaction with all 4 videos, 93.4% (99/106) of responders were "very satisfied," with 0.9% (1/106) reporting dissatisfaction. For the first video ("What is AF?"), 99.1% (107/108) of responders reported satisfaction with the content, compared to 99.0% (100/101) for the second ("AF Management"), 99.0% (98/99) for the third ("Stroke risk and anticoagulation"), and 98% (90/92) for the fourth ("Lifestyle modification"). There were no reports of dissatisfaction for the first 3 videos, and 1% (1/92) of responders reported dissatisfaction for the fourth video. Patient satisfaction with the clinician-created educational videos, as obtained through 5-point Likert scales, is represented in Figure 3.

Figure 3. Patient satisfaction with clinician-created videos. AF: atrial fibrillation.



Visual Analogue Scales

Median scores on the four 0-100 visual analogue scales ranged from 82 to 90. The audiovisual module resulted in median reported patient-perceived scores of 90 (IQR 82.5-97) for improving patient decision-making, 89 (IQR 81-95) for improving consultation anxiety, 90 (IQR 81-97) for improving potential treatment adherence, and 82 (IQR 70-90) for the clinician's narration adding benefit to the patient experience. Patient responses to the 0-100 visual analogue scales are presented in Figure 4.

Friedman test results yielded a Friedman statistic value of 33.3 (P<.001). The Nemenyi post hoc analysis showed that only "Importance of clinician narration" was significantly different (P=.001) from all the other evaluations. The other evaluations did not differ significantly from each other. These results are presented in Table 1.

Figure 4. Patient responses to the audiovisual module.

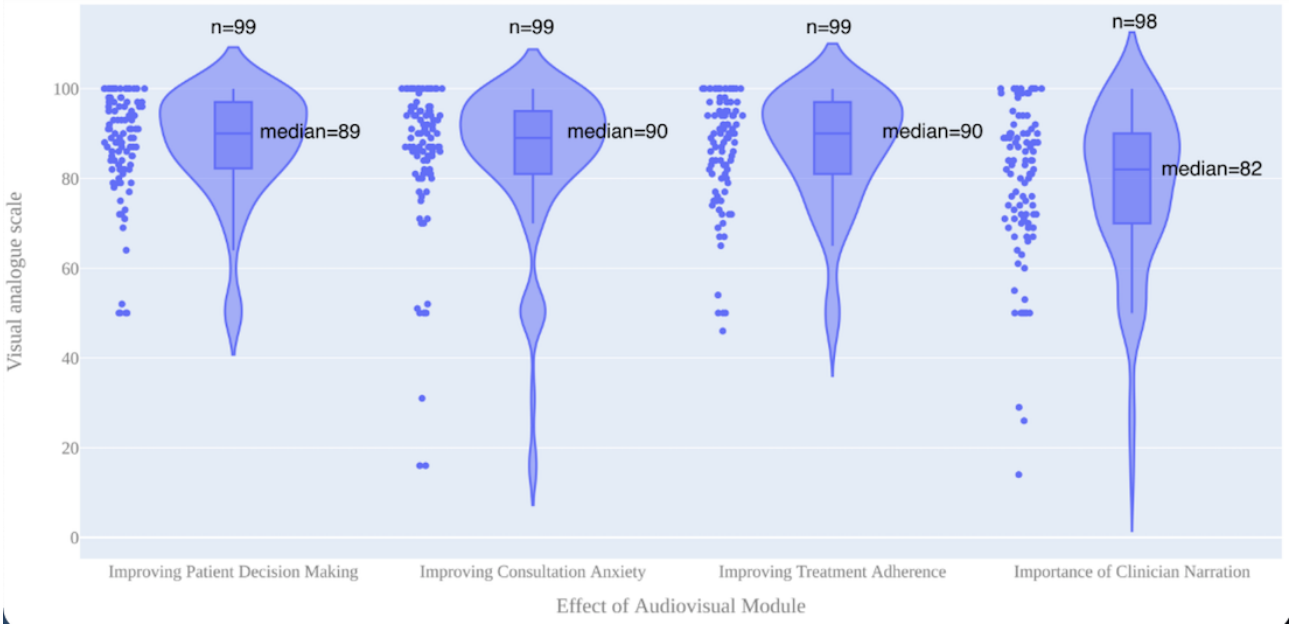


Table 1. Analysis of patient responses using the Friedman test.

Evaluation	Improving consultation anxiety	Improving patient decision making	Improving potential treatment adherence	Importance of clinician narration
Improving consultation anxiety	1	.70	.90	.001
Improving patient decision making	.70	1	.49	.001
Improving potential treatment adherence	.90	.49	1	.001
Importance of clinician narration	.001	.001	.001	1

Discussion

Principal Findings

A clinician-created audiovisual patient education module with content focusing on improving consultation efficiency and shared decision-making received scores indicating a high level of acceptability and patient-perceived utility. The video content was developed by a clinician using electronic resources that are relatively common in the developed world, during interstitial time between clinical duties, and was delivered using mobile smart devices while patients were waiting for their appointments. The majority of participants perceived the clinician's creation and narration of the module to be positive and effective in delivering the educational content of the disease-specific videos.

Shared decision-making provides a potential solution for achieving adequate efficiency while improving patient autonomy [28]; however, this may not translate to clinical practice if the appropriate approach to implementation is not taken [29]. An element of usefulness in our approach is that it not only improves shared decision-making, but also uses waiting time (sunk time cost) for an improved patient experience that does not add to the overall length of the consultation. Further, our approach demonstrates that clinicians can use off-the-shelf tools to simply create their own highly customized educational content tailored specifically for their patients. Further, it is implementable with minimal additional resources.

Patient education has been shown to be more effective when delivered in an audiovisual format than when presented solely through visual pamphlets or verbal one-to-one dialogue [30]. However, clinical utility for the management of chronic disease is limited when audiovisual patient education has required additional outpatient appointments [31]. This intervention used shorter duration, highly focused videos, allowing delivery in the waiting room so that patients would not have to make additional visits. Increasing access to unreliable, inaccurate, and outdated sources via the internet can increase confusion and cause difficulties during consultations for the management of patients' conditions [32]. This can potentially be reduced through the provision of up-to-date and reliable information directly from a patient's own treating clinician, as a supplement to scheduled consultations. Our approach allows for the provision of reliable health education in a manner that is streamlined for integration within both the clinician (through time and resource efficiency) and patient (through tailored, accessible education) experience of outpatient consultation.

The audiovisual educational module demonstrated utility in improving patient-reported decision-making ability for the subsequent outpatient consultation for AF management. However, due to a lack of any of the validated outcome measures or objective endpoints that are found within the existing literature of studies investigating shared decision-making in AF management [33], comparison between previous studies and our study is compromised. The high levels of patient satisfaction with both the videos and clinician narration suggest that there may be potential usefulness in clinician-created audiovisual educational content for the management of chronic disease. Further, anxiety [34], particularly that associated with the "white coat" effect [16], and long-term treatment adherence [17,35] have a significant impact on a patient's decision-making ability regarding the management of any chronic disease. Accordingly, our positive findings imply potential value in these domains. Our finding of patient-reported improvements to potential treatment adherence is in line with the existing literature, which has demonstrated the efficacy of video-assisted patient education in positively modifying the behaviors of patients with chronic disease if designed and delivered correctly [36].

There were limitations to this study that require future evaluation. Our study did not have a control group that enabled comparison; the study was observational and baseline characteristics of the participants were not collected. However, we prospectively included a consecutive series of eligible patients to limit patient bias, and all patients answered the same questionnaire. Our study was limited by subjective responses from patients as outcome measures, instead of outcome measures such as recurrence of AF or occurrence of its complications. The data collected referred specifically to the patients' own perceptions, which may carry inherent bias. We did not collect data using validated measures of patient-reported experience or health literacy. Further, we delivered the educational module only in English, and excluded non–English-speaking patients. Within the literature search that informed the curriculum for our educational module, sorting search results in Scopus by total numbers of citations identified the most prominent articles within the search time frame, but added a source of bias regarding the data informing our intervention. As our study was conducted in 2019, any evidence published since then has not been integrated. Further, only one database was searched prior to the development of our curriculum, so some literature may have been missed. The study was limited to a single center, so this approach's multicenter applicability has not been tested. Additionally, although the clinician in our study was able to carry out our approach in a time- and resource-efficient manner, this approach may not translate to certain doctors with different levels of resources, time within schedules, and technology skills.

Findings from this pilot study may be useful for future research in this area. Although audio narration was used in this study, future studies may benefit from the inclusion of video of the treating clinician and investigation of subsequent effects on patient trust, anxiety reduction, and potential adherence. Clinical interactions within settings outside the management of chronic disease at outpatient clinics may also benefit from this approach and should be investigated. Usefulness of the approach relative to the socioeconomic status of the health care provider may be important to delineate for the maximization of global scalability. Further, exploration of utility for health professionals in other areas of medicine, surgery, nursing, and allied health ought to be explored. Study design in this future research can be improved by incorporating a comparison (ideally with randomization) against other forms of patient education as well as more concrete endpoints, such as objective health metrics or validated scoring schemas. The measures of patient perceptions that were recorded in this pilot study may be better assessed via a longitudinal approach that facilitates the evaluation of temporal trends. Explanations for changes in patient perceptions

throughout the course of the videos may have greater clarity if more qualitative data points are also collected in addition to measures of satisfaction.

Conclusions

This approach to outpatient consultation for the management of chronic disease may provide benefit for shared decision-making between clinicians and patients, overall leading to the improvement of care while maintaining a patient-centered focus. It benefits clinicians by combining their individual content knowledge with technology to create highly customized disease-specific audiovisual educational material for their patients. It benefits patients by allowing them to learn about their condition in a nonconfrontational situation without additional investment of time or effort. Patient satisfaction may be improved by converting a potentially negative situation (the sunk time cost of waiting for a medical appointment) to a positive experience. This pilot study demonstrated the potential utility of this approach in a specific setting; however, it may have widespread applicability across a large number of clinical scenarios, including those outside the management of chronic disease and outside the outpatient setting. Future research should explore this potential widespread applicability of our approach through studies of larger size and strong design.

Authors' Contributions

JGK was involved in the design of the study, the development of the associated intervention, and the preparation of this manuscript. DM was involved in the development of the associated intervention, data collection, and the preparation of this manuscript. WWBC was involved in data collection and the preparation of this manuscript. CKC was involved in the preparation of this manuscript. AT was involved in the design of the study, the development of the associated intervention, and the preparation of this manuscript.

Conflicts of Interest

CKC is supported by an NHMRC (National Health and Medical Research Council) Investigator grant. The other authors have no conflicts to declare.

Abstract

Background: Patient portals have been introduced in many countries over the last 10 years, but many health information managers still feel they have too little knowledge of patient portals. A taxonomy can help them to better compare and select portals. This has led us to develop the TOPCOP taxonomy for classifying and comparing patient portals. However, the taxonomy has not been evaluated by users.

Objective: This study aimed to evaluate the taxonomy's usefulness to support health information managers in comparing, classifying, defining a requirement profile for, and selecting patient portals and to improve the taxonomy where needed.

Methods: We used a modified Delphi approach. We sampled a heterogeneous panel of 13 health information managers from 3 countries using the criterion sampling strategy. We conducted 4 anonymous survey rounds with qualitative and quantitative questions. In round 1, the panelists assessed the appropriateness of each dimension, and we collected new ideas to improve the dimensions. In rounds 2 and 3, the panelists iteratively evaluated the taxonomy that was revised based on round 1. In round 4, the panelists assessed the need for a taxonomy and the appropriateness of patient engagement as a distinguishing concept. Then, they compared 2 real portals with the final taxonomy and evaluated its usefulness for comparing portals, creating an initial requirement profile, and selecting patient portals. To determine group consensus, we applied the RAND/UCLA Appropriateness Method.

Results: The final taxonomy consists of 25 dimensions with 65 characteristics. Five new dimensions were added to the original taxonomy, with 8 characteristics added to already existing dimensions. Group consensus was achieved on the need for such a taxonomy to compare portals, on patient engagement as an appropriate distinguishing concept, and on the comprehensibility of the taxonomy's form. Further, consensus was achieved on the taxonomy's usefulness for classifying and comparing portals, assisting users in better understanding portals, creating a requirement profile, and selecting portals. This allowed us to test the usefulness of the final taxonomy with the intended users.

Conclusions: The TOPCOP taxonomy aims to support health information managers in comparing and selecting patient portals. By providing a standardized terminology to describe various aspects of patient portals independent of clinical setting or country, the taxonomy will also be useful for advancing research and evaluation of patient portals.

Introduction

Background

The delivery of knowledge-based care depends on patient engagement, where patients take an active role in their care [1-3]. Patient portals are considered a health information technology that promotes patient engagement [4-6] by providing patients with online tools to take an active role in their care [7-9]. Since patient portals are more than just static repositories for patient data [10,11], they support the new vision of health services that enable patient-provider information sharing [12,13], thus contributing to empowering patients [14,15], supporting shared decision making [16], and engaging patients actively in their care [6,17]. A patient portal is an internet-based application combining knowledge and software tools [18,19] that allow patients to have autonomous access to their electronic health record (EHR) anywhere at any time [20,21]. Besides its core function of providing EHR access [22], the features of a patient portal range from viewing visit notes, requesting medication refills, appointment scheduling, access to test and lab results, secure messaging with the health provider, e-visits, or reporting patient-generated health data [17,23-26]. Patient portals are used in different organizational settings such as independent physician practices and hospitals, group practices, or large, integrated health care delivery organizations [27-29].

The Need for a Taxonomy of Patient Portals

The widespread use of the internet, rise of mobile computing, and progress in patients' technical aptness have led to an increase in the use of patient portals in various countries such as the United States, Denmark, and Australia [12,28,30]. However, there are countries where patient portals are still not widely used [31,32]. A benchmarking study presented by Ammenwerth et al [33] in 2020 analyzed the eHealth progress of 14 countries worldwide with different health systems and different levels of economic development. The study showed that the use of patient portals and the provided patient portal functionalities vary significantly between the countries. While Finland and South Korea, for example, allow patients the best access to their health record data, 6 of the 14 analyzed countries do not offer their population any access to their health data online [33].

The low use of patient portals in both developing and high-income countries [31,34] creates a problematic situation for the health informatics professionals who are responsible for strategic and tactical information technology management in their health care institution or department; we will call these professionals "health information managers." On the one hand, there already exists a very heterogeneous landscape and a broad diversity of patient portals [12,27,35,36] regarding their intended deployment and functionalities [25,30,37]. In contrast, many health information managers still feel they have too little knowledge of patient portals [32]. They admit having difficulties understanding the portals' various application areas and scopes, defining their general requirements, and selecting a patient portal for their specific context or problem [32]. Health information managers are responsible for planning, organizing, and following up on all activities related to health information technology [38,39]. This also involves selecting, introducing, and managing patient portals for their health care institution [32].

To support health information managers with a tool for comparing patient portals and defining which general type and functionalities of patient portals they need, we developed the TOPCOP taxonomy (Taxonomy of Patient Portals based on Characteristics of Patient Engagement) [32]. The need for such a patient portal taxonomy had already been stressed in a recently published Cochrane Review on the impact of patient portals [40]. The TOPCOP taxonomy is shown in Figure 1. A comprehensive description of the dimensions is published elsewhere [32].

Figure 1. The TOPCOP taxonomy of patient portals [32]: A patient portal is described regarding 7 aspects that cover 20 dimensions. A patient portal can be described by selecting 1 characteristic per dimension.

ASPECTS	DIMENSIONS	CHARACTERISTICS		
Portal Design	D1: Care Sector Target	primary care	secondary care	generic
	D2: Portal Specialization	universal	disease-specific

The Development of the TOPCOP Taxonomy

A taxonomy is a classification system to classify similar objects of a domain into groups based on distinct characteristics and offers a set of decision rules [41-44]. The reduction of complexity, identifying similarities and differences among objects [45,46], and the understanding of interrelationships are major advantages of taxonomies [44,47,48]. Taxonomies thus support researchers and practitioners in better understanding a domain and distinguishing among its objects [49,50]. The TOPCOP taxonomy was built by applying the formal taxonomy-building method proposed by Nickerson et al [51]. This method specifies the necessary steps and integrates 2 optional, iterative development approaches to conceptionally and empirically build and empirically evaluate a taxonomy [51,52]. The TOPCOP taxonomy was created conceptionally based on a literature review to assess the characteristics and functionalities of patient portals [32]. It was evaluated empirically by classifying patient portals offered on the market and health providers' portals online [32].

A taxonomy is determined by the user's intended purpose, which guides the taxonomy's development by focusing on the specific phenomenon of interest [50,53]. Different users or different purposes may therefore lead to a different taxonomy [51,54]. We created the TOPCOP taxonomy for health information managers to classify and compare patient portals [32]. Further, the taxonomy should serve the health information managers in defining the general type and functionalities of patient portals and should help them select the most suitable solution offered on the market. The dimensions were built to distinguish among patient portals with the scope on patient engagement.

Since there is no objective metric to define the usefulness or quality of a taxonomy [44,51,55], the method by Nickerson et al [51] provides a set of conditions to determine usefulness. Applying these conditions during the building process, the taxonomy's usefulness was empirically validated by classifying all patient portals of interest with the taxonomy [32].

The Requirement for a Taxonomy's Evaluation

According to design science research, taxonomies are fundamental design artifacts to provide knowledge and understanding of a problem domain [49]. In design science research, the design process for an artifact is divided first into building and then into evaluating [56,57]. Following the design science research paradigm, one suitable criterion to evaluate a taxonomy is by having users assess its usefulness in achieving its intended purpose [58,59]. Therefore, we now wanted to evaluate and further improve the TOPCOP taxonomy together with the projected users, guided by the evaluation criteria of the taxonomy's usefulness related to its intended purpose.

Methods

The Delphi Technique

Overview

We applied a modified Delphi approach to evaluate the TOPCOP taxonomy. The Delphi technique is a qualitative method, first described by Dalkey and Helmer [60]. It is used

in many research areas such as business, policy science, education, health sciences, information science, and health informatics [61-65]. Since there is no consistency in the methods used for evaluating a taxonomy [49], we opted for the Delphi technique because it is commonly agreed that Delphi research elicits sound scientific evidence [66]. Further, various researchers argue that qualitative methods may be particularly appropriate for evaluating design artifacts [67] including taxonomies.

The Delphi technique was particularly suited for our study as it aims to obtain a highly reliable consensus of group opinions on the research items [68] and has been used by researchers to evaluate taxonomies in the past [69-73]. The method is adequate to explore a domain [63], elicit new evidence, and generate new ideas [68,74]. Since the aim of this study was to collect new ideas on dimensions, improve the existing TOPCOP taxonomy, and achieve consensus on the appropriateness of the dimensions by the taxonomy's users, we considered Delphi to be the best approach as it goes beyond collecting simple intuitive expert opinions [75]. Further, the method applies relatively rigorous control over the interviewing methods, the controlled opinion feedback, and the summary of the results [76].

Using a series of survey rounds delivered in multiple iterations, interspersed with controlled opinion feedback [76], we were able to collect new ideas and correlate the panelists' opinions on our research items anonymously to improve the taxonomy [60,62,75]. Further, the method is highly flexible [77], accommodating many variations [78-80], and can be used to conduct evaluation studies [81], allowing us to adapt and modify the technique to evaluate our taxonomy. While the classic Delphi aims to generate opinions from experts to make forecasts [60,82], we wanted to collect and correlate the opinions of the taxonomy's users to improve and evaluate the TOPCOP taxonomy. We now outline the methodological approaches applied to our study.

Selection of the Panelists

There are no agreed standards on how to select the participants for Delphi studies [75,83]. We applied a criterion sampling strategy, which is a preferred approach in many Delphi studies [84]. Since the taxonomy should help health information managers to compare patient portals, eligible individuals had to hold a role within a health provider's organization where they would be actively involved in a patient portal's selection process. We applied the snowball method [85] to reach out to potential panelists involving patient portal vendors known from the taxonomy development phase [32]. The snowball method has been legitimized and used in many other Delphi studies [75,86,87]. Since there is no standard method for identifying the best number of individuals for inclusion in a Delphi study [86,87], we determined this number based on our research aim and availability of expertise as proposed by several researchers [88-90].

We selected 13 health information managers from Germany, Switzerland, and Austria as we wanted to include panelists from countries with diverse health systems and different progress in eHealth [31,33]. By sampling panelists from different countries but who speak the same language, we aimed to avoid a possible language bias as the survey questions and the complex explanations of the dimensions could otherwise be misinterpreted [91]. Since homogeneous panels tend to find consensus more quickly than heterogeneous panels [92,93], we wanted to enhance credibility through diversity, considering the broadest possible range of participants' experiences with patient portals and geographic diversity to depict the real situation of different health systems. The educational backgrounds of health information managers are not uniform but may be diverse [39]. We, therefore, included panelists with different educational backgrounds in our sample. In Table 1, we present the final panel.

Table 1. Study sample selection.

Panelist number	Country	Gender	AE[a]	PB[b]	Role	WE[c] (years)	EPP[d] (years)	INST[e]	SPP[f]
1	Austria	Male	MEng	Computer engineer	Head of department	27	5	HCP[g]	Yes

[d]EPP: experience with patient portals.

[e]INST: institution.

[f]SPP: would be involved in selecting a patient portal.

[g]HCP: health care provider.

[h]HCO: health care organization.

Determination of the Number of Survey Rounds for Evaluation

As per common agreement, the number of survey rounds is guided by the nature of the study and the level of consensus achieved among the participants during each iteration [75,76,94]. Our study was planned to be performed in 4 assessment cycles, guided by the elicitation of evidence and the achievement of group consensus. In the first 3 rounds, we aimed to collect ideas to improve the taxonomy and to achieve group consensus on every single dimension of the taxonomy related to its appropriateness for comparing patient portals. In round 4, the panelists were asked to evaluate the final taxonomy as a whole as proposed by Wiliam and Black [95], related to its intended use. The survey rounds were performed between January 2021 and April 2021.

Achievement of Consensus—the RAND/UCLA Appropriateness Method

The goal of the Delphi technique is to achieve a consensus of opinions from a group of individuals concerning a particular topic or task [87,96,97]. However, there is no general agreement on what statistical aggregation or method is best to determine consensus [98]. Since we wanted to assess the appropriateness of the taxonomy, we considered the concept of the RAND/UCLA Appropriateness Method, called RAM [99], most suitable to determine achievement of consensus in our study. While the RAM method is widely used to determine the appropriateness of health care services [100,101], we applied the model's consensus measure to evaluate the appropriateness of the taxonomy's dimensions for classifying and comparing patient portals.

The RAM method uses the median to measure the central tendency of the panelists' ratings, and ratings should be spread over a 1-9 rating scale [89,99]. The RAM method offers various conditions to constitute disagreement of opinions [99], from which we chose DS9, the strictest definition of disagreement [99]. DS9 means that a dimension is appropriate for comparing patient portals if group consensus with a median of 7-9 without disagreement is achieved. Considering all ratings, disagreement exists when at least one rating is a 1 and at least one is a 9. A dimension is considered uncertain for comparing patient portals if group consensus achieves a median of 4-6 or if there is any median with disagreement. A dimension is considered inappropriate for comparing patient portals if group consensus achieves a median of 1-3 without disagreement. The DS9 measure was applied for all assessments to determine achievement of group consensus. The DS9 measure is summarized in Table 2.

Table 2. The DS9 RAND/UCLA Appropriateness Measure with dispersion: considering all ratings, at least one is a 1, and at least one is a 9.

Appropriateness	Panel median	Dispersion condition
Appropriate	7-9	Without disagreement
Uncertain	4-6	Or any median with disagreement
Inappropriate	1-3	Without disagreement

Applying Anonymity to Express Opinions Freely

The complete study was conducted anonymously, which means that none of our panelists knew who participated in the survey and no interaction was possible between them. Anonymity allowed greater freedom for our panelists to express their views [102,103] and opinions freely as it avoids the problem of dominant contributors possibly influencing individual opinions [104,105].

Introductory Conversations to Enhance Adherence of Panelists and to Create a Common Understanding of the Research Topics

We were aware of the known problem that participants might drop out [77] due to the time-consuming commitment, unforeseen shortage of time, loss of interest, or distraction between the rounds, risking a poor response rate [83]. To promote motivation and strengthen adherence, we conducted an introductory conversation with each panelist separately, as proposed by Daniel and White [106], using the Zoom video conferencing tool [107]. The scope was to give the panelists the possibility to ask questions related to the aim of the study, the research process, and their role in the study and to create a common understanding on all topics.

Set-Up of the Online Survey

All interviews were carried out with online questionnaires using a commercial survey product [108]. The survey was piloted by 4 different persons other than the researchers. The survey contained quantitative and qualitative questions. The quantitative ratings served to assess the dimensions' appropriateness (rounds 1-3) and the final taxonomy as a whole (round 4). To assess the dimensions, we presented only 1 dimension with its characteristics per page (example Figure 2) and added a comprehensive definition of the existing characteristics and the newly proposed characteristics to assure that all panelists had the same understanding of the dimensions.

We provided a Likert scale ranging from 1 to 9 as proposed by RAM [99] for assessment. The open-ended qualitative questions provided in rounds 1-3 allowed the panelists to comment on their ratings if the rating fell into values between 1 and 6. Further, the qualitative questions allowed the panelists to improve the taxonomy by making proposals for new characteristics or dimensions. All proposals had to follow the knowledge-guiding principle of being suitable for promoting patient engagement. The comments and proposals were presented in the subsequent round for the panelists' reflection. Comments related to ratings, to changes of existing dimensions, or to new characteristics and dimensions were assigned accordingly. The comments were quoted verbatim with no changes made to the original. At the beginning of each survey round, we provided short guidelines on evaluating the research items and presented the results of the previous round. In round 1, we presented the initial TOPCOP taxonomy (Figure 1). In round 2, we presented the ratings from the first round (Multimedia Appendix 1) demonstrating achievement of group consensus. In round 3, we presented the results from the second round demonstrating for which new characteristics and dimensions group consensus was achieved or not achieved (Multimedia Appendix 2). In round 4, we presented the jointly improved, final taxonomy.

Figure 2. Example for the display of a single dimension for rating.

The 4 Rounds of the TOPCOP Taxonomy's Improvement and Evaluation

Round 1: Assessment of the Existing Dimensions and Proposals for Improvement of the Taxonomy

In the first round, the panelists were asked to assess the appropriateness of the existing TOPCOP taxonomy's dimensions for classifying and comparing patient portals. Further, they were asked to propose unsuitable or missing characteristics related to the existing dimensions and to suggest new dimensions to improve the taxonomy guided by their needs.

Round 2: Assessment of the Newly Proposed Characteristics and Dimensions of Round 1

In the second round, the panelists were first asked to assess the proposals of round 1 for new characteristics to refine existing dimensions. Each proposal was presented with all existing and all new characteristics (Multimedia Appendix 3). Related to the proposals of adding new characteristics to the existing dimensions or merge characteristics, we stressed that the panelists should evaluate the appropriateness of the new or merged characteristic of improving the existing dimension to compare patient portals. Then, the panelists were asked to assess the appropriateness of the new dimensions proposed in round 1 for classifying and comparing patient portals.

Round 3: Re-Evaluation of Dimensions Where Group Consensus Was Not Achieved in Previous Rounds

In round 3, the panelists were asked to re-evaluate those dimensions and characteristics proposed in round 1 but where no group consensus could be reached in round 2. From some panelists' comments, we understood that their assessments were guided by national legal requests rather than by evaluating a general area of application. We, therefore, added a note stressing that the scope of this study was to create a generally applicable taxonomy and that specific national requirements should not guide the rating. Since the panelists were to re-evaluate dimensions already assessed in round 2, we provided all panelists with their first rating compared to the group ratings (Figure 3) as recommended by RAM [99]. This was intended to help them better reflect on their rating considering the group opinion.

Figure 3. Example of a panelist's rating in comparison with the group ratings.

Round 4: Evaluation of the Final TOPCOP Taxonomy as a Whole

Since a taxonomy is complete and adequate when it satisfies the requirements of the purpose for which it was built [58], in round 4, the panelists were asked to evaluate the usefulness of the final taxonomy as a whole [109], related to its intended use. Round 4 was divided into 2 consecutive steps: first performing a case study and then assessing the taxonomy's usefulness.

First, evaluation is based on comparison [110]. Therefore, the panelists were requested to classify and compare 2 real-world patient portals with the final TOPCOP taxonomy to test its usefulness in a case study. We provided the panelists with 2 anonymized product descriptions from important software companies along with instructions on how to carry out the comparison. Both patient portals could be used for any care sector. However, one was a tethered patient portal while the other was an integrated patient portal. We selected these 2 patient portals because they differ in many characteristics, allowing the panelists to see the taxonomy's usefulness in comparing very different patient portals.

Second, after the case study was performed, the panelists were asked to assess the usefulness of the taxonomy as a whole. To investigate the panelists' opinions related to taxonomies for patient portals, we started with the following questions: (Q1) How important do you consider the need for a taxonomy for comparing patient portals? (Q2) How suitable do you consider patient engagement as a guiding concept for comparing patient portals?

Further, the health information managers were asked to make proposals for other guiding concepts that they considered useful to compare patient portals. Since we determined patient engagement as a guiding concept to distinguish among patient portals for the TOPCOP taxonomy, we aimed to collect alternative proposals suitable for future research: (Q3) What other guiding concepts may be appropriate for comparing patient portals?

To assess the taxonomy's usefulness as a whole [111], 6 research questions related to the performed case study were presented. Since understanding an artifact is a fundamental requirement for its usefulness, the panelists were first asked to evaluate whether the final taxonomy was understandable: (Q4) How understandable is the form and structure of the final taxonomy? Then, they were asked to assess whether the improved TOPCOP taxonomy is useful related to its intended use: (Q5) How useful is the final taxonomy for classifying patient portals following patient engagement? (Q6) How useful is the final taxonomy for comparing patient portals following patient engagement? (Q7) How useful is the final taxonomy for assisting you in better understanding patient portals based on characteristics supporting patient engagement? (Q8) How useful is the final taxonomy for creating an initial requirement profile for patient portals based on characteristics supporting patient engagement? (Q9) How useful is the final taxonomy for selecting patient portals offered on the market based on characteristics supporting patient engagement?

Question Q3 was set up as an open-ended question to collect the panelists' proposals in the best possible way [112]. To categorize the proposals, we analyzed the responses by applying the summarizing content analysis [113], an inductive analysis method proposed by Mayring [114]. All other items were assessed by applying the RAM approach [99].

Results

Results of Round 1: Assessment of the Existing Dimensions and Proposals for Improvement of the Taxonomy

The panelists were asked to evaluate the TOPCOP taxonomy by assessing every single dimension related to its

appropriateness for classifying and comparing patient portals. In Figure 4, we present the assessment for the 20 dimensions of the initial TOPCOP taxonomy (Figure 1) indicating the median for each dimension. All 13 panelists evaluated all 20 dimensions. Since each dimension's median ranged between 7 and 9 without disagreement, group consensus on the dimensions' appropriateness was achieved for all 20 dimensions [99].

Figure 4. Achieved consensus for the existing dimensions of the TOPCOP taxonomy after round 1. The grey column shows the median value without disagreement. All 13 panelists assessed all dimensions.

ASSESSED DIMENSIONS	RATINGS												
D1: Care Sector Target	7	7	7	8	8	9	9	9	9	9	9	9	9

D6: Prescription Renewal	2	6	7	7	7	7	8	8	8	9	9	9	9
D7: Portal Customizability	5	6	7	7	7	7	8	8	9	9	9	9	9
D8: E-Consult	7	8	8	8	8	8	9	9	9	9	9	9	9
D9: System Notifications	6	7	8	8	8	8	8	8	9	9	9	9	9
D10: Patient Education	7	7	7	8	8	8	9	9	9	9	9	9	9
D11: Therapy Instructions	5	5	7	7	7	7	8	8	8	8	9	9	9
D12: Health Monitoring	7	7	7	8	8	9	9	9	9	9	9	9	9
D13: Visit Preparation	7	7	7	8	8	8	8	9	9	9	9	9	9
D14: Declaration of Will	6	6	7	7	7	8	8	8	8	9	9	9	9
D15: Second Opinion	4	7	7	7	7	7	7	7	7	8	9	9	9
D16: Study Sign-Up	5	6	7	7	7	7	7	7	7	8	8	9	9
D17: Record Access	6	7	7	9	9	9	9	9	9	9	9	9	9
D18: Records Management	3	5	7	8	8	8	8	9	9	9	9	9	9
D19: Health Data Amend	7	7	8	8	9	9	9	9	9	9	9	9	9
D20: Health Data Upload	7	8	8	8	9	9	9	9	9	9	9	9	9

Further, the panelists were asked to propose unsuitable and missing characteristics to refine the existing dimensions and to suggest new dimensions to improve the taxonomy.

Two panelists proposed refining dimension D6 Prescription Renewal by merging the characteristics "basic renewal" and "advanced renewal" to create the characteristic "with renewal" instead. They argued that differentiating the dimension into the initial 2 characteristics is confusing rather than strengthening

the distinguishability of patient portals. Seven panelists proposed 8 new characteristics to improve the existing dimensions D1, D2, D5, D6, D8, D9, D11, and D12 (Figure 5 shows the content of each dimension). Five panelists proposed the new dimensions Account Protection, App Expandability, Medical Specialty, Medication Summary, Portal Type, and Web Accessibility to enhance the taxonomy. We present all the proposals for improvement of round 1 in Figure 5.

Figure 5. Proposals from round 1 for new characteristics and dimensions to improve the taxonomy.

Results of Round 2: Assessment of the Newly Proposed Characteristics and Dimensions of Round 1

In round 2, the panelists had to assess the proposals from round 1 (Figure 5). They were asked to evaluate the merger of the characteristics of dimension D6. Further, they assessed the appropriateness of the suggested characteristics of dimensions D1, D2, D5, D8, D9, D11, and D12.

All 13 panelists assessed the proposed 8 characteristics and justified their rating whenever it fell between 1 and 6. As demonstrated in Figure 6, the median assessment for the appropriateness of all changes ranged between 7 and 9 without

disagreement. Therefore, all 8 characteristics were appropriate for improving the taxonomy and became part of the taxonomy [99].

The panelists were further requested to evaluate the appropriateness of the proposed dimensions D21 Account Protection, D22 App Expandability, D23 Medical Specialty, D24 Medication Summary, D25 Portal Type, and D26 Web Accessibility.

In Figure 7, we demonstrate that for all these dimensions, the median ranged between 7 and 8. However, the condition for disagreement [99] was fulfilled for dimensions D21 Account Protection and D26 Web Accessibility. Therefore, only dimensions D22, D23, D24, and D25 were considered appropriate for improving the taxonomy and became part of the taxonomy. Since no panelist made any proposal for changing an existing dimension or for a new dimension in round 2, only dimensions D21 and D26 became subject to re-evaluation in round 3.

In Figure 8, we present the taxonomy in progress after round 2 showing for which characteristics group consensus was achieved and for which dimensions no group consensus was achieved.

Results of Round 3: Re-Evaluation of Dimensions Where Group Consensus Was Not Achieved in Previous Rounds

In round 3, the panelists were asked to again assess the new dimensions D21 Account Protection and D26 Web Accessibility as group consensus was not achieved in round 2. All 13 panelists assessed both dimensions.

As demonstrated in Figure 9, a median of 8 without disagreement [99] was achieved for dimension D26. Dimension D26 was therefore appropriate and became part of the taxonomy. For dimension D21, a median of 7 was achieved. However, as at least one rating is a 1 and at least one rating is a 9, disagreement existed among the panelists [99]. All 5 panelists who assessed dimension D21 with values of 1 and 3 argued consistently that a patient portal must provide the highest data protection due to legal or patient requirements. Therefore, as strong account protection is a mandatory requirement, dimension D21 is not appropriate for distinguishing among patient portals. Comparing the ratings of dimension D21 for rounds 2 and 3 showed that, besides the fact that disagreement was re-confirmed in round 3, 3 ratings deteriorated (Figure 9), which means that group consensus converged even more strongly towards disapproval of dimension D21. To avoid the known risk of fatiguing the panelists with too many evaluation rounds [92], we did not launch another evaluation round. Since no group

consensus was achieved, dimension D21 was not integrated into the taxonomy.

After assigning the new dimensions to suitable aspects and organizing and numbering the dimensions accordingly, the final TOPCOP taxonomy resulted in 25 dimensions based on 65 characteristics assigned to 7 aspects and is presented in Figure 10. In Multimedia Appendix 4, we provide a detailed description of the dimensions and characteristics.

Figure 9. Achieved consensus by all 13 panelists on dimensions D21 and D26 after round 3 in comparison with the consensus in round 2.

Results of Round 4: Evaluation of the Final TOPCOP Taxonomy as a Whole

In round 4, the panelists were asked to assess the general need for a taxonomy, the appropriateness of patient engagement as a guiding concept, and the TOPCOP taxonomy's usefulness related to its intended purpose. All 13 panelists participated in round 4.

In Figure 11, we present the evaluations' results for the research questions Q1, Q2, and Q4–Q9. Since group consensus was achieved without disagreement [99] for all research questions, no further interview round was launched.

Figure 11. Achieved consensus by all 13 panelists on the research questions Q1, Q2, Q4–Q9. The grey column shows the median without disagreement. p: patient.

Q6: How useful is the final taxonomy for comparing p. portals following patient engagement?	2 7 7 7 7 7 **8** 8 8 8 8 9 9
Q7: How useful is the final taxonomy for assisting you in better understanding p. portals based on characteristics supporting patient engagement?	3 6 6 7 7 7 **7** 8 8 8 9 9 9
Q8: How useful is the final taxonomy for creating an initial requirement profile for p. portals based on characteristics supporting patient engagement?	6 7 7 7 7 7 **8** 8 8 8 9 9 9
Q9: How useful is the final taxonomy for selecting p. portals offered on the market based on characteristics supporting patient engagement?	6 7 7 7 8 8 **8** 8 8 8 9 9 9

The results shown in Figure 11 can be interpreted as follows. The panelists clearly agreed that there is a need for a taxonomy to distinguish among patient portals (median of 8 for Q1). Twelve panelists considered patient engagement to be an appropriate distinguishing concept for comparing patient portals (median of 8 for Q2). Only the panelist who assessed question Q2 with a rating of 3 proposed "System Architecture, Data Types, and Interoperability" as a more appropriate concept for comparing patient portals. Further, the panelists were asked to propose alternative distinguishing concepts appropriate for comparing patient portals (Q3). Since research question Q3 was an open-ended question, it is not part of Figure 11. Therefore, we present the proposed alternative concepts in Table 3.

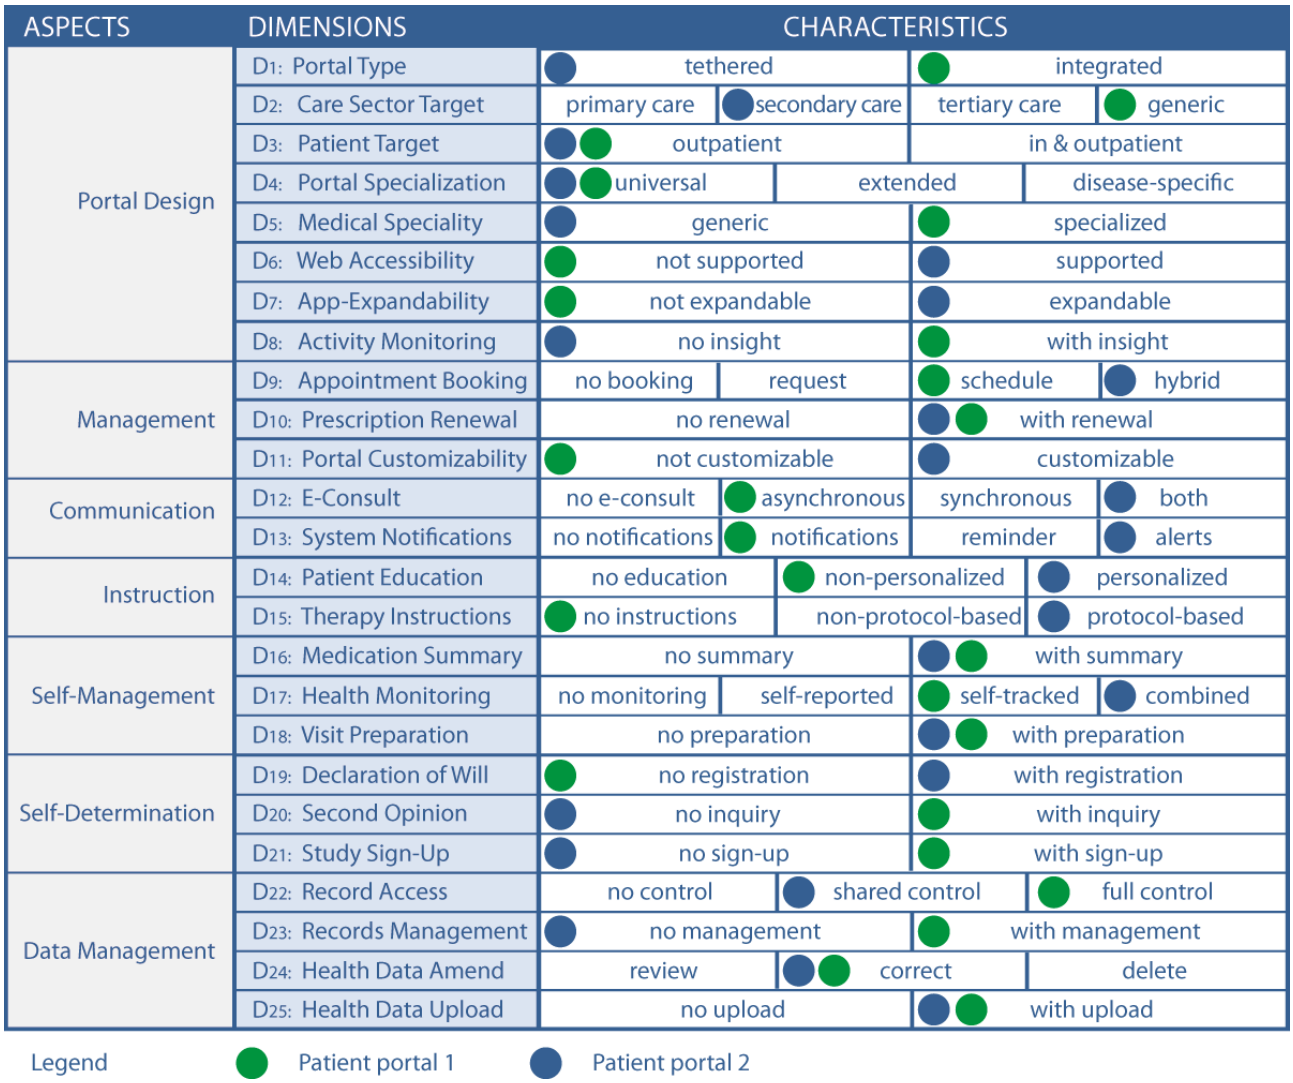
Table 3. Alternative distinguishing concepts proposed in round 4.

Proposed alternative distinguishing concepts (Q3)	Number of panelists proposing an alternative distinguishing concept
Comparison of patient portals based on characteristics promoting "Health Literacy"	1
Comparison of patient portals based on characteristics supporting "Improvement of Health Outcomes"	1
Comparison of patient portals based on characteristics related to "System Architecture, Data Types, and Interoperability"	3
Comparison of patient portals based on characteristics related to "Improvement of Work Efficiency and Cost Savings"	2

We continued interpreting the results presented in Figure 11, which relate to the case study and the assessment of the taxonomy's usefulness. With a median of 8, the panelists considered the form and structure of the final taxonomy to be understandable (Q4). However, 1 panelist who assessed Q4 with a rating of 4 argued that the taxonomy contains too many dimensions while, on the contrary, 1 panelist who assessed Q4 with a rating of 7 proposed refining the taxonomy with additional subcharacteristics to achieve a more accurate comparison of patient portals. All panelists considered the final taxonomy to be appropriate for classifying patient portals, giving ratings between 7 and 9 with a median of 8 (Q5). Further, they considered, with a median of 8, the taxonomy to be appropriate for comparing patient portals (Q6) and appropriate for better understanding of patient portals based on characteristics supporting patient engagement (median 7 for Q7).

Since the TOPCOP taxonomy is also intended to help health information managers select patient portals offered on the market, the panelists were requested to assess its usefulness in this regard. With a median of 8, the group consensus was achieved on both the taxonomy's usefulness for creating an initial requirement profile for patient portals (Q8) and selecting patient portals offered on the market based on characteristics supporting patient engagement (Q9). To sum up, by applying the TOPCOP taxonomy to compare 2 patient portals, we could indeed show that it is useful in contrasting and comparing patient portals from different vendors. In Figure 12, we show an example of a panelist's comparison. By marking each patient portal's characteristics, the differences and similarities of the 2 patient portals could be easily recognized.

Figure 12. Example of a comparison of 2 real patient portals carried out with the TOPCOP taxonomy by marking the respective characteristics.



Additional Findings: The Taxonomy-Evaluation-Delphi Approach (TED)

Evaluation is a challenging, essential, and crucial component of the research process [110,115]. One criterion for assessing artifacts such as taxonomies is by evaluating their usefulness related to their intended purpose [111,116]. However, there are only very few taxonomy-specific evaluation guidelines [117], but multiple evaluation approaches can be applied in health informatics [118-120]. Szopinski et al [49] analyzed the various approaches researchers applied to evaluate taxonomies in the information system's domain and demonstrated that the Delphi technique was hardly used. Analyzing 61 evaluation approaches, they found just 1 study where the Delphi technique was used

to evaluate the taxonomy [49]. In this study, panelists were asked to classify items into a deductively developed taxonomy and assess if the items were classified correctly [121]. In contrast, our modified Delphi approach aims to (1) first improve a conceptually and empirically created taxonomy [32] in multiple rounds by the users and (2) then evaluate the jointly created taxonomy by achieving users' consensus on the usefulness of the taxonomy. Therefore, the health information managers first compared the real-world patient portals with each other by performing a use case and then assessed the taxonomy related to its intended use. In Table 4, we describe the differences between the classic Delphi technique and our approach. The modified Delphi approach we used is, to the best of our knowledge, a new Delphi approach in health informatics for evaluating a taxonomy. We, therefore, call this approach the Taxonomy-Evaluation-Delphi (TED) approach.

Table 4. Comparison of the classic Delphi technique with the Taxonomy-Evaluation-Delphi (TED) approach.

Criteria/Delphi	Classic Delphi	TED approach
Objective	To make forecasts to plan ahead [60,82]	To collect new ideas to improve the taxonomy and to have the usefulness of a conceptually and empirically created taxonomy evaluated by the intended users
Approach	Obtain the most reliable consensus on the estimation of numerical quantity [105]	Obtain the most reliable consensus on the taxonomy's usefulness related to its intended purpose guided by the user's needs
Anonymity	No strict anonymity [60]	Strict anonymity
Consensus metric	Median without dispersion	Median with dispersion based on the RAM[a] method [99]
Panelists	Experts[b] with a deep understanding of the issues of concern [122]	The taxonomy's users with different levels of experience and understanding of the issue of concern
Number of rounds	Guided by the level of group consensus achieved [75,76,94]	Guided by elicitation of new evidence [95] and the level of group consensus achieved [75,76,94]
Procedure	Questionnaires and follow-up interviews [60]	Introductory conversations, online questionnaires, and performing a case study
Outset	Qualitative questions to collect initial knowledge to create/refine the research subject [60]	Quantitative questions to assess dimensions and characteristics, qualitative questions to collect new ideas to improve the taxonomy, and a case study to compare real patient portals as a basis for the taxonomy's evaluation
Result	Agreement on numerical quantities [60]	Improved and evaluated useful taxonomy based on the users' needs

[a]RAM: RAND/UCLA Appropriateness Method.

[b]There is ambiguity regarding the term expert concerning the Delphi technique as there is no unequivocal definition [82,96,123].

Discussion

Principal Findings

With this study, we were able to demonstrate that the need for a taxonomy to compare and classify patient portals exists among health information managers and that the concept of patient engagement to compare and select patient portals is considered appropriate.

Applying a modified Delphi approach, we improved the TOPCOP taxonomy based on the specific needs of the users. The final TOPCOP taxonomy consists of 25 dimensions with 65 characteristics, compared to 20 dimensions and 49 characteristics of the initial TOPCOP taxonomy.

We were able to demonstrate that the health information managers considered the final taxonomy to be useful in classifying and comparing patient portals. Further, we demonstrated that the final TOPCOP taxonomy supports the users in better understanding patient portals and assists them in selecting patient portals offered on the market. We were able to collect 4 alternative ideas on distinguishing concepts to compare patient portals that may serve for future research. As an additional outcome of our study, we created, to the best of our knowledge, a new Delphi approach in health informatics for evaluating a taxonomy.

Comparison With Prior Work

At present, there exists only a limited number of publications related to patient portal taxonomies. Ammenwerth et al [20] developed a taxonomy that aims to distinguish patient portals in a systematic review dealing with their effect on patient empowerment and health-related outcomes. Roehrs et al [124] developed a taxonomy that aims to identify open questions related to personal health record (PHR) data types, features, and architecture types. A PHR provides patients with web-based access to their health data that is under the control of the patient [124], while an EHR typically is under the control of the provider [7,19,22]. Fernández-Alemán et al [125] analyzed free web-based PHRs to identify their features and functions to better understand the PHR market. They created a framework of 4 dimensions intended to support patients in selecting a PHR that best fits their needs [125]. Scheplitz et al [126] created a framework for patient portal functionalities to record all possible functions to identify specification gaps related to software development. Walker et al [8] developed a framework to evaluate how well health information technology can support patient engagement by applying 5 engagement scoring levels.

These attempts only provide part of a potential patient portal taxonomy and are developed for different users and purposes. Since the user determines the intended purpose of a taxonomy

and the purpose guides the development by focusing on a specific phenomenon of interest, different users or purposes may lead to different taxonomies [46,51,55]. Further, a useful taxonomy must yield utility for a specific problem domain [58]. To sum up, the found taxonomies are not suitable to yield utility for health information managers for classifying and comparing patient portals based on characteristics appropriate for promoting patient engagement and understanding the differences and similarities. Therefore, the TOPCOP taxonomy was specifically developed for health information managers to compare and select patient portals offered on the market.

Limitations

Our approach to evaluating the TOPCOP taxonomy has some potential limitations.

First, panelists were selected from Germany, Austria, and Switzerland while the scope of the TOPCOP taxonomy is to support health information managers from any country. Since we were not able to attract participants from other countries, we aimed to assemble the panel as heterogeneously as possible, with different educational backgrounds and work experience, to achieve the best possible understanding of different viewpoints. Further, by selecting participants from 3 countries, we were able to map expertise from 3 different health care systems and integrate experiences with different levels of health care systems' digitization.

The second limitation relates to the panelists' experience with patient portals. Patient portals are not widely used in Germany, Austria, or Switzerland [32], and the experience with patient portals varied from little experience to much experience among the selected health information managers. Including participants with little experience with patient portals may lead to different results than if the participants had a deep understanding. As the taxonomy is not intended to only serve highly experienced but also inexperienced users, a composition of the panel that considers different levels of experience and understanding may increase the variety of viewpoints and the range of user needs related to the taxonomy. This variety may make the taxonomy even more useful [127].

The third limitation relates to the risk that the panelists may misunderstand what to evaluate. During the initial phone calls with potential participants, we noticed that some users assumed that the taxonomy's evaluation related to the suitability of functionalities for patient portals. However, the evaluation related to a dimension's appropriateness for classifying and comparing patient portals based on patient engagement. To ensure that there was no confusion, we explained the difference in individual introductory video conferences. Further, in the survey's introductory part, we outlined the scope of the evaluation and formulated the questionnaire's questions with unambiguous wording.

The fourth limitation is related to the Delphi technique itself. Delphi aims to obtain group consensus on opinions [68], but the achievement of consensus does not necessarily mean that the correct answer was found [84]. Besides, the composition of the panel may influence the research outcome [88,128]. To address these problems, we assembled the panel as heterogeneously as possible to integrate the broadest possible viewpoints and experience with patient portals. The selection of the panel was guided by the goal of achieving the best expertise available.

To determine the achievement of group consensus, we applied the RAND/UCLA concept appropriate for evaluation [101] and widely used to assess the appropriateness of health care services [100,129]. The survey was conducted anonymously to avoid the problem of dominant panelists possibly influencing individual opinions [102]. By applying all these measures, we believe that we were able to reduce any inherent bias in a possible method in the best way.

Practical Implication

The scope of the TOPCOP taxonomy is to serve health information managers with different degrees of knowledge related to patient portals and for various areas of application. The taxonomy may thus serve health information managers as a starting point to better understand the complex domain of patient portals since it describes the various aspects of patient portals. Further, 2 or more patient portals can be described by marking the respective characteristics. This shows the differences and similarities of the patient portals (Figure 12) and so supports the health information managers in classifying and comparing patient portals.

Since each health care institution may have different requirements related to a patient portal, the TOPCOP taxonomy can serve to create a requirement profile. By marking those characteristics in the taxonomy that best meet the needs of a health care institution, health information managers can create an initial requirement profile. This profile can then be used for a targeted search and selection of suitable portals offered on the market.

By providing a standardized terminology to describe various aspects of patient portals independent of clinical setting or country, the TOPCOP taxonomy is also useful for advancing research and evaluation of patient portals. It can, for example, be used to systematically describe patient portals as part of systematic reviews on their impact. The need for a taxonomy in this context has already been stressed in patient portal reviews [40].

Conclusions

The TOPCOP taxonomy aims to support health information managers in comparing and selecting patient portals. By providing a standardized terminology to describe various aspects of patient portals independent of clinical setting or country, the taxonomy will also be useful for advancing research and evaluation of patient portals. Since the health information managers contributed to the taxonomy's development, we were able to improve the taxonomy's quality and usefulness based on the users' needs.

The taxonomy consists of a manageable number of characteristics and dimensions and is therefore flexible for future changes. If needed, new dimensions can be added or removed according to future technological development. Further, due to its flexible form, the users can adjust the taxonomy to their

personal needs. The initial TOPCOP taxonomy was developed by analyzing patient portals from 15 countries worldwide. It was then improved by health information managers with various degrees of patient portal experience from 3 countries with different levels of health care digitization. We, therefore, consider our taxonomy suitable to compare and classify patient portals from any country. The taxonomy may also contribute to the progress of health care digitization as it may enhance human resources capacity and effectiveness.

Abstract

Background: Personal health records (PHRs) are eHealth tools designed to support patient engagement, patient empowerment, and patient- and person-centered care. Endorsement of a PHR by health care providers (HCPs) facilitates patient acceptance. As health care organizations in the Kingdom of Saudi Arabia begin to adopt PHRs, understanding the perspectives of HCPs is important because it can influence patient adoption. However, no studies evaluated HCPs' acceptance of PHRs in the Kingdom of Saudi Arabia.

Objective: The aim of this study was to identify predictors of HCPs' acceptance of PHRs using behavioral intention to recommend as a proxy for adoption.

Methods: This cross-sectional study was conducted among HCPs (physicians, pharmacists, nurses, technicians, others) utilizing a survey based on the Unified Theory of Acceptance and Use of Technology. The main theory constructs of performance expectancy, effort expectancy, social influence, facilitating conditions, and positive attitude were considered independent variables. Behavioral intention was the dependent variable. Age, years of experience, and professional role were tested as moderators between the main theory constructs and behavioral intention using partial least squares structural equation modeling.

Results: Of the 291 participants, 246 were included in the final analysis. Behavioral intention to support PHR use among patients was significantly influenced by performance expectancy (β=.17, *P*=.03) and attitude (β=.61, *P*<.01). No moderating effects were present.

Conclusions: This study identified performance expectancy and attitude as predictors of HCPs' behavioral intention to recommend PHR to patients. To encourage HCPs to endorse PHRs, health care organizations should involve HCPs in the implementation and provide training on the features available as well as expected benefits. Future studies should be conducted in other contexts and include other potential predictors.

Introduction

Overview

A wide range of eHealth technologies has become available over the past 2 decades as countries have introduced eHealth initiatives to support the goals for patient engagement and person-centered care [1]. Legislation around the world advocates for patients to have electronic access to their health information through personal health records (PHRs) [2]. PHRs are an eHealth tool to increase patient engagement and empowerment by allowing individuals to keep track of their personal health information. The Markle Foundation defined PHRs as "an Internet-based set of tools that allows people to access and coordinate their lifelong health information and make appropriate parts of it available to those who need it" [3]. Person-centered care and patient engagement are considered pillars of any high-functioning health care system, and PHRs can contribute to both [4,5]. While various terms have been used interchangeably with PHR in the literature (eg, patient portal, patient web portal, computerized patient portal, patient accessible electronic health record [EHR], tethered PHR, electronic PHR), the broader term of PHR will be used predominantly throughout this paper.

PHR adoption has been associated with a wide range of benefits, including better patient–provider relationships, improvements in patient engagement, better medication adherence, positive health outcomes (eg, blood pressure and glycemic control), and increased organizational efficiencies [6]. As the benefits of PHR adoption are achieved, health care costs potentially decrease as individuals become empowered to take better control of their health and rely less on interactions with the health care system [6]. However, multiple studies have shown low adoption rates [7-9]. Even though the 2009 Health Information Technology for Economic and Clinical Health (HITECH) Act and its Meaningful Use criteria accelerated PHR access in the United States [10], only 15%-30% of patients use PHRs while 90% of health care systems offer them [11]. Outside of the United States, a systematic review showed adoption rates of around 0.13% in the United Kingdom and 5% in other European countries [7].

Various barriers to PHR adoption have been identified [7,9,12,13]. In the systematic review by Niazkhani et al [13], the barriers were characterized as patient demographic factors (eg, age, gender); environment/medical practice (eg, providers' communication about PHRs, physician resistance); technological (eg, perceived PHR usefulness, perceived PHR complexity); and chronic disease characteristics (eg, patients' feeling of control over the disease, number of comorbidities). Health care providers' (HCPs) attitudes are a major contributing factor in patients' adoption of PHRs [14-16]. HCPs play a key role in supporting and engaging patients through their attitudes, behavior, and endorsement of services [17]. Although studies have shown a high level of patient interest in PHRs [5,18-20], there has been a disconnect between interest and uptake. This is partially due to HCPs' reticence toward the acceptance and promotion of their use [5,21,22].

Researchers around the world have studied HCPs' attitudes and perceptions of PHRs. Nazi [22] explored the experiences and perspectives of HCPs (physicians, nurses, and pharmacists) related to patients' use of the My HealtheVet PHR in the United States and found that many HCPs had limited familiarity with the PHR features, contributing to its underutilization [22]. The author identified the following 8 factors to be key in the implementation, adoption, and use of PHRs: (1) showing the relevance of PHRs; (2) increasing the perceived value by focusing on unique services; (3) providing education and training; (4) integrating PHRs into the existing technology; (5) aligning PHR functions with the workflow; (6) offering incentives to individuals or teams; (7) making information accessible; and (8) supporting asynchronous and bidirectional communication.

A study in Finland, which included a wide range of HCPs (eg, nurses, social workers, dentists, physicians, physical therapists, and psychologists), found that the most important factors influencing HCPs' support for a national patient portal were expected positive influences on their work, the usability of the portal, and benefits for the patients [17]. However, only few (13%) respondents felt they had received adequate information about the portal. The authors recommended HCPs be informed about PHR benefits to garner their support. In Canada, Wiljer et al [23] endorsed institutional strategies such as "continuous organizational reassurance," education, and a physician champion to stimulate a paradigm shift to patient-centered care for successful PHR implementation. In a Swedish study of oncology HCPs (nurses and physicians), the authors compared HCPs working in outpatient clinics with those working in primary care units [24]. A greater proportion of HCPs in primary care believed there were benefits of patients using PHRs such as better adherence (50% vs. 35%), greater ability to clarify important information (50% vs. 26%), and improved patient communication (36% vs. 20%) [25].

In the Kingdom of Saudi Arabia, enhancing patient-centered care through patient involvement with technology is an objective of The National Transformation Program, a component of Vision 2030. The Ministry of National Guard Health Affairs (MNGHA)

implemented the MNGHA Care PHR in 2018. No studies have evaluated HCPs' acceptance of PHRs in the country.

The aim of this study was to identify a set of factors that affect the intention to recommend the use of MNGHA Care PHR among HCPs. To promote patient engagement and patient-centered care, a better understanding of how HCPs perceive PHRs is needed.

Theoretical Background

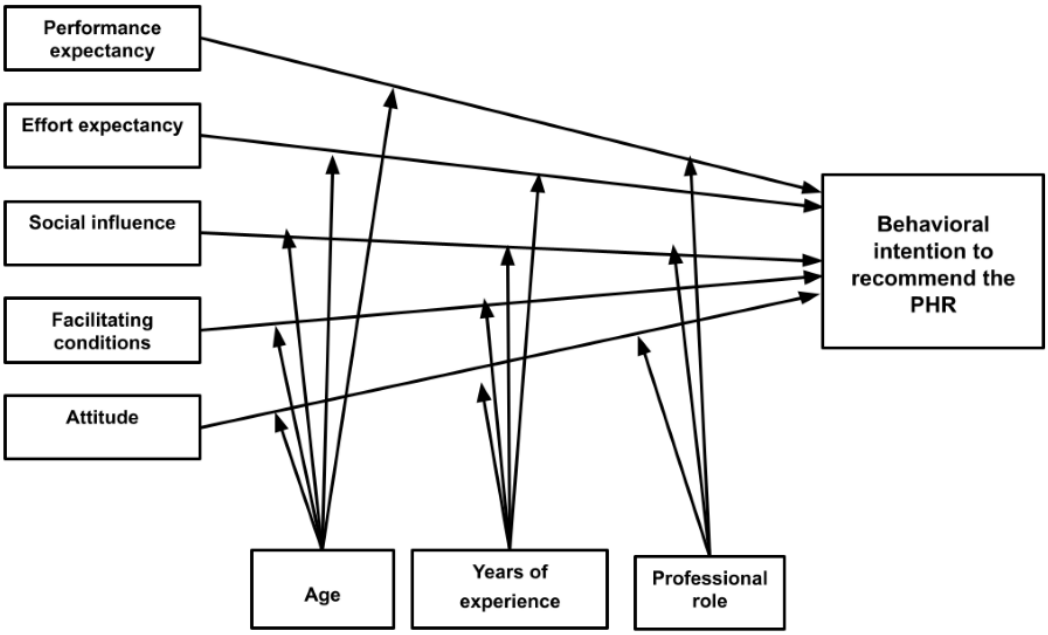
In 2003, Venkatesh et al [26] developed the Unified Theory of Acceptance and Use of Technology (UTAUT) to provide a comprehensive framework to explain acceptance, intention, and usage of information technology in organizations. It is an integration of 8 theories—theory of reasoned action, technology acceptance model (TAM), motivational model, theory of planned behavior (TPB), combined TAM–TPB, model of personal computer utilization, diffusion of innovation theory, and social cognitive theory [26]. The core constructs of performance expectancy, effort expectancy, social influence, and facilitating conditions directly act on behavioral intention and, ultimately, predict the use of the technology. Gender, age, voluntariness, and experience are moderators in the framework. The model explained approximately 77% of the variance in behavioral intention and 52% of the variance in technology use [26]. Since its development, UTAUT has been used to explain technology acceptance in different user groups in a wide range of contexts with various technologies, strengthening the generalizability [27]. UTAUT has also been used broadly in other health care areas, including telemedicine [28,29], electronic medical/health records [30-34], electronic documentation systems [35], picture archiving and communication systems [36], and health information systems [37,38].

Research Model and Hypotheses

Most studies have not examined the full UTAUT with the moderation effects but rather the main effects alone, combined with a subset of the moderators, or with new constructs or mechanisms [39]. Venkatesh et al [39] proposed that future research should use UTAUT as the baseline model to transform the theory from static to dynamic. New endogenous mechanisms or new moderation mechanisms are the most common types of extensions [39]. While UTAUT includes the technological dimension (performance expectancy and effort expectancy) and organizational/environmental dimension (social influence and facilitating conditions), the individual dimension is not included. Nonetheless, individual traits (attitude, personal innovativeness, computer self-efficacy) may significantly predict the acceptance of technology [27,40,41]. Constructs representing individual traits are frequently used as endogenous mechanisms to extend UTAUT.

The research model for this study includes the 4 core UTAUT constructs: performance expectancy, effort expectancy, social influence, and facilitating conditions (Figure 1). The construct of attitude was added as an individual characteristic. Unlike the original UTAUT model, we did not include behavior in the proposed model because we were unable to objectively assess use. Instead, we measured intention to recommend PHR, using it as a proxy for HCPs' acceptance. Behavioral intention is frequently a proxy for actual technology adoption in the literature [42-44].

Figure 1. Adapted UTAUT model. PHR: personal health record; UTAUT: Unified Theory of Acceptance and Use of Technology.



Proposed differences between this model and the original UTAUT model are shown in Table 1. The moderators chosen for this study were age, years of experience, and professional role. Previous literature indicated that age was inversely

associated with eHealth adoption. For example, electronic medical record use was inversely associated with physician age [45]. A potential explanation is that, in the initial stages of technology use, older users are believed to be more influenced by experience, and ease of use is more important [26]. Next, years in practice has been associated with acceptance of eHealth [45]. As the number of years since medical school graduation increased, physicians became less likely to accept eHealth technologies [45]. There have also been differences in eHealth acceptance by professional role [45]. Nonphysicians used advanced EHR features less than physicians, and specialists (eg, obstetrician/gynecologists) were less likely to use an EHR in their practices [45]. Voluntariness of use and gender were dropped as moderators in the proposed model. PHR use is not mandatory; therefore voluntariness of use is not relevant [26]. In the health care context, professional role takes precedence over gender and no differences in acceptance by gender were expected [34].

Table 1. Original Unified Theory of Acceptance and Use of Technology (UTAUT) versus adapted UTAUT for health care providers.

[a]UTAUT: Unified Theory of Acceptance and Use of Technology.

[b]PE: performance expectancy.

[c]BI: behavioral intention.

[d]EE: effort expectancy.

[e]SI: social influence.

[f]Use: actual usage.

[g]FC: facilitating conditions.

[h]ATT: attitude.

This study tested the following hypotheses:

- H1: Performance expectancy positively influences behavioral intention to recommend the PHR
- H2: Effort expectancy positively influences behavioral intention to recommend the PHR
- H3: Social influence positively influences behavioral intention to recommend the PHR
- H4: Facilitating conditions positively influence behavioral intention to recommend the PHR
- H5: Attitude positively influences behavioral intention to recommend the PHR
- H6: Age, years of experience, and professional role selectively moderate the relationships between the main constructs and behavioral intention to recommend the PHR

Methods

Study Design

A cross-sectional study utilizing a survey was conducted at a large, integrated health care system in the Kingdom of Saudi Arabia. The survey was administered to HCPs across the organization to assess acceptance of the PHR. Since 2018, patients have had access to the MNGHA Care PHR, which includes the following features: scheduling appointments, requesting medical reports and prescription refills, viewing radiology reports, checking laboratory results, and receiving vaccination reminders [46]. Additionally, personal health information such as weight, blood pressure, blood sugar, and exercise details can be uploaded. Finally, MNGHA Care contains links to health education information and a self-assessment feature permitting patients to enter information related to pain control, performance status, and quality of life.

Setting and Participants

The study population consisted of HCPs from MNGHA hospitals and primary health care centers in Dammam, Riyadh, Jeddah, Madinah, Al Ahsa, and Qassim, including physicians, dentists, pharmacists, nurses, physical and occupational therapists, optometrists, technicians (pharmacy, medical imaging, medical and pathology laboratory, dental), paramedics, and dietitians.

Instrument and Data Collection

Data were collected using an anonymous self-administered online survey between April and May 2021. The initial version of the survey included 63 items adapted from previously published technology acceptance surveys used in health care in 3 parts [26,47-51]. The first part captured demographic characteristics including age, gender, region, facility type,

profession, specialty area (for physicians), years in profession, years at MNGHA, and nationality. The second part contained 4 general PHR questions: (1) Have you heard of MNGHA Care?; (2) Do you have an MNGHA Care account?; (3) Have you used MNGHA Care yourself?; and (4) Have you recommended patients to use MNGHA? This section also included Likert-scale statements associated with PHR acceptance along with an open-ended question and a checklist. The third section related to acceptance of secure messaging and included Likert-scale statements, an open-ended question, and a checklist.

The instrument was built on QuestionPro [52] and pilot tested with 7 HCPs (2 physicians, 3 pharmacists, and 2 nurses) working within MNGHA. The QuestionPro survey link and a cover letter explaining the purpose of the study were emailed to these 7 HCPs to obtain feedback regarding survey length, clarity, and flow of the questionnaire. After comments were compiled, 12 items were removed, and some were modified to improve clarity and to decrease survey length. The final version of the survey included 51 items and was approved by the institutional review boards at the Virginia Commonwealth University and King Abdullah International Medical Research Center.

For this study, the focus was on parts 1 and 2 of the instrument. However, the open-ended question and checklist from part 2 are not included in this paper. Responses to the PHR acceptance items were provided on a 5-point Likert scale from strongly disagree (1) to strongly agree (5). Acceptance was operationalized as the intention to recommend patients use the PHR using the statement "I will probably recommend patients use MNGHA Care in the future" [49].

Performance expectancy was defined as the degree to which the HCP believes a PHR will be beneficial in the health care delivery process [20]. It was measured with the following 4 items:

1. MNGHA Care is a useful tool to help patients feel more involved in their care [47,53].
2. I believe MNGHA Care helps patients to better manage their health [48].
3. MNGHA Care will increase patient satisfaction with their health care [48].
4. MNGHA Care can improve the quality of patient care [51].

Effort expectancy is the degree of ease associated with use of the PHR [20]. It was measured with the following 3 items:

1. Information in MNGHA Care should be easy for our patients to understand [48,53].
2. I believe most patients have the skills needed to use MNGHA Care [47].
3. I think it is not difficult for our patients to learn to use MNGHA Care [47].

Social influence is the degree to which an individual perceives important others believe the PHR should be used [20]. It was measured with the following 2 items:

1. I believe our patients support the use of MNGHA Care [48].
2. In general, the organization has supported the use of MNGHA Care [26].

Facilitating conditions was defined as the degree to which an individual believes an organizational and technical infrastructure exists to support use of the PHR [20]. It was measured with the following 3 items:

1. I have enough information about MNGHA Care [26,48].
2. There is technical help for patients who use MNGHA Care [26].
3. I know the goals of MNGHA Care [26].

Attitude was defined as positive feelings related to patients using the PHR [54]. It was measured with the following 4 items:

1. MNGHA Care is a valuable tool [26,47].
2. It is a good idea for patients to use MNGHA Care [26,47].
3. MNGHA Care is a positive advancement in this digital age [47].
4. I believe MNGHA Care will be used by many patients [47].

Although behavioral intention and social influence used less than 3 items, partial least squares structural equation modeling (PLS) supports using single-item measures [55] and earlier research using PLS has used less than 3 items for measuring constructs [56,57].

Sampling

A snowball and convenience sampling strategy was used to recruit HCPs from across the organization. HCPs were initially recruited through the hospital's email list in combination with WhatsApp as it is a widely used social media platform for professional communication. They were asked to forward the survey to other HCPs. Follow-up reminders were also sent out. The target sample size for this study was 200 HCPs, which has been considered a fair sample size for statistical analysis with structural equation modeling [58]. To encourage participation, there was a random drawing for twenty five 37.5 Saudi Arabian Riyal (US $10) Amazon gift cards.

Statistical Analyses

Descriptive statistics were analyzed using SPSS version 25 (IBM) [59]. PLS was used to test the research model using SmartPLS version 3.0 [60]. The advantage of PLS is the ability to estimate complex research models without distributional assumptions [61]. Compared with traditional SEM, PLS has greater statistical power, which means that there is a higher likelihood of identifying significant relationships if they are actually present in the population [61]. Furthermore, PLS has been widely used in empirical studies of technology acceptance, including with UTAUT [26,27,34] and with PHR acceptance [50,62]. To test the research model, a measurement model was used to evaluate construct reliability, indicator reliability, convergent validity, and discriminant validity. A structural model was tested after ensuring reliability and validity.

Results

Demographic Characteristics

Overall, 291 HCPs participated in the survey. However, after removing the data for missing values, a usable sample of 246 was used for further analysis. Table 2 presents the demographic characteristics. Most were 40-49 years old (95/246, 38.6%),

female (158/246, 64.2%), non-Saudi (132/246, 53.7%), nurses (106/246, 43.1%), in Riyadh (81/246, 32.9%), over 10 years of experience (167/246, 67.9%) and over 10 years at MNGHA (128/246, 52.0%), and hospital based (228/246, 92.7%).

Table 2. Demographic characteristics (N=246).

Variables	Values, n (%)
Age	
20-29 years	37 (15.0)
30-39 years	77 (31.3)
40-49 years	95 (38.6)
50 years and above	37 (15.0)

[a]MNGHA: Ministry of National Guard Health Affairs.

General PHR Use Characteristics

The majority of HCPs were aware of MNGHA Care (225/246, 91.5%), had an account (213/246, 86.6%), used MNGHA Care (202/246, 82.1%), and recommended it to patients (198/246, 80.5%).

Measurement Model

The measurement model testing results are summarized in Table 3. After removing missing data, the usable sample for hypothesis testing was 246. The variance inflation factor of all items was below the threshold of 5, showing no evidence of multicollinearity. Item loadings were all above 0.40 and in the range of 0.70-0.93. Composite reliability was above the threshold of 0.70, showing good internal consistency. Moreover, the average variance extracted (AVE) of the constructs were greater than 0.50 and in the range of 0.55-0.81, indicating convergent validity.

Discriminant validity was tested using the Fornell–Larcker criterion. The square roots of the corresponding AVE are shown in italics, with each construct's AVE higher than its highest correlation with any other construct (Table 4). Results in Tables 3 and 4 provide evidence of the validity and reliability of the constructs used in the model.

Table 3. Measurement model statistics.

Construct and items	Mean	SD	VIF[a]	Loadings	CR[b]	AVE[c]

Structural Model

The R^2 was used to assess the structural model. Overall, the model explained 70% of the variance in the intention to recommend the PHR among HCPs (Figure 2). Table 5 presents the structural model results, while Table 6 presents the test for moderating effects.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to examine factors that influence HCPs' intention to recommend PHRs to patients in the Kingdom of Saudi Arabia. Prior studies in the country evaluated the challenges in implementing PHRs and identified HCP resistance as a barrier [63,64]. Although HCPs are not the primary users of PHRs, their endorsement can positively influence patient engagement with this technology [12]. While some providers find promoting the PHR to be an additional burden, those providers who present a PHR to their patients as a tool to supplement their care can facilitate patient adoption [9]. Our study found a high level of awareness among HCPs, with 88.2% (217/246) having an account and 82.1% (202/246) recommending patients use the PHR. In our previous study in patients, HCPs and hospital staff were primarily responsible for recommending the PHR in 58.7% of patients who reported using MNGHA Care [18].

Predictors of patient adoption of PHRs may differ from those that affect HCPs to endorse a PHR [7,12]. Therefore, the research model for HCPs was slightly different from the one used for patients [18]. The proposed theoretical model explained 70% of the variance in HCPs' behavioral intention to recommend PHRs to patients. Performance expectancy and attitude were significantly associated with behavioral intention to recommend the PHR. Much of the literature has shown performance expectancy as the strongest predictor of intention to use technology among HCPs [30,38,47]. In patient and consumer studies of PHRs, performance expectancy has also been a positive predictor of adoption [50,65-67]. However, the attitude was the strongest predictor of behavioral intention in our study. Other studies on PHR adoption have also found attitude to be an important predictor [47,51].

Our findings did not support the hypothesis that age, years of experience, and professional role moderate behavioral intention. Several studies have shown that older and more experienced HCPs are more resistant to health information technology and are less comfortable with using technology [35]. Physicians also have been found to be less enthusiastic about the introduction of eHealth services [33]. In our study, most had over 10 years of experience as an HCP (190/289, 65.7%) and more than 10 years in MNGHA (149/289, 51.6%). Furthermore,

while Moll and Cajander [25] found differences in attitudes of HCPs who worked in primary care units compared with outpatient clinics, most HCPs in this study were from the hospital (265/284, 93.3%), limiting the ability to draw comparisons.

Implications for Theory
