We thank Elsevier language editing. This work was supported by the National Natural Science Foundation of China (grant numbers 81771937, 81871455) and partly supported by PKU-Baidu Fund（project of intelligent auxiliary diagnosis using medical images）and Luzhou Science and Technology Bureau Fund (research project of constructing health big data platforms and service systems for combined medical and nursing institutions for elderly care).

Authors' Contributions

The work presented here was carried out in collaboration among all authors. JL conceived and designed the study. JL, XZ, TW, and YL performed the literature review and undertook data acquisition and data analysis. JL drafted the manuscript, and JL and JZ significantly revised the manuscript. ZZ, DS, BT, and JX supervised the review methodology and data interpretation and supplied valuable suggestions for improvement.

Abstract

Background: Evidence suggests that eHealth tools adoption is associated with better health outcomes among various populations. The patterns and factors influencing eHealth adoption among the US Medicaid population remain obscure.

Objective: The objective of this study is to explore patterns of eHealth tools adoption among the Medicaid population and examine factors associated with eHealth adoption.

Methods: Data from the Health Information National Trends Survey from 2017 to 2019 were used to estimate the patterns of eHealth tools adoption among Medicaid and non-Medicaid populations. The effects of Medicaid insurance status and other influencing factors were assessed with logistic regression models.

Results: Compared with the non-Medicaid population, the Medicaid beneficiaries had significantly lower eHealth tools adoption rates for health information management (11.2% to 17.5% less) and mobile health for self-regulation (0.8% to 9.7% less). Conversely, the Medicaid population had significantly higher adoption rates for using social media for health information than their counterpart (8% higher in 2018, *P*=.01; 10.1% higher in 2019, *P*=.01). Internet access diversity, education, and cardiovascular diseases were positively associated with health information management and mobile health for self-regulation among the Medicaid population. Internet access diversity is the only factor significantly associated with social media adoption for acquisition of health information (OR 1.98, 95% CI 1.26-3.11).

Conclusions: Our results suggest digital disparities in eHealth tools adoption between the Medicaid and non-Medicaid populations. Future research should investigate behavioral correlates and develop interventions to improve eHealth adoption and use among underserved communities.

KEYWORDS

Medicaid program; eHealth; internet access; digital divide; health information technology

Introduction

Though progress has been made with improving the “digital divide” in the United States, disparities in internet access remain among underserved populations such as the elderly and individuals in lower socioeconomic classifications [1]. This digital divide can have profound implications on public health because internet access is hypothesized as a “super-determinant”

of health [2]. One primary way by which the internet may improve health outcomes is through the adoption of electronic health (eHealth). eHealth is the application and integration of information and communication technologies (ICT) to improve patients' health care, enable more reliable connections between patients and health providers, and reduce health disparities [3,4].

Standard eHealth tools used by consumers include the utilization of electronic health records (EHRs), health-related social media channels to seek or share health information, and online patient-provider communication (OPPC) channels such as online portals, email, and social media [5]. Recent advancements in information technology (IT) expanded the adoption of eHealth tools to smart devices such as mobile health tools (eg, smartphone apps, wearable devices such as Fitbit, and smartwatches) [6] and virtual assistants (eg, Amazon Alexa) for health information [7].

Findings from the literature suggest that eHealth adoption is associated with health-protective outcomes among individuals. Previous studies purport that health IT adoption among individuals promotes healthy behaviors such as fruit and vegetable intake [8,9]. In addition, patients' use of online eHealth tools to communicate with providers is associated with increased access to health-related information, reduction of health care expenditures, improved emotional support, and enhanced clinical management and self-care [10-12]. Available findings also suggest that social media use among patients is associated with a positive impact on facilitating self-care [13-16]. With respect to prescription medication adherence, the use of eHealth tools to refill prescribed drugs is positively correlated with statin adherence among patients experiencing cardiovascular disease [17,18]. The US Department of Health and Human Services (HHS) recognizes the value that internet access and eHealth tools have on health outcomes, so they developed national goals in Healthy People 2020 to bolster access [19]. The HHS also created the Office of the National Coordinator, which has been advancing consumer eHealth via incentive programs, supporting developers to build eHealth tools, and strengthening trust and protecting privacy in health information technology (HIT) tools [20].

There is an emerging body of literature reporting the factors that influence eHealth tools adoption by consumers. Attributes related to geography, socioeconomic status, and gender are suggested to be associated with the utilization of eHealth tools. Geographic disparities in health IT uses were found between rural and urban residents. Specifically, rural residents were less likely to access online medical records [21]. Higher levels of education contribute to managing electronic personal health information (ePHI) online [22], OPPC [5], and use of health IT for self-regulation [8], which indicates that having a higher education is associated with better eHealth adoption and utilization. Gender has a mixed effect on eHealth tools adoption, depending on the scenario. Men with a risk of cardiovascular disease (CVD) have a higher likelihood of using wearable devices than people without CVD risk. However, there does not appear to be a difference among women [6]. Females had a significantly higher probability of using ePHI online management compared to males [22,23], but there is no significant difference in online patient-provider communication [5,23]. Income level was reported to be positively associated with eHealth sum score, a composite score representative of using technology to access health care [22,24].

Given that this study's focus population are Medicaid enrollees, a primary area of interest is the impact education and income have on individuals qualifying for this service. The inverse relationship between socioeconomic status and adverse health outcomes is well documented in public health literature. In the United States, increased household income is associated with longer life expectancy [25]. Though the causative nature of the relationship between cardiovascular disease and socioeconomic factors is yet to be fully understood, being classified in a lower socioeconomic stratum is linked to poor health outcomes such as hypertension, diabetes mellitus, and coronary heart disease [26]. Due to factors such as these and the unique challenges that financial hardship has on access to medical care [27], the United States government amended provisions in the Social Security Act, which established a health insurance program for impoverished citizens (ie, Medicaid). Findings with respect to internet access [28] parallel those of the underserved in the United States. Moreover, not to imply that being on Medicaid causes poor health outcomes, there is literature suggesting that Medicaid beneficiaries have poorer health outcomes that can lead to long-term cardiovascular complications compared to privately insured individuals [29].

Acknowledging the fact that one must have internet access to utilize eHealth tools and that national efforts should be made in the US to increase accessibility, there remain certain sectors of the population that are limited in this capacity. Nevertheless, given considerations of the potential health benefits that eHealth adoption may confer and current health disparities among Medicaid beneficiaries, a question we propose is “Are eHealth adoption rates among Medicaid beneficiaries comparable to those of people who are not on Medicaid?” To our best knowledge, no study has portrayed a comprehensive picture of eHealth tools adoption among adult Medicaid beneficiaries, an underserved population. Medicare and Medicaid EHR Incentive Programs have been promoting HIT adoption among providers and achieved a significant impact [20]. However, how Medicaid beneficiaries adopt eHealth tools was mostly unknown nationally. Due to the unique characteristics of Medicaid beneficiaries, the factors of eHealth adoption among the adult Medicaid population might also have different effects compared to those for the non-Medicaid community. Analyses from this study are focused on contrasting these characteristics between the two groups to provide research that may lead to health policy implications that positively impact America's underserved.

In this study, we use 3 years of the US Health Information National Trends Survey (HINTS) data to investigate the following research objectives (RO): RO1, comparison of eHealth tools adoption among Medicaid beneficiaries versus non-Medicaid insured individuals from 2017 to 2019; RO2, the association of Medicaid status with eHealth adoption; and RO3, compared to the non-Medicaid population, what factors are associated with increased eHealth adoption among the Medicaid population. To examine these questions, we assessed seven domains of eHealth tools utilization outcomes that covered a variety of HIT tools such as secure internet portals, EHRs,

patient-provider email messaging, mobile health apps, and wearable devices as described in the report [20].

Methods

Data and Sample

We extracted 3 waves of HINTS data that include the calendar years of 2017, 2018, and 2019. HINTS is a two-stage, cross-sectional, and nationally representative survey sampled from noninstitutionalized adults in the United States [30]. Since eHealth tools adoption is mainly dependent on internet access, HINTS 2017-2019 data operationalize internet access by participants who self-reported access to the internet in the following ways: regular dial-up telephone line, broadband, WiFi, and 3G or 4G cellular network. With this criterion, we excluded respondents who reported no internet access and obtained a sample size of 2513 respondents in 2017, 2704 respondents in 2018, and 4264 respondents in 2019.

Dependent Variables

We constructed seven primary outcomes that represented a variety of eHealth tools adoption and utilization behaviors. OPPC [5] is composed of three items: (1) used electronic means to communicate with a doctor, (2) whether tablet or smartphone helped discuss with health care providers, and (3) used online medical record to securely message health care providers. Health information management (HIM) [23] is composed of two items: (1) used electronic means to track health care charges and (2) used electronic means to look up medical test results. Mobile health for self-regulation (MHSR) [8] is composed of three items: (1) have apps related to health and wellness, (2) used electronic medical device to track health, and (3) used tablet or smartphone to help track progress on a health-related goal. Social media for health information (SMHI) [23] is composed of three items: (1) used internet to participate in an online forum or support group, (2) used internet to watch a health-related video on YouTube, and (3) used internet to share health information on social networking sites.

Sharing information [31] is composed of four items: (1) shared health information with a health professional via electronic device or smartphone, (2) electronically sent medical information to another health care provider, (3) electronically sent medical information to a family member or another person, and (4) electronically sent medical information to a service or app that helps manage and store health information. Buy or refill medicine (BRM) [32] is composed of two items: (1) used online medical record to request a refill of medications and (2) used electronic means to buy medicine or vitamins online. Decision making [31] is composed of two items: (1) used online medical record to help you make a decision about how to treat an illness or condition and (2) tablet or smartphone helped make a decision about how to treat an illness or condition. The definitions of each outcome are shown in Multimedia Appendix 1. The composite scores were constructed by summing their dichotomous items with responses “No” and “Yes” converted to 0 and 1, respectively, except that scores higher than 1 in SMHI were recoded to 2 due to sparsity of participants who share information via multiple channels.

Key Independent Variables and Covariates

Medicaid status is determined by participants' self-reported Medicaid insurance plan. Internet access diversity score was measured by whether participants had only one channel or multiple channels to access the internet. CVD risk was defined by having at least one of three conditions: hypertension, a heart condition, or diabetes. Depression was defined by whether respondents had been told they have depression or an anxiety disorder by a doctor or health professional. Demographic and socioeconomic variables included gender, age, race or ethnicity, education, residency, US Census region, and annual household income (Multimedia Appendix 2).

Statistical Analysis

We used descriptive statistics (frequencies and proportions) to demonstrate sample characteristics and eHealth tools adoption distribution patterns of HINTS data from 2017 to 2019. Pearson chi-square tests were performed to examine the association between Medicaid insurance status and other variables, including demographic, socioeconomic status, and eHealth outcomes. We considered a *P* value of less than or equal to .05 to be statistically significant. To answer RO2, we conducted ordinal logistic regressions for each of the seven eHealth outcomes using Medicaid status as the factor of primary interest. Base models included survey year as the only covariate, while adjusted models included the variables of age group, gender, education, Census region, residency, income, and internet access diversity. To answer RO3 and provide a comparison of detailed factor profiles in each population, we conducted ordinal logistic regression for each outcome within the Medicaid sample and non-Medicaid sample independently. In addition to demographic and socioeconomic factors, we included cardiovascular disease, depression, and internet access diversity as independent variables in the models. All statistical analyses except frequencies were conducted through jackknife weight procedures to represent national population-level estimates and obtain more precise confidence intervals. All analyses were performed in SAS 9.4 (SAS Institute).

Results

Table 1 presents the sample characteristics of both Medicaid and non-Medicaid population from 2017 to 2019. Compared to the people who were not enrolled in the Medicaid program, the Medicaid population is more likely to be young, belong to an underrepresented minority (Hispanic and non-Hispanic Black), and have low education and low family income. Generally, there is no significant difference in the distributions of residency between Medicaid and non-Medicaid populations. Interestingly, the proportions of people who have multiple ways to access the internet were not significantly different between Medicaid (68.6%) and non-Medicaid participants (67.6%), though the proportion of Medicaid beneficiaries who have no internet access at all was significantly higher than that of the non-Medicaid population (Multimedia Appendix 3).

Table 1. Demographic characteristics of sample from 3 iterations, 2017-2019, by Medicaid insurance status.

[a]Chi-square tests were conducted to obtain *P* values adjusted for sampling weights.

[b]Percentages were weighted by jackknife weighting methods to represent US population-level estimates.

[c]Not available.

We investigated eHealth tools adoption rates among Medicaid and non-Medicaid populations. Table 2 shows the frequencies and weighted proportions of respondents by eHealth tools adoption scores. The higher scores suggest a better adoption and utilization of eHealth tools. Chi-square test results suggested no statistically significant disparity between Medicaid and

non-Medicaid respondents for sharing information, decision making, OPPC, or BRM, with exceptions for BRM in 2017 and OPPC in 2018. In the Medicaid population, the respondents were densely distributed in the score "0" of HIM with a range of 51.1% to 64.9%, which was 11.2% to 17.5% higher than that of the non-Medicaid population (P<.001). In 2018, 42.1% of Medicaid respondents had a 0 score for MHSR, which is 7.7% higher than non-Medicaid (P=.02). However, in 2019, the proportion of Medicaid respondents who reported a MHSR score of 0 dropped to 27.9%, only 0.8% higher than that of non-Medicaid. The proportions of Medicaid respondents were 7.8% and 9.4% less in scores 2 and 3 for MHSR compared to those of the non-Medicaid population (P<.001). Contrary to HIM and MHSR, Medicaid respondents had significantly higher SMHI adoption rates than non-Medicaid respondents in 2018 (8% higher, P=.01) and 2019 (10.1% higher, P=.01).

[f]DM: decision making.

[g]HIM: health information management.

[h]BRM: buy or refill medicine.

[i]MHSR: mobile health for self-regulation.

[j]SMHI: social media for health information.

[k]OPPC: online patient-provider communication.

Multimedia Appendix 4 shows that the effects of Medicaid status on BRM and OPPC were attenuated after adjusting multiple covariates. Consistent with Table 2, Medicaid beneficiaries were significantly less likely to use eHealth tools for HIM (OR 0.64, 95% CI 0.50-0.82) and MHSR (OR 0.63, 95% CI 0.53-0.76), but more likely for SMHI (OR 1.35, 95% CI 1.12-1.63). To address RO3, we further assessed the factor effects such as demographic, socioeconomic, health, and internet access on these three eHealth categories in the Medicaid and non-Medicaid populations independently. Table 3 and 4 shows that in the non-Medicaid population, HIM and MHSR were more likely to be adopted by individuals who were female, were well educated, had high-income households, and had more than one source of internet access. Having cardiovascular disease or depression was also significantly associated with HIM and MHSR. Among the non-Medicaid respondents, the SMHI was significantly associated with factors such as gender, race, age, depression, and internet access diversity (Table 5). However, there were fewer factors significantly associated with eHealth tools adoption among the Medicaid respondents. Education (P=.03), CVD risk (OR 2.16, 95% CI 1.18-3.93; P=.01), depression (OR 1.67, 95% CI 1.07-2.6; P=.02), and internet access diversity (OR 2.87, 95% CI 1.55-5.30; P=.001) were factors significantly associated with HIM (Table 3). Education (P=.02), CVD risk (OR 2.55, 95% CI 1.52-4.3; P<.001) and internet access diversity (OR 2.72, 95% CI 1.69-4.38; P<.001) were factors significantly associated with MHSR (Table 4). Internet access (OR 1.98, 95% CI 1.26-3.11; P=.004) was the only significant factor associated with SMHI (Table 5).

Discussion

According to Ambrosi and colleagues [33], the digital divide can be operationalized in multiple forms. The most common way of defining the digital divide relates to the inequalities of ICT access, for example, complete lack of access to the internet or a smart device. Findings from this study suggest that the Medicaid population is at higher odds of having no access to the internet when compared to the non-Medicaid population. Though worthy of attention and immediate addressing, the elimination or significant reduction of this type of disparity will be an undertaking that will likely not happen in the near future. The second form of the digital divide is caused by different use patterns among individuals who already have access to ICT. An example is people who only use the basic functions (talk and texting) within a smartphone that has many more available features. The key objectives of our study focused on the latter scenario and aimed at assessing the profiles and patterns of digital inequality between the Medicaid and the non-Medicaid populations with some form of internet access on a national level in the United States. We found that the Medicaid population had lower adoption on HIM and MHSR than the non-Medicaid population, which is consistent with a previous study about the effect of socioeconomic status [34]. According to Venkatesh and colleagues' unified theory of acceptance and use of technology (UTAUT), effort expectancy (degree of ease of use of technology) and social influence are important direct factors that are positively associated with the intention and behavior of consumers' technology adoption [35]. Underserved populations like that of Medicaid beneficiaries may perceive eHealth tools to be a more challenging resource to adopt due to lower education as well as eHealth literacy, the ability to access, process, understand, and use the features of the technology [36]. Social influence may also play a critical role in limiting Medicaid participants' use of smart devices to full capacity, though the effect of social influence has not been widely tested among the Medicaid population. Interestingly, we found that the Medicaid population was more likely to use social media to engage in health-related activities. The barriers for underserved communities to regularly access medical resources may push Medicaid participants to use social media as a cost-effective alternative source of medical information. This increased adoption of social media use among the Medicaid population could be a potential double-edged sword. On the one hand, the low quality of medical information on social media may mislead patients to avoid seeking treatment from regular health professionals. Conversely, well-designed social media interventions that specifically target underserved populations could be developed to promote eHealth technology adoption and eHealth literacy through social media. The challenge of this approach is that current social media artificial intelligence and machine learning algorithms may not have the ability to differentiate social media posts that are beneficial and detrimental to users' understanding of health. Therefore, increased exposure to social media interventions may also increase exposure to misleading social media posts.

Several studies have examined the predictors of eHealth tasks or tools adoption among the general population [8,34,37]. Being female, being younger, and having higher income was consistently associated with higher eHealth adoption in general populations, which is consistent with our results based on the non-Medicaid population. However, these factors were not significantly associated with any of the three major eHealth categories: HIM, MHSR, and SMHI. The attenuation of these factor effects in underserved populations was also reported in several studies [38,39], but none has compared the factor effects of underserved populations to their counterparts, nor have they explained the reason. It is possible that the use of eHealth tools among underserved populations like Medicaid beneficiaries was determined by other key factors (eg, effort expectancy and social influence), of which the levels do not vary much across subgroups of gender, age, or income level. Unlike income, attained education was significantly associated with both HIM and MHSR, and the effects were not monotonically increasing with higher education level. Therefore, education may not be the factor directly influencing eHealth tools adoption among this population, or the effect of education was confounded by hidden factors. Medicaid beneficiaries with CVD risk were significantly more likely to engage in HIT and use an eHealth app for health benefits. On the other hand, Medicaid participants with depression demonstrated significantly higher odds only in HIM. The adoption of MHSR involves more self-discipline and motivation, which might be a hurdle for depressive Medicaid respondents to use their smart devices for health-related purposes. This also leaves room for developing interventions or tools to facilitate depressive patients to monitor their mental health and improve their adoption of eHealth tools to monitor their physical health as well. Finally, findings suggest that

enhancing internet access diversity was significantly associated with improving HIM, MHSR, and SMHI among both Medicaid and non-Medicaid groups. The odds ratios of shifting internet access from a single source to multiple sources were almost doubled among the Medicaid population compared to their counterparts. Internet access diversity, aligned with infrastructure and supports, may determine the facilitating conditions which directly influence the technology use behaviors based on UTAUT [35]. Thus, providing underserved populations with more sources to access the internet or smart devices (eg, cheap 4G data plan, free public WiFi hot spot, affordable Android smartphone) could be a cost-effective means to improve their eHealth adoption and use. In fact, the Lifeline program, which has been providing discounts on phone service for low-income consumers starting in 1985, has adopted broadband (3G) as a support service since 2016 [40]. As such, increasing awareness of the Federal Communications Commission's Lifeline program is an immediate short-term goal to increase access to smartphones and broadband internet for families eligible for Medicaid.

We believe our study has several strengths. To our best knowledge, this study is the first to investigate eHealth technology and tools adoption among underserved populations, especially the Medicaid enrollees, at the national level in the United States. Therefore, sample selection bias was greatly reduced compared to studies that recruited a small sample size of local participants [38,39]. Additionally, we assessed eHealth technology and tools adoption using seven composite scores constructed from 19 items, which provides a comprehensive picture and reduces measurement errors from using single items. Finally, providing increased attention on this topic will hopefully open a new area of research that may have profound effects on the nation's health and economy. Given the above important contributions to the literature, we acknowledge the limitations of the study. Like other studies using HINTS data sets, our study is based on cross-sectional surveys. Therefore, it could not account for all confounding variables or evaluate causal relationships. The questionnaires designed by HINTS were not suitable to investigate the psychometric constructs that impact eHealth technology adoption directly. In addition, the HINTS data are based on self-reported data from respondents. We are unable to confirm if their answers to the eHealth-related questions were without errors. We found a small portion of respondents reported never accessing the internet, but they also reported a positive response to eHealth technology utilization, though we have excluded those respondents to eliminate spuriousness.

To effectively reduce the disparities in eHealth tools adoption between underserved populations and their counterparts, certain factors must be taken into account when developing interventions or infrastructures for Medicaid beneficiaries. Our study offers initial insights into the factors among the nation’s underserved population. Nevertheless, the fundamental drivers of eHealth use among the Medicaid population may not be fully revealed yet. In addition to confirming this study's findings, future studies should take our investigation to a more granular level and examine the intention and behaviors of eHealth tools utilization among underserved populations under the framework of existing models such as UTAUT. Additionally, the effects of interventions aimed at improving eHealth utilization (eg, improving internet access diversity) could be studied more closely to further validate our findings.

Abstract

Background: Social media provides the potential to engage a wide audience about scientific research, including the public. However, little empirical research exists to guide health scientists regarding what works and how to optimize impact. We examined the social media campaign #datasaveslives established in 2014 to highlight positive examples of the use and reuse of health data in research.

Objective: This study aims to examine how the #datasaveslives hashtag was used on social media, how often, and by whom; thus, we aim to provide insights into the impact of a major social media campaign in the UK health informatics research community and further afield.

Methods: We analyzed all publicly available posts (tweets) that included the hashtag #datasaveslives (N=13,895) on the microblogging platform Twitter between September 1, 2016, and August 31, 2017. Using a combination of qualitative and quantitative analyses, we determined the frequency and purpose of tweets. Social network analysis was used to analyze and visualize tweet sharing (*retweet*) networks among hashtag users.

Results: Overall, we found 4175 original posts and 9720 retweets featuring #datasaveslives by 3649 unique Twitter users. In total, 66.01% (2756/4175) of the original posts were retweeted at least once. Higher frequencies of tweets were observed during the weeks of prominent policy publications, popular conferences, and public engagement events. Cluster analysis based on retweet relationships revealed an interconnected series of groups of #datasaveslives users in academia, health services and policy, and charities and patient networks. Thematic analysis of tweets showed that #datasaveslives was used for a broader range of purposes than indexing information, including event reporting, encouraging participation and action, and showing personal support for data sharing.

Conclusions: This study shows that a hashtag-based social media campaign was effective in encouraging a wide audience of stakeholders to disseminate positive examples of health research. Furthermore, the findings suggest that the campaign supported community building and bridging practices within and between the interdisciplinary sectors related to the field of health data science and encouraged individuals to demonstrate personal support for sharing health data.

KEYWORDS

social media; public engagement; social network analysis; medical research

Introduction

Social Media Use by Academics

Social media platforms such as Twitter, LinkedIn, and Facebook have changed the way scientists interact with others, both socially and professionally. Although the specifics may vary between individuals, platforms, and scientific disciplines [1], common scholarly purposes for using social media among academics include discovering peers and enhancing collaboration, sharing links or citations to their own or others work, communicating the proceedings of conferences and meetings, raising their own profiles, engaging in discussions and keeping up to date with scholarly work, answering questions and solving problems, and discovering job opportunities [2-13].

There is also a growing interest in using social media to engage a wider audience about scientific research, including the public [6,14,15]. A recent scoping review of health scientists' strategies by Fontaine et al [16] identified 9 types of science communication strategies used by health scientists, directed at areas such as content, engagement, intention, presentation, and statistics. However, the same review concluded that empirical studies in this field were lacking, representing a missed opportunity to understand how to optimize science communication strategies.

A Social Media Campaign for Health Informatics Research: #datasaveslives

The social media campaign #datasaveslives [17] was established in 2014 by the Northern England branch of the Farr Institute for Health Informatics Research, a publicly funded, UK-wide research collaboration involving academic institutions and health partners. The campaign started with a simple goal: to promote the positive use of data in health research on social media. A select group of academic organizations belonging to, or affiliated with, the Farr Institute subsequently formally adopted #datasaveslives as part of their communications and stakeholder engagement strategies [18]. These supporters then encouraged a wider audience of people who supported health data research to use the hashtag #datasaveslives on social media sites (primarily Twitter) to index and share examples that demonstrate how health data from patient records and other sources could be used to create public health benefits. The second objective is to spark interest and dialog about using health data for research purposes among wider audiences, including patients, members of the public, health care professionals, and policy makers.

About Twitter

Twitter is a popular microblogging social media platform founded in 2006 [19]. It allows users to post short messages (previously 140 characters, more recently extended to 280) known as *tweets*, which may also include URL links, multimedia content (eg, images or videos) and/or references to other users (signified using the @ symbol, plus a username). Hashtags may also be used by assigning the # character to a term of their choice; this is a useful way of indexing and searching for tweets on a similar topic. Users can view and engage with tweets in a number of ways, including liking, replying to, and sharing (*retweeting*) others' posts. They can also follow others to *subscribe* to see their tweets. Tweets are public by default, although users can change their settings at any time to restrict their visibility to their Twitter followers. Users can also choose to write a short description about themselves (known as a *bio*) and add their location.

Study Aim

The aim of this study is to examine how the #datasaveslives hashtag has been used on Twitter in the context of the use of data in health research and by whom. The analysis will determine how often the hashtag has been used and shared and examine the content posted alongside the hashtag to determine the range of purposes for its use. This will provide insights into the strategic use of social media campaigns by academics and explore their potential for encouraging wider dialog within and between scientific communities and broader audiences.

Specifically, the following objectives (and research questions in brackets) were defined:

1. Determine the frequency of tweets and retweets featuring the hashtag #datasaveslives, including the most frequently shared tweets (how often was #datasaveslives tweeted?).
2. Characterize the range of stakeholder groups that use and share #datasaveslives and visualize retweet relationships between users (who tweets #datasaveslives and how were tweets shared between users?).
3. Identify and explore the different purposes that people used #datasaveslives for when tweeting (what did people use #datasaveslives to tweet about?).

Methods

Design and Objectives

We used a mixed methods design, combining elements of descriptive statistics, social network analysis, and qualitative research. This approach, which used a combination of qualitative and quantitative analysis, was adopted to allow a richer analysis of Twitter posts, over and above what could be achieved by available social media analytics tools.

Data Set, Variables, and Definitions

The data set comprised all publicly available tweets (N=13,895) that included the hashtag #datasaveslives posted between September 1, 2016, and August 31, 2017. This year was selected because it was perceived to represent a peak in campaign activity, thereby providing a sufficiently large and diverse sample of tweets for analysis. These were procured from Twitter's historical data service in January 2018.

The following variables pertaining to the tweet text and metadata associated with the tweet were retained for the analysis: tweet ID, tweet text (*body*), a list of hashtags included in tweets, number of retweets, and date posted (recoded into day, month, and year).

Twitter classifies each tweet as either an original *post* or a *share*. Posts were defined as tweets where the user either created a new tweet with their own original text or where a user shared another user's tweet and added new text to accompany it (*quote*

tweets). Shares (more commonly referred to as *retweets*) referred to cases when the user had shared a post created by another user with their followers without changing or adding new text. In all cases, tweets were only included if they referenced #datasaveslives somewhere in the body of the tweet, whether in the shared text or the text newly added by the user.

Where available, we also retained the following data pertaining to individual users who posted tweets, specifically: username, bio (optional self-written text about the user in 160 characters or less), friend count (users they had elected to follow), and follower count (users who had elected to follow them).

For analysis purposes, we defined official supporters as the 6 user accounts belonging to the sites of the Farr Institute and the Connected Health Cities (CHC) programme, all of whom adopted #datasaveslives as part of their formal strategies (@FarrInstitute, @CHCNorth, @HeRC_Farr, @FarrScotland, @FarrCIPHER, and @FarrLondon).

Data Preprocessing and Analysis

Historical Twitter data were preprocessed using Python (version 3.7.2). Briefly, the *pandas* Python library was used to convert data from a JavaScript Object Notation (JSON) format into a two-dimensional data frame for cleaning, recoding, and validation tasks in preparation for data analysis.

Statistical analyses were completed using RStudio (version 1.1.456). To address objective 1, descriptive statistics were used to determine weekly and monthly frequencies of tweets featuring #datasaveslives and percentages of the most commonly shared tweets (retweets). Pearson R was used to determine the associations between weekly counts for posts and retweets. For the most commonly shared retweets, the total potential reach was estimated by summing the follower count for every user who shared the tweet.

To address objective 2, users were grouped according to tweet frequency, and their characteristics were analyzed in terms of median counts for followers, friends, and posts. Gephi (version 0.9.2), a social network analysis tool, was used to analyze and visualize relationships between users of #datasaveslives. We focused on the retweet network as a way of understanding the sharing practices and underlying network structures between users. Statistics about the overall network and individual vertices were generated based on who retweeted whom, including clustering coefficients and measures of centrality. These were used to produce an undirected network graph visualizing the connections (edges) between users (vertices). To detect communities and calculate modularity, we used the Louvain method for community detection, which has been shown to outperform similar modularity methods in terms of speed and efficiency [20]. The graph was laid out using the Force Atlas layout algorithm. Common words used in user bios and tweet texts were also identified for each cluster (excluding commonly used words, eg, *and*, *or*, *views*).

To address objective 3, thematic analysis [21] was used to analyze the textual content of tweets featuring #datasaveslives qualitatively. Owing to the large size of the data set, it was not deemed practical or necessary to read and code all tweets. All original posts accompanying the hashtag were imported into NVivo 12 [22] for analysis. After reading a convenience sample of tweets (the first 200 tweets in date order), we defined an initial coding structure, covering the range of purposes tweets appeared to be used for. All original posts were sorted using the random number generator function in Microsoft Excel and then reviewed, coded, recoded, and collated into key themes in an iterative fashion by LH. Tweets were coded until saturation occurred, that is, until no substantially new themes were found. Approximately 1000 tweets were manually reviewed in total. The final set of themes was decided upon following a discussion between the authors.

Ethics and Governance

Data were collected and processed in line with Twitter's terms and conditions. As this information was nonsensitive and already in the public domain, formal ethical approvals were not required to complete the project.

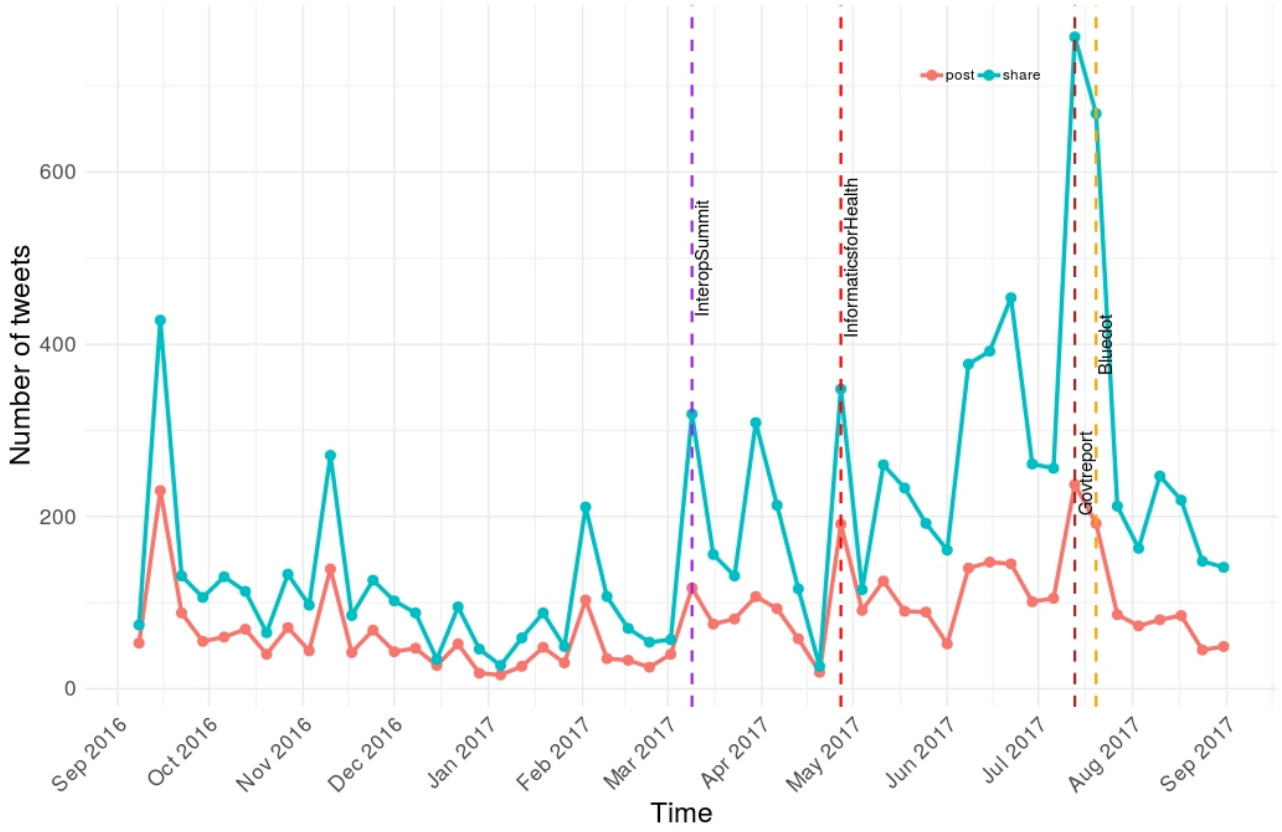
On advice from our university's research ethics office and in line with wider social media research guidelines [23], we took the following measures to protect Twitter users' privacy and confidentiality expectations: first, only tweets of users with accounts set to *public* were included in the analysis. Second, we gained permission to quote verbatim posts by individual users who were not clearly part of identifiable public groups or bodies or tweeting in an official capacity (eg, government organizations, university departments, heads of department). During the course of identifying popular tweets, we discovered that some posts or accounts had subsequently been deleted by users following the time of data collection; in such cases, tweets were not quoted although they were retained for the purposes of aggregated quantitative and qualitative analyses.

Results

How Often Was #datasaveslives Tweeted?

During the observation period, there were 13,895 tweets containing #datasaveslives (Figure 1). Overall, 30.05% (4175/13,895) were original posts and 69.95% (9720/13,895) were retweets. Among the original posts, 34.80% (1453/4175) were quote tweets. The mean number of total weekly tweets was 267.21 (SD 200.06), although this varied substantially (range 43-994). There was a strong positive correlation between weekly counts for posts and retweets (r=0.927, df=50; P<.001).

Figure 1. Tweet frequency over time by tweet type.



The highest number of tweets was observed during the week commencing July 6, 2017 (237 posts and 757 retweets), during which the UK government published a response [24] to a national review of security, consent processes, and opt-outs relevant to health data [25]. During the same week, there were also tweets about public engagement activities at high-profile cultural festivals in Cheshire (Bluedot Festival, England) and Edinburgh (Edinburgh Festival Fringe, Scotland). There were also high frequencies of tweets from official supporters during the week beginning April 20 (week 34), when there was a health informatics conference (Informatics for Health) hosted in Manchester in England.

Overall, 6 of the 10 most frequently shared tweets were from accounts associated with organizations, networks, or events (Table 1); only 1 originated from the account of an official supporter (@HerC_Farr). There was a modest, though significant, positive correlation between retweet count and follower count (r=0.214, df=4173; P<.001).

Table 1. The top 10 most frequently shared tweets.

[a]As of August 31, 2017.

[b]Group numbers cross-referenced with Table 3.

[c]Calculated as the sum of followers across all users who retweeted the original post. This method overestimates the total potential reach as it cannot account for the overlap of followers between users, and in any case, it is unlikely that all followers would view posts.

[d]N/A: not available.

Who Tweets #datasaveslives?

There were 3649 unique Twitter users who posted or shared content, including #datasaveslives (Table 2). Approximately 1 in 10 (1573/13895, 11.32%) of all #datasaveslives tweets, and 1 in 6 of posts that used original text (421/2722, 15.46%), were by official supporters. The tweet type was significantly associated with an official supporter status; official supporters used posts with original text relatively more often than others (26.76% vs 18.67%; χ_1^2=57.5; *P*<.001).

Among the 3649 users who posted or shared #datasaveslives at any time during the time window observed, 64.87% (2367/3649) did so only once (range 1-455). Users who tweeted 10 times or more accounted for just 4.88% (178/3649) of users, yet produced 54.33% (7549/13,895) of tweets; 16 users tweeted 100 times or more. This included 5 of the 6 official supporters, plus the accounts of affiliated organizations and projects. A total of 13 of the 16 accounts were associated with groups. In addition to official supporter organizations, these included health charities, professional membership organizations, event organizers, and projects. Notably, one of these frequent tweeters was a patient advocate and campaigner (n=102 tweets).

Table 2. Tweet frequency by tweet type and user type.

Tweet type	Tweet frequency by user type, n (%)		Total tweets (n=13,895), n (%)	Total unique users (n=3649), n (%)[a]
	Official supporter (n=1573)	Other (n=12,322)		
Original posts				
Original text	421 (26.76)	2301 (18.67)	2722 (19.60)	613 (16.80)
Quote	243 (15.44)	1210 (9.82)	1453 (10.46)	551 (15.10)
Shares				
Retweet	909 (57.79)	8811 (71.51)	9720 (69.95)	3157 (86.52)

[a]Owing to the overlap between users who use posts and shares, this column does not add up to 100%.

How Were Tweets Shared Between Users?

We visualized retweet relationships between Twitter users as an undirected network graph (Figure 2). Retweet connections were created when a user shared content by another user that included the hashtag. The analysis of retweets (n=9720) generated a network of 3392 users and 5749 unique connections between pairs of users (average degree=3.39; average path length=4.02; diameter=12).

Figure 2. Retweet network graph showing relationships between users who tweet and retweet #datasaveslives.

Cluster analysis using the Louvain method of community detection revealed 98 relatively well-connected groups (modularity=0.684). These were arranged in *hub and spoke* structures, with smaller numbers of relatively more tightly connected users at the center of each group. The 5 largest clusters or groups contained 60.70% (2059/3392) of users in

the network; 69 groups were very small, containing 5 or fewer users.

We examined the size, users, and words used in user bios for the largest 10 groups yielded by the cluster analysis (Table 3). The largest 2 groups (1 and 2) included all 6 official supporter accounts and were closely connected. Groups 1 and 2 shared similar vocabulary, both for tweets and user bios (eg, *health*, *research*, and *university*).

Table 3. Users in the #datasaveslives retweet user network by group.

Group	Users, n (%)	Most influential organizational user accounts (eigenvector centrality)[a]	Top 5 words used in user bios (n)	Top 5 words used in user tweets (n)

[a]Maximum of 3 users in the top 10 accounts.

[b]NHS: National Health Service.

Closer examination indicated some distinctions between groups 1 and 2. Group 1 users were more strongly affiliated with Northern England (particularly Manchester), whereas group 2 users frequently referenced places, organizations, and events located in Scotland. Group 1 was closely connected with group 5, which had a distinct topic focus on cancer data. Group 2 showed a stronger connection with group 6, which was associated with major medical records information technology (IT) projects based in the North East of England. Group 6 was, in turn, connected with group 4, populated by National Health Service (NHS) staff and delegates of a major health care IT conference (indicated by *#interopsummit*).

Group 3 indicated connections with both groups 1 and 2, and included users with connections to the NHS, health care policy, and major charities. Commonly used words in this group suggested a more applied focus among users (eg, *policy* and *care*). Group 3 was also loosely connected to group 8, distinctly notable for comprising users who self-identified as patients, carers, and advocates.

What Did People Use #datasaveslives to Tweet About?

The thematic analysis of tweet content yielded 4 key ways in which #datasaveslives was used: to share information and updates, for reporting and discussion at events, to show support for data sharing, and as a call to action. Although themes have been described separately for clarity, in practice there was substantial overlap, with the same tweets often being classified under multiple themes (Table 4).

Table 4. Examples of tweets with overlapping themes.

[b]Data are applicable to themes.

[c]N/A: not applicable.

To Index and Share Information

The most common types of posts featuring #datasaveslives, particularly by official supporters and members of groups 1, 2, and 3 (Figure 2 and Table 3), were tweets sharing information about users' own projects, research findings, and news. These included announcements about new projects or funding, updates on progress, and sharing results from research. Although some tweets directly referenced peer-reviewed scientific literature by linking to journal publications, more often they were linked to less formal sources, including project websites, case studies, blogs, and videos:

> *Thanks to data we know that the smoking ban in Scotland has been a success [link to case study on website] #datasaveslives* [@FarrScotland, Group 2]

> *Highlights from Informatics for Health 2017 by @HeRC_Farr: Watch the video at [website link] #IforH2017 #datasaveslives* [@FarrInstitute, Group 2]

Twitter users also used #datasaveslives to highlight the work of others and signpost wider news and policy developments in areas relevant to health data science. These included news stories published by universities, health service organizations, professional bodies, and reports in popular media, including the local and national press and television and radio programs:

> *BBC News - Artificial intelligence predicts when heart will fail [link to news report] #DataSavesLives* [@EmpowerD4H, Group 13]

In the vast majority of cases, references for data sharing were positive or at least neutral; occasionally, however, there was evidence of more critical commentary about certain uses of health data:

> *Check out how @ukhomeoffice using health information is denying patients healthcare [link to news story] #DataSavesLives until it doesn't* [@einsteinsattic, Group 2]

Among tweets in this category, hyperlinks to other websites were very common; indeed, a subgroup of tweets were identified that included a hyperlink and the hashtag, indicating the use of #datasaveslives as purely an index function. This was mainly used by official supporters.

For Reporting and Discussion at Events

Frequently, #datasaveslives was used to tag tweets related to events, including conferences, meetings, and public engagement activities. Tweets included the promotion of forthcoming events, discussion of past events, or even live reporting and commentary about events, talks, and discussions that were currently underway. In the case of larger events, such as conferences, #datasaveslives frequently appeared alongside other official event hashtags (eg, #iforh2017, #interopsummit). Images of slides, presenters, delegates, visitors, and stalls were commonly included alongside the text:

> *Looking forward to meetings workshops and exciting stuff at @ExpoNHS tmrw #datasaveslives#nhs* [@ruthlady, Group 1]

To Show Support for Data Sharing

One further use of #datasaveslives was to demonstrate personal support for sharing health data in general or backing the #datasaveslives campaign itself. A total of 26 users included the text #datasaveslives within their Twitter bio. Many tweets of this type included images of individuals or groups at events pointedly posing with eye-catching placards, badges, or clothing featuring the hashtag:

> *Thanks for coming to chat wear your badge with pride!* [@FarrInstitute, Group 1]

Some tweets included a positive statement about reasons for supporting data sharing, either within the tweet or written on placards pictured in the tweet. The reasons referenced included sharing health data for research, sharing data as part of routine health care, or sharing data as part of larger projects that combined elements of both. Some tweets within this category signposted wider evidence supporting data sharing, such as collections of case studies where health data had been used for patient benefit. These were especially common among groups 4 and 5. Some drew on first-hand experiences and opinions:

> *For more examples of how #datasaveslives in mental health read this @MQmentalhealth blog. See our case studies [link to website]* [@Patient_Data, Group 3]

> *The type of treatment that I had depended so much on the data of patients who went before me' - patient advocate - #datasaveslives* [@useMYdata, Group 8]

As a Call to Action

We also identified a category of tweets that were used to make requests for others to act, participate, or respond in some manner. Commonly, these included advertisements to register for or submit papers to future events, participate in research studies, visit exhibition stands at conferences, or apply for jobs. There were also requests to provide feedback, opinions, or information:

> *We're inviting applications for a 2yr Clinical Research Fellow to study for an MD. Cardiology trainees please. #heartattack #datasaveslives* [@UoLCardioEpi, Group 9]

> *Help guide our consent modelling framework: happy to share a copy of your care org's consent forms? TY/please DM #datasaveslives #ontology* [@GreatNorthCare, Group 6]

Discussion

Principal Findings

This study investigated how a dedicated hashtag was used to promote the reuse of health data for research purposes and public benefit, how often, and by whom. Originally launched by the Farr Institute for Health Informatics Research, #datasaveslives came to be adopted by several distinct, diverse, yet interconnected groups in the United Kingdom with shared interests in health informatics, policy, and research. Our findings suggest that reasons for tweeting #datasaveslives evolved beyond the original objective of indexing information to a broader range of purposes, including event reporting, encouraging participation and action, and showing support for sharing health data.

Comparisons With Previous Work

Among the wider range of communities who shared content tagged with #datasaveslives, we detected 2 communities in particular who were research-focused, geographically distinct, and strongly interconnected. These were, in turn, connected with distinct professional communities with wider interests—some with access to sizable networks, funding, and influence—including government departments, the NHS, policy makers, patient advocates, and major charities. Our findings fit with the wider literature, which indicates that scientists can use Twitter not only to communicate with each other but also to engage broader audiences, including policy makers and the public [3,6].

One of the initial, more obvious uses of the hashtag was to index information about the use of health data as part of research and innovation, and make it more readily retrievable to a wider, not exclusively scientific, audience. Moreover, people also used the hashtag to publicly demonstrate support for data sharing and each other. This is compatible with the wider literature, which suggests that academics use hashtags to categorize information [26] and encourage interaction and community building [27-29]. These uses seem pertinent, given that our period of observation followed the high-profile failure of the care.data scheme, a major government initiative in England to share patient data [30]. Indeed, two of the most frequently shared tweets in our analysis concerned subsequent proposals to change government policy, addressing data security and consent [24,25]. Previous studies have shown how responses to care.data on Twitter attracted critical commentary [31], including from interest communities in politics, health care, and the media [32]. Before the observation period examined in this study, concerns had been raised about access to patient data by commercial companies, especially where these uses were perceived to be primarily motivated by profit rather than public benefit [30,33-35]. This study contrasts with these findings, showing how #datasaveslives was used in the wake of public backlash to care.data to spread mainly positive messages about data use and reuse, and to increase transparency, demonstrate solidarity, and provide supportive networks among health, data, and IT professionals.

In declaring an intent to promote the reuse of health data for research purposes, the #datasaveslives campaign could be regarded as a behavioral intervention of sorts, encouraging credible users to endorse and share supportive messages. As with other behavioral interventions conducted via social media, attention should be directed toward identifying the active ingredients of interventions [36]. Our thematic analyses of tweet content revealed 2 noteworthy and interrelated strategies used as components to achieve campaign aims. First, #datasaveslives was used at events frequented by influential communities, generating spikes in activity generated by commentary about the proceedings of meetings and events in real time. So-called *live-tweeting* has become more common at scientific conferences and has the advantage of increasing transparency and rapidly

disseminating information among a far larger audience over and above those who physically attend [37,38]. Using #datasaveslives, either alone or in addition to more specific conference hashtags, might have amplified the reach of information while avoiding the limited audience and *shelf-life* of more niche conference hashtags.

Second, offline activities at events were used to drive the generation of web-based multimedia content; events were used as photo opportunities for individuals willing to publicly endorse #datasaveslives, leveraged by attractive branded physical merchandise. Drawing on evidence from previous studies, which have identified health behavior change techniques particular to social media, reviewed by Simeon et al [36], these photo opportunities might be framed as *virtual rewards*, in turn encouraging further *overt endorsements* in the form of likes, retweets, and comments. Indeed, similar social media strategies have been used in both the health sciences and the corporate sectors, such as identifying target communities, gaining support from credible and/or influential users, developing engaging multimedia content, updating content regularly, improving the visual presentation of content, and encouraging participation via small concrete actions [16,39,40].

Strengths and Limitations

This study benefits from the analysis of a near-complete sample of #datasaveslives public tweets for an active year during the campaign. Nonetheless, we could not have captured all mentions and uses of #datasaveslives during this period. Private and previously deleted tweets were excluded. Owing to the limited use of other social media platforms by official supporters, our analysis only considered Twitter posts tagged with the keyword #datasaveslives. It is notable that other important public health outreach campaigns—including during outbreaks [41], as part of science communication [16] and to promote health behavior change [36]—have commonly used a wider range of social media platforms, particularly Facebook. The content, strategies, and communities observed in this study may be specific to Twitter and should not be generalized to other social media or content-sharing platforms. Furthermore, the network analysis was limited to retweets; we did not capture other types of engagement, such as follower networks, or use directed networks, as done by other studies [32]. Thus, certain nuances of information flow may have been lost, indicating influential relationships. Demographic data about users were not made available by Twitter for analysis, limiting our understanding of sample characteristics. Finally, we accept that we were unable to quantify, much less characterize, the much wider audience who saw, read, or otherwise engaged with tweets, in particular patients and members of the wider public not connected to organizations.

Future Research

The health data science community has stated a vision to be team-based, transparent, and inclusive, seeking involvement from a wide range of interdisciplinary stakeholders, including patients and the public [42]. Future research would benefit from examining how the use and users of #datasaveslives have changed over time and suitable ways of determining the overall impact of varying strategies to engage key communities, such as members of the public. Using such opportunities for social media to contribute toward building networks and engaging in dialog in open forums would seem eminently compatible with this vision.

Conclusions

The rise of social media has provided unprecedented opportunities for academic organizations and individual scientists to communicate with a much wider range of stakeholders than ever before, including the public. This study shows how a simple hashtag campaign on Twitter was used to disseminate credible scientific information and increase the visibility of research activities, with evidence to suggest this supported community building and bridging practices among interdisciplinary sectors allied to health data science.

Our findings are of interest to a variety of stakeholders who share an interest in supporting the reuse of health data for public benefit. By revealing the different communities who share such interests, analyzing content thematically, and demonstrating how information flows between them, our findings can be used to better understand the mechanisms underpinning stakeholder engagement campaigns conducted on social media and how to optimize these further.

Acknowledgments

This paper is dedicated to the memory of Alan Campbell. LH is funded via a UK Research and Innovation Fellowship at Health Data Research UK (ref: MR/S004025/1). Access to the data was funded by CHC, which was funded by the Department of Health and Social Care in England. The views expressed are those of the authors and not necessarily those of the Health Data Research UK, CHC, or the Department of Health and Social Care. The authors thank James Cunningham and Miguel Belmonte for their assistance with data preparation and visualization. They also acknowledge the work of Stephen Melia, in tirelessly promoting #datasaveslives. He may not have been the first person to coin the phrase *data saves lives*, but he was (probably) the first to put a hashtag in front of it.

Conflicts of Interest

LH and MT were previously funded by the CHC program and the Health e-Research Center, which founded the #datasaveslives campaign reported in this paper.

KEYWORDS

machine learning; data leakage; prediction

Applications of machine learning algorithms to predict the incidence of health outcomes have an enormous potential to improve clinical practice and lower health care costs [1]. Machine learning is a subset of artificial intelligence that uses data to improve decisions through experience, which is especially promising in a data-driven world. Dr Ye and colleagues' article on hypertension incidence prediction in the *Journal of Medical Internet Research* adds to this literature [2], but its potential contribution and applicability are hindered by a major flaw.

The objective of the study was to "develop and validate prospectively a risk prediction model of incident essential hypertension within the following year." The authors follow good prediction protocols by applying a high-performing machine learning algorithm (XGBoost) and by validating the results on unseen data from the following year. The algorithm attained a very high area under the curve (AUC) value of 0.870 for incidence prediction of hypertension in the following year.

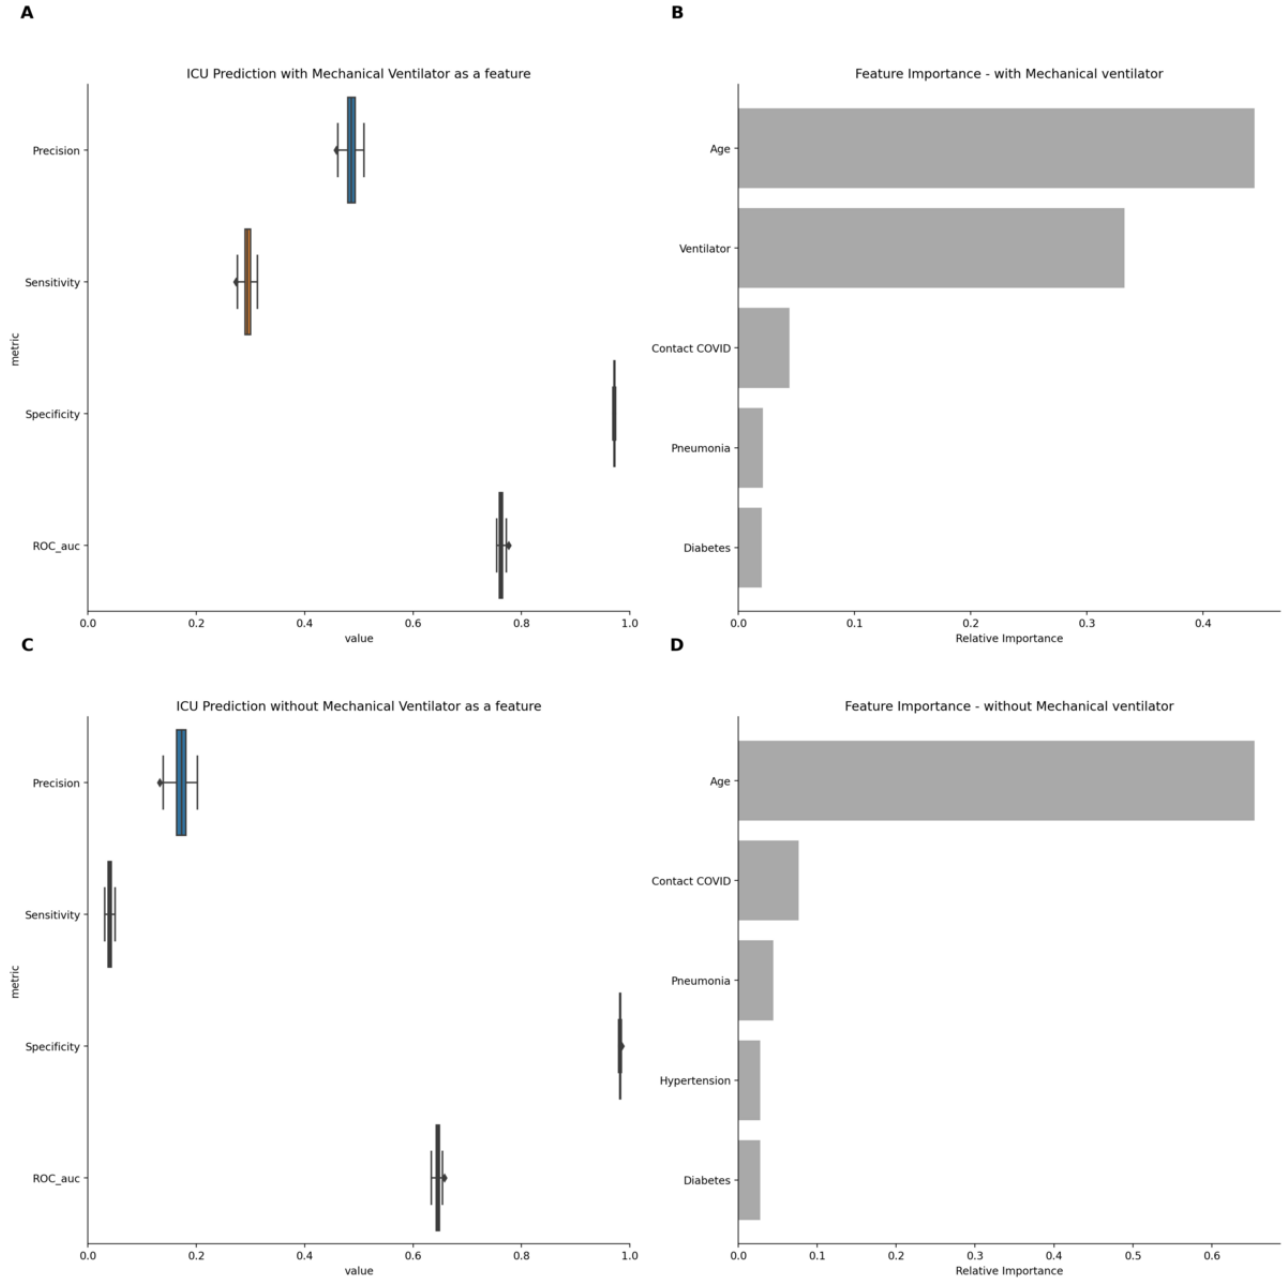
The authors follow this impressive result by commenting on some of the most important predictive variables, such as demographic features, diagnosed chronic diseases, and mental illness. The ranking of the variables that were most important for the predictive performance of hypertension is included in a multimedia appendix; however, the above-mentioned variables are not listed near the top. Of the six most important variables, five were: lisinopril, hydrochlorothiazide, enalapril maleate, amlodipine besylate, and losartan potassium. All of these are popular antihypertensive drugs.

Data leakage occurs when one or more features used to train the algorithm has hidden within itself the result of the outcome, and is considered one of the most frequent mistakes in machine learning [3]. This is different from predictive importance, that is, the relative effect of each variable in increasing or decreasing the expected outcome, as it usually comes after the outcome. Therefore, it is a consequence of the outcome that is being predicted and not the other way around.

A classic example from machine learning textbooks is the inclusion of the ID number of the patient as a predictor. While this should not have predictive importance if randomly assigned, it is common that patients coming from the same hospital have similar ID numbers in multicenter data sets. In the case of cancer prediction, for example, machine learning algorithms will learn that similar ID numbers that come from oncology hospitals have a higher probability of cancer.

As an example, we used real data to test the effect of including mechanical ventilation to predict intensive care unit (ICU) admission among patients with COVID-19 [4]. This is another example of data leakage, as mechanical ventilation usually only occurs after ICU admission and should not be used to predict its risk. Figure 1 shows the decrease in the prediction metrics for ICU admission with the exclusion of mechanical ventilation as a predictor, with the area under the ROC (receiver operating characteristic) curve decreasing from 0.76 to 0.64, and precision from 0.49 to 0.17.

Figure 1. Performance metrics for the prediction of intensive care unit (ICU) admission with and without the use of mechanical ventilation as a predictor.



By including the use of antihypertensive drugs as predictors for hypertension incidence in the following year, Dr Ye and colleagues' work opens the possibility that the machine learning algorithm will focus on predicting those already with hypertension but did not have this information on their medical record at baseline. While this would work for a prediction competition, where data science teams compete to produce the best predictive model such as in a Kaggle challenge [5], it is not of particular scientific or clinical interest. In the case of the latter, just one variable (the use of a hypertension drug) is sufficient for physicians to infer the presence of hypertension, while for the former, the knowledge of this being a highly predictable event (as measured by the AUC) is severely impaired.

In order to identify the presence of data leakage in prediction studies, it is important to have a conceptual pathway of how the predictors longitudinally affect the outcome variable, as there is no statistical method that is capable of pointing out the presence of data leakage. Improving the predictive performance of specific data sets for different diseases is an important new field in epidemiology and data science. The authors can still

contribute to this literature by providing the new AUC of the prediction after addressing the data leakage issue.

KEYWORDS

dementia; caregiver; technology

We read with interest the recent paper entitled "Using Technology to Facilitate Fidelity Assessments: The Tele-STAR Caregiver Intervention" by Lindauer et al [1]. The authors concluded that Tele-STAR contributed to low caregiver burden and showed good fidelity as an intervention method.

Internet-based videoconferencing technology is an important source of support for caregivers of persons with dementia. Researchers have previously demonstrated the positive potential of computer-mediated interventions and technology-based cognitive behavioral therapy interventions for caregivers of people with dementia [2,3]. Others have raised the difficulties in measuring intervention fidelity in a consistent manner [4,5], which raises the importance of consistency when considering fidelity evaluations. Moreover, as the study reported results that may be attributed to both in-home and telehealth intervention experiences of participants, it may be useful to consider the interplay of these aspects.

Lindauer and colleagues [1] reported a slight reduction in caregiver burden, attributed to an improvement in caregivers' responses to patients with dementia, facilitated by the Tele-STAR intervention. Caregiver burden is an important consideration in the field of dementia care. A recent study found an internet-based intervention to be effective in increasing the positive aspect of subjective appraisal for caregivers of persons with dementia [6]. In addition, we have studied the subjective appraisal of both negative and positive aspects in this population [7]. Assessments that take into account both sides of subjective appraisal are capable of providing a broad understanding of a caregiver's context, and we would argue that an outcome that takes both into account would be more useful than current practices allow for.

The support that can be offered to caregivers using internet-driven technologies should continue to be explored, and the study conducted by Lindauer and colleagues [1] provides useful data in this regard. We agree that internet-based interventions will be beneficial to caregivers of persons with dementia in the future.

KEYWORDS

spouse abuse; domestic abuse; apps; patient information; antenatal care; COVID-19

After reading the viewpoint by Wu et al [1] on opportunities for the delivery of antenatal care online during the COVID-19 pandemic, we would like to draw attention to a potential further aspect of this analysis. The authors surveyed 983 Chinese pregnant women and concluded that online antenatal care is likely to be an effective alternative for pregnant women, enabling them to access basic care without attending the hospital[1]. This is optimal with regards to minimizing the infection risk during the pandemic. However, it is important to remember that for a proportion of women, these antenatal visits provide a critical opportunity for physicians to screen for domestic abuse.

A cross-sectional study, also assessing a population of Chinese pregnant women, found that 15.62% of their subjects were identified as victims of domestic abuse [2]. Data released by the World Health Organization suggest that the number of women affected by domestic violence during pregnancy may be between 1% and 28% [3]. This proportion is by no means negligible.

In many countries, antenatal screening for domestic abuse when consulting with the patient is sporadic. One study of Canadian doctors found that 33% of professionals surveyed “never or only rarely” asked women about domestic abuse during antenatal appointments [4]. Provision of antenatal care online could result in even fewer women being able to confide in their doctor and receive much-needed assistance with respect to abusive situations at home. This might be due to women feeling less able to seek help through an online service compared to face-to-face consultations.

The COVID-19 pandemic has complicated this situation further. The London metropolitan police reported that since lockdowns were introduced in the United Kingdom, 380 more calls per week related to domestic abuse have been recorded [5]. Unpacking this data further, it is noteworthy that the majority of these reports of abuse were from third-party callers, perhaps due to the increased presence of neighbors [5]. This suggests that while there may be a potential surge in domestic abuse due to lockdown restrictions, this may not be associated with an increased probability of victims reporting the crime.

We suggest that to best address this gap in their proposal, Wu et al [1] should factor in how their proposed online antenatal care delivery system could incorporate adaptations to provide help to victims without compromising their safety. One possible method of achieving this could be to add a layer to any application developed through which women could find support numbers for relevant domestic abuse charities or alert their doctor to their need for a face-to-face appointment to discuss their home situation. It is important for this feature to be sufficiently blended into the app such that it would not alert suspicion from the perpetrator and thus compromise the safety of any woman seeking help.

KEYWORDS

telemedicine; coronavirus; COVID-19; medical education

We read with interest the recently published paper by Peine et al [1] on the views of health professionals on telemedicine. By surveying health professionals from across a variety of clinical settings and demographics, interesting results were obtained illustrating high levels of acceptance of telemedicine among health professionals in Germany. Acquiring an accurate view of telemedicine has never been more important than during the COVID-19 pandemic, where the usage of telemedicine to communicate safely with patients has increased dramatically.

The authors have made use of the word telemedicine throughout the paper, without specifically defining its meaning in this context. In fact, a 2007 study found up to 104 different peer-reviewed definitions of telemedicine [2] or “eHealth” across many different studies. Thus, we ask the authors of the study to clarify what they meant by telemedicine and if this term was defined for all study participants. We support a definition that encompasses the integration of technology mediums into the delivery of more accessible, improved, and cost-effective health care. The use of telemedicine extends beyond its role as a communication medium; it can be a resource for both health care professionals and patients, an instrument for diagnosis and screening, or a device to globalize medicine.

We note that a strength demonstrated in the survey was the large number of participants and the variety of different health professionals included, making it highly representative of the overall German health professional body. However, now that telemedicine has been incorporated into our day-to-day practice of medicine, it is extremely important to explore specific challenges of telemedicine to individual specialties. For example, recent research has shown that it may be difficult to form a trusting patient-doctor relationship using technology, which may be especially impactful in psychiatry and mental health care [3]. For this reason, the results of this study may reveal additional insight if responses were stratified by specialty. By identifying particular problems, solutions pertaining to each specialty may be discovered. For example, virtual reality (VR) technology that replicates a doctor’s office may help to create an environment where a lasting doctor-patient relationship can be established.

In addition, although a variety of health professionals were surveyed, we feel the views of medical students and clinical tutors are clearly missing from this study. As the first generation to fully experience the intersection of telemedicine and medical education, the opinions of this group could shape the future of medicine and better prepare upcoming doctors for practice in the post–COVID-19 era. By surveying medical students, a demographic that is mostly proficient in technology, we can find more innovative usages of telemedicine for maximal benefit to both doctors and patients.

From this, we conclude that despite the numerous benefits of telemedicine in clinical practice, there is a multitude of challenges to overcome. Major investment into technological infrastructure and training seems to be an unavoidable expense for the advancement of telemedicine. As telehealth becomes an integral part of the new global health care system, we must strive to research and actively work toward its incorporation in health services for efficient patient care at all levels.

KEYWORDS

COVID-19; social media; mass media; information quality

We read with great interest the recent article by Lin et al [1], which investigated the impact of mass and social media on psychobehavioral responses among medical students in China. We thank the authors for investigating this important issue in such a multifaceted manner. As medical students from four different medical schools in London, we questioned whether certain correlations discussed in the study could be examined further to elucidate the results and allow for some extrapolation. The results from this study are quite intriguing, and we believe this deeper analysis could spark other institutions around the world to examine the powerful effect of media on behaviors during a pandemic.

Since the study is based on Chinese media, we were unfamiliar with the quality of disseminated information related to COVID-19, particularly on social media. According to Ren et al [2], while Western media tends to center around controversy and individual experts, Chinese media sources focus on "mainstream positions" put forth by health agencies [3,4]. We suggest that an overview of how media sources are presented in China would be extremely useful in contextualizing the results of the study for non-Chinese audiences.

Furthermore, while the article's findings suggest that exposure to mass media and social media could increase positive attitudes and reduce emotional response among university students, we believe that the credibility of the information on these platforms greatly contributes to the results. Misinformation and "fake news," particularly on the internet, have become rampant [5]. The article presumes that the results are due to medical students being more discerning consumers of health information. While this may be possible, we suggest that analyzing the quality of the information consumed by the students, that is, whether the information was credible or not, would allow stronger correlations to be drawn as to why students had positive behavioral responses and lower trait anxiety.

This analysis on the quality of mass and social media could be done in a number of ways. For example, examining the quality of data could involve recruiting some participants from the current study to respond to health information of differing qualities. The information could be put into two categories: credible information and misinformation about COVID-19. Repeating the STAI-6 (Spielberger State-Trait Anxiety Inventory, 6 items) and the psychobehavioral response

questionnaire on this controlled set of stimuli might yield more data on why mass and social media exposure reduced trait anxiety and changed behavior in the study population.

Lastly, we suggest that the data be further analyzed to examine whether the psychobehavioral and anxiety responses varied by age in the students. This suggestion stems from the observed trend that different age groups engage with different mass or social media platforms. Perhaps the quality and the type of mass or social media may have an effect on the observed results.

Implementing some of these suggestions could use the previously gathered data and provide a uniquely detailed viewpoint that could expand the results of the study. These additions and future steps could inspire cross-institutional collaboration, allowing us to better understand how media across the world can affect the behavior and anxiety levels of key populations during a pandemic.

Abstract

The telehealth revolution in response to COVID-19 has increased essential health care access during an unprecedented public health crisis. However, virtual patient care can also limit the patient-provider relationship, quality of examination, efficiency of health care delivery, and overall quality of care. As we witness the most rapidly adopted medical trend in modern history, clinicians are beginning to comprehend the many possibilities of telehealth, but its limitations also need to be understood. As outcomes are studied and federal regulations reconsidered, it is important to be precise in the virtual patient encounter approach. Herein, we offer some simple guidelines that could assist health care providers and clinic schedulers in determining the appropriateness of a telehealth visit by considering visit types, patient characteristics, and chief complaint or disease states.

(J Med Internet Res 2021;23(2):e24785) doi:10.2196/24785

KEYWORDS

telehealth; patient safety; COVID-19; coronavirus; informatics; safety; harm; risk; access; efficiency; virtual care

Introduction

The telehealth revolution has been heralded for its potential to increase health care access and improve the efficiency of health care delivery. Previously, telehealth had been strategically rolled out to settings wherein the need for a relationship is less pressing (eg, radiology), outcomes can be remotely assessed in principle (eg, dermatology), or access to care is severely limited (eg, rural areas) [1]. COVID-19 prompted a near-universal expansion of telehealth utilization. Many applaud this change [2]. However, virtual patient care can bring unintended consequences that eclipse its benefits, including potentially limiting the patient-provider relationship, quality of examination, the efficiency of health care delivery, and overall quality of care [3-6]. As safety protocols for in-person evaluation have been developed, critical examination raises serious dilemmas about the harms of telehealth that can inform a new agenda for how to best utilize telehealth in the COVID-19 era. As we witness the most rapidly adopted medical trend in modern history, clinicians are beginning to comprehend the possibilities of telehealth, but its limitations also need to be understood.

The Rise of Telehealth in Response to COVID-19

Around the globe, patients are wary of entering health care settings, and providers fear unnecessary exposure for both patients and themselves, thereby creating a familiar dilemma of an unprecedented variety: How to best care for patients while *first doing no harm?*

In response, health systems have rapidly transitioned patient care away from in-person encounters towards telehealth [7]. This transition was facilitated by legislative changes designed to enable the “good faith” provision of health care at a distance, thereby limiting COVID-19 transmission [8]. New reimbursement policies have expanded access to a range of telehealth services offered by medical providers, clinical psychologists, licensed clinical social workers, and other health care workers.

In a matter of weeks, the application of patient-facing technology spread across all outpatient settings, including primary and preventative, medical and surgical specialty, and

mental health care. Equipped with remote monitoring, access to multi-provider video visits, and virtual translators, some specialty clinics adopted a 100% virtual approach. Telehealth found its way into emergency departments, hospital wards, intensive care units, and even interdisciplinary services such as occupational and physical therapy [9]. Telehealth was originally regarded as a form of health care delivery largely reserved for specific, resource-limited settings, but it is now embedded in the daily practice of providers across the spectrum of patient care.

Unintended Consequences of Telehealth

First, the most obvious potential harm of telehealth is an incomplete or inaccurate physical examination. Advances in patients' technological assessments have historically led to the abandonment of physical touch and examination in general—COVID-19 potentiated this issue [10]. Several reports have documented the steps to perform a virtual physical examination that can be applied to a wide range of patient encounters [11]. For example, Tanaka et al [12] describe creative ways of performing a virtual orthopedic examination. However, there are real limitations to a virtual examination, including the potential requirement of assistance from a caregiver, inadequate patient-home environment or space, poor lighting or discoloration with resultant poor visualization, increased time required to perform an assessment, and other technical issues [6,13,14]. In particular, the assessment of a patient's movement and motor function is limited, in part due to the need for a patient-assisted examination that can be challenging to capture on video [6,15,16]. Other aspects of a physical examination simply cannot be done via telehealth, such as auscultation of heart or lung sounds [17]. Thus, the true effectiveness of a telehealth physical examination and its subsequent impact on diagnosis, clinical management, and medical outcomes is yet to be determined in all settings.

In some instances, health care providers have abandoned the physical aspect of the "history and physical." The Centers for Medicare and Medicaid Services reimburse for telehealth annual well visits—an encounter that historically offered providers an opportunity to perform a thorough examination for subtle abnormalities is now often performed purely on the telephone. In other settings, reliance on technology has replaced physical examination. Inpatient cardiology consults are now performed by providers using apps on their devices (eg, iPhones and iPads) that allow real-time electrocardiography with an acceptable neglect of a careful, in-person examination of neck veins and body tissue to assess fluid status.

Beyond the clinical value, many patients feel comforted and reassured after a physical examination. Others perceive a virtual examination as inadequate regardless of its true quality [18]. "We must not forget the importance of a doctor's hands" [19]—a phrase that used to symbolize compassion is now, based on Google search results, associated with COVID-19 safety information and online advice to self-isolate.

Second, the roll-out of telehealth undermines the patient-provider relationship and the essential humanistic qualities of care providers. Although the world has become accustomed to online relationships, a trusting and personal connection between the patient and the health care provider, a vital aspect of health care, can be challenging to build with purely digital interaction. Multiple patient experience studies have consistently reported difficulties in communicating or connecting with providers during telehealth visits [3,6]. A desire for building an improved rapport with their providers is one of the most popular reasons why many patients prefer in-person visits [20]. In particular, the establishment of primary care or the initial consultation, similar to a first date, may not be welcomed by all and could negatively affect patient experience or the development of a sense of "my doctor." A survey of primary care patients during the pandemic found that telehealth was considered the most appropriate in the presence of a pre-existing clinical relationship [21]. An analysis of 620 patient satisfaction survey outcomes from clinic encounters found that new visit type was associated with lower patient satisfaction (parameter estimate -0.75; 95% CI -1.00 to -0.049) [22]. Consider the impact on the patient-centered care model, in which empathy, two-way communication, and direct eye-to-eye contact are considered crucial elements to improving health literacy and engaging patients in their own disease management [23]. Depending on the situation, telehealth may add one more barrier to understanding complex medical disease and patient compliance.

Third, the expansion of virtual services to rates beyond what was previously expected has resulted in inefficiencies in health care delivery. A mass of health care organizations rapidly transitioned and onboarded providers to telehealth encounters in a matter of weeks during the early-stage of the COVID-19 pandemic [24]. Although telehealth can provide thorough, safe, and effective medical care remotely, there is a learning curve associated with its implementation, and its success requires logistics that are frequently overlooked. For instance, clinics have not been appropriately restructured to support telehealth visits, resulting in under-utilization of talent. For example, medical assistants now play a role similar to that of front-desk personnel, thereby considerably limiting their participation in patient care. As such, the existing infrastructure, education, and administrative support surrounding telehealth must be tailored and broadened.

Safety of Health Care Facilities

The rapid expansion of telehealth was intended to protect uninfected patients from the risks of COVID-19 during periods of uncertainty. Although disease transmission is known to occur in medical facilities, growing evidence suggests that health care workers are more likely to be exposed to the virus while performing extra-occupational activities [25,26]. More experience in handling COVID-19 cases, coupled with an increasing knowledge base of its characteristics and modes of transmission, has led to the establishment of evidence-based protocols proven to facilitate the safe delivery of traditional brick-and-mortar patient care [27,28]. Retrospective studies have shown that transmission of the virus among health care workers is considerably reduced when these protocols are followed [29]. Proper hand hygiene, facial coverings, use of appropriate personal protective equipment, and implementation

of social distancing practices allow the safe return of routine in-person services [30]. Additionally, the redesign of clinic spaces and the use of electronic registration with automated messaging to avoid crowded waiting areas can further enhance the safety of in-person patient encounters. As such, providers now can be more precise in which patients are seen physically rather than virtually.

Updating Telehealth for the COVID-19 Era

For certain encounters, it makes intuitive sense to conduct telehealth visits remotely, and this may ultimately become the standard of care in the wake of the COVID-19 pandemic. For example, during a medication review for patients with chronic medical conditions, a physician can ask the patient to point the camera to the labels of the pills they are actually taking. On the other hand, some chief complaints require a physical encounter—a newly recognized palpable mass, for instance. The problem lies in the equivocal encounters: the patient who keeps physicians up at night, making them wonder if they should have recommended a trip to the dreaded emergency department, or the well-child, who is up to date on immunizations but has not had their weight or development assessed. As clinics reopen, finding the optimal balance of in-person and telehealth patient encounters is one of the most critical questions facing health care delivery. Appropriateness of telehealth visits likely varies according to the type of service being offered, medical specialty, health system, and geographic location.

We offer some simple guidelines to consider in determining the appropriateness of a telehealth visit (Table 1); these guidelines may be utilized by health care providers and, importantly, clinic schedulers. First, the visit type should be considered. New patient visits, even those that perhaps are safe to perform virtually, may benefit from face-to-face encounters to familiarize patients with their care and build a trusting relationship. Follow-up visits or new patients unlikely to need a physical examination may be appropriately managed via telehealth. Second, many patient characteristics are important to be considered, including health literacy, the structure of social support systems, hearing ability or visual acuity, and simple preference. A simple assessment of these 2 factors can likely be made by clinic schedulers with no further context of a patient's medical history. Thus, appropriate delineation of telehealth utilization in the outpatient setting can be made primarily without the consultation of a provider. However, for borderline patients, a provider can consider the chief complaint and chronicity of disease state as key determinants of whether in-person care with a highly reliable physical examination is necessary. When a physical examination may change either the diagnosis or management strategy, the patient should be seen in-person. This distinction can often be determined based on the chief complaint [31]. Finally, the technological capabilities of the patient must not be overlooked or taken for granted.

In the future, precision in the approach and delivery of the telehealth patient encounter is essential. The telehealth revolution has been impressive and has made substantial contributions to the global management of this pandemic, but significant work remains to ensure the best health care delivery for our patients. We have an opportunity to simultaneously embrace the necessity and benefits of telehealth while supporting strategies that optimize patient outcomes and humanism in medicine. Universally, health care workers have labored under extraordinary circumstances with incredible and heart-warming fortitude. Front-line providers have reminded us of the virtue of health care. There is no certainty about what the postpandemic world will look like. However, there will always be patients in need, and it is our responsibility to ensure they receive the high-quality physical and personal care they deserve.

Table 1. Characteristics to consider for determining the appropriateness of telehealth.

Characteristic	Appropriate for telehealth	Potentially inappropriate for telehealth
Visit type	Follow-up visit for known/diagnosed disease state or patient condition	New patient (establishment of primary care or new consultation)
	Follow-up postprocedure visit with no patient complaints	Annual physical examination or well-child check
	Recurring medication or chronic medical condition review	Acute visit prompted by an acute change in patient condition
	Initial or follow-up visit for mental health conditions	Initial psychiatry visits or annual follow-up for controlled substances
Patient characteristics	Existing, trusting, personal connection with the provider	Distrusting of health care professionals
	High health literacy	Low health literacy
	Robust social support system	Low social support system
	Anxious in health care settings	Poor vision or hearing
	Lives remotely or has inadequate transportation	Prefers in-person
	Prefers telehealth	
Chief complaint or disease state characteristics	Physical examination unlikely to be diagnostic	Physical examination may aid in diagnosis or prognosis
	N/A[a]	Examination findings may influence initial workup and/or management
	Focused physical examination can be performed virtually (ie, visual examination)	Focused examination cannot be performed virtually (ie, palpation of mass)
	Chief complaint with standardized initial workup and management	Chief complaints that often result in referral to acute care settings
Other considerations	English as a second language (interpreter required)	Patient has a poor internet connection
	Patient or close family member technologically savvy	Patient lacks technological capabilities to join video visit/telehealth encounter
	Patient with multiple family members at home who can join telehealth visit	N/A

Abstract

Background: Government responses to managing the COVID-19 pandemic may have impacted the way individuals were able to engage in physical activity. Digital platforms are a promising way to support physical activity levels and may have provided an alternative for people to maintain their activity while at home.

Objective: This study aimed to examine associations between the use of digital platforms and adherence to the physical activity guidelines among Australian adults and adolescents during the COVID-19 stay-at-home restrictions in April and May 2020.

Methods: A national online survey was distributed in May 2020. Participants included 1188 adults (mean age 37.4 years, SD 15.1; 980/1188, 82.5% female) and 963 adolescents (mean age 16.2 years, SD 1.2; 685/963, 71.1% female). Participants reported demographic characteristics, use of digital platforms for physical activity over the previous month, and adherence to moderate- to vigorous-intensity physical activity (MVPA) and muscle-strengthening exercise (MSE) guidelines. Multilevel logistic regression models examined differences in guideline adherence between those who used digital platforms (ie, users) to support their physical activity compared to those who did not (ie, nonusers).

Results: Digital platforms include streaming services for exercise (eg, YouTube, Instagram, and Facebook); subscriber fitness programs, via an app or online (eg, Centr and MyFitnessPal); facilitated online live or recorded classes, via platforms such as Zoom (eg, dance, sport training, and fitness class); sport- or activity-specific apps designed by sporting organizations for participants to keep up their skills (eg, TeamBuildr); active electronic games (eg, Xbox Kinect); and/or online or digital training or racing platforms (eg, Zwift, FullGaz, and Rouvy). Overall, 39.5% (469/1188) of adults and 26.5% (255/963) of adolescents reported using digital platforms for physical activity. Among adults, MVPA (odds ratio [OR] 2.0, 95% CI 1.5-2.7), MSE (OR 3.3, 95% CI 2.5-4.5), and combined (OR 2.7, 95% CI 2.0-3.8) guideline adherence were higher among digital platform users relative to nonusers. Adolescents' MVPA (OR 2.4, 95% CI 1.3-4.3), MSE (OR 3.1, 95% CI 2.1-4.4), and combined (OR 4.3, 95% CI 2.1-9.0) guideline adherence were also higher among users of digital platforms relative to nonusers.

Conclusions: Digital platform users were more likely than nonusers to meet MVPA and MSE guidelines during the COVID-19 stay-at-home restrictions in April and May 2020. Digital platforms may play a critical role in helping to support physical activity engagement when access to facilities or opportunities for physical activity outside the home are restricted.

KEYWORDS

digital health; moderate- to vigorous-intensity physical activity; muscle-strengthening exercise; online platforms; COVID-19

Introduction

Physical activity plays an important role in the prevention and treatment of noncommunicable diseases, which account for 70% of deaths worldwide [1]. A recent study of 168 countries estimated that 3.9 million (15%) premature deaths could be averted annually if more people engaged in recommended levels of physical activity [2]. The World Health Organization recommends that, each week, adults should accumulate at least 150 minutes of moderate-intensity physical activity, 75 minutes of vigorous-intensity physical activity, or an equivalent combination of moderate- to vigorous-intensity physical activity (MVPA); in addition, youth aged 5 to 17 years should accumulate at least 60 minutes of MVPA daily [3]. Adults are also advised to perform muscle-strengthening exercises (MSEs) at least twice per week, and adolescents are advised to perform them at least three times per week [3]. The guidelines are consistent with those in Australia [4,5]. Globally, 19% of adolescents [6] and 73% of adults achieve the MVPA guidelines according to the most recent estimates [7]. National survey data from 2017-2018 show that fewer Australians engaged in the recommended physical activity levels than the global average, with 55% of adults (18-64 years) and 10% of adolescents (15-17 years) achieving the recommended MVPA [8], and 1 in 6 adults (15%) and adolescents (16%) adhering to the MSE guidelines [8]. These prevalence data have been observed in the general population under free-living conditions. However, conditions have changed considerably as a result of government responses to COVID-19, which led to unprecedented and widespread social distancing measures to control its spread [9].

In Australia, for example, the federal government announced strict *stay-at-home* orders in late March 2020. Although the length of these restrictions varied by state and territory, opportunities to perform some physical activities outside the home, such as at gyms and sport clubs, were impacted nationwide [9,10]. Google Trends data showed that online queries of how to perform physical activity and exercise peaked in Australia during the first 2 weeks that the stay-at-home restrictions were imposed [11]. While this shows that people were investigating ways to keep active during this period, it does not provide information on the sort of support or the types of programs people may have used to be active during this time. Over the same period, there was an exponential increase in the use of the internet and associated digital platforms, such as websites and smartphone apps, as they became essential for education, work, and social interactions [12]. Digital platforms have previously shown promise for increasing physical activity among individuals of all ages in intervention studies [13-15]. However, use among Australians prior to the pandemic was low. Surveys of Australian adults (≥15 years of age) in 2018 showed that just 18.7% of adults used apps for tracking activity or training, and engagement with websites or online tools (7.1%) and online videos for sport (2.5%) was low [16].

Understanding the types of digital platforms used during the unprecedented pandemic situation could provide insight into their potential role for supporting individuals in meeting MVPA, MSE, and combined physical activity recommendations when individuals are unable to access traditional physical activity settings and facilities. This study aimed to explore the use of digital platforms for physical activity in Australia during April and May 2020 and to examine associations between the use of digital platforms and adherence to physical activity guidelines among adults and adolescents.

Methods

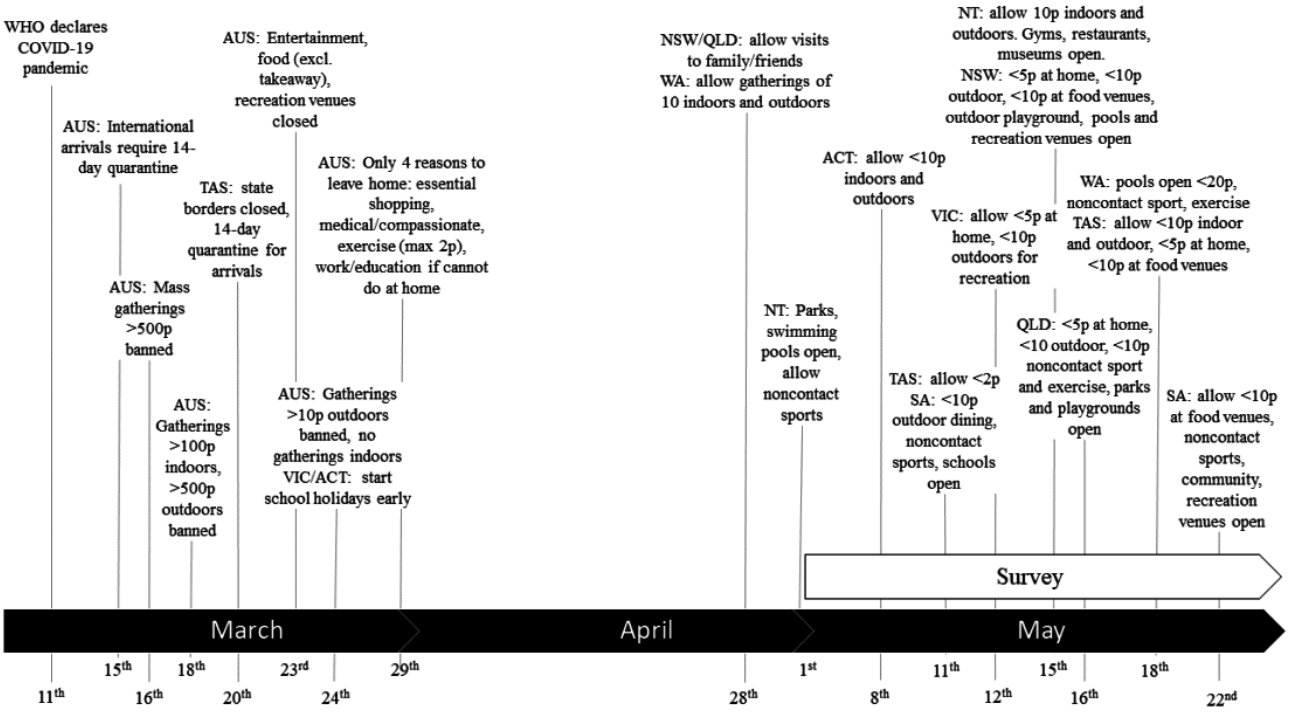
Overview

Data were drawn from the baseline sample of the Our Life at Home study (OL@H), collected May 4-31, 2020. OL@H is a longitudinal study designed to investigate the impact of the Australian Governments' response to managing the COVID-19 pandemic on movement behaviors and on the health and well-being of Australians aged 13 to 75 years over a 2-year period. OL@H received ethical approval from the Deakin University Human Ethics Advisory Group-Health (HEAG-H 59_2020).

Context

From March 29, 2020, strict stay-at-home orders were imposed by the Australian Government. As a result, all organized and social sports were suspended, and gyms and recreation facilities temporarily closed. People were allowed to leave their home to exercise as long as they maintained a 1.5-meter distance from those not living in their household. Each state and territory had the power to decide on and enforce their own restrictions, with several states easing restrictions on organized sport and recreation facilities in early May due to no or low recorded cases of COVID-19 (see Figure 1).

Figure 1. Australian federal- and state-imposed restrictions to stop the spread of COVID-19. ACT: Australian Capital Territory; AUS: Australia; NSW: New South Wales; NT: Northern Territory; p: people; QLD: Queensland; SA: South Australia; TAS: Tasmania; VIC: Victoria; WA: Western Australia; WHO: World Health Organization.



Sample

Individuals living in Australia were recruited via social media advertising (eg, Facebook and Instagram), researcher and stakeholder organization networks, and snowballing techniques, wherein participants were asked to share the study information with others they knew (eg, word of mouth). Of 14,764 individuals who clicked on the link to the survey, 6474 provided informed consent (43.8% response rate), of which 4079 (63.0%) were adolescents (13-17 years) and 2395 (37.0%) were adults (18-75 years).

Measures

Demographic Characteristics

Participants reported their age (years), sex (male, female, other, or prefer not to say), usual daily responsibilities (paid employment status, home duties or carer responsibilities, and student status; yes or no), number of people living in the household, whether the English language was spoken at home (yes or no), and state or territory of residence.

Adherence to the Physical Activity Guidelines

Adherence to physical activity guidelines was assessed using valid and reliable survey items [17-19]. Participants were asked to indicate how many days per week (none, 1 day/week, 2 days/week, 3 days/week, 4 days/week, 5 days/week, 6 days/week, or 7 days/week) they performed MVPA during a usual week over the past month (ie, April or May 2020) and in February 2020 (ie, pre-COVID-19 restrictions) for 30 minutes (adults aged ≥18 years) or 60 minutes (adolescents aged 13-17 years). Adult responses were dichotomized at 5 or more days per week (ie, ≥150 minutes/week), and adolescent responses were dichotomized at 7 days per week (ie, ≥60 minutes/day). Participants were also asked whether they performed (yes or no) MSE during a usual week (at home over the past month [April or May] or at home or at a gym during February); those who said *yes* were then asked to report the number of times per week (ie, frequency) that they performed MSE during a usual week. This was used to determine adherence to the MSE guidelines (adolescents: ≥3 times/week; adults: ≥2 times/week). Adherence to the combined guidelines was also calculated for the past month (April or May) and February.

Digital Platforms for Physical Activity

Participants were asked to respond to the question "Are you currently doing any form of sports or physical activities using online or digital platforms to assist or guide your activity?" (yes or no). A comprehensive list of digital platforms was identified in collaboration with key stakeholders. Participants who responded *yes* were asked to report the frequency (number of times per week) and duration (total minutes per week) spent using each of six types of online or digital platforms: streaming services for exercise (eg, YouTube, Instagram, and Facebook); subscriber fitness programs, via an app or online (eg, Centr and MyFitnessPal); facilitated online live or recorded classes, via platforms such as Zoom (eg, dance, sport training, and fitness class); sport- or activity-specific apps designed by sporting organizations for participants to keep up their skills (eg, TeamBuildr); active electronic games (eg, Xbox Kinect); and/or online or digital training or racing platforms (eg, Zwift, FullGaz, and Rouvy).

Statistical Analysis

Demographic characteristics, physical activity, and digital platform use were presented descriptively. Demographic differences between those who used digital platforms (ie, users)

compared to those who did not (ie, nonusers) were calculated using chi-square tests and *t* tests. Unadjusted logistic regression models were used to identify associations between sample characteristics (ie, age, sex, English-speaking household, number of people in household, employment status, home duties or carer responsibilities, and student status) and MVPA, MSE, and combined physical activity guideline adherence. Adjusted multilevel logistic regression models were then run to examine associations between the use of digital platforms and adherence with MVPA, MSE, and both MVPA and MSE guidelines. All multilevel models accounted for clustering by state or territory of residence and were adjusted for sample characteristics found to be significant in univariate models (see Multimedia Appendix 1) and guideline adherence during February 2020. Analyses were stratified by age group (ie, adults and adolescents). All analyses were performed using Stata v16 (StataCorp LLC).

Results

Table 1 presents the sample characteristics for adult and adolescent participants. In total, 1188 adults and 963 adolescents provided complete physical activity guideline adherence and digital platform data and were included in analyses. Among adults, the mean age was 37.4 (SD 15.1) years, the majority were female, and two-thirds had a tertiary degree. In the past month, 33.0% (392/1188), 37.3% (443/1188), and 17.7% (210/1188) of adults met the MVPA, MSE, and both guidelines, respectively, and 39.5% (469/1188) used online or digital platforms to assist or guide their physical activity. Among those who used digital platforms for physical activity, the median frequency was 4 (IQR 2-6) times per week and the median duration was 105 (IQR 60-180) minutes per week. Among adolescents, the mean age was 16.2 (SD 1.2) years, and more than two-thirds were female. In the past month, 7.2% (69/963), 28.1% (271/963), and 3.6% (35/963) of adolescents met the MVPA, MSE, and both guidelines, respectively, and 26.5% (255/963) used online or digital platforms to guide or assist their physical activity. Among those who used digital platforms for physical activity, the median frequency was 4 (IQR 3-7) times per week and the median duration was 120 (IQR 60-260) minutes per week.

Table 1. Sample characteristics.

Characteristic	Adults (n=1188)	Adolescents (n=963)
Age in years, mean (SD)	37.4 (15.1)	16.2 (1.2)
Sex (female), n (%)	980 (82.5)	685 (71.1)
Employment status (working), n (%)	625 (52.6)	248 (25.8)
Home duties or carer responsibilities (yes), n (%)	180 (15.2)	127 (13.2)
Student status (yes), n (%)	258 (21.7)	622 (64.6)
Number of people in household, mean (SD)	3.2 (1.4)	4.3 (1.3)
English-speaking household (yes), n (%)	1155 (97.2)	931 (96.7)
State or territory of residence, n (%)		
Australian Capital Territory	47 (4.0)	23 (2.4)
New South Wales	217 (18.3)	234 (24.3)
Northern Territory	9 (0.8)	4 (0.4)
Queensland	124 (10.4)	197 (20.5)

[a]N/A: not applicable; *P* values were not calculated for this item.

Among those who had used digital platforms to guide or assist their physical activity, the most common were streaming services (adults: 197/469, 42.0%; adolescents: 102/255, 40.0%), facilitated online classes (adults: 144/469, 30.7%; adolescents: 77/255, 30.2%), and subscriber fitness programs (adults: 139/469, 29.6%; adolescents: 35/255, 13.7%) (see Figure 2). The types of digital platforms used were generally similar for adults and adolescents; however, proportionally fewer adolescents used subscriber fitness programs.

Figure 2. Use of each type of digital platform for physical activity among users.

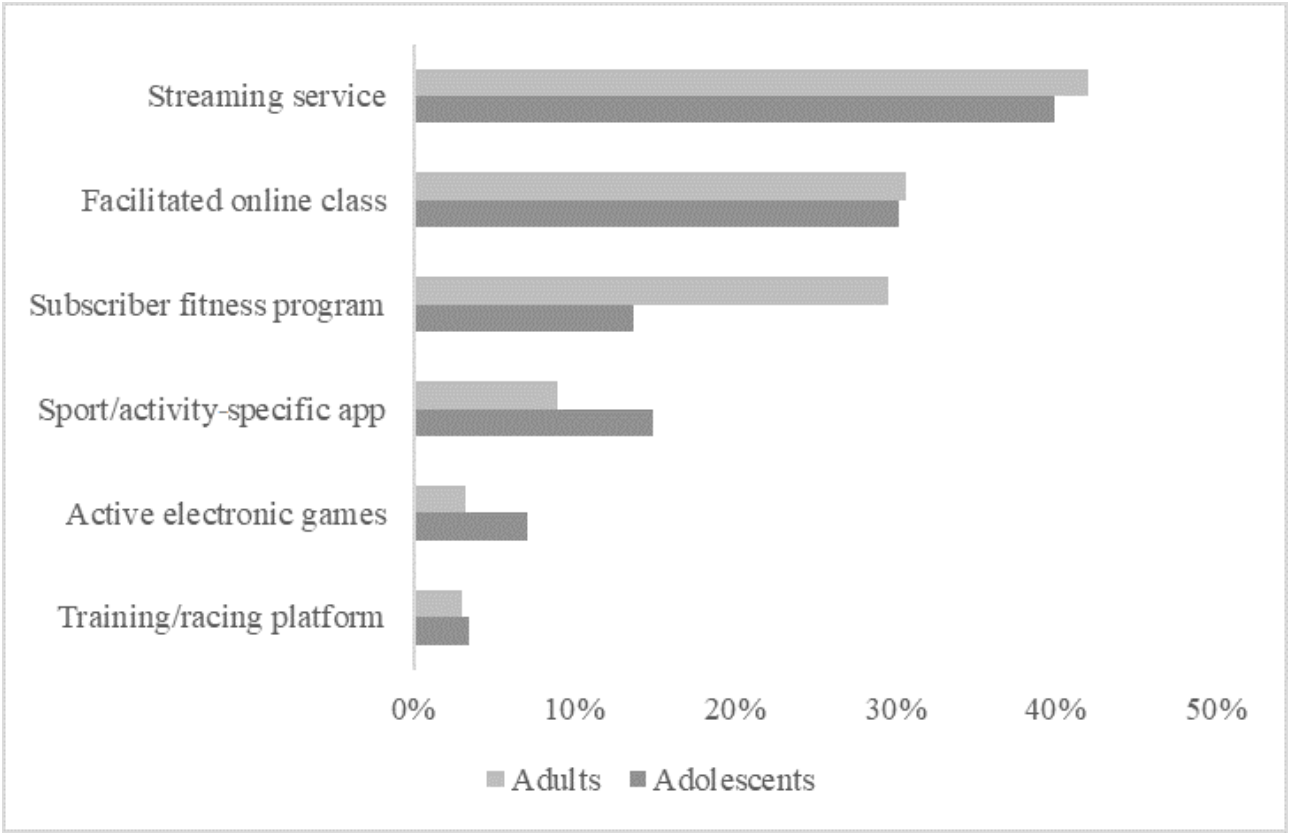

Table 3 presents the unadjusted and adjusted odds ratios for physical activity guideline adherence, accounting for state or territory of residence and adjusting for significant confounders (see Table S1 in Multimedia Appendix 1) and guideline adherence during February. In the adjusted models, adults who used digital platforms had 2 times the odds of meeting MVPA guidelines, over 3 times the odds of meeting MSE guidelines, and almost 3 times the odds of meeting the combined guidelines compared to nonusers. Adolescents who used digital platforms had more than 2 times the odds of meeting MVPA guidelines, over 3 times the odds of meeting MSE guidelines, and more than 4 times the odds of meeting the combined guidelines compared to nonusers.

Table 3. Adjusted odds ratios (ORs) for the associations of physical activity guideline adherence and use of digital platforms.

Model	Digital platform use for adults, OR (95% CI)[a]			Digital platform use for adolescents, OR (95% CI)[a]		
	MVPA[b]	MSE[c]	Combined	MVPA	MSE	Combined
Unadjusted model (reference: nonusers)	1.97 (1.54-2.52)	3.79 (2.96-4.87)	3.22 (2.36-4.39)	2.43 (1.47-3.99)	3.09 (2.27-4.20)	5.05 (2.50-10.18)
Adjusted model (reference: nonusers)	1.99 (1.49-2.66)[d]	3.34 (2.49- 4.47)[e]	2.73 (1.95-3.81)[f]	2.40 (1.32-4.35)[g]	3.07 (2.12-4.44)[h]	4.32 (2.09-8.95)[i]

[a]All accounted for clustering by state or territory and were adjusted for February guideline adherence.

[b]MVPA: moderate- to vigorous-intensity physical activity.

[c]MSE: muscle-strengthening exercise.

[d]Additionally adjusted for age, number of people living in household, home duties or carer responsibilities, and student status.

[e]Additionally adjusted for employment and home duties or carer responsibilities.

[f]Additionally adjusted for home duties or carer responsibilities.

[g]Additionally adjusted for student status.

[h]Additionally adjusted for sex and home duties or carer responsibilities.

[i]Additionally adjusted for home duties or carer responsibilities.

Discussion

Principal Findings

Findings from this study showed that digital platforms may play a critical role in supporting physical activity engagement during times when people have limited access to traditional settings or opportunities for physical activity outside the home. Individuals who used a digital platform were more likely to report achieving recommended levels of MVPA and MSE during April and May when strict stay-at-home orders were imposed for most of the nation.

Data sourced from the Global Digital Overview in January 2020 highlighted the ubiquitous use of digital platforms in Australia; 88% of the adult population had access to the internet, 71% used social media (eg, Facebook and Instagram), and 26% of internet users reported using health and fitness apps [20]. While there are no directly comparable data, data from our study suggest that a higher proportion of Australians used digital platforms for physical activity during April and May 2020 compared to 2018 [16], with a higher rate of use observed among adults compared with adolescents. In addition to the established use of mobile fitness programs [21], our findings suggest that people also used digital platforms for facilitated online live or recorded activity classes and for streaming services.

More females than males used digital platforms to guide or assist their physical activity, which is similar to previous research [22,23]. This may reflect the ability of digital platforms to support information sharing, self-monitoring, and internal accountability, which are often considered important for increasing physical activity motivation among females [24,25]. It may be that females participate more in instructor-led activities (eg, yoga, Pilates, and dance) [26], whereas males tend to engage in more organized sport and weight training [8], both of which are less adaptable to online delivery via digital platforms. Safety concerns when exercising alone outdoors or after dark and fear of judgement are known barriers to physical activity uptake by women [27,28]; this may have also informed women's decisions to use digital platforms to undertake physical activity in the home. Alternatives such as digital platforms may play an important role in ensuring that women achieve sufficient physical activity levels. Digital platforms can be used at any time of the day and offer convenience of use in the home, which may explain the larger proportion of adults working in paid employment using digital platforms for physical activity compared to those not working.

In this sample, 33% of adults reported meeting MVPA guidelines during the April and May stay-at-home period, which is considerably lower than the Australian average of 55% of 18- to 64-year-olds in 2017-2018 [8]. It should be noted that the MVPA measure in this study required adults to engage in 30 minutes per day of MVPA on at least 5 days per week, whereas the Australian Bureau of Statistics physical activity measure was based on a minimum total of 150 minutes of moderate-intensity physical activity, 75 minutes of vigorous-intensity physical activity, or an equivalent combination per week [8]. Among adolescents, just 7% met guidelines for MVPA, which was slightly lower than the Australian average of 10% of 15- to 17-year-olds [8]. These differences may have been due to the reduced ability to access traditional settings for physical activity, such as schools [29], work [30], and fitness and recreation facilities [31], or to participate in sport or active travel [32]. In contrast, the proportion of adults and adolescents in this sample who met the MSE guidelines during the April and May stay-at-home period was considerably higher than the Australian average [8]. MSE includes bodyweight activities that may not require specialized equipment or facilities; can be performed in a confined space, such as at home; and may have been promoted via digital platforms (eg, livestreams on YouTube) during the stay-at-home restriction phase.

Our results showed support for the use of digital platforms to engage in physical activity and MSE when access to traditional settings and facilities for physical activity was restricted. Adults and adolescents who used digital platforms to guide or assist physical activity were more likely to meet the MVPA, MSE, and combined physical activity guidelines compared to those

who did not use digital platforms. This is consistent with evidence from Germany [33] and the United States [22] that showed that adults who used physical activity and health apps engaged in more physical activity compared to those who did not. This study builds on the evidence that digital technologies can promote and support physical activity among adults and adolescents [13,34-39]. Streaming services were the most frequently used digital platform to guide or assist physical activity, so future studies should further explore how they can best support physical activity engagement for all demographic groups and how they can be used as a physical activity promotion tool. Streaming services are mostly free to use and, thus, present an opportunity for relevant government or nongovernment organizations to make use of this platform for education, instruction, and promotion of physical activity to the general public.

Overall, the findings highlight a willingness to engage with technology for MVPA and MSE when access to traditional settings or opportunities for physical activity outside the home are limited, particularly among females and working adults. Further research is needed to explore what motivated or discouraged people from using digital platforms during this period of reduced options for activity outside the home environment. Future work could also explore whether the use of digital platforms for physical activity replaced usual physical activity behaviors from before the restrictions or complemented other physical activities (eg, attending a fitness class in person) and how digital platforms can best support continued engagement in physical activity once restrictions are reduced.

Limitations

The large sample size and measures of MVPA, MSE, and combined guideline adherence are strengths of this study. However, the majority of participants were female and English speaking; in addition, 50% of adults and 32% of adolescents were from one state—Victoria—and, thus, are not representative of the wider Australian population. As the survey was completed online, English-language proficiency was required, which may have also reduced the generalizability of the findings to culturally and linguistically diverse populations. The measure used to capture MVPA guideline adherence in this study was valid and reliable [17-19]; however, it may not accurately capture individuals who engaged in shorter durations of vigorous-intensity physical activity yet still met the guidelines (eg, 30 minutes/day and 3 days/week). Participants were asked to report on MSE specifically in the home during April and May and at home or a gym in February; as such, this may not have captured all MSE performed (eg, in other locations). In addition, this study relied on self-report of physical activity and, as such, potential for recall bias must be acknowledged.

Conclusions

In this study, fewer than half of the adults and one-third of adolescents reported using digital platforms to assist or guide their physical activity during the COVID-19 stay-at-home period in April and May 2020. Both adults and adolescents who used digital platforms for physical activity were more likely to meet the MVPA, MSE, and combined physical activity guidelines compared to those who did not use digital platforms. This suggests that digital platforms can play a critical role in supporting physical activity engagement. There is a need for future research to understand sustained use, gender preferences, and motivations for the use of digital platforms to guide or assist physical activity, in particular via streaming services, given their popularity during COVID-19.

Acknowledgments

The authors thank all of the participants in OL@H. OL@H was supported by Deakin University Social and Early Emotional Development funding. JV and NR are each supported by an Australian National Heart Foundation Future Leader Fellowship (JV: ID 101928; NR: ID 101895). Abstract

Background: The COVID-19 pandemic led to the implementation of worldwide restrictive measures to reduce social contact and viral spread. These measures have been reported to have a negative effect on physical activity (PA). Studies of PA during the pandemic have primarily used self-reported data. The single academic study that used tracked data did not report on demographics.

Objective: This study aimed to explore patterns of smartphone-tracked activity before, during, and immediately after lockdown in the United Kingdom, and examine differences by sociodemographic characteristics and prior levels of PA.

Methods: Tracked longitudinal weekly minutes of PA were captured using the BetterPoints smartphone app between January and June 2020. Data were plotted by week, demographics, and activity levels at baseline. Nonparametric tests of difference were used to assess mean and median weekly minutes of activity at significant points before and during the lockdown, and as the lockdown was eased. Changes over time by demographics (age, gender, Index of Multiple Deprivation, baseline activity levels) were examined using generalized estimating equations (GEEs).

Results: There were 5395 users with a mean age of 41 years (SD 12) and 61% (n=3274) were female. At baseline, 26% (n=1422) of users were inactive, 23% (n=1240) were fairly active, and 51% (n=2733) were active. There was a relatively even spread across deprivation deciles (31% [n=1693] in the least deprived deciles and 23% in the most [n=1261]). We found significant changes in PA from the week before the first case of COVID-19 was announced (baseline) to the week that social distancing restrictions were relaxed (Friedman test: χ^2_2=2331, P<.001). By the first full week of lockdown, the median change in PA was 57 minutes less than baseline. This represents a 37% reduction in weekly minutes of PA. Overall, 63% of people decreased their level of activity between baseline and the first week of COVID-19 restrictions. Younger people showed more PA before lockdown but the least PA after lockdown. In contrast, those aged >65 years appeared to remain more active throughout and increased their activity levels as soon as lockdown was eased. Levels of PA among those classed as active at baseline showed a larger drop compared with those considered to be fairly active or inactive. Socioeconomic group and gender did not appear to be associated with changes in PA.

Conclusions: Our tracked PA data suggests a significant drop in PA during the United Kingdom's COVID-19 lockdown. Significant differences by age group and prior PA levels suggests that the government's response to COVID-19 needs to be sensitive to these individual differences and the government should react accordingly. Specifically, it should consider the impact on younger age groups, encourage everyone to increase their PA, and not assume that people will recover prior levels of PA on their own.

Introduction

It is well established that sufficient physical activity (PA) is important for good health [1,2]. PA substantially reduces risks of common noncommunicable diseases including cardiovascular disease, diabetes, some cancers, and depression [1]. However, the COVID-19 pandemic resulted in worldwide implementations of restrictive measures to reduce social contact and viral spread. These varied by country, but have generally involved restrictions on nonessential movement and are likely to have had an impact on PA levels. Several papers have expressed concern about the negative consequences of reduced PA during these restrictions and the value of maintaining PA [3-6].

In the United Kingdom, throughout the COVID-19 lockdown, people were allowed to spend time outside for PA, with the exception of those who were "shielding" or those self-isolating due to COVID-19 exposure or symptoms. From March 23, 2020, to May 8 (Wales), May 11 (Scotland), or May 13 (England), individuals were allowed out for exercise once per day, respectively; subsequently, this changed to as often as was desired. This contrasted with more restrictive lockdowns seen in other countries, like Spain or France, where leaving home for exercise was not permitted. The inclusion of daily exercise in the United Kingdom lockdown guidance could account for the Sport England findings that 62% of 2000 people surveyed said they felt exercise was more important than before COVID-19 [7].

Evidence on the impact of pandemic restrictions on PA behavior varies and there are multiple methodological approaches available, each with strengths and limitations. Google Trends data showed that interest in exercise in April 2020 was higher than at any other time since records began. However, these data cannot tell us whether this increased interest was among those already habitually active or whether it translated into behavior change [8].

Cross-sectional surveys have been most commonly employed and have generally shown substantial declines in PA. The ECLB-COVID19 international survey gathered data from 1047 respondents from Africa (40%), Asia (36%), Europe (21%), and elsewhere (3%) April 6-11, 2020. They found substantial drops in PA in response to COVID-19 restrictions (eg, a 24% drop in the number of days/week of moderate-intensity PA and a 34% drop in the number of minutes of walking per day) [9]. Rogers and colleagues [10] conducted an online survey April 6-22, 2020, that found 25% of respondents reported doing less PA, while 12% reported doing more. Predictors of doing less PA were being female, not having access to a garden, having various pre-existing conditions, and expressing sentiments about personal or household risks. Older people (aged >70 years) were more likely to be doing the same intensity level of PA. People aged 20-34 were significantly more likely to have changed their PA levels to be either more or less intense than prior to the lockdown. More positive results were reported in a survey starting March 17, 2020, with 75% of respondents meeting PA guidelines. Meeting guidelines was associated with being female, being aged ≥65 years, having higher household income, and having had higher prior levels of PA, but negatively associated with prior physical symptoms [11].

All these surveys, which only captured the very early phases of the pandemic, used convenience sampling, using social media and snowballing approaches for recruitment. These approaches, while fast and low cost, can lead to sampling biases. In addition, it is very hard for individuals to accurately recall weekly minutes of PA even within recent timeframes (such as the last 7 days), let alone recalling PA prior to COVID-19 restrictions. Thus, these surveys are missing a reliable baseline measure. However, in recent years, many people have started routinely tracking their PA through the use of apps and wearables. This gives us a source of data that is longitudinal, predating the pandemic, and not reliant on self-report/recall.

One of the most widely used such technologies is the Fitbit; a blog by Fitbit described declines in PA in the week ending March 22, 2020 [12], including a 9% decline in step activity in the United Kingdom. All 20 countries studied showed declines, with the largest being a 38% decline in Spain, which had a more restrictive lockdown. By June 2020, Fitbit reported step count levels increasing but not yet back to the same level as last year, except among older women (aged 50-64 years), who surpassed the previous year's levels. Younger Fitbit users seemed to be making the smallest step count gains. Fitbit differentiates between steps and active minutes, which are defined as more "vigorous and intentional" activity that is important for heart health. Vigorous activity had increased during the lockdown, but appeared to be returning to the same levels as last year across all age groups [13]. Similar trends were seen among users of Garmin fitness trackers, showing a reduction in steps and an increase in more vigorous PA [14]. Neither data set has been described in academic reports.

The largest tracking study to date had walking data from 455,404 users of a smartphone app in 187 countries and found a 27% decrease in steps between baseline and a month after the announcement of COVID-19 as a pandemic [15]. No demographic data were available, meaning it was not possible to characterize users or explore sociodemographic patterns.

Therefore, the aims of this study were to explore patterns of tracked activity (ie, walking, running, and cycling) in the United Kingdom before, during, and immediately after the COVID-19 restrictions were in place and to explore variations by demographic characteristics.

Methods

Overview

Participants were individuals in the United Kingdom registered with BetterPoints. BetterPoints is a free, publicly available, smartphone-based program that offers rewards (points, lottery style tickets, and virtual rewards such as medals) for the amount of PA tracked per week. Points can ultimately be converted to

financial rewards (exact amounts and types are dependent on the program sponsor). Program sponsors include local government/councils, National Health Service trusts, Clinical Commissioning Groups, Development Corporations and, increasingly, large corporate entities. Further information about BetterPoints can be found on their website [16].

Individuals must be aged ≥14 years to register with the program. Registered users who had tracked any PA at all between January 22 and June 17, 2020, were included in the study. On registration with the app, users are asked to provide year of birth (used to derive approximate age), gender (male/female/other), and home post code (used to derive the Index of Multiple Deprivation [IMD] decile via the UK Government website [17]).

This study was approved by the UCL ethics committee (ID 401.001). When registering with the BetterPoints program, individuals agree and consent to the Terms and Conditions and Privacy Statement, including that their tracked data will be used to monitor patterns and that their "anonymized data may be shared with trusted non-BetterPoints entities to do research."

PA was tracked by the BetterPoints smartphone app. Users could track their activities via a menu where they select activity types such as walking, running, or cycling, or they could turn on automatic tracking. From March 2020, automatic tracking became the default. BetterPoints uses proprietary algorithms to combine data from the chipsets in the phone (motion sensors, accelerometers, built-in classifiers) with additional data pertaining to speed, global positioning system data, and various map data sources to classify activity types automatically. The BetterPoints system records 0 if no valid activity is tracked. This is designed to avoid categorizing small amounts of movement (eg, walking around the house). The person must move over a distance, at a certain speed and acceleration, for the movement to qualify as walking, running, or cycling. To run automatic tracking, the smartphone must have a motion co-processor or accelerometer that monitors movement. Most current smartphones support this automatic tracking, including the Apple iPhone 5S (iOS) or above and nearly all Android-based phones. Smartphone sensors in iOS and Android phones have been shown to provide valid estimates of PA in naturalistic settings compared to ActiGraph [18] and pedometers [19].

The BetterPoints app displays data in a dashboard view of total weekly minutes of PA, which incorporates time spent walking, running, and cycling.

Analysis

This was a retrospective study design using existing data in the context of a constantly evolving pandemic response, so pragmatic decisions had to be made, including about how to define a baseline period and which follow-up measurement periods should be included in some analyses. Key dates in the United Kingdom's COVID-19 pandemic response were chosen, within the context of the data having a resolution of one week and attempting to reduce the number of unnecessary post hoc statistical tests. A summary of our measurement dates is provided in Table 1. Our weeks run from Wednesday to Tuesday because our data set began January 1, 2020, which was a Wednesday. The week commencing January 22, 2020, was selected as the baseline. This was the week before the first case of COVID-19 was reported in the United Kingdom.

Table 1. Baseline and follow-up measurement dates for analysis.

Date (week commencing)	Significant events
January 22	Study baseline (the week before the first COVID-19 case in the United Kingdom was announced)
March 11	Nonessential travel banned and social distancing introduced
March 18	The lockdown began on March 23
March 25	First full week of the lockdown
May 13	The lockdown was relaxed (multiple excursions for exercise allowed)
June 17	First full week with nonessential shops reopened (reopened on June 15)

Demographics were summarized using descriptive statistics. Participants were grouped into Sport England Active Lives' categories of active (≥150 minutes of PA per week), fairly active (30-149 minutes), and inactive (0-29 minutes), according to the minutes of activity participants engaged in during the baseline week (commencing January 22, 2020) [20].

PA data were highly skewed, with many zero values (39% of all data values), so data were analyzed in three ways. First, median and mean PA were plotted by week, overall and median by demographics and activity levels at baseline. Next, nonparametric tests were used to compare PA over time. We performed a Friedman test to determine if there were significant differences in activity over time, then Wilcoxon tests were conducted to compare key follow-up weeks to baseline. Change in PA was calculated by computing baseline minus follow-up week. The mean, median, and interquartile range of this change score were then calculated. The change was also expressed as a percentage of baseline. Change categories were used to describe the proportion of people who had decreased, increased, or maintained their activity levels from baseline to the first full week of COVID-19 restrictions. These analyses were conducted in SPSS (Version 26, IBM Corp).

Finally, parametric tests were performed; specifically, generalized estimating equations (GEEs), a further generalization of the generalized linear model (GLM), were used to take into account the variance structure of the outcome data being from the same individuals over multiple weeks. We wanted to use a negative binomial regression, appropriate for the highly skewed data [21], but the GEE models failed to converge, presumably the result of a large number of zero values

and high correlations between each week and the next. Instead, additional change scores were created. We calculated 20 sets of values using the amount of PA in each week minus the previous week for that individual. This change score is more amenable to analysis, producing a symmetric distribution (skew=–0.1). However, it is very leptokurtic (kurtosis=17.9). We carried out a modified square root transformation as shown in equation 1:

$$\text{transformed value} = \text{sign}(x) \times \sqrt{(|x|)} \quad (1)$$

This reduces the length of the data distribution's tails and the kurtosis (now 3.3). We were then able to fit a linear regression GEE to the data. We used Huber-White sandwich robust variance estimators. These analyses were conducted in Stata (Version 11, StataCorp).

Results

Demographics

In total, 5395 users registered at least some activity each week from the week commencing January 22 to June 17, 2020, and were included in the current analysis. Participant characteristics are provided in Table 2. There were 130 missing values for gender data. In addition, 15 cases of approximate age >100 years were recoded as missing. Since there was no missing data for the primary outcome (PA) and <4% missing data for age or IMD, the decision was made not to impute these values. Users were on average 41 years old (SD 12; range 14-93 years). In addition, 61% of users identified as female, 37% as male, and 0.4% as other. There was a relatively even spread across deprivation deciles, with 31% falling in the least deprived deciles, and 23% in the most. At baseline, 26% of users were inactive, 23% were fairly active, and 51% were active.

Table 2. Participant characteristics and proportions of missing data (N=5395).

Characteristics	Values
Age (years), mean (SD)[a]	41.02 (12.2)
Age categories (years), n (%)	
14-24	463 (8.6)
25-34	1210 (22.4)
35-44	1554 (28.8)
45-54	1246 (23.1)
55-64	567 (10.5)
≥65	168 (3.1)
Gender, n (%)	
Male	1971 (36.5)
Female	3274 (60.7)
Other	20 (0.4)
Index of Multiple Deprivation, n (%)	
1-3 (most deprived)	1261 (23.4)
4-7	2240 (41.5)
8-10 (least deprived)	1693 (31.4)
Missing	201 (3.7)
Baseline physical activity, n (%)	
Inactive	1422 (26.4)
Fairly active	1240 (23.0)
Active	2733 (50.7)

[a]There were 187 missing values.

Plots and Nonparametric Tests

Plots of PA over the study period are shown in Figures 1-5. PA started to decline the week commencing March 11, 2020, when nonessential travel and social distancing measures were introduced. This decline continued until the first week of full lockdown, after which it appeared to remain fairly static throughout most of the lockdown, apart from a blip for the week commencing June 3, which had inclement weather.

Figure 1. Weekly minutes of physical activity (mean and median). Important dates are marked on the x-axis as follows. (A) January 22: Baseline, week before first COVID-19 case announced in the United Kingdom. (B) March 11: Social distancing measures introduced. (C) March 18: Lockdown begins. (D) March 25: First full week of lockdown. (E) May 13: Lockdown measures relaxed. (F) June 17: Shops reopen.

(A) January 22: Baseline, week before first COVID-19 case announced in the United Kingdom. (B) March 11: Social distancing measures introduced. (C) March 18: Lockdown begins. (D) March 25: First full week of lockdown. (E) May 13: Lockdown measures relaxed. (F) June 17: Shops reopen.

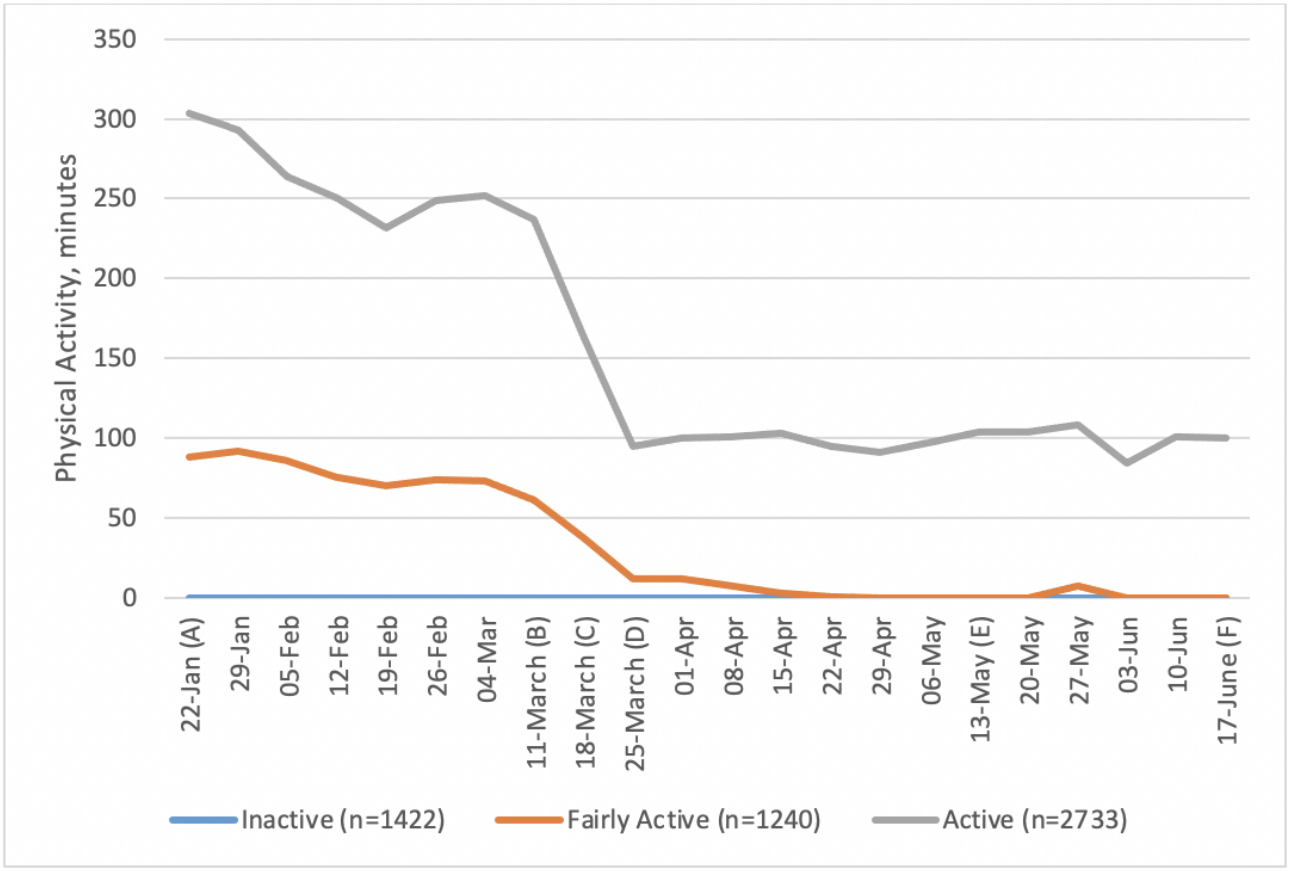

Figure 5. Weekly minutes (median) of activity by indices of multiple deprivation. Important dates are marked on the x-axis as follows. (A) January 22: Baseline, week before first COVID-19 case announced in the United Kingdom. (B) March 11: Social distancing measures introduced. (C) March 18: Lockdown begins. (D) March 25: First full week of lockdown. (E) May 13: Lockdown measures relaxed. (F) June 17: Shops reopen.

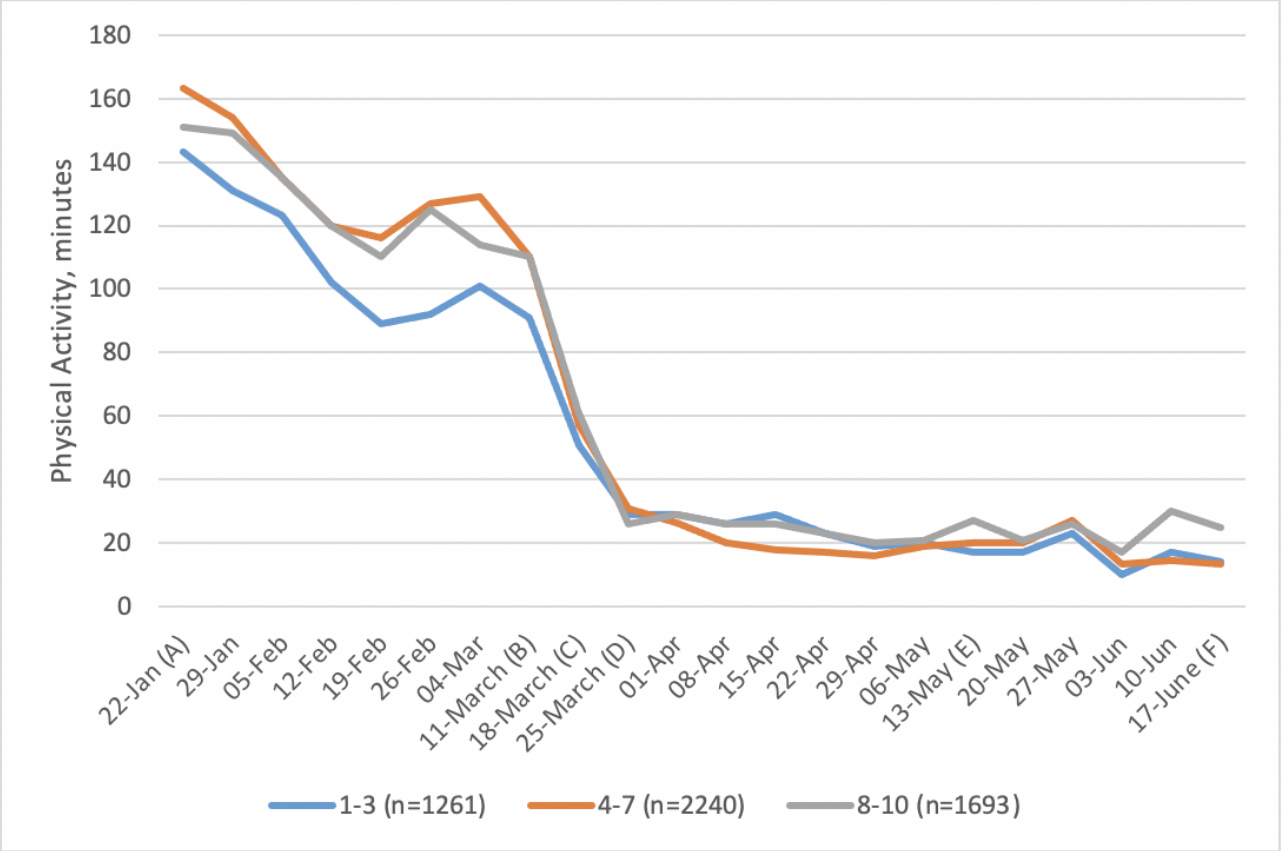

Median weekly minutes of PA and the results of statistical tests of difference are presented in Table 3. There were significant differences in PA between the week before the first case of COVID-19 was announced (baseline) and the week that social distancing restrictions were relaxed (Friedman test: χ^2_2=2331, P<.001).

Table 3. Summary of physical activity at baseline, through lockdown, and beyond (January 22-June 17, 2020; N=5395).

Time points	Physical activity (minutes), median (IQR)	Friedman test
Baseline	152 (20-306)	N/A[a]
Social distancing introduced (March 11)	104 (0-273)	N/A
Lockdown begins (March 18)	57 (0-209)	N/A
First full week of Lockdown (March 25)	28 (0-158)	N/A
Lockdown relaxed (May 13)	21 (0-199)	N/A
Shops reopen (June 17)	17 (0-197)	χ^2_2=2331, P<.001

[a]N/A: not applicable.

There were statistically significant changes in weekly minutes of tracked PA at all time points leading up to lockdown and in the weeks following the easing of lockdown measures (Table 4). There was a 2-minute reduction in activity between the baseline week (January 22, 2020) and the week nonessential travel and social distance restrictions were introduced. The week that the lockdown was announced, PA dropped by more than 30 minutes. By the following week (the first full week of lockdown restrictions), PA was down by 57 minutes compared with baseline. The drop in PA from baseline to the lockdown represents a 37% reduction in PA.

Table 4. Wilcoxon tests of change in physical activity from baseline to key weeks during the COVID-19 restrictions (January 22-June 17, 2020).

Key events (week commencing)	Mean change (minutes)	Percentage decrease from baseline	Median change (minutes)	Percentage decrease from baseline	*P* value
Social distancing introduced (March 11)	30	15	2	1	<.001
The lockdown begins (March 18)	67	33	32	21	<.001
First full week of the lockdown (March 25)	95	47	57	37	<.001
The lockdown is relaxed (May 13)	69	34	42	28	<.001
General shops reopen (June 17)	71	35	41	27	<.001

Overall, 63% of people decreased their level of activity between baseline and the first week of COVID-19 restrictions, 16% of people did not change their PA, and 21% increased their PA. The median change in PA was very similar for males and females (Figure 2). There appeared to be an effect of age, whereby younger people engaged in more PA before lockdown and the least amount of PA after lockdown (Figure 3). In contrast, those aged ≥65 years appeared to remain more active throughout and increased their activity levels as soon as the lockdown was eased.

Levels of PA among those classed as active at baseline showed a dramatic drop (Figure 4). Median levels of PA among those classed as fairly active at baseline also dropped but less dramatically. People who were inactive at baseline remained inactive throughout. Socioeconomic group did not appear to be associated with changes in PA (Figure 5).

GEE Models

A linear GEE was fitted to the data, with transformed week-on-week change in PA as the dependent variable. We explored the independent variables of gender, approximate age (as a continuous variable), deprivation decile, baseline activity level (inactive, fairly active, or active), and week (as a categorical variable). Examination of the data suggested an autoregressive correlation structure was appropriate. We fitted an AR(1) structure [22]. The resulting coefficients do not have a simple interpretation given the use of transformed data, but positive values indicate week-on-week increases in PA, while negative values indicate week-on-week decreases. Larger coefficients indicate larger changes. Sensitivity analyses were carried out using different assumptions for the correlation structure and with alternative modelling approaches. Similar results were found.

A basic model was fitted with just week as an independent variable, included as a categorical variable. This was statistically significant (χ^2_{20}=1759, *P*<.001). We then tested a model with the additional independent variables of age, gender, baseline activity, and deprivation index. This was statistically significant (χ^2_{24}=2562, *P*<.001). A likelihood ratio test showed improved fit from the additional variables (χ^2_4=895, *P*<.001). This indicated that older individuals showed more week-on-week increases in PA; that those who were most active showed more week-on-week decreases; and a pattern of increases and decreases over time matching Figure 1. All of these effects are independent of each other. There was no statistically significant relationship between week-on-week change and either gender or deprivation index, as shown in Table 5.

Table 5. Statistical analysis.

Variable	Coefficient	*P* value
Age (per decade)	0.08	<.001
Gender	–0.01	.50
Baseline activity (3 levels)	–0.38	<.001
Deprivation index	0.00	.60
Change from previous week to week n		
To week 2	0.84	<.001
To week 3	0.61	.001
To week 4	0.32	.07
To week 5	1.10	<.001
To week 6	0.54	.002
To week 7	0.33	.06
To week 8 (social distancing introduced)	–2.45	<.001
To week 9 (the lockdown begins)	–1.90	<.001
To week 10 (first full week of the lockdown)	0.55	.001
To week 11	0.62	<.001
To week 12	0.27	.10
To week 13	0.20	.20
To week 14	0.17	.30
To week 15	0.97	<.001
To week 16	0.94	<.001
To week 17 (the lockdown is relaxed)	0.28	.09
To week 18	0.83	<.001
To week 19	–1.40	<.001
To week 20	0.88	<.001
To week 21	0.50	.002
To week 22 (general shops reopen)	Baseline	Baseline

We additionally wanted to investigate whether the relationship with age varied over time. We simplified the time variable, dividing the weeks into three phases: weeks 1-7 (prelockdown), weeks 8-9 (the lockdown started), weeks 10-21 (the lockdown continued). A model using these phases as independent variables rather than individual weeks does not fit as well, but it fits well enough to allow the investigation of interaction effects. We tested the addition of two interaction terms for age in the "lockdown started" phase and the "lockdown continued" phase: these were statistically significant (likelihood ratio test, χ^2_2= 49, *P*<.001). This confirmed that older participants showed less decrease in PA when the lockdown began, and a greater increase in PA as the lockdown continued, confirming the interpretation of Figure 3.

Discussion

This longitudinal study of tracked PA, before, during, and after COVID-19 restrictions, showed large decreases in PA. Significant decreases in PA were observed at all time points from the week that social distancing measures were introduced, throughout the lockdown and the week measures were relaxed. PA was still significantly lower by the week commencing June 17, when nonessential shops reopened. The week that the lockdown was announced, median PA was down by 30 minutes and by the first full week of the lockdown, it had reduced by nearly an hour a week (57 minutes). This drop in PA represents a 37% reduction in individuals' weekly minutes of PA. Older people were significantly more likely to maintain and then increase their PA levels during the lockdown. Those who were most active to begin with showed the biggest falls in PA, but they had the furthest to fall. Although men showed more PA on average throughout, in our GEE model there was no effect of gender on the decline of PA. The deprivation index did not show any relationship with PA, although IMD is only an approximate measure of an individual's socioeconomic status, and the lack of evidence here may not translate into a lack of important socioeconomic effects.

Decreases in our study were substantially larger than the 9% drop observed from UK Fitbit step data [12]. Fitbit data ended

the week of March 22, which was just before the full lockdown restrictions were in place, and our data showed a 21% decrease in PA in the same week (week commencing March 18; our weeks ran Wednesday-Tuesday). Our smartphone-based measure may have overestimated the decline, since activity like incidental steps accumulated in the home or workplace would not have been captured. However, our study also showed greater decreases in PA than found in the large international tracking study by Tison and colleagues [15], who also using smartphone tracking. UK data from that study showed approximately a 10% decrease in mean steps from their prepandemic baseline level (mean daily steps from January 19 to March 11, 2020) to March 25, compared with a 37% decrease in tracked minutes in this study. It is not until the first week of April that percentage decreases in UK step counts converged with our findings, at around a 33% decrease from baseline, although our data included an estimate of time spent cycling as well as walking/running. The percentage drop in weekly PA in our findings is also in line with the international ECLB-COVID19 study, which found a reported 34% drop in the number of minutes of walking per day [9].

Overall, our findings are less optimistic than some studies of PA response to the pandemic that relied on data captured at the start of social restrictions. Increased interest in and intention to exercise have been reported elsewhere [8,20]. If such intentions existed in our sample, it appears they were only translated into action among older age groups. Those who were more active at baseline had the largest drops in PA and inactive people remained so throughout, contrary to findings that suggest a surge in PA during lockdown [10,11,23]. Perhaps of most concern are the fairly active group, who were close to doing recommended levels of PA for a number of weeks prior to lockdown and then dropped to doing no PA, with no sign of change as the lockdown was eased. We should not presume that these people will just automatically return to their prelockdown levels of exercise as restrictions are lifted. Measures to encourage this group back to prior levels of PA and continue to build on those efforts seem worthwhile.

In our study, older people showed less of a decrease in PA when the lockdown was introduced and recovered their PA levels during the lockdown faster than their younger counterparts. Concordant results were found by Fitbit [13] and by Smith and colleagues [11,24]. Our findings build on these prior results in suggesting that differences in maintained and increased PA in older age groups continued throughout the lockdown (and beyond). It is particularly interesting to note that approximately half of our sample of older adults were aged >70 years; that group had been urged by the UK Government not to go outside for even one daily bout of exercise. Although this is reassuring news about PA behavior in those aged >65 years, the large reduction in PA levels and failure to show any recovery for those below middle age is concerning. This picture suggests that policy interventions may be better focused on the long-term impact of restrictions on younger groups, which supports conclusions from recent research [11].

It was not possible to establish why we observed this pattern with age in our data. However, there is evidence that younger people are more worried about COVID-19, which may be a factor [25]. It is also feasible that factors like working/schooling from home had a stronger influence in younger age groups, but this is an area for future study.

Our study only tracked PA accumulated outdoors; some people may have substituted outdoor PA with indoor PA. BetterPoints users were given the opportunity to record activities such as “Be active at home” and “Try something new” during the lockdown, but analysis of this data was beyond the scope of the present analysis and may be included in future studies. The inclusion of live-streamed and prerecorded exercise classes in the app is currently being explored, while ways to routinely capture this type of activity and further surveying of users to understand whether they shifted to indoor exercise is underway. Wearables data suggest that while step counts may have reduced during the pandemic, vigorous activity may have increased, although these gains have not necessarily been maintained as we emerged from the lockdown [13]. This kind of activity may have continued among the previously active group but cannot be known from the current data.

While the approach of using app data gives us a good baseline and more valid measures of PA, we do have a sample bias as the results depend upon who uses BetterPoints. It may be that older adults who are using the BetterPoints app are a particular group who are more interested in exercise in the first place. Other limitations inherent in using data collected from smartphones include variability in how people carry and interact with their phones and variability in how many people track data on any given day. Although data on age, gender, and IMD were collected, information on other important demographics (like ethnicity) were not. In addition, although the app is free to use, smartphone ownership may be less common in some groups (eg, those with very low income). Only 79% of the UK population has a smartphone (2019 data), which means we cannot be sure how representative our data are of the UK population [26].

We have shown that tracked PA data suggests larger drops in PA during the United Kingdom’s COVID-19 lockdown than indicated previously. Significant differences by age group and prior PA levels suggests that blanket conclusions cannot be drawn about the impact of social distancing measures on population PA. The importance of better understanding in how to engage with and support different groups in tailored ways cannot be underestimated. Government response to COVID-19, particularly during the current situation where renewed outbreaks lead to local restrictions being imposed, needs to be sensitive to these individual differences and the government must react accordingly.

Authors' Contributions

All authors designed the study. HM handled data extraction and management. HM and HP did the analyses. HM wrote the first draft. All authors reviewed and edited the manuscript, revising it for intellectual content. All authors gave their final approval for publication and agreed to be accountable for all aspects of the work.

Conflicts of Interest

HM works for BetterPoints but is also studying for a doctorate at UCL. The study's other authors have no financial connection to BetterPoints. The company only shared anonymized data in line with privacy and data protection laws as approved by the UCL Ethics Committee and did not provide input into the study design, results, or analysis of the research. AF and HP have had a recent research project with Six to Start, who make apps promoting physical activity.

Abstract

Background: The COVID-19 pandemic has had a profound global impact on governments, health care systems, economies, and populations around the world. Within the East Asia and Pacific region, some countries have mitigated the spread of the novel coronavirus effectively and largely avoided severe negative consequences, while others still struggle with containment. As the second wave reaches East Asia and the Pacific, it becomes more evident that additional SARS-CoV-2 surveillance is needed to track recent shifts, rates of increase, and persistence associated with the pandemic.

Objective: The goal of this study is to provide advanced surveillance metrics for COVID-19 transmission that account for speed, acceleration, jerk, persistence, and weekly shifts, to better understand country risk for explosive growth and those countries who are managing the pandemic successfully. Existing surveillance coupled with our dynamic metrics of transmission will inform health policy to control the COVID-19 pandemic until an effective vaccine is developed. We provide novel indicators to measure disease transmission.

Methods: Using a longitudinal trend analysis study design, we extracted 330 days of COVID-19 data from public health registries. We used an empirical difference equation to measure the daily number of cases in East Asia and the Pacific as a function of the prior number of cases, the level of testing, and weekly shift variables based on a dynamic panel model that was estimated using the generalized method of moments approach by implementing the Arellano-Bond estimator in R.

Results: The standard surveillance metrics for Indonesia, the Philippines, and Myanmar were concerning as they had the largest new caseloads at 4301, 2588, and 1387, respectively. When looking at the acceleration of new COVID-19 infections, we found that French Polynesia, Malaysia, and the Philippines had rates at 3.17, 0.22, and 0.06 per 100,000. These three countries also ranked highest in terms of jerk at 15.45, 0.10, and 0.04, respectively.

Conclusions: Two of the most populous countries in East Asia and the Pacific, Indonesia and the Philippines, have alarming surveillance metrics. These two countries rank highest in new infections in the region. The highest rates of speed, acceleration, and positive upwards jerk belong to French Polynesia, Malaysia, and the Philippines, and may result in explosive growth. While all countries in East Asia and the Pacific need to be cautious about reopening their countries since outbreaks are likely to occur in the second wave of COVID-19, the country of greatest concern is the Philippines. Based on standard and enhanced surveillance, the Philippines has not gained control of the COVID-19 epidemic, which is particularly troubling because the country ranks 4th

in population in the region. Without extreme and rigid social distancing, quarantines, hygiene, and masking to reverse trends, the Philippines will remain on the global top 5 list of worst COVID-19 outbreaks resulting in high morbidity and mortality. The second wave will only exacerbate existing conditions and increase COVID-19 transmissions.

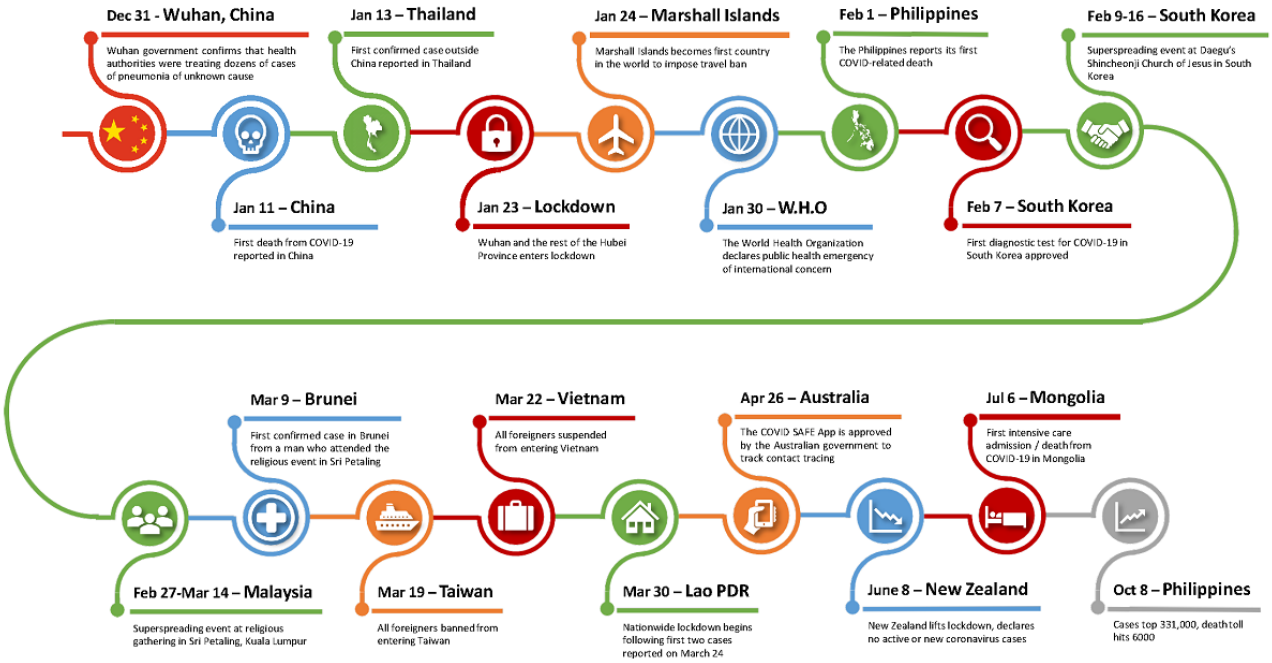
Introduction

Background

COVID-19, caused by SARS-CoV-2, was first identified in Wuhan, Hubei Province, China, in December 2019 [1]. Since then, it has spread around the globe including to every country in the East Asia and Pacific region, severely straining governments, health care systems, economies, and quality of life globally (Figure 1). East Asia and the Pacific, as defined by the World Bank, consists of American Samoa, Australia, Brunei Darussalam, Cambodia, China, Fiji, French Polynesia, Guam, Hong Kong, Indonesia, Japan, Kiribati, People's Democratic Republic of Korea, Republic of Korea, Lao People's Democratic Republic, Macao, Malaysia, Marshall Islands, Federated States of Micronesia, Mongolia, Myanmar, Nauru, New Caledonia, New Zealand, Northern Mariana Islands, Palau, Papua New Guinea, the Philippines, Samoa, Singapore, Solomon Islands, Thailand, Timor-Leste, Tonga, Tuvalu, Vanuatu, and Vietnam [2]. Not all of these countries collect or report COVID-19 caseloads and deaths, such as North Korea. As of October 28, 2020, the World Health Organization (WHO) reports a total of 43,540,739 cases and 1,160,650 deaths in these countries [3]. This global region encompasses countries of diverse income levels, political systems, cultures, populations, geography, climate, and health care systems, factors which have profoundly influenced not only the effects of the virus but also the response of each member country.

Figure 1. COVID-19 timeline in East Asia and the Pacific. WHO: World Health Organization. PDR: People's Democratic Republic.



Government Response and Public Health Policy

The extreme quarantine implemented in Wuhan and the entire Hubei region of China mandated all residents to shelter in place without exception [4]. Wuhan imposed travel restrictions in and out of the city in addition to canceling gatherings, closing public places, and shutting down schools and universities [5]. China allocated significant resources for public health service and epidemic prevention and control [6].

The prompt response by East Asian countries was informed by the 2003 severe acute respiratory syndrome (SARS) and 2015 Middle East respiratory syndrome (MERS) outbreaks [7,8]. Singapore and Vietnam's strategy of comprehensive surveillance

to detect and contain as many cases as possible has been highly successful in controlling or eliminating SARS-CoV-2 [9,10]. Taiwan's response to the 2003 SARS epidemic also informed COVID-19 response [11,12]. The Taiwan Centers for Disease Control aggressively traced confirmed cases while the government distributed masks and personal protection equipment [13,14]. Taiwan's interconnected public health, medical, and insurance infrastructure reduces barriers to doctor appointments and follow-up visits, allowing their health care system to capture more cases. Furthermore, their single-payer model allows for centralized health records of population-level longitudinal data, a valuable tool for analyzing the spread of the pandemic [11].

South Korea was the hardest hit country outside of the Middle East during the MERS outbreak in 2015, prompting the Korea Centers for Disease Control (KCDC) to prepare for the next infectious disease outbreak [15]. When COVID-19 breached Korea's borders, the KCDC actively performed contact tracing, quarantined exposed individuals, and diagnosed and isolated new cases with rapid and extensive testing [16-19].

New Zealand eradicated COVID-19 by introducing some of the strictest lockdown measures early on, allowing the government to pursue an elimination approach rather than the typical, mitigation-based model of pandemic planning. Schools and nonessential workplaces were closed, social gatherings banned, and severe travel restrictions applied [20-22]. Australia implemented similar though somewhat less stringent lockdown measures and border closures, resulting in substantially lower crude case fatality and hospitalization rates than many other high-income countries [23,24].

Some low- to middle-income countries such as Vietnam and Mongolia have also been able to implement successful responses to the pandemic despite limited resources or shared borders with China. As a result of Mongolia's travel restrictions, lockdown measures, and surveillance of active infections, they reported no confirmed cases until March 10, 2020, and no intensive care admissions or deaths until July 6, 2020 [25]. Vietnam responded immediately to its first cases by activating an emergency prevention system involving intense surveillance, quarantine, and contact tracing. Those who broke social distancing measures were severely punished. As of July 8, 2020, the nation had the highest test per confirmed case ratio in the world [26-31]. This approach differs vastly from the widespread testing strategy employed by South Korea, which, although seen by many as a best practice in fighting the pandemic, is more resource intensive [32].

In contrast, the Philippines has become Southeast Asia's coronavirus hotspot, overtaking Indonesia with a caseload exceeding 360,000 people with nearly 7000 deaths and no coherent strategy for defeating the virus [33]. Although their first case was reported in January 2020, a national lockdown was not enacted until March, and when citizens took to the streets to protest a lack of food and supplies 2 weeks later, President Rodrigo Duterte threatened that the police and military would shoot those who did not comply with stay-at-home orders [34-36]. Once the lockdown was lifted in June, cases quickly began to climb again. In addition, the Philippines was late to initiate COVID-19 measures including testing, isolation, and contact tracing [33]. Their result paralleled the United States with a similar outcome. The first wave is still raging through the islands while the second wave commences around the globe [37].

The Pacific Islands have been some of the least affected nations in the world due to their unique ability to shut down border traffic [38]. As of August 2, 2020, only 6 countries of the Pacific Islands (Papua New Guinea, Fiji, French Polynesia, Guam, New Caledonia, and Northern Mariana Islands) have recorded positive COVID-19 cases. Among the 12 countries without any confirmed cases, 10 are in this region (Kiribati, Marshall Islands, Micronesia, Nauru, Palau, Samoa, Solomon Islands, Tonga, Tuvalu, and Vanuatu). Furthermore, many nations recently strengthened their infectious disease prevention, surveillance, and response systems due to the re-emergence of measles in the area in 2019 [38-40].

Health Systems, Vulnerable Populations, and Health Disparities

The East Asia and Pacific region encompass a wide range of health care systems with varying capacities for pandemic preparedness. In New Zealand, approximately one-fifth of the government's spending goes to the health sector, and health services are either free or heavily subsidized [41]. In contrast, some of the world's smallest, least developed, and most isolated nations in need of health system strengthening are in the Pacific Islands region [42].

In the Philippines, 43% of the urban population lives in slums, and people living in densely populated urban slums are unlikely to have the space or economic means to practice social distancing [43,44]. The majority of Filipinos pay out of pocket for health care, a prohibitive cost that disproportionately affects the country's 7.5 million senior citizens, many of whom live in rural areas [45]. These barriers to access are exacerbated by the fact that hospitals in the Philippines are currently overwhelmed and reaching maximum capacity [45].

In Cambodia, more than 3 million people lack access to safe water, and 6 million lack access to improved sanitation. This disproportionately affects rural communities, where approximately 77% of Cambodians live, placing them at greater risk from the pandemic [46,47].

Meanwhile, the pandemic has added an additional layer of complexity to Indonesia's longstanding problem of food insecurity and reliance on food imports. In 2018, 55% of the Indonesian population experienced moderate or severe food insecurity. Unemployment and other loss of income associated with the pandemic have likely exacerbated this problem, with 70% of low-income households reporting a loss of income and about the same proportion reporting shortages of some foods or not eating as much as they should, placing 24 million children at risk of food insecurity [48].

Myanmar has attempted to combat the aggravating effects of food insecurity on its already underfunded health sector by providing emergency rations through strategies such as community-based food banks [49,50], although 10%-15% of

the population report consuming reduced quantities of nutritious foods [51].

Individuals with underlying medical conditions are also known to be at greater risk of COVID-19. In Australia, Indigenous Australians constitute a uniquely vulnerable population due to the increased prevalence of diabetes and respiratory and cardiovascular conditions, as well as high reported smoking rates [52,53]. China is notorious for having the worst air pollution problem in the world, which may correlate with susceptibility to respiratory infections [54-56].

Despite early exposure, a high population density, an aging population, and little social distancing measures, Japan reports low rates of infection and death from COVID-19 [57,58]. This has led to some hypotheses that the Bacille Calmette-Guérin (BCG) vaccine against tuberculosis may protect against the virus, as countries that mandate the BCG vaccine have relatively low per capita death rates from COVID-19 [57,59].

Economy

Tourism is an important source of revenue for many economies in developing Asia and the Pacific [50,60,61]. For countries like Palau, where international tourism receipts are close to 50% of the GDP (gross domestic product) and over a third of international tourists are from China, the decline in tourism due to COVID-19 has been devastating [60].

China is a major trade destination for many developing Asian economies such as Mongolia, the Philippines, Singapore, Taipei, and Vietnam [60]. Long quarantine-like conditions have the potential to deeply harm export-based economies such as Mongolia, where coal exports were reduced due to border restrictions [25].

Culture

While Western cultures endorse individualism and a more independent self-concept, Eastern cultures emphasize collectivism and a concept of the self as interdependent with others, which may motivate individuals to remain committed to COVID-19 precautions even at the expense of personal freedoms [62]. Some of the actions that have enabled Asian countries to contain the spread of the virus have been challenging to Western notions of privacy and individual freedom; such measures have been almost universally accepted in Asian countries [26,32]. Therefore, interpersonal transmission of the virus may be less likely in East Asian countries [63].

Public health departments, as well as universities and media outlets, are tracking the novel coronavirus using raw data, including the number of new infections, testing, positivity, R_0 (reproduction number), deaths, local hospital capacity, etc [39,64-93]. Public health surveillance informs policy on "flattening the curve" of COVID-19 [94-97]. Epidemiologists have utilized various modeling techniques to forecast the numbers of cases and deaths attributed to the virus [98-102]. Both the WHO and the Center for Systems Science and Engineering at Johns Hopkins University have developed tracking tools [98]. While helpful, these static metrics suffer from incomplete case ascertainment and data contamination [94,96]. Existing surveillance is a proxy for the true coronavirus caseload because public health surveillance systems tend to pick up the most severe cases [103,104], which is especially problematic when tracking SARS-CoV-2 because most carriers are asymptomatic, presymptomatic, or only have mild symptoms [105-108]. Public health surveillance that can control for these limitations are needed. Moreover, metrics that detect how transmission speed of the novel coronavirus, shifts in the pandemic, acceleration in speed, and persistence of COVID-19 based on prior infections are needed to supplement existing measures [83].

Objective

The objective of our research is to use a longitudinal trend analysis study design in concert with dynamic panel modeling and method of moments to correct for existing surveillance data limitations [94,96]. Specifically, we will measure significant weekly shifts in the increase, decrease, or plateaued transmission of SARS-CoV-2. Our study will measure the underlying causal effect from last week that persists through this week, with a 7-day persistence rate to explain a clustering/declustering effect. The 7-day persistence rate represents an underlying disease transmission wave, where a large number of transmissions that resulted in a large number of infections today then "echoes" forward into a large number of new transmissions and hence a large number of new cases 7 days later. If positive, it is consistent with, for example, a mega-event (eg, the large religious gathering at Daegu's Shincheonji Church of Jesus in South Korea) that causes an increase in the number of cases in adjoining days, among other explanations [16]. If zero or nonsignificant, it is indicative of a constant rate of new infections and/or a constant size of the infectious population. In summary, we will measure negative and positive shifts in the transmission of SARS-CoV-2 or acceleration/deceleration rates that are not limited by sampling bias.

Methods

We conducted a longitudinal trend analysis for our study design using data extracted from the internet. The COVID Tracking Project [109], Our World in Data [110], and The Foundation for Innovative New Diagnostics [111] compiles data from multiple sources on the web [112]; data for the most recent 4 weeks were accessed from the GitHub repository [113-115]. This resulted in a panel of 26 countries in East Asia and the Pacific with 30 days in each panel (n=780). An empirical difference equation was specified in which the number of positive cases in each country for each day is a function of the prior number of cases, the level of testing, and weekly shift variables that measure whether the contagion was growing faster, at the same rate, or slower than the previous weeks. This resulted in a dynamic panel model that was estimated using the generalized method of moments (GMM) approach by implementing the Arellano-Bond estimator in R (The R Foundation) [94,96,116]. Additionally, we report on the novel dynamic surveillance metrics of speed, acceleration, and jerk [94,96].

Results

Country Regression Results

Regression results are presented for 26 East Asian and Pacific countries in Table 1. Weekly surveillance data in Tables 2-6 and Figure 2 [117] are based on these regressions.

The Wald statistic for the regression was significant (χ^2_5=49,836,424; *P*<.001). The Sargan test was not significant, failing to reject the validity of overidentifying restrictions (χ^2_{294}=18; *P*=.99).

Table 1. Arellano-Bond dynamic panel data modeling of the number of daily infections reported by country in East Asia and the Pacific, October 5-18, 2020.

Variable	Statistic	*P* value
L1Pos[a]	*r*=–0.007	.89
L7Pos[b]	*r*=0.887	<.001
Cumulative tests	*r*=0.000	.15
Weekend	*r*=–0.603	<.001
Wald statistic for regression	χ^2_5=49836424	<.001
Sargan statistic for validity	χ^2_{294}=18	.99

[a]L1Pos: the statistical impact of a 1-day lag of speed on today's value of speed.

[b]L7Pos: the statistical impact of the 7-day lag of speed on today's value of speed. New cases per day tend to have an echo effect 7 days later. Reported as the weekly average number of new cases per day that are attributable to the weekly average of the 7-day lag of the number of new cases per day.

Figure 2. COVID-19 weekly trends in East Asia and the Pacific [117].

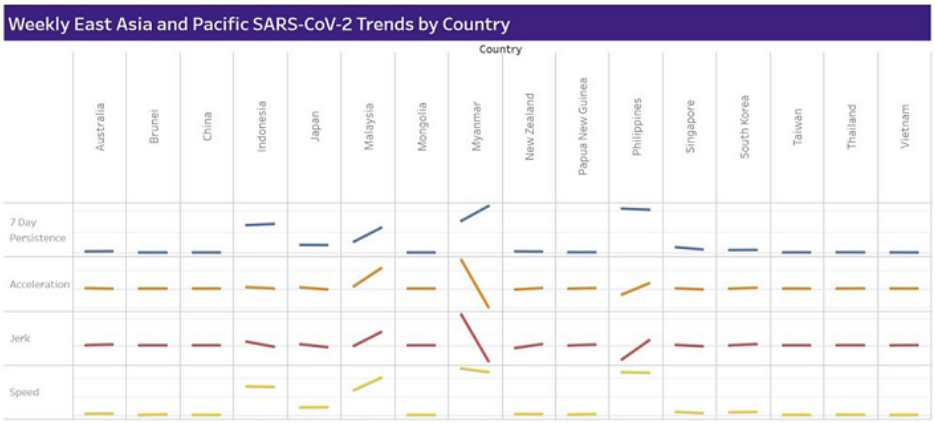


Table 2, for the week of October 5-11, and Table 3, for the week of October 12-18, present traditional surveillance metrics including new COVID-19 cases, cumulative COVID-19 cases, 7-day moving average of COVID-19 infections, infections per 100,000 population, deaths, cumulative deaths, and 7-day moving average of deaths rates per 100,000 population. Overall, in East Asia and the Pacific, by the second week, there were 9951 new daily cases of COVID-19, 1,076,042 cumulative cases of COVID-19, a 7-day moving average of 8005, an infection rate per 100,000 population of 0.4344, 216 daily deaths, and 28,053 cumulative deaths.

For the week of October 5-11, Indonesia led the East Asian and Pacific region with the highest number of new cases at 4294, followed by the Philippines at 2156 and Myanmar at 2158. The number of deaths follow the same pattern for Indonesia, the Philippines, and Myanmar at 88, 86, and 32 deaths, respectively.

For the week of October 12-18 (Table 3), Indonesia, the Philippines, and Myanmar continued to lead the region with 4301, 2588, and 1287 new COVID-19 infections and 84, 72, and 39 deaths, respectively. The cumulative number of deaths for the region reached 28,053 by the second week in October.

Table 2. Static surveillance metrics for the week of October 5-11, 2020.

Country	New COVID-19 cases, n	Cumulative COVID-19 cases, n	7-day moving average of new cases	Rate of infection	New deaths, n	Cumulative deaths, n	Death rate per 100k

Tables 4 and 5 provide the novel surveillance metrics for the weeks of October 5-11 and October 12-18, respectively. During the week of October 5-11 (Table 4), French Polynesia had the highest speed or velocity of new cases at 37 per 100,000 population, followed by Guam at 32.6 cases per 100,000 population. The highest rates of acceleration per 100,000 population was 0.312 for Myanmar, 0.025 for Malaysia, and 0.015 for Indonesia. The highest jerk rates were 0.228, 0.027, and 0.008 for Myanmar, Indonesia, and Japan, respectively. French Polynesia and Guam ranked 1 and 2 for 7-day persistence at 28.68 and 25.14, respectively, meaning these cases were statically attributed to those persons infected 7 days earlier.

Table 4. Novel surveillance metrics for the week of October 5-11, 2020.

Country	Speed[a]	Acceleration[b]	Jerk[c]	7-day persistence effect on speed[d]
Australia	0.07	0	0	0.05
Brunei	0	0	0	0

[a]Daily positives per 100k (weekly average of new daily cases per 100k).

[b]Day-to-day change in the number of positives per day, weekly average, per 100k.

[c]Week-over-week change in acceleration, per 100k.

[d]New cases per day per 100k attributed to new cases 7 days ago.

Table 5 presents the novel surveillance metrics for the second week of our study period. Between October 12 and 18, French Polynesia ranked first in speed of new infections at 56.5 per 100,000, followed by Guam at 46 per 100,000. French Polynesia and Guam are several standard deviations higher than the rest of the East Asian and Pacific region. French Polynesia had the highest acceleration rate at 3.17 per 100,000 population, and Polynesia had the highest positive jerk at 15.4 per 100,000 population. French Polynesia and Guam had the largest 7-day persistence during the October 12-18 period (Table 6). In summary, French Polynesia, Malaysia, the Philippines, South Korea, and New Zealand have positive speeds, acceleration, jerks, and 7-day persistence, indicating an upwards shift in the pandemic.

Table 5. Novel surveillance metrics for the week of October 12-18, 2020.

Country	Speed[a]	Acceleration[b]	Jerk[c]	7-day persistence effect on speed[d]
Australia	0.08	0	0.01	0.06
Brunei	0.03	0	0	0
China	0	0	0	0
French Polynesia	56.52	3.17	15.45	33.04
Guam	46.03	–7.60	–19.13	28.72
Indonesia	1.52	0	–0.01	1.38
Japan	0.42	–0.01	–0.01	0.36

[a]Daily positives per 100k (weekly average of new daily cases per 100k).

[b]Day-to-day change in the number of positives per day, weekly average, per 100k.

[c]Week-over-week change in acceleration, per 100k.

[d]New cases per day per 100k attributed to new cases 7 days ago.

Table 6. Seven-day persistence difference.

Country	7-day persistence	
	October 11, 2020	October 18, 2020
French Polynesia	28.69	33.04
Guam	26.14	28.72
Philippines	2.12	2.06
Myanmar	1.53	2.24
Indonesia	1.32	1.38

The most populous countries in East Asia and Pacific include China, Indonesia, Japan, Philippines, and Vietnam (Table 7). Countries with larger populations are at risk for having more COVID-19 infections by virtue of size, but this was not necessarily the case when comparing population size to the speed, acceleration, jerks, and 7-day persistence in Tables 4 and 5.

For comprehensive surveillance of static or traditional surveillance metrics with novel surveillance metrics for East Asia and Pacific, see Multimedia Appendices 1-3.

Table 7. Most populous East Asian countries.

Country[a]	Population as of 2020, N
China	1,439,323,776
Indonesia	273,523,615
Japan	126,476,461
Philippines	109,581,078
Vietnam	97,338,579

[a]Does not include countries that do not track or report COVID-19 cases (eg, North Korea).

Discussion

Countries in the East Asia and Pacific region have had differential success in combating the COVID-19 pandemic, with some countries among the most successful in the world at containing the pandemic and others in serious jeopardy. China, Taiwan, South Korea, and Japan had early outbreaks that were successfully contained through stringent protective measures. Some of the smaller islands in the Pacific encountered the disease much later than other countries, but after initial exposure, French Polynesia and Malaysia had outbreaks that swiftly affected their nations.

While South Korea, New Zealand, and Australia are demonstrating some increases in speed, acceleration, jerk, and 7-day persistence, these nations had successfully implemented COVID-19 control policies that literally eliminated COVID-19. However, as wave two of the COVID-19 pandemic has recently began the cycle of transmissions, these countries had either low caseloads or zero caseloads; hence, any new cases are going to result in increased rates of transmission. The new cases in countries that previously eradicated COVID-19 indicate a need to reinstate public health guidelines to keep the second wave of COVID-19 transmission from gaining a larger foothold. Moreover, other countries in East Asia and the Pacific who are presently dealing with the first wave will have novel infections from wave two as well, such as Indonesia and the Philippines who have the highest cumulative infections and cumulative deaths from COVID-19. While the Philippines was decelerating during the week of October 5-11, it reversed course and now has a positive acceleration.

The region's biggest successes are Singapore, New Zealand, Vietnam, South Korea, and China. In theory, it is likely easier to control for outbreaks in island nations such as Singapore and New Zealand; however, not all islands experienced their level of prevention and mitigation. Moreover, relative to population size (Table 7), South Korea, Vietnam, and China experienced an initial COVID-19 outbreak and took preventative measures to control further spread successfully.

Abstract

Background: Amid the COVID-19 pandemic, public health policies to curb the spread of SARS-CoV-2 and its associated disease, COVID-19, have resulted in significant alterations to daily routines (eg, work-from-home policies) that may have enabled longer sleep duration among the general population.

Objective: We aimed to examine changes in estimated sleep duration in 5 major metropolitan areas before and after the start of the COVID-19 pandemic.

Methods: We conducted a prospective observational study using estimated sleep duration data obtained from a smartphone app. The data were obtained from regular users of the smartphone app before and after the World Health Organization declared COVID-19 a pandemic in March 2020. We compared within-subject estimated sleep duration before and during the COVID-19 pandemic using generalized linear mixed models.

Results: Among the 2,871,037 observations, 957,022 (33.3%) were from users in London; 549,151 (19.1%) were from users in Los Angeles; 846,527 (29.5%) were from users in New York City; 251,113 (8.7%) were from users in Seoul; and 267,224 (9.3%) were from users in Stockholm. The average age of the users in the sample was 35 years (SE 11 years). Prior to the COVID-19 pandemic, people residing in Seoul had the shortest estimated sleep duration (mean 6 hours 28 minutes, SE 11.6 minutes) and those residing in Stockholm had the longest estimated sleep duration (mean 7 hours 34 minutes, SE 9.9 minutes). The onset of the COVID-19 pandemic was associated with a 13.7 minute increase in estimated sleep duration when comparing March 2019 and March 2020 (95% CI 13.1-14.3, $P<.001$) and an increase of 22.3 minutes when comparing April 2019 and April 2020 (95% CI 21.5-23.1, $P<.001$).

Conclusions: The average estimated sleep duration increased sharply in the months after the onset of the COVID-19 pandemic. This finding suggests that the implementation of COVID-19 mitigation strategies has provided people worldwide with increased opportunities to sleep, which may enhance the response of the immune system to viral pathogens.

Introduction

Public health officials worldwide have implemented stringent measures to curb the spread of SARS-CoV-2 and its associated disease, COVID-19. In some regions, actions to mitigate COVID-19 have been drastic, such as mandatory shelter-in-place regulations, while regulations in other regions have been more lenient [1]. In either case, life has changed markedly for much of the global population.

Research conducted amid crises of similar magnitude to the COVID-19 pandemic has shown that sleep is disrupted during and after such events [2-5]. For instance, research conducted after the 2003 severe acute respiratory syndrome (SARS) outbreak in China demonstrated an increase in insomnia symptoms associated with the onset of the outbreak [4]. In the context of a natural disaster, researchers found that 40% of people who survived an earthquake in Japan reported sleep difficulties in the years following the disaster, and 8% reported short sleep duration [6]. Although previous literature would suggest that sleep duration is likely to decline, sleep duration may increase worldwide during the COVID-19 pandemic for several reasons. First, due to the highly contagious nature of SARS-CoV-2 and the lack of a vaccine, social distancing and work-from-home recommendations and policies have been widely implemented to curb the spread of the virus [7]. As much of the global population is spending less time commuting, more time at home, and less time socializing, it is possible that their sleep duration will increase, contrary to what has been observed during previous crises.

Sleep is a critical element of immune system function [8,9]. Experimental studies have shown that inadequate sleep results in increased susceptibility to viral infection [10,11]. Research has also shown a heightened ability to mount an immune response among those who obtain a healthy, sufficient duration of sleep (ie, 7-9 hours) [12-14]. As the COVID-19 pandemic unfolds, surveillance of sleep duration may be important to identify poor sleep practices and to develop evidence-based interventions and campaigns to enhance sleep in response to this crisis as necessary. To further our understanding of sleep during the COVID-19 pandemic, we analyzed smartphone app–estimated sleep durations of individuals residing in London, England; Los Angeles, California, United States; New York City, New York, United States; Seoul, South Korea; and Stockholm, Sweden, before the onset of the COVID-19 pandemic (January 2019 through April 2019) and after the onset of the pandemic (January 2020 to April 2020).

Methods

Participants

We conducted a prospective observational study using data obtained from the smartphone-based sleep tracking software app Sleep Cycle. We obtained data from regular users of the app who tracked sleep on 80% or more of the days between January 1, 2019 and April 12, 2020 (at least 374/468 days). To understand geographic variations in sleep during the COVID-19 pandemic, we obtained data from individuals living in 5 major metropolitan areas (London, Los Angeles, New York City, Seoul, and Stockholm).

The selection of geographical regions was guided by several factors. First, urban regions were included in this study because there is a lower density of users in rural regions, which could have hindered comparison between rural and urban regions. Second, there were interesting differences in COVID-19 prevalence, preparedness, and mitigation strategies by geographic region. For instance, Sweden did not limit social mobility among its residents as strictly as other regions, such as the United States. Additionally, South Korea had experience combating a pandemic from the 2003 SARS outbreak. Therefore, we requested data from large urban centers on 3 different continents with the aim of exploring different patterns in estimated sleep duration from country to country that may be reflective in part of different prevalence, preparedness, or mitigation strategies implemented in these various countries.

The Sleep Cycle app logs a participant's place of residence by the coordinates identified by their smartphone GPS, which participants agree to provide when using the app. Only users who agreed to Sleep Cycle's privacy policy, which dictates that data may be used for research purposes, were included in the data set.

Estimated Sleep Duration

Users open the app when they go to bed and first attempt to sleep; they place their smartphone either next to their bed or on their mattress, and they close the app either after the built-in alarm clock wakes them or when they wake naturally from sleep. Sleep is calculated by the app as the time interval between these two digital sleep diary events (first attempt to sleep and waking) [15], in accordance with the 2016 Consumer Technology Association standards for wearable sleep monitors [16], herein termed "estimated sleep duration." We obtained an anonymized data set that included dated estimated sleep durations for each user between January 1, 2019 and April 12, 2020. The data set comprised 2,974,922 observations. We removed observations with a duration shorter than 1 hour from the data set to mitigate the impact of napping on the estimated sleep duration. These shorter observations represented 3.5% of the sample (103,885/2,974,922 observations). Removal of these shorter observations resulted in a final data set with 2,871,037 observations for analysis.

Statistical Analyses

Descriptive statistics were used to characterize the demographic characteristics of the sample. To evaluate population-level changes in estimated sleep duration during the COVID-19 pandemic while accounting for established seasonal variation,

we compared the estimated sleep duration by geographic location in the same calendar month between years using generalized linear mixed models. This method included hierarchical random effects for the city and study participants, which accounted for the dependence between repeated measures and the clustering of respondents in each location. This design enabled us to compare estimated sleep duration over time before and after the COVID-19 pandemic (eg, March 2019 vs March 2020) in each geographic location. All analyses were performed in Stata Statistical Software for Mac Version 16 (StataCorp LLC).

Results

In total, 2,871,037 nights from 8218 unique users between January 1, 2019 and April 12, 2020 were available for analysis. Of the 2,871,037 estimated sleep durations analyzed, 957,022 (33.3%) were from London; 549,151 (19.1%) were from Los Angeles; 846,527 (29.5%) were from New York City; 251,113 (8.7%) were from Seoul; and 267,224 (9.3%) were from Stockholm. The average age of users in the sample was 35 years (SE 11 years). Prior to the COVID-19 pandemic, those residing in Seoul had the shortest average estimated sleep duration (mean 6 hours 28 minutes, SE 11.6 minutes) and those residing in Stockholm had the longest average estimated sleep duration (mean 7 hours 34 minutes, SE 9.9 minutes); the average estimated sleep durations were 7 hours 32 minutes (SE 5.5 minutes) in London, 7 hours 21 minutes (SE 8.4 minutes) in Los Angeles and 7 hours 22 minutes (SE 6.3 minutes) in New York City. Table 1 displays descriptive demographic and estimated sleep duration characteristics by city prior to the COVID-19 pandemic.

Table 1. Descriptive statistics summarizing the participants' demographic characteristics and sleep data by city prior to the COVID-19 pandemic (N=2,871,037 nights; N=8,218 users).

Characteristic	Value	95% CI	SE
London (n=957,022 nights)			
Age (years), mean	34.4	34.3-34.4	0.0
Gender (n=2687 users), n (%)			
Male	1423 (53.5)	51.8-55.6	0.0

Female	418 (48.2)	44.8-51.5	0.0
Estimated sleep duration	7 hours 34 minutes	7 hours 33 minutes–7 hours 34 minutes	9.9 minutes

As shown in Figures 1 and 2, there was an increase in estimated sleep duration starting in February 2020 compared to February 2019, which coincided with the onset of the COVID-19 pandemic in the 5 cities across 3 continents.

Figure 1. Estimated sleep duration by month (January to April) in 2019 and in 2020 for the total sample. The I-bars represent the 95% CIs.

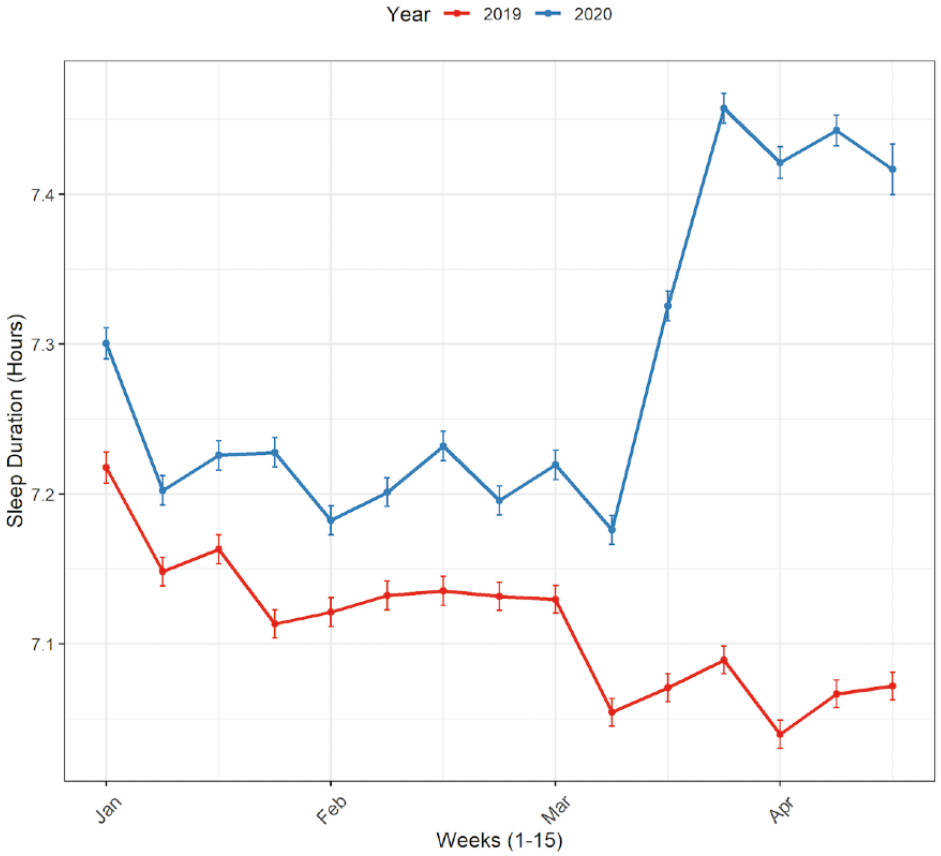

Figure 2. Estimated sleep duration by months (January to April) in 2019 and in 2020 for the total sample by city.

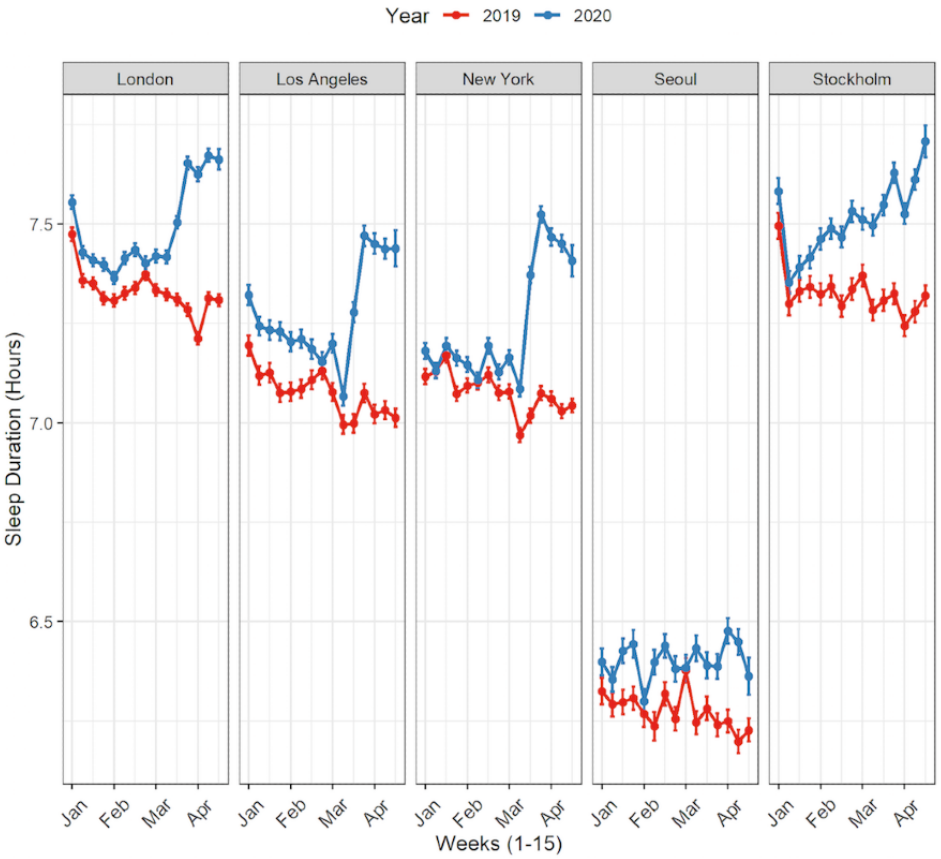
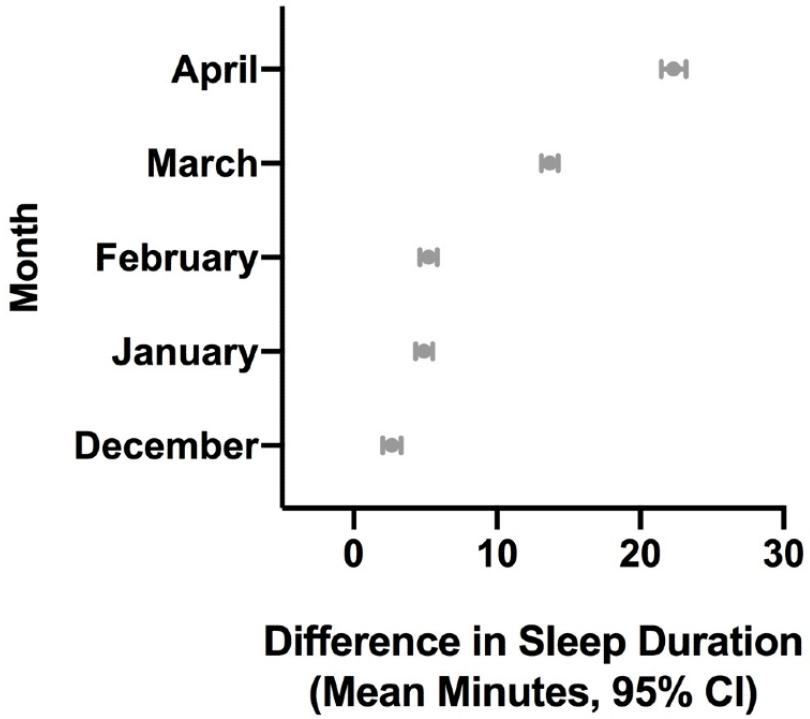


Results from the generalized linear mixed models are displayed in Figures 3-8. As shown in Figure 3, estimated sleep duration increased after the onset of COVID-19 in the total sample. In the total sample, comparing January 2019 to January 2020, we

observed increases of 4.9 minutes of estimated sleep duration (95% CI 4.3-5.5 minutes; *P*<.001); comparing February 2019 to February 2020, we observed increases of 5.2 minutes of estimated sleep duration (95% CI 4.81-5.91 minutes; *P*<.001); comparing March 2019 to March 2020, we observed increases of 13.7 minutes of estimated sleep duration (95% CI 13.1-14.3 minutes; *P*<.001); and when comparing April 2019 to April 2020, we observed increases of 22.3 minutes of estimated sleep duration (95% CI 21.5-23.2 minutes; *P*<.001) (Figure 3).

Figure 3. Difference in estimated sleep duration during the COVID-19 pandemic compared to the same month in the previous year in the total sample.



Models examining estimated sleep duration after the COVID-19 outbreak by city are displayed in Figures 4-8. Seoul had the smallest increase when comparing April 2019 and April 2020 (12.2 minutes, 95% CI 9.5-14.4 minutes; *P*<.001), while New York had the largest (24.5 minutes, 95% CI 23.1-25.9 minutes, *P*<.001), followed by London (20.8 minutes, 95% CI 19.5-22.1 minutes; *P*<.001).

Figure 4. Difference in estimated sleep duration during the COVID-19 pandemic compared to the same month in the previous year in London.

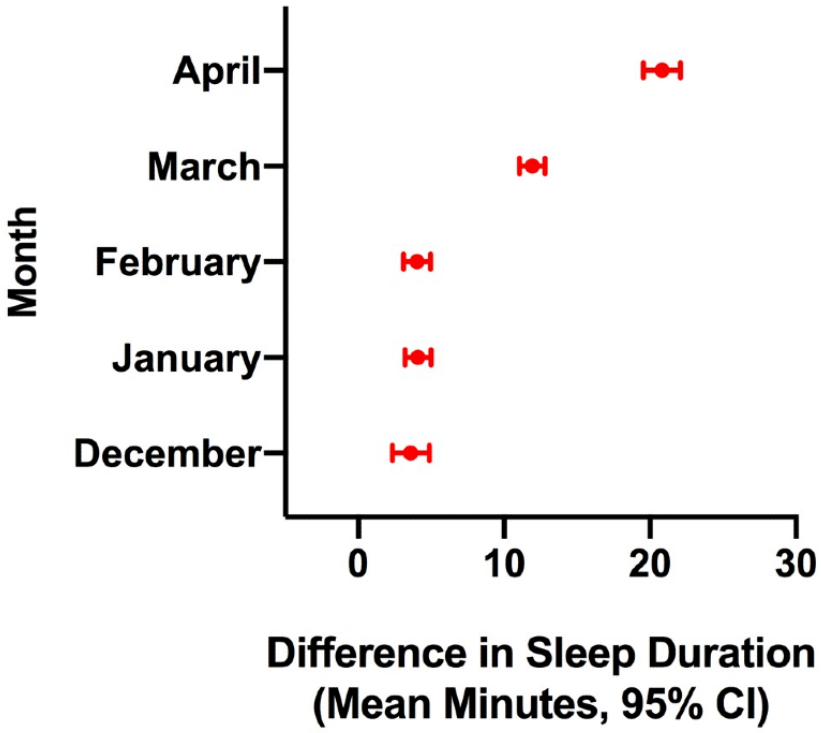


Figure 5. Difference in estimated sleep duration during the COVID-19 pandemic compared to the same month in the previous year in Los Angeles.

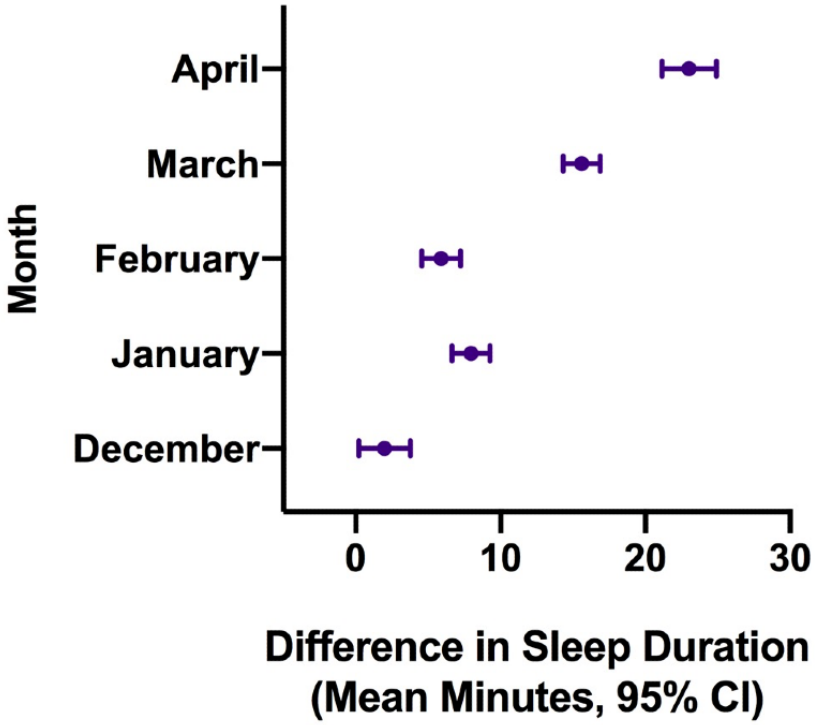

Figure 6. Difference in estimated sleep duration during the COVID-19 pandemic compared to the same month in the previous year in New York.

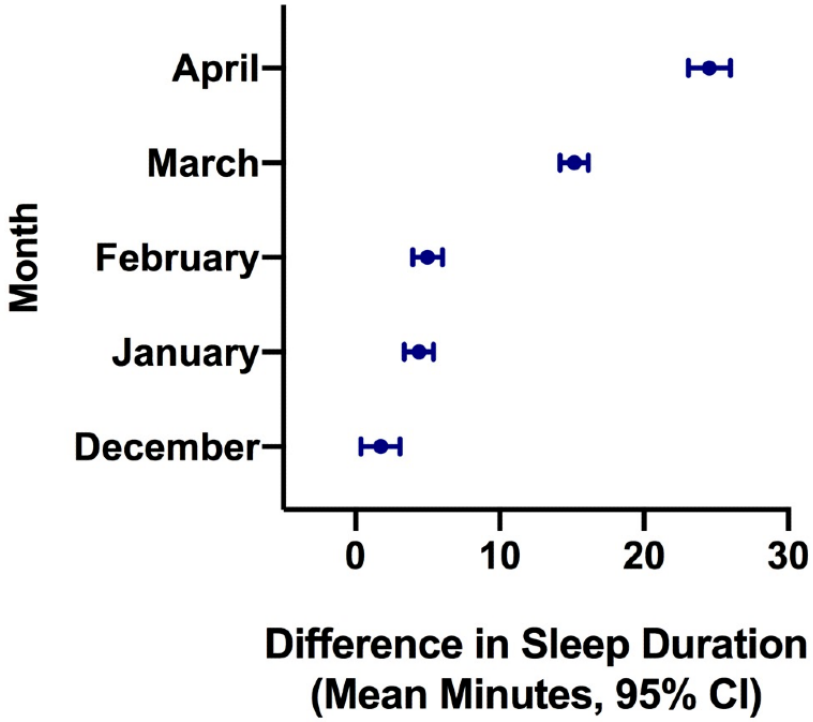

Figure 7. Difference in estimated sleep duration during the COVID-19 pandemic compared to the same month in the previous year in Seoul.

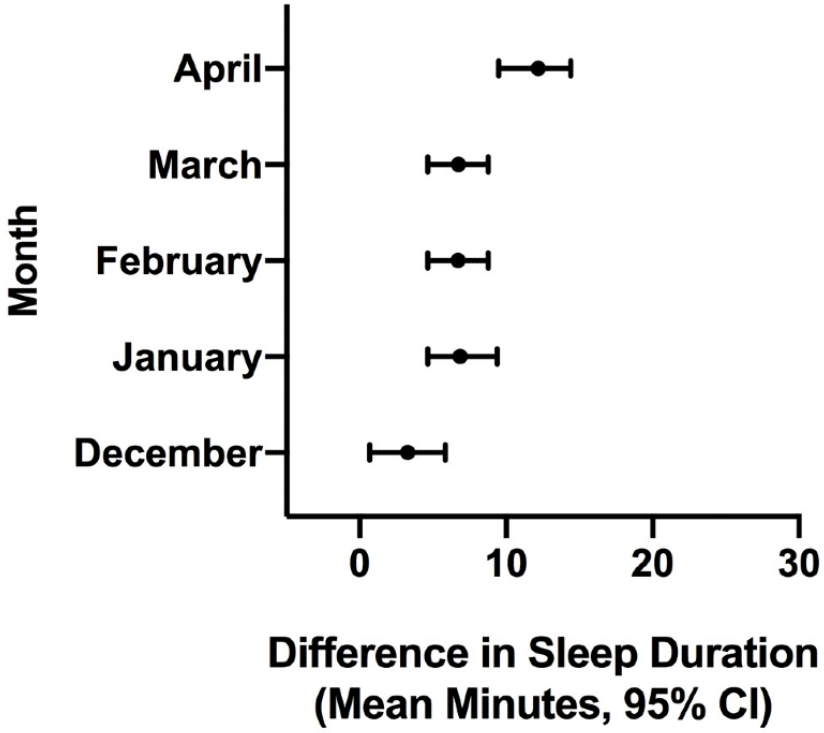

Figure 8. Difference in estimated sleep duration during the COVID-19 pandemic compared to the same month in the previous year in Stockholm.

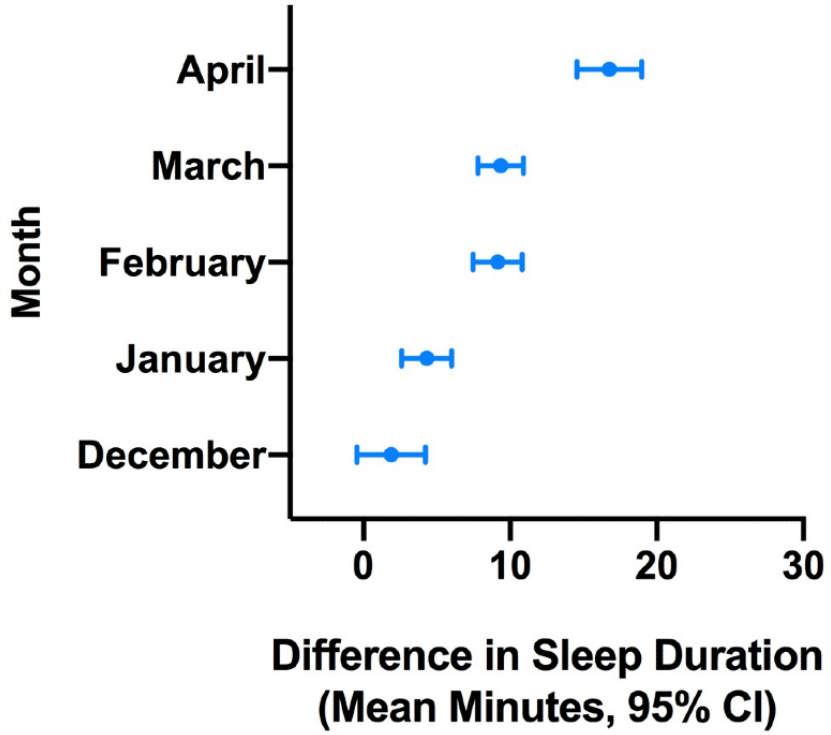

Discussion

Principal Findings

The results of this study, based on 2.9 million nightly recordings of smartphone-estimated sleep duration, demonstrate an abrupt, significant increase in estimated sleep duration in the months after COVID-19 was declared a pandemic and international health crisis by the World Health Organization [17] compared with the same months from the same individuals in the prior year. Further, the average estimated sleep duration in several regions was at or below the lower range of the recommendation for healthy sleep before the pandemic (ie, 7 hours or less), even among those concerned about sleep enough to track it; however, this duration increased to be within the range of healthy, sufficient sleep amid the onset of the COVID-19 pandemic. Our data, gathered from a daily sleep tracker smartphone app, reveal that on average there were significant increases in estimated sleep duration in London, Los Angeles, New York City, Seoul, and Stockholm concomitant with the onset of the COVID-19 pandemic, consistent with data from subjective, retrospective self-reports among 425 adults in 3 European countries [18]. We hypothesize that these increases in smartphone app–estimated sleep duration, together with the recently reported increases in sleep and wake time regularity following the onset of the COVID-19 pandemic [19], have occurred as a consequence of stay-at-home orders, nonessential business closures, and work-from-home policies implemented to slow community spread of the infection. Sufficient sleep duration is a critical element of immune system functioning, with inadequate sleep resulting in increased susceptibility to viral infection and reduced antibody production after vaccination [8,9]. We cannot exclude the possibility that individuals in this study were experiencing longer times in bed as opposed to longer estimated sleep duration. Nevertheless, if the observed increase in estimated sleep duration, as detected by the app, in fact represents an increase in actual sleep amid the COVID-19 pandemic, this may have been an important factor in reducing the risk of progression to COVID-19 following exposure to SARS-CoV-2 [10,11] and in enhancing the ability of people with COVID-19 to mount an effective immune response [12,13].

Additionally, we detected notable differences in sleep by geographic region. The average estimated sleep duration prior to the COVID-19 pandemic of app users in Seoul was >1 hour shorter than those in London and Stockholm, which is consistent with prior research, and >40 minutes shorter than those in New York City and Los Angeles. This is consistent with prior research, which documented that sleep deprivation is common in South Korea [20,21]. Moreover, app users in Seoul also demonstrated the smallest increase in estimated sleep duration during the COVID-19 pandemic, at 11 minutes per night compared to the increases of 20 minutes in other cities. The smaller increase in Seoul compared to other cities could be related to the outbreak of SARS in South Korea in 2003, which may have afforded an opportunity for the country to prepare and contain the spread of the virus without the more drastic mitigation measures, such as extended stay-at-home regulations, that were levied in other countries. Further, as the increase was very small, it also may be due to a natural month-to-month variation as opposed to trending in the direction of increased sleep duration as observed in the other cities. Although Sweden did not initially institute the stringent COVID-19 containment measures other countries chose to enact (eg, shelter-in-place policies), the estimated sleep duration increased in Stockholm at a rate similar to that in other regions that did institute stringent containment policies at the time. This may reflect that people residing in Stockholm are following precautions to another

people worldwide, despite not being restricted to their homes. Finally, the observed increase in estimated sleep duration in New York City of >20 minutes could be explained in part by the high number of cases of COVID-19 in New York City and the associated strict stay-at-home policies.

The increase in the estimated sleep duration observed in this study in response to the COVID-19 pandemic of between 12 and 24 minutes is of similar magnitude to the approximately 25-minute increase in total sleep time induced by controlled-release zolpidem [22]. Thus, the COVID-19 mitigation policies are associated with an increase in estimated sleep duration comparable to the impact of a hypnotic medication. This may be clinically important, as sleep deficiency—which is highly prevalent in developed countries—increases susceptibility to viral infection and diminishes the immune response to vaccination [10,11].

Although we detected an increase in estimated sleep duration after the onset of COVID-19 in several different metropolitan areas, the amount of sleep disturbance may have changed after the onset of the pandemic. Previous research has shown that sleep quality suffers in the face of major crises [2]. Specifically, research has documented a significant increase in sleep difficulty and arousal from sleep amid the 2003 SARS outbreak [4], during the bombings in Israel during the Persian Gulf War [3], and in the aftermath of natural disasters [5,6], consistent with the reported increase in self-reported insomnia symptoms in Wuhan, China, at the start of the COVID-19 pandemic [23]. Our data indicating an increase in the estimated sleep duration do not preclude the possibility that more people were suffering from disturbed sleep. Additional studies administering validated questionnaires assessing insomnia symptoms as well as self-reported sleep quality would be required to address this question.

Limitations and Future Research

This study is subject to a number of limitations. (1) Although a strength of our study is the large number of respondents offering user-generated sleep data over time and across several geographic regions, a limitation is that we did not obtain data pertaining to sleep latency, awakenings from sleep, or time in bed after waking. (2) Although users do not commonly use the app for napping, we removed observations that were shorter than 60 minutes. Future research may examine naps and how napping behaviors changed due to the COVID-19 pandemic and its mitigation strategies. Further, we did not have access to sleep timing data, which would have been useful in understanding whether users were going to sleep earlier or sleeping later as a result of the COVID-19 pandemic. (3) Employment or income demographics, which are not collected by Sleep Cycle, may represent unmeasured, confounding variables in our study. For instance, individuals from higher socioeconomic groups were more likely to remain employed and to work from home during the COVID-19 pandemic [24]. Those who were furloughed or remained employed and were allowed to work from home may have had more flexible work hours and spent significantly less time commuting, allowing them to spend more time in bed [25]. Moreover, with the proliferation of low-cost delivery services (eg, food and other goods) in major urban centers, users who were able to work from home may have had increased available time for sleep [26]. These results may therefore not be generalizable to those working essential jobs, whose work hours and commuting time may have increased during the COVID-19 pandemic and who may be underrepresented in this sample. (4) The sleep tracker smartphone app is not validated, and because it does not account for waking after sleep onset, it is possible that the tracker overestimates sleep duration. (5) Those who download and use the sleep tracker smartphone app consistently may be more interested in sleep and health in general, which may represent selection bias, survivorship bias, and less generalizability to the general public.

Our study identifies several avenues for future research; some reflect the limitations of the app. First, it is important to explore whether the findings we observed are transient or will persist for an extended period and whether other aspects of sleep changed during the COVID-19 pandemic. Second, data from the Sleep Cycle app require validation using objective measures, such as polysomnography or actigraphy. Third, it would be informative to determine the prevalence of sleep disturbance or insomnia symptoms, such as difficulty falling asleep or difficulty maintaining sleep, among users of this app. Finally, an exploratory qualitative investigation with users of Sleep Cycle may help to determine if actual sleep duration in fact increased during the COVID-19 pandemic or if users experienced more sleep difficulties despite having increased time in bed.

Conclusion

Public health officials' policies to mitigate the COVID-19 pandemic have required profound changes in peoples' daily routines worldwide. Using approximately 2.9 million nights of objectively recorded sleep on 3 continents via a sleep tracking smartphone app, we observed an abrupt, significant increase in average estimated sleep duration among 8218 unique users in 5 cities in the months after the onset of the COVID-19 pandemic. Thus, not only have COVID-19 mitigation strategies reduced the potential of infection with SARS-CoV-2, but the resulting increase in sleep episode duration may also have improved the ability of the immune system to resist infection. Future research should explore whether this observation is transient or persists over the long term and whether other aspects of sleep have changed amid the COVID-19 pandemic.

Acknowledgments

All authors contributed to the conceptualization of this study. RR, MDW, and MA conducted the statistical analysis. This work was supported in part by gifts from Sleep Cycle and Alexandra Drane. RR and MA created the visuals. RR drafted the manuscript. All authors reviewed and approved the final manuscript. The authors thank Dr. Daniel Sääf from Sleep Cycle for aiding in the data acquisition.

Conflicts of Interest

Abstract

Background: During the COVID-19 pandemic, new digital solutions have been developed for infection control. In particular, contact tracing mobile apps provide a means for governments to manage both health and economic concerns. However, public reception of these apps is paramount to their success, and global uptake rates have been low.

Objective: In this study, we sought to identify the characteristics of individuals or factors potentially associated with voluntary downloads of a contact tracing mobile app in Singapore.

Methods: A cohort of 505 adults from the general community completed an online survey. As the primary outcome measure, participants were asked to indicate whether they had downloaded the contact tracing app TraceTogether introduced at the national level. The following were assessed as predictor variables: (1) participant demographics, (2) behavioral modifications on account of the pandemic, and (3) pandemic severity (the number of cases and lockdown status).

Results: Within our data set, the strongest predictor of the uptake of TraceTogether was the extent to which individuals had already adjusted their lifestyles because of the pandemic (z=13.56; *P*<.001). Network analyses revealed that uptake was most related to the following: using hand sanitizers, avoiding public transport, and preferring outdoor over indoor venues during the pandemic. However, demographic and situational characteristics were not significantly associated with app downloads.

Conclusions: Efforts to introduce contact tracing apps could capitalize on pandemic-related behavioral adjustments among individuals. Given that a large number of individuals is required to download contact tracing apps for contact tracing to be effective, further studies are required to understand how citizens respond to contact tracing apps.

contact tracing; COVID-19; mobile app; digital health; epidemiology

Introduction

Background

In May 2020, Google and Apple released the Exposure Notification System, which is an application programming interface that logs the following: who a phone user has been in contact with, for how long, and at what distance [1]. This release came 2 months after COVID-19 was declared a pandemic [2], allowing governments to identify and isolate contacts of confirmed cases through a process known as “contact tracing” [3,4].

Less than a year after the first reported cases, over 33 million individuals have tested positive for COVID-19 worldwide and more than 1 million have died [5]. To limit disease spread, over

half of the global population has been subjected to lockdowns involving school closures, workplace shutdowns, and movement restrictions [6]. Although these lockdowns are effective in tapering the epidemic curve [7], they are costly to the global economy and are unsustainable [8]. However, allowing the virus to spread unhindered could overwhelm the health care system and result in large-scale mortality [9,10].

To address both infection control and economic concerns, several countries have turned to contact tracing to keep the economy running [11,12]. Epidemiological modeling suggests that if (1) cases are effectively identified (through rigorous testing protocols), (2) contact tracing is comprehensive (identifying all possible exposure), and (3) contacts are quarantined in a timely manner, this strategy can curb the spread of the virus [4,11]. In an optimal scenario, 80% of contacts should be traced on the same day an individual tests positive [3,11].

Conventional Versus Digital Contact Tracing

Early during the pandemic (and in previous infectious disease outbreaks), contact tracing was manually performed [13]. Using a range of interview and surveillance techniques, a human contact tracer would typically identify an average of 36 contacts for each positive case [14]. Although this strategy allows for high levels of case detection when there are few cases [15], its labor-intensive format—requiring ~12 h of tracing for each positive case [16]—is difficult to scale up. Additionally, individuals who test positive may forget whom they have been in contact with, thus undermining the effectiveness of the process [11].

Considering these limitations of manual contact tracing, several mobile apps have been developed to facilitate automated contact tracing [17], for example, COVID Watch in the United States [18], COVIDSafe in Australia [19], and Corona-Warn-App in Germany [20]. These apps primarily track Bluetooth signals from phones in the vicinity [3], capturing contacts without the restraints of staffing or recall biases [4,11]. Further, phone apps can notify individuals swiftly after a contact tests positive, allowing them to be quickly isolated [3].

Understanding the Predictors of Uptake

Despite the potential of digital contact tracing, a recent meta-analysis concluded that owing to implementation barriers, manual contact tracing should remain the order of the day [12]. One major barrier pertains to the uptake of mobile apps. Several modelling studies have assessed parameters needed for the COVID-19 reproduction number (R_0) to fall below 1 [3,11,21]. R_0 refers to the number of infections spread from 1 positive case, and a value less than 1 indicates that the virus has been contained. For this to be achieved, contact tracing apps need to be downloaded by at least 56% of the population [21], which is much higher than the average rate of downloads globally (9%) [22].

To increase uptake, Qatar made it mandatory for residents to use the official contact tracing app [23]. Although this legislation led to high download rates (>90% [24]), the potential backlash from the public (eg, because of privacy concerns [25,26]) implies that few countries are likely to follow suit. Correspondingly, public health agencies would benefit from an understanding of the predictors of voluntary downloads [27], providing an empirical basis to nudge citizens and residents to voluntarily download contact tracing apps [28].

The Current Study

Given the urgent need to boost contact tracing apps, this study is the first to identify sociodemographic factors predicting voluntary uptake. Our study was conducted in Singapore, where the world's first nationwide contact tracing app TraceTogether was launched in March 2020 [29]. TraceTogether uses a centralized approach adopted by several governments [19]; namely, randomly generated user IDs are generated and shared via Bluetooth with phones in close proximity [30]. When individuals test positive for COVID-19, they consent to add both their own user IDs and those of their contacts to a centralized database. This is used to identify matches, and exposure notifications are then sent from the server to close contacts [31,32]. (As an alternative model, a decentralized approach could be used where both matches and notifications are made through the user's phone [33].)

As Singapore was the forerunner of this technology, the app has accrued 2.3 million users within 6 months, including approximately 40% of Singapore's resident population or 50% of all smartphone users (considering a smartphone penetration rate of 82%) [34,35]. Correspondingly, our study represents a "best case scenario" for app uptake after several months have elapsed. In terms of the epidemic curve, our study was conducted between April and July 2020, as the country was in a lockdown (April to May 2020). This period witnessed a peak in daily COVID-19 cases (April: >1000/day or 175 per million population), which gradually tapered over time (July: >100/day or 17.5 per million population).

Methods

Study Design and Population

Between April 3 and July 17, 2020, we recruited 505 adults who met the following eligibility criteria: (1) at least 21 years of age and (2) had lived in Singapore for a minimum of 2 years. All participants responded to online advertisements. Within the constraints of online sampling owing to the pandemic, we strove to obtain a representative sample by placing advertisements in a wide range of online community groups (eg, Facebook or WhatsApp groups among individuals in residential estates, universities, and workplaces) and by using paid online advertisements targeting the broad spectrum of Singapore residents.

Prior to study enrolment, participants provided informed consent in accordance with a protocol approved by the Yale-NUS College Ethics Review Committee (#2020-CERC-001; ClinicalTrials.gov ID NCT04468581). They then completed a 10-min online survey hosted on the platform Qualtrics [36]. Data were collected in accordance with the second phase of a larger study tracking COVID-19 responses, and findings from the first phase have been described previously [37,38].

Outcome Variable: Use of TraceTogether

As the primary outcome variable, participants were asked to indicate whether they had downloaded the government's contact tracing app TraceTogether (binary variables: 1=they had, 0=they had not).

Predictors

Demographics and Situational Variables

As predictors of TraceTogether usage, participants then reported the following demographic data: age, gender, citizenship, ethnicity, marital status, education level, house type (a proxy of socioeconomic status in Singapore), and household size. Based on the survey timestamp, we also included the following as predictors: (1) the total number of cases in Singapore to date, (2) whether the nation was in a lockdown at the time of participation (0=no, 1=yes), and (3) a self-reported measure of confidence the government could control COVID-19 spread (4-point scale: 1="not confident at all," 4="very confident").

Other Behavioral Modifications

As a basis of comparison, participants were also asked to identify which of 18 other behavioral modifications they had made as a result of the pandemic (apart from downloading TraceTogether). Specifically, participants were asked whether they had (1) washed their hands more frequently, (2) used hand sanitizers, (3) worn a mask in public voluntarily (before a law was passed), (4) avoided taking public transport, (5) stayed home more than usual, (6) avoided crowded places, (7) chosen outdoor over indoor venues, (8) missed or postponed social events, (9) changed their travel plans voluntarily, (10) reduced physical contact with others (eg, by not shaking hands), (11) avoided visiting hospitals or other health care settings, (12) avoided visiting places where COVID-19 cases had been reported, (13) maintained distance from people suspected of recent contact with a COVID-19–positive individual, (14) maintained distance from people who might have recently traveled to countries with an outbreak, (15) maintained distance from people with flu-like symptoms, (16) relied more on online shopping (eg, for groceries), (17) stocked up on more household supplies and groceries than usual, or (18) taken their children out of school (for each item, 0=the measure was not taken, 1=the measure was taken). These values were then summed to compute an aggregated measure of behavioral change (out of 18), and were included as a predictor to assess whether contact tracing usage was associated with conventional behavioral modifications one undertakes during an epidemic [39,40].

As part of the survey, participants were also asked to specify any other behavioral modifications (n=9, 1.8%) or no other behavioral modification (n=2, 0.4%). However, these data were excluded from the statistical analyses owing to the low base rate of affirmative responses.

Data Analysis Plan

For primary analysis, binary logistic regression was used to identify predictors TraceTogether uptake. In the first model (model 1), participants' demographics were included as predictors (age, citizenship, gender, marital status, education level, ethnicity, household type, and household size). Citizenship (base=others), gender (base=female), marital status (base=single), and ethnicity (base=Chinese) were coded as dummy variables. In the second model (model 2), we repeated the first model with the inclusion of situational variables (log-transformed total number of COVID-19 cases to date and lockdown status). Finally, in the third model (model 3), we repeated the second model with the inclusion of the total number of behavioral modifications as a predictor. All data were analyzed using SPSS (version 23, IBM Corp) and R (version 3.6.0, The R Foundation), with the type 1 familywise error rate controlled at α=.05 via Bonferroni correction (Bonferroni-adjusted α=.003 [.05/17 predictors]).

Results

Demographics of the Sample

Table 1 shows the wide range of demographic characteristics of our study cohort (N=505). Compared to the resident population, the sample was matched in the following characteristics: ethnic composition, household size, and housing type (a proxy of socioeconomic status in Singapore) (≤10% difference). However, compared to the resident population, the present participants were more likely to be female (n=313, 62.0% vs 51.1%), single or dating (n=234, 46.4% vs 31.6%), to have a higher level of education or no tertiary education (n=65, 12.9% vs 51.7%), and to be citizens of Singapore or of other countries (n=456, 90.3% vs 61.4%).

Table 1. Baseline characteristics of survey respondents (N=505).

Variable	Value
Age (years), mean (SD)	37.82 (11.31)
Number of behavioral modifications, mean (SD)	9.81 (3.82)
Gender, n (%)	
Female	313 (62.0)
Male	192 (38.0)
Citizenship, n (%)	
Singaporean	456 (90.3)
Others	49 (9.7)
Highest education, n (%)	
No formal education	2 (0.4)
Primary school	2 (0.4)
Secondary school	23 (4.6)
Junior college	26 (5.1)
Institution of Technical Education	12 (2.4)

[a]HDB: Housing & Development Board.

Binary Logistic Regression

Of the 505 participants, 274 (54.3%; 95% CI 49.8%-58.7%) reported having downloaded TraceTogether. The download rate in this sample matches that of smartphone users in the resident population [34], and Table 2 describes the characteristics of users and nonusers.

Table 3 shows parameter estimates from logistic regression analyses of the predictors of TraceTogether uptake. No demographic or situational variable significantly predicted downloads (models 1 and 2). After controlling for these variables, the number of behavioral modifications emerged as a significant predictor (model 3); that is, with each unit increase in the number of behavioral modifications adopted, participants were 1.10 times more likely to download TraceTogether (z=13.56; P<.001).

Table 2. Characteristics of the users of TraceTogether (N=505).

Variable	TraceTogether usage	
	Users (n=274)	Nonusers (n=231)

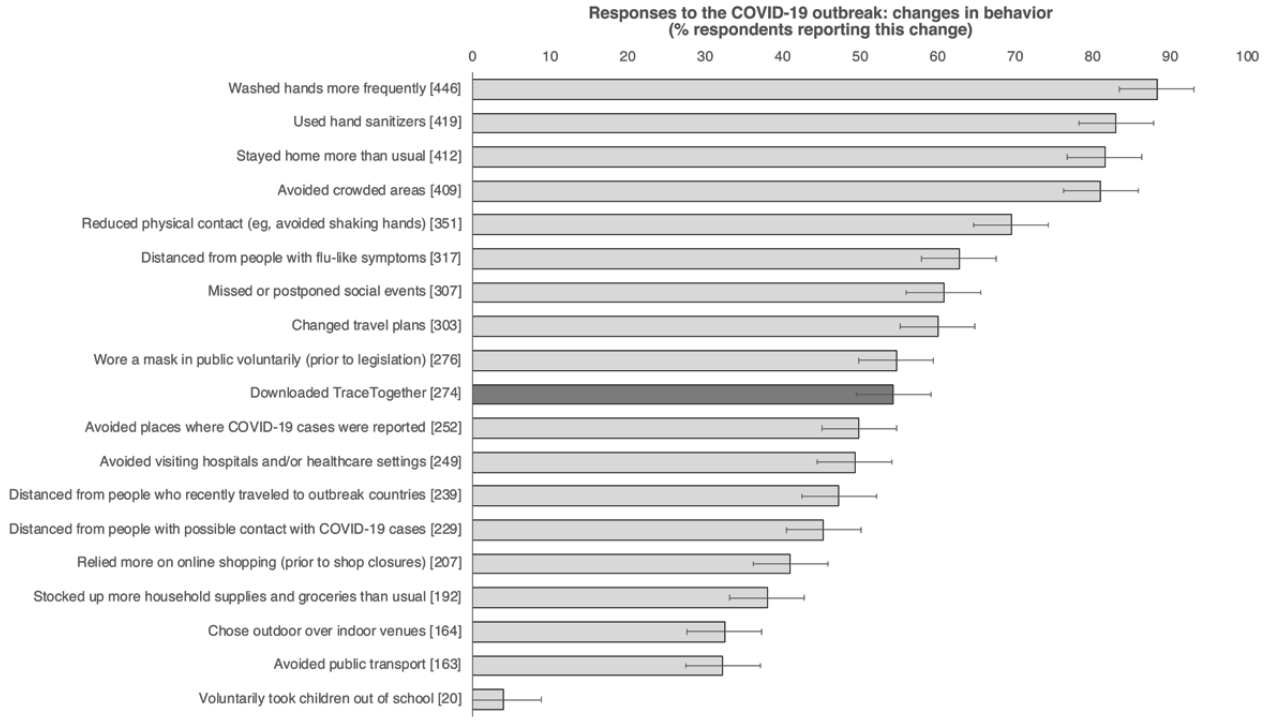
Post Hoc Network Analysis

In the logistic regression analyses, TraceTogether downloads were predicted from the number of behavioral modifications because of the pandemic. To understand this association better, we conducted further exploratory analyses.

As shown in Figure 1, the majority of participants had modified their behaviors to curb the spread of COVID-19. The use of TraceTogether ranked 10th in the frequency of adoption (274/505, 54.3%), similar to the frequency of voluntary mask wearing (n=276, 54.7%).

Figure 1. Self-reported behavioral modifications , other than downloading TraceTogether, among the study participants undertaken in response to the COVID-19 outbreak in Singapore. Error bars=95% CI. Numbers in brackets represent the total number of respondents who reported the behavioral change.

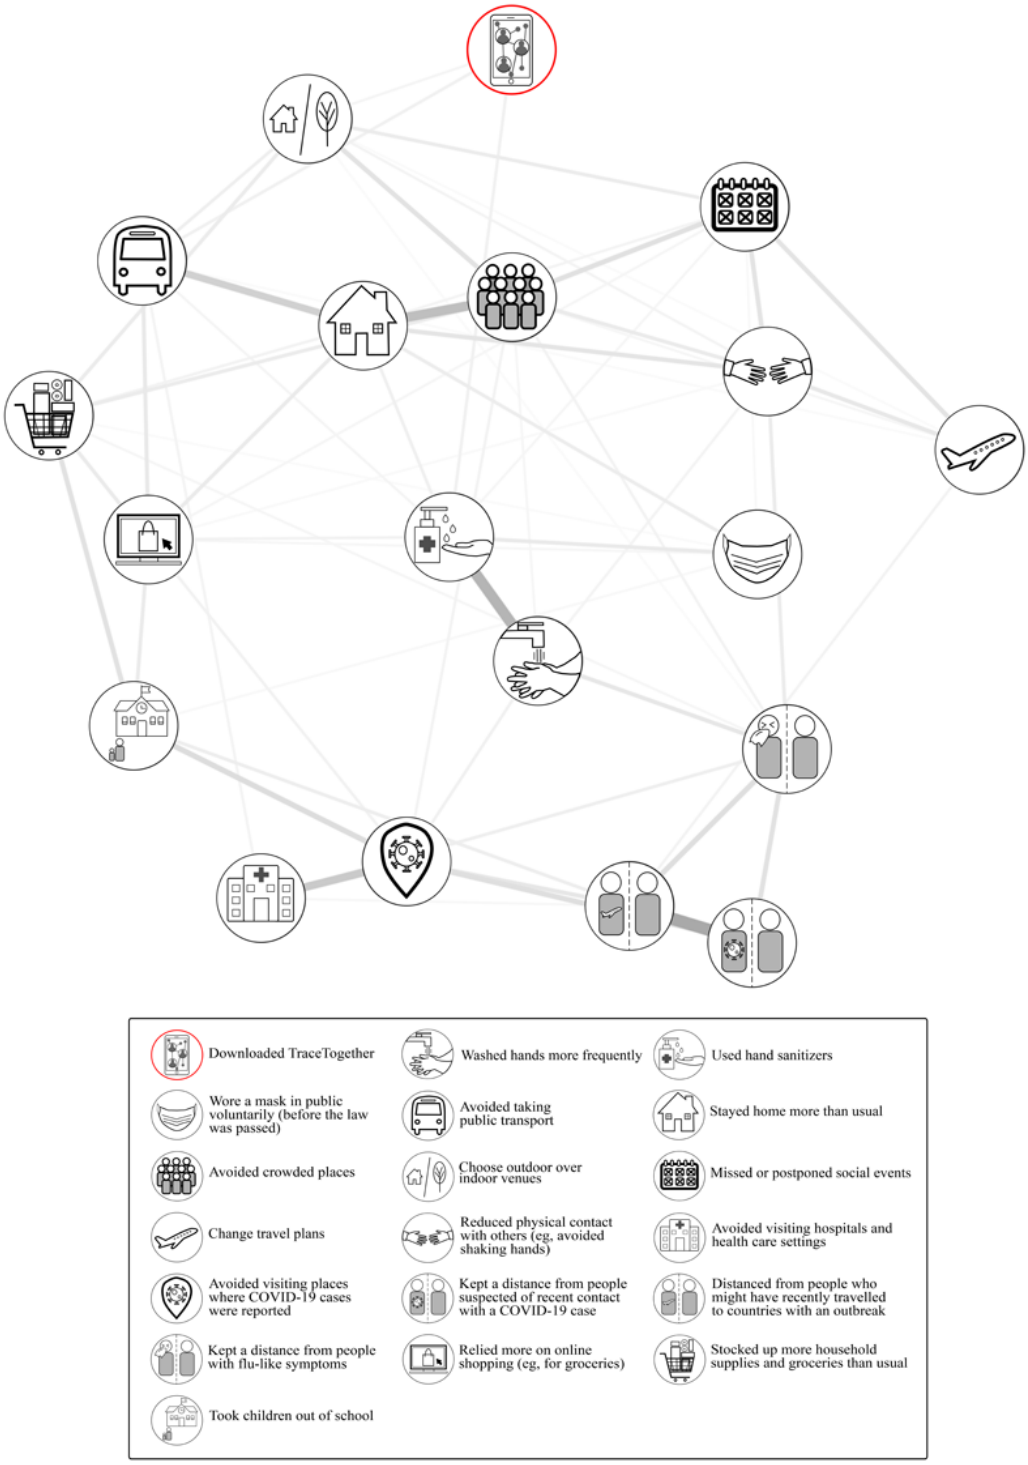


A corollary question is how TraceTogether usage is associated with other health protective behaviors; that is, how likely were people to download TraceTogether if they had modified their behavior in other ways? To address this question, we conducted network analyses by estimating a mixed graphical model (MGM) with the R package *mgm* [41]. MGM constructs weighted and undirected networks where the pathways among behaviors represent conditionally dependent associations, having controlled for the other associations in the network. Similar to partial correlations, each association (or "edge") is the average regression coefficient of two nodes. To avoid false-positive findings, we set small associations to 0 for the main models.

As shown in Figure 2, TraceTogether usage was associated with hand sanitizer use, avoidance of public transport, and a preference for outdoor vs indoor venues. The adjacency matrix (ie, numerical values for the average regression coefficient between two nodes) for Figure 2 is presented in Multimedia Appendix 1.

For sensitivity analysis, we performed logistic regression analysis using TraceTogether downloads as the dependent variable, and 18 other behavioral modifications (see Methods) as the predictors. Our conclusions did not change, as indicated in Multimedia Appendix 2.

Figure 2. A model depicting how TraceTogether usage relates to other pandemic-related behavioral changes. Line thickness represents the strength of an association.



Discussion

As lockdowns owing to COVID-19 ease globally, digital contact tracing will play an increasingly critical role in managing the epidemic curve. However, this requires the public to actively download a contact tracing app—a step that has proven elusive among public health agencies worldwide [12]. This study is the first to examine the demographic, behavioral, and situational factors potentially predicting the voluntary use of TraceTogether.

Behavioral Modifications

As our primary outcome, we observed that the number of behavioral modifications significantly predicted the use of TraceTogether. In other words, a person who had already changed his/her lifestyle on account of the pandemic was also

likely to download a contact tracing app. Network analyses revealed that downloads clustered with (1) using hand sanitizers, (2) avoiding public transport, and (3) preferring outdoor to indoor venues. This finding may suggest that public health campaigns could capitalize on other behavioral modifications when seeking to promote app downloads, for example, by printing information regarding a contact tracing app on the packaging of hand sanitizers or by framing the use of digital contact tracing as a preventive behavior. Policy makers might also expect app download rates to track behavioral modifications, anticipating, for example, higher download rates when the public fears an increase in COVID-19 cases (leading to more behavioral modifications) [42].

Theoretically, our findings further corroborate those of previous studies on how individuals change their behaviors during a pandemic. Based on prior outbreaks, a taxonomy of modifications had been identified whereby (1) "avoidant behaviors" are measures taken to avoid contact with potential carriers (eg, avoiding crowded places), while (2) "prevention behaviors" are those associated with maintaining hygiene (eg, regular hand washing) [42]. Extrapolating to the technological realm, our findings suggest that the use of a contact tracing app cuts across this taxonomy, since downloads were associated with *both* avoidant (avoiding public transport and preferring outdoor venues) and prevention behaviors (using hand sanitizers). Moving forward, we urge further studies to revise these classification systems in light of new technological developments.

Demographic and Situational Factors

Apart from behavioral modifications, it is notable that no demographic (eg, age, gender, etc) or situational variable (eg, number of COVID-19 cases and lockdown status) significantly predicted TraceTogether uptake. Prior to our study, it would have been conceivable that only a subset of the population would download a contact tracing app (eg, demographic groups based on gender, educational level, or age) [27,38,43]. By contrast, our findings highlight how uptake of digital contact tracing apps cuts across demographic groups.

While the lack of significant associations may be counterintuitive, a recent study reported similar results when predicting COVID-19–related behavioral modifications [42]. In a multinational survey, Harper et al [42] similarly observed that demographic and situational variables were unrelated to behavioral modifications owing to the pandemic. Since behavioral modifications predicted the use of a digital contact tracing app in our study, it seems reasonable to observe an analogous pattern here; that is, our results are unlikely to be based on false-negative outcomes.

As public health agencies develop strategies to promote downloads for contact tracing apps, the pattern of our findings may in turn suggest that demographic-specific messages are not needed. This is encouraging because the behavioral sciences offer widespread measures to "nudge" the general population [44]. In this case, the general public simply needs a one-off nudge to download the contact tracing app, after which the app functions independently in the background. Thus, if governments can nudge users in this first step (eg, by introducing incentives to download or by introducing contact tracing as an opt-out feature of existing government apps), it may be possible to attain the download rates necessary for contact tracing to be effective. Simultaneously, we urge further studies on the acceptance of such strategies; considering public concerns regarding privacy [25,26], any widespread intervention would need to be introduced cautiously.

Limitations

Our study has several limitations of note. As the first study of its kind, we made several choices at the exclusion of others. First, we opted for a cross-sectional design that precludes strong conclusions regarding causality. Second, we included an online sample to minimize person-to-person contact during the pandemic. Although we sampled individuals from a wide array of demographic groups, respondents were not representative of the general nationwide population; this may have deterred the establishment of potential associations among variables (eg, by including a high proportion of educated participants). Third, our survey relied on participants' self-reported use of a contact tracing app. Although our download rate is similar to that of the general population, further studies may seek to verify actual usage (eg, by incorporating survey questions in a contact tracing app). Fourth, our survey was not intended to measure every aspect of TraceTogether usage, and there were several notable omissions (eg, reasons why individuals chose to use or not use the app, phone ownership, and usage-related questions). Indeed, our model metrics (eg, small Nagelkerke R^2) indicate small effect sizes, highlighting the need for further studies to include a more comprehensive set of variables that may account for app downloads. Finally, we examined TraceTogether—an app with a centralized contact tracing protocol. Future studies are required to assess whether our findings extend to apps with decentralized protocols or to other forms of digital contact tracing that do not rely on mobile apps (eg, public acceptance of cloud-based contact in South Korea).

Conclusion

In conclusion, the potential contribution of digital technology to pandemic management is receiving increasing attention. What remains unclear, however, is how this technology is received and how best to promote its uptake. Focusing on contact tracing, this study shows that downloads of a mobile app was best predicted from the adoption of other infection control measures such as increased hand hygiene. In other words, the introduction of digital contact tracing is not merely a call to "trace together" but rather to "modify together," to use contact tracing apps as part of the broader spectrum of behavioral modifications during a pandemic.

Abstract

Background: SARS-CoV-2, the virus that caused the global COVID-19 pandemic, has severely impacted Central Asia; in spring 2020, high numbers of cases and deaths were reported in this region. The second wave of the COVID-19 pandemic is currently breaching the borders of Central Asia. Public health surveillance is necessary to inform policy and guide leaders; however, existing surveillance explains past transmissions while obscuring shifts in the pandemic, increases in infection rates, and the persistence of the transmission of COVID-19.

Objective: The goal of this study is to provide enhanced surveillance metrics for SARS-CoV-2 transmission that account for weekly shifts in the pandemic, including speed, acceleration, jerk, and persistence, to better understand the risk of explosive growth in each country and which countries are managing the pandemic successfully.

Methods: Using a longitudinal trend analysis study design, we extracted 60 days of COVID-19–related data from public health registries. We used an empirical difference equation to measure the daily number of cases in the Central Asia region as a function of the prior number of cases, level of testing, and weekly shift variables based on a dynamic panel model that was estimated using the generalized method of moments approach by implementing the Arellano-Bond estimator in R.

Results: COVID-19 transmission rates were tracked for the weeks of September 30 to October 6 and October 7-13, 2020, in Central Asia. The region averaged 11,730 new cases per day for the first week and 14,514 for the second week. Infection rates increased across the region from 4.74 per 100,000 persons to 5.66. Russia and Turkey had the highest 7-day moving averages in the region, with 9836 and 1469, respectively, for the week of October 6 and 12,501 and 1603, respectively, for the week of October 13. Russia has the fourth highest speed in the region and continues to have positive acceleration, driving the negative trend for the entire region as the largest country by population. Armenia is experiencing explosive growth of COVID-19; its infection rate of 13.73 for the week of October 6 quickly jumped to 25.19, the highest in the region, the following week. The region overall is experiencing increases in its 7-day moving average of new cases, infection, rate, and speed, with continued positive acceleration and no sign of a reversal in sight.

Conclusions: The rapidly evolving COVID-19 pandemic requires novel dynamic surveillance metrics in addition to static metrics to effectively analyze the pandemic trajectory and control spread. Policy makers need to know the magnitude of transmission

rates, how quickly they are accelerating, and how previous cases are impacting current caseload due to a lag effect. These metrics applied to Central Asia suggest that the region is trending negatively, primarily due to minimal restrictions in Russia.

Introduction

Background

On December 29, 2019, 4 cases of “pneumonia of unknown etiology” were reported in Wuhan, Hubei Province, China [1]. What began as 4 isolated cases escalated into a global pandemic of SARS-CoV-2, the virus that causes COVID-19. To date, the caseload has reached 68,645,081 confirmed cases, and 1,564,496 deaths have been confirmed globally [2]. Nations have been greatly impacted by the pandemic, which has resulted in significant morbidity and mortality, food insecurity, and an economic recession that has not bottomed out. Global leaders are struggling to balance disease control with salvaging their plummeting economies in the face of a global pandemic [3]. This study aims to examine where and when SARS-CoV-2 was transmitted in Central Asia within the context of a global pandemic by delving into the environmental, sociocultural, and public health characteristics of COVID-19. For the purposes of this study, we use the World Bank’s definition of Central Asia, which includes Armenia, Azerbaijan, Cyprus, Faeroe Islands, Georgia, Gibraltar, Kazakhstan, Kosovo, Kyrgyzstan, Macedonia, Russia, Tajikistan, Turkey, Turkmenistan, and Uzbekistan [4].

History of Central Asia

Central Asia is largely composed of nation states that are former Soviet Union member countries. The Union of Soviet Socialist Republics (USSR) was dissolved in 1991 after controlling the region for 68 years, following a coup d’état during President Gorbachev’s administration. The former Soviet Union left a lasting legacy in the former national republics [5]. The USSR shifted from a centralized government and systems to independent states. Many essential institutions, such as national currency systems and military forces, were developed from the ground up. Many of these fledgling nations failed to achieve democracies, which led to more chaos and conflict. The “colored revolutions” from 1999-2005, a series of mass protests and riots, lead to the overthrow of the semiauthoritarian regimes in Serbia, Georgia, Ukraine, and Kyrgyzstan [6].

Public health systems in these new nations in Central Asia faced many challenges, including endemic infectious diseases [7] such as tuberculosis, HIV, and substance use disorders [8,9]. Alcohol poisoning is relatively common in the former USSR [10], contributing to low life expectancy in Russia [11,12]. Central Asia has one of the highest prevalence rates of tobacco misuse [13]. Misuses of alcohol, tobacco, and other substances represent both direct and indirect COVID-19 risk factors. Drinking alcohol, smoking, and misusing substances increases a person’s risk of being infected with SARS-CoV-2 and having worse outcomes if infected [14-17]. Moreover, persons who are self-isolating are at higher risk of substance use disorders [18-20]. Substance use disorders also contribute to increases chronic disease [21-23]. During past epidemics, reduced access to medical care for individuals with serious illness, such as HIV or tuberculosis, resulted in more deaths from complications due to a lack of health care resources [24,25].

Food and Water Security

Progress in food security [26] has stalled in Central Asia in recent years, with growth in malnourished and undernourished populations [27]. Malnourishment is a function of poverty [28,29].

Food insecurity is linked to environmental conditions caused by overuse of the Aral Sea, which has been depleted by 90% since 1960 to irrigate large areas of land [30,31]. Safe water is not available for 22 million people (31% of the population) throughout Kazakhstan, Kyrgyzstan, Uzbekistan, Tajikistan, and Turkmenistan. The majority of the affected individuals live in rural areas, where there are limited sewer connections and septic tanks [32]. People living near the highly polluted Aral Sea have higher levels of tuberculosis, anemia, and cancer, and they may be at higher risk of debilitating SARS-CoV-2 infection [33].

Beyond access to food, obesity is becoming more pervasive [34] as Central Asian foods mirror the “Western diet” of high fat and low grains [26]. Traditional dishes have high contents of sodium, likely due to the “Silk Road” pattern in which countries along the former Silk Road, a trade route through Central Asia established in the second century BC [35,36], use large quantities of salt for food preservation [37]. Obesity also contributes to chronic metabolic diseases and is associated with worse outcomes in those infected with SARS-CoV-2 [38].

Current Politics

Because Kazakhstan and China share a border, preventative measures in Kazakhstan were established as early as January

6, 2020, enforcing increased border sanitation and monitoring arrivals from China [39]. The first cases of COVID-19 in Kazakhstan, discovered in people arriving from Germany and Italy, were recorded on March 13. A state of emergency was announced on March 16; schools converted to remote learning, and quarantines were established in some areas as early as March 19 [39].

Many countries in the region have had disruptions in the labor market. The oil economies in Kazakhstan and Azerbaijan have been negatively impacted [40]. Tajikistan has experienced rising unemployment [29], and the poverty rate has risen across Central Asia [41-46].

State governments have attempted to minimize the impact of the virus; complaints about lack of adequate personal protective equipment in Russia were suppressed [47], medical authorities who gave public health advice in Turkey were criminally investigated [48], and the oppressive Turkmenistan government denied the existence of even a single case of SARS-CoV-2 [49].

In the electoral authoritarian regime of Azerbaijan, lockdown was established immediately following the first confirmed case of SARS-CoV-2 on February 28. The capital of Azerbaijan instated highly restrictive rules and shut down its border with the Islamic Republic of Iran, where cases were spreading quickly, the next day [50].

In Azerbaijan, violations of the quarantine mandate were punishable by fines, custodial restraint, and prison time [51]. Severe rules were briefly in place; people aged over 65 years were prohibited from leaving their homes [50], and citizens were required to send an SMS text message to a government telephone number to request permission to leave their home for up to three hours. The government inactivated the cellular service of political rivals so that they could not request permission to leave their residences and thus were confined to their homes [51]. The pandemic has been exploited as a means to restrict individual human rights in other countries as well; government access to private cell phone data was allowed in Armenia [52], and protests were restricted in Russia [53]. In both Uzbekistan and Tajikistan [54], penalties were introduced for the spread of false information about the virus through the media.

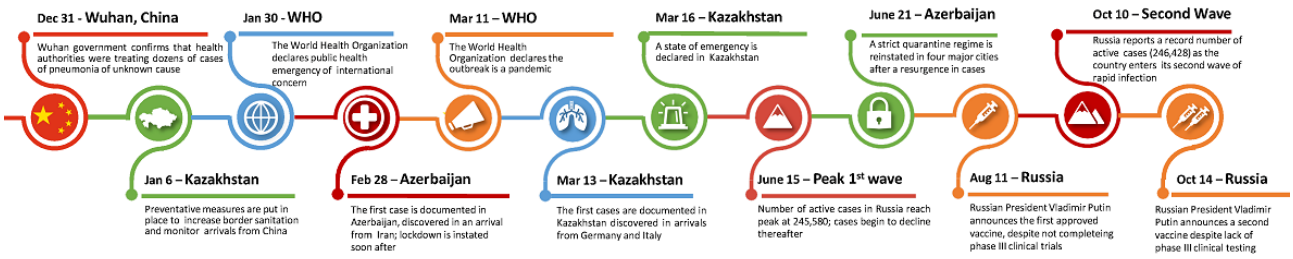
While Azerbaijan initially slowed the spread of the virus [55] and relaxed restrictions in May, the strict quarantine regime was reinstated in four major cities on June 21, 2020, after a surge in cases.

Shocking the international community, Russian President Vladimir Putin announced on August 11 that their country's health regulator was the first in the world to approve a SARS-CoV-2 vaccine for mass use [56]. This approval has been criticized as unsafe because the standard phase III clinical trials for new drugs were not completed at the time of his announcement [57]. While Russia's first approved vaccine, known as "Sputnik V," was still undergoing phase III trials, on October 14, President Putin announced the approval of a second SARS-CoV-2 vaccine [58]. Without adequate testing, we do not know the possible detrimental side effects of these vaccines, which may undermine attempts by the international community to provide safe immunization [56].

Other than vaccine efforts, Russia has not implemented significant public health measures. During the first wave of infections in March 2020, no financial support was given to small or medium-sized businesses despite instructions for employees to stay home on paid leave [59]. However, in mid-April, it was announced that over 100 billion rubles (US $1.325 billion) would be allocated to support small and medium-sized businesses [54]. The number of active cases in Russia reached a peak of 245,580 on June 15 and then began to decline [60]. With the second wave of infections in October after loosening restrictions, Russia saw a spike in cases and reported the fourth highest number of SARS-CoV-2 cases worldwide, behind the United States, India, and Brazil [61]. Russia reported a record number of 29,039 active cases on December 6 [60]. Despite record numbers of daily cases, with 26,097 new cases on December 8 for a total of 2,541,199 cases, protective measures continued to be rolled back. While gloves and masks are required in the Moscow metro, citizens must register their telephone number before entering a bar or nightclub; moreover, museums are closed, international flights are gradually being reinstated, and students in first through fifth grade are returning to school [62]. As early as July, the mayor of Moscow announced that wearing masks would no longer be required outdoors as new COVID-19 cases dwindled in the capital [54]. Figure 1 shows the timeline of the COVID-19 pandemic from December 2019 to October 2020 in Central Asia.

Without an effective vaccine to prevent COVID-19, Central Asian leaders require an effective SARS-CoV-2 surveillance system that enables their governments to make safe and informed decisions [63-70]. Public health departments [71-76] plus several universities [77] and media outlets [78,79] are tracking the novel coronavirus using raw data regarding the number of new infections, testing, positivity, basic reproduction number (R_0), and deaths, among other measures, such as local hospital capacity.

Figure 1. Timeline of the COVID-19 pandemic in Central Asia.



To that end, the objective of our research was to use a longitudinal trend analysis study design in concert with dynamic panel modeling and method of moments approaches to correct for existing surveillance data limitations [80,81]. Specifically, we measured significant weekly shifts in the increase, decrease, or plateaued transmission of SARS-CoV-2. Our study measured the underlying causal effect from the previous week that persisted through the current week, with a 7-day persistence rate to explain a clustering or declustering effect. The 7-day persistence represents an underlying disease transmission wave, where a large number of transmissions that resulted in a large number of infections on 1 day then "echoes" forward into a large number of new transmissions and hence a large number of new cases in the next 7 days. An example of the 7-day lag would be large sporting events in the United Kingdom that drew large crowds over an extended period of time even after cases were confirmed in the country. Other potential "super-spreader" events occurred in Turkmenistan, when a mass cycling rally was held on April 7 to celebrate World Health Day [82]. In summary, we measured negative and positive shifts in the transmission of SARS-CoV-2 or its acceleration and deceleration rates. We measured negative and positive shifts in the transmission of SARS-CoV-2 as well as the speed, acceleration or deceleration, and jerk rates along with the 7-day persistence, which do not suffer from sampling bias. For details, see Oehmke et al [80,81]. Our surveillance metric will provide public health surveillance data to inform governments that are making decisions regarding disease control, mitigation strategies, and reopening policies as they continue to manage this unprecedented situation.

Methods

This study relies on a longitudinal trend analysis of data collected from the Foundation for Innovative New Diagnostics (FIND) [83]. FIND compiles data from multiple sources across individual websites, statistical reports, and press releases. Data for the most recent 8 weeks were accessed from a GitHub repository that compiles data from multiple sources on the web; data for the most recent 4 weeks were accessed from the GitHub repository [84]. This resulted in a panel of 14 countries in Central Asia with 47-50 days in each panel (N=696). An empirical difference equation was specified in which the number of new positive cases in each country at each day is a function of the prior number of cases, the level of testing, and weekly shift variables that measure whether the contagion was growing faster than, the same as, or slower than in the previous weeks. This resulted in a dynamic panel model that was estimated using the generalized method of moments approach by implementing the Arellano-Bond estimator in R (R Project) [85].

Arellano-Bond estimation of difference equations has several statistical advantages: (1) it enables statistical examination of the predictive ability of a model and the validity of the model specification; (2) it corrects for autocorrelation and heteroscedasticity; (3) it has good properties for handling data with a small number of time periods and large number of states; and (4) it corrects for omitted variables and provides a statistical test of correction validity. With these advantages, the method is applicable to ascertaining and statistically validating changes in the evolution of the pandemic within a period of ≤1 week, such as changes in the reproduction rate. See Oehmke et al [80,81] for a detailed discussion of the methods. Finally, we calculated these indicators to inform public health leaders of where to take corrective action at a local level. China enjoyed great success at controlling the pandemic by closing down smaller geographical regions, preserving the larger economy and preventing other adverse outcomes from a national quarantine.

Results

Country Regression Results

We analyzed the 12 countries that are included in the Central Asia region as defined by the World Bank. The results of the associated regression supporting the weekly surveillance metrics are captured in Table 1. The Wald statistic for regression was significant (χ^2_7=14,217, P<.001). The Sargan statistic for validity was insignificant (χ^2_{550}=9, P>.99) and failed to reject the validity of overidentifying restrictions.

As shown in Table 1, the 1-day lag coefficient is positive and significant (1.075, P<.001), suggesting a clustering effect where the number of cases on a given day impact the number of cases on adjoining days. The 7-day lag coefficient and the impact of the limited testing over the weekend on case counts (the "weekend effect") are both insignificant. The shift parameters for the weeks of October 6 and 13 are also insignificant, suggesting that there were no major changes in the rate of disease transmission in the region between these 2 weeks in general. The coefficient for cumulative tests is insignificant.

Table 1. Arellano-Bond dynamic panel data modeling of the number of daily infections reported by country in Central Asia from September 30 to October 13, 2020.

Variable	Values	*P* value
1-day lag coefficient	1.075	<.001
7-day lag coefficient	–0.051	.89
Cumulative tests	0.000016	.55
Shift parameter, week of October 6	–0.157	.53
Shift parameter, week of October 13	–0.417	.12
Weekend effect[a]	–0.009	.99

[a]Weekend effect: impact of limited testing over the weekend on case counts.

Interpretation: Central Asian Regression Results

The 7-day lag and shift parameters suggest that there have been no recent changes in disease transmission rates. Additionally, there is no weekend effect or cumulative test effect.

Surveillance Results

Static and dynamic surveillance metrics for the weeks of October 6 and 13 are reflected in Tables 2-6, and Table 7 shows the most populous countries in Central Asia as of 2020. Tables 2 and 3 capture static metrics, including the number of new COVID-19 cases, number of cumulative COVID-19 cases, 7-day moving average of new cases, rate of infection, new deaths, cumulative deaths, 7-day moving average of number of deaths, and death rates. Novel dynamic metrics are reflected in Tables 4 and 5. These metrics include (1) speed, or the weekly average of new daily cases per 100,000 persons, (2) acceleration, or the day-to-day change in speed, (3) jerk, or the week-over-week change in acceleration, 4) 7-day persistence effect, or the number of new cases per 100,000 persons reported on a particular day that are associated with new cases reported 7 days previously. These novel metrics enable analysis of the impact of previous cases on current cases and identification of potential changes of the pandemic trajectory in the future.

Table 2 reflects static surveillance metrics for the week of September 30 to October 6, and Table 3 reflects those metrics for the week of October 7-13. The region averaged 11,730 new cases per day for the period ending on October 6 and 14,514 for the period ending on October 13. The infection rate increased across the region from 4.74 per 100,000 persons to 5.66. This increase in infection rate was accompanied by a slight increase in death rate from 0.09 per 100,000 persons to 0.11. Up to October 13, the region had reported 2,040,812 cumulative COVID-19 cases.

Table 2. Static surveillance metrics for the week of September 30 to October 6, 2020.

Country	New COVID-19 cases, n	Cumulative COVID-19 cases, n	7-day moving average of new cases	Infection rate (per 100,000 persons)	New deaths, n	Cumulative deaths, n	7-day moving average of the death rate	Death rate (per 100,000 persons)
Armenia	406	53,083	454.57	13.73	6	990	4.57	0.20

[a]Speed: daily positives per 100,000 persons (weekly average of new daily cases per 100,000 persons).

[b]Acceleration: day-to-day change in the number of positives per day (weekly average per 100,000 persons).

[c]Jerk: week-over-week change in acceleration per 100,000 persons.

[d]7-day persistence effect on speed: number of new cases per day per 100,000 persons.

Table 5. Novel surveillance metrics for the week of October 7-13, 2020.

Country	Speed[a]	Acceleration[b]	Jerk[c]	7-day persistence effect on speed[d]
Armenia	21.7	1.6	0.7	–0.8
Azerbaijan	2.1	0.2	0.2	–0.1
Cyprus	3.0	0.6	0.4	–0.1
Georgia	13.8	0.1	0.5	–0.7
Kazakhstan	0.5	0	0	0
Kosovo	3.6	0.5	0.3	–0.1
Kyrgyzstan	4.6	0.4	0.2	–0.1
North Macedonia	14.4	–1.0	–1.6	–0.5
Russia	5.2	0.1	0.0	–0.2
Tajikistan	8.7	0.2	0.0	–0.4
Turkey	0.4	0	0.0	0
Uzbekistan	1.9	0	0.0	–0.1

[a]Speed: daily positives per 100,000 persons (weekly average of new daily cases per 100,000 persons).

[b]Acceleration: day-to-day change in the number of positives per day (weekly average per 100,000 persons).

[c]Jerk: week-over-week change in acceleration per 100,000 persons.

[d]7-day persistence effect on speed: number of new cases per day per 100,000 persons.

Table 6. Comparison of 1-day persistence in the four countries in Central Asia with positive significant positive accelerations for the week of October 6, 2020.

Country	1-day persistence	
	Week of September 30	Week of October 6
Armenia	16.1	21.5
Georgia	13.0	16.5
North Macedonia	8.8	14.8
Russia	7.0	9.1

Table 7. Most populous countries in Central Asia as of 2020.

Country	Population as of 2020, n
Russia	145,953,632
Turkey	84,621,255
Uzbekistan	33,469,203
Kazakhstan	18,776,707

Russia and Turkey had the highest 7-day moving averages in the region, at 9836 and 1469, respectively, for the week of October 6, and 12,501 and 1603, respectively, for the week of October 13 (Tables 2 and 3). In terms of infection rate, accounting for population, Russia was at 7.95 per 100,000 persons and Turkey was at 1.81 for the week of October 06. The countries that had the highest infection rates in the region included Georgia, at 14.76 per 100,000 persons, and Armenia, at 13.73. For the following week, the infection rate in Armenia jumped to the highest in the region, at 25.19 per 100,000 persons, while Georgia had a very slight increase to 15.29. Kazakhstan had the lowest infection rate in the region, at 0.36 per 100,000 persons for the week of October 6.

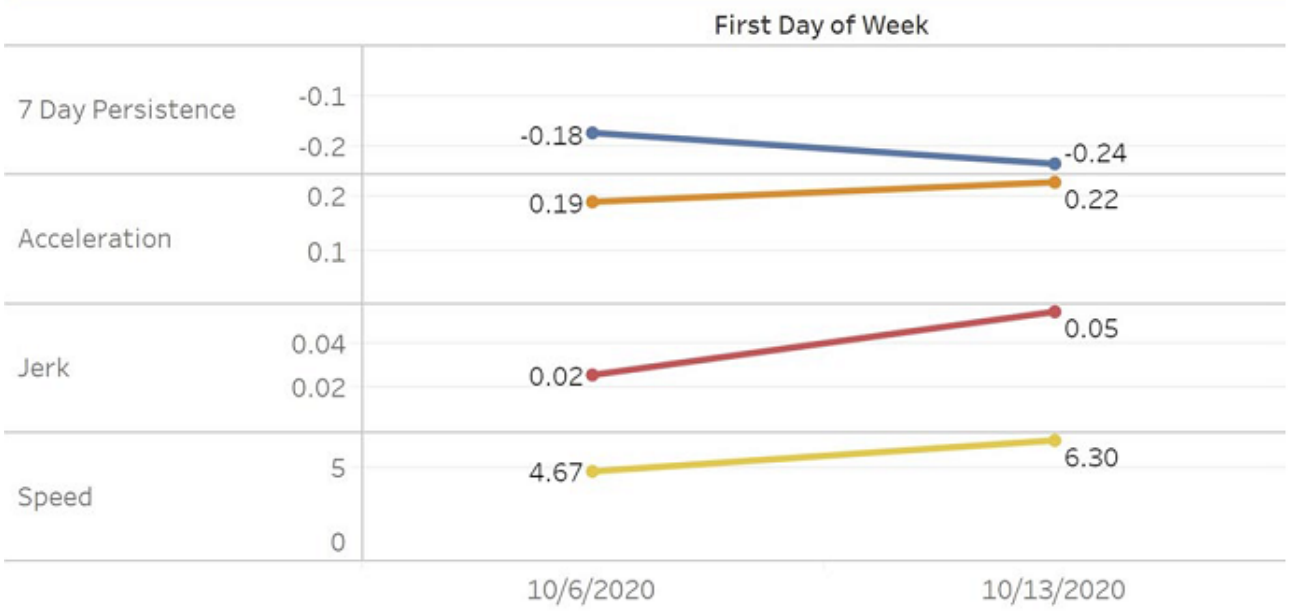
Russia and Turkey also had the highest 7-day moving averages of deaths in the region, with Russia at 157.57 per 100,000 persons for the week of October 6 and Turkey at 60.43. Together, they accounted for approximately 90% of the deaths reported in the region. Up to October 13, the region had reported 38,461 cumulative deaths. For the week of 10/06, North Macedonia and Armenia had the highest death rates per 100,000 persons in the region, at 0.38 and 0.20, respectively. Armenia maintained a death rate of 0.20 per 100,000 persons the following week. Georgia had the highest death rate the week of 10/13 at 0.24 per 100,000 persons, up from 0.11 the previous week.

The 1-day persistence is an indicator of a clustering effect where an event on a particular day causes an increase in the number of cases on adjoining days. As shown in Table 6, the 1-day persistence was highest in Armenia at 16.1, and it increased to 21.5 the following week. North Macedonia saw a large increase from 8.8 to 16.5, with Georgia and Russia seeing smaller increases from 13.0 to 14.8 and 7.0 to 9.1, respectively.

Largely consistent with infection rates, Armenia, Georgia, and North Macedonia had the highest speed or average of new daily cases per 100,000 persons. During the week of October 6, Armenia had a speed of 15.4, increasing to 21.7 the following week. Georgia had a speed of 13.0, which increased slightly the following week to 13.8. North Macedonia had a speed of 9.0, which increased to 14.4. The region overall had an increase in speed from 4.2 to 5.2.

Speed is best used in conjunction with acceleration and jerk, which can provide further insight into potential pandemic trajectory changes. Four countries in the region had significant positive accelerations for the week of October 6: Georgia at 0.9, North Macedonia at 0.8, Armenia at 0.4, and Russia at 0.3. North Macedonia, Armenia, and Russia also had positive jerks. During the following week, in addition to the highest speed, Armenia had the highest acceleration and jerk in the region. Figure 2 shows shows weekly trends of SARS-CoV-2 in Central Asia [86], and additional trends can be found in Multimedia Appendices 1-5.

Figure 2. Weekly SARS-CoV2 trends in Central Asia [86].



Discussion

Principal Results

COVID-19 poses a significant threat to the Central Asian region, which is largely composed of former Soviet republics. These countries continue to suffer from food insecurity, high levels of poverty, and variation in health care quality and access as the region continues on its journey of transitioning from a centralized Soviet medical system. The population also suffers from multiple endemic infections, such as HIV/AIDS and tuberculosis. Russia and Turkey comprise the bulk of the population in Central Asia, and these countries are facing growing burdens of chronic disease and some of the highest obesity rates in Europe. Due to the combination of these factors, the region is vulnerable to negative outcomes from the COVID-19 pandemic. To date, the region has seen variations in policy intervention to control the spread of COVID-19 and mitigate outbreaks. Some countries, such as Kazakhstan and Azerbaijan, imposed strict and early lockdowns, while others, such as Russia, imposed more limited interventions.

Metrics tracking the progression of COVID-19 in Central Asia to date have largely been static, including measures such as new cases, cumulative cases, deaths, and 7-day moving averages. These metrics provide a view of the current state of the pandemic but are unable to provide any insight into the change in the speed of the pandemic over time or potential shifts in its trajectory, evolving from controlled spread to rapid growth or vice versa. These metrics also provide limited utility in comparing countries to each other and in analyzing countries with smaller populations. Novel metrics such as speed, acceleration, and jerk help contextualize static metrics and provide a view of trajectory over time, enabling potential anticipation of how the pandemic will evolve in the future.

Considering the static and dynamic metrics, it is apparent that the Central Asian region is trending negatively. The region saw an increase in 7-day moving average of new cases, infection rate, and speed for the week of October 13 compared to the week of October 6, with continued positive acceleration. This trend is largely driven by Russia and Turkey, which together encompass over 70% of the region's population and showed the highest 7-day moving averages in the region. Russia has the fourth highest speed in the region and continues to experience positive acceleration.

Kazakhstan, the fourth most populous country in the region, had the lowest infection rate for the week of October 6. This is

likely due to a continued emphasis on policy interventions to curb the spread of COVID-19. Authorities in Kazakhstan took some of the earliest precautions to prevent infections and continue to strictly enforce pandemic mitigation measures, including halting the easing of restrictions due to the global spike in COVID-19 cases in recent weeks.

Turkey, while contributing a significant portion of the total cases in the region due to its population size, has maintained relatively low infection rates of 1.81 and 1.96 per 100,000 persons for the weeks of October 6 and 13, respectively. Turkey has taken significant precautions to mitigate the spread of the virus, and authorities continue to enforce rigorous mask wearing and social distancing guidelines along with local quarantines when necessary.

Armenia is experiencing uncontrolled spread of COVID-19, with an infection rate of 13.73 per 100,000 persons for the week of October 6 quickly jumping to 25.19, the highest in the region, the following week. The pandemic speed, consistent with the infection rate trajectory, increased from 15.4 to 21.7, with an acceleration increase from 0.4 to 1.6. This change is likely due to the recent lifting of the COVID-19 state of emergency, which allowed the resumption of in-person schooling and international flights, among other activities.

After Armenia, Georgia and Russia had the highest infection rates in the region for the week of October 13. Russia continues to resist implementing interventions to curb the spread of COVID-19, with no mask mandates, capacity caps, or nightlife restrictions. In addition to the significant focus on developing an effective vaccine, there has been limited intervention to manage the spread of COVID-19 in Russia. This policy stance is impacting the trajectory of the region, which is trending negatively with no sign of a reversal in sight.

Conclusion

The rapid evolution, novel outbreaks, and frequently fluctuating trajectory of COVID-19 cannot be adequately assessed using static public health measures alone. Static measures, including the number of new COVID-19 cases, number of cumulative COVID-19 cases, 7-day moving average of new cases, rate of infection, number of new deaths, number of cumulative deaths, 7-day moving average of number of deaths, and death rates, provide a current view of the state of the pandemic. However, these measures do not provide any insight into how the trajectory of the pandemic may change over time.

Generally, the approach to modeling the spread of COVID-19 is to assume there is an underlying contagion model [87] and then to attempt to measure those model parameters [88], which involves contact tracing to determine the spread of the disease [89-92]. With an incubation period of up to 14 days [93], modeling this spread can take months. Early estimates of COVID-19 were developed using the method by Lipsitch et al [94], which was used for contact tracing in Wuhan and Italy; however, the statistical properties were weak [95-100]. Zhao et al [96] estimated the serial interval distribution and R_0 based on only 6 pairs of cases, which is insufficient to understand the transmission of COVID-19 [101]. This results in relaxing of the assumptions in these models, such as disaggregating the population by geography and modeling within-geography and across-geography personal interactions [102]. Martcheva [103] developed a dynamic model from several contagion models and their possible dynamics [104,105]. They are limited to the statistical inference of parameter values from actual data [106].

Novel surveillance metrics allow for a more nuanced analysis of the COVID-19 pandemic and together with static metrics, can enable policymakers to make informed decisions to control the spread of the pandemic and prevent further outbreaks. Novel dynamic metrics include speed, acceleration, jerk, and 7-day persistence, and they provide potential insight into how the pandemic will evolve in the future.

The analysis of Central Asia using static and novel surveillance metrics suggests that the region is precariously positioned and trending negatively. Russia, the largest country by population, continues to have high infection rates and one of the highest speeds of infection. With no sign of increasing restrictions, it is unlikely that this trend will reverse and that outbreaks in the region will be controlled.

Limitations

Our data are limited by reporting methods across individual countries. Some countries, such as Turkmenistan, refuse to acknowledge COVID-19 cases. Variation in testing and infrastructure may impact the number of cases reported by other countries. The data are reported at a national level, which does not enable any subnational analysis.

Comparison to Prior Work

This study is part of a broader research program at Northwestern Feinberg School of Medicine (The Global SARS-CoV-2 Surveillance Project: Policy, Persistence, & Transmission). Novel surveillance metrics, including speed, acceleration, jerk, and 7-day persistence, have been developed by this research program and are being applied to all global regions.

Abstract

Background: The COVID-19 pandemic is affecting people with dementia in numerous ways. Nevertheless, there is a paucity of research on the COVID-19 impact on people with dementia and their care partners.

Objective: Using Twitter, the purpose of this study is to understand the experiences of COVID-19 for people with dementia and their care partners.

Methods: We collected tweets on COVID-19 and dementia using the GetOldTweets application in Python from February 15 to September 7, 2020. Thematic analysis was used to analyze the tweets.

Results: From the 5063 tweets analyzed with line-by-line coding, we identified 4 main themes including (1) separation and loss; (2) COVID-19 confusion, despair, and abandonment; (3) stress and exhaustion exacerbation; and (4) unpaid sacrifices by formal care providers.

Conclusions: There is an imminent need for governments to rethink using a one-size-fits-all response to COVID-19 policy and use a collaborative approach to support people with dementia. Collaboration and more evidence-informed research are essential to reducing COVID-19 mortality and improving the quality of life for people with dementia and their care partners.

(J Med Internet Res 2021;23(2):e26254) doi:10.2196/26254

KEYWORDS

Twitter; social media; dementia; COVID-19; health policy; experience; support; disorder; theme; collaborate; quality of life

Introduction

The COVID-19 pandemic is having an impact on people with dementia. In Canada, almost two-thirds of all COVID-19–related deaths have been people with dementia [1]. In the United Kingdom, 50% of COVID-19–related deaths in care homes have been people with dementia [2].

In comparison to other groups, people with dementia are among the most vulnerable to the COVID-19 pandemic [3]. Although people with dementia are not necessarily more susceptible to COVID-19, advancing age, frailty, and coexisting health conditions often associated with dementia (eg, cardiovascular disease, hypertension, or diabetes) increase the risk of complications [4,5]. Moreover, social isolation measures (eg, stay-at-home orders, visitation bans, and lockdowns in care facilities) from COVID-19 may increase the risk of hospitalization and mortality for people with dementia [6].

People with dementia also face a heightened risk of COVID-19 exposure due to cognitive impairment and memory loss [3]. For example, people with dementia may have challenges remembering or understanding self-protection protocols such as wearing a mask, using proper hand hygiene, and maintaining physical distance from others [7,8]. Despite these challenges, there is a paucity of knowledge on the COVID-19 pandemic's impact on people with dementia.

There is an urgent need to understand the experiences of people with dementia and their care partners in the COVID-19 pandemic [8-10]. Mitigation strategies that include physical distancing make it difficult to conduct timely and collaborative research, with many universities suspending recruitment and in-person studies during the pandemic [11]. Given these difficulties, examining the impact of COVID-19 requires ingenuity and innovation.

With over 330 million monthly users [12], the microblogging and social networking website Twitter [13] presents an innovative opportunity to examine the COVID-19 impact on people with dementia. For example, Twitter users are publicly sharing lived experiences of COVID-19 and dementia. The purpose of this study is to use Twitter to understand the COVID-19 experiences of people with dementia and their care partners.

Methods

Recruitment

We scraped tweets posted in the English language containing synonyms for dementia (eg, "Alzheimer's disease" and "Lewy Body disease") and synonyms for COVID-19 (including nontechnical phrases such as "Corona") during the period from February 15 to September 7, 2020, from Twitter using the GetOldTweets application programming interface in Python [14]. The Tweets were not geo-tagged.

Twitter is a social media and microblogging website where users share their posts with the public. Following on existing studies, there is a general consensus that tweets posted publicly on Twitter can be used for research [15,16]. Tweets on the Twitter website are located within the public domain; informed consent was not obtained.

Data Exclusion

From the approximately 20,800 tweets that were gathered using these criteria, we applied filters referring to candidates for the US presidential election (eg, synonyms for "Donald Trump" and "Joe Biden"). In addition, the filter "Tom Seaver" was used to delete tweets of public reactions to the major league baseball player who was reported to have died on August 31, 2020, of complications due to COVID-19 and dementia with Lewy bodies. Retweets and nonoriginal tweets were also excluded. Finally, to increase the likelihood of scraping tweets that described personal experiences with dementia during the era of COVID-19, we excluded tweets that did not include synonyms for familial relationships (eg, "father," "mother," and "grandparent") or friends and acquaintances (eg, "buddy," "pal," and "neighbour"). This filtering procedure resulted in a total of 5063 tweets that were extracted into an Excel (Microsoft Corporation) spreadsheet for qualitative line-by-line coding as the basis for thematic analysis.

Data Analysis: Coding and Intercoder Consistency

To develop a robust codebook, authors JDB and MEO read and reread 300 tweets. The researchers independently assigned codes to each of the 300 tweets. After coding the tweets, the two researchers met to discuss their code lists and developed an initial codebook. The initial codebook consisted of 18 codes with code definitions, keywords, and specific examples (eg, tweets).

To test intercoder consistency, a team of six researchers pilot-tested 100 tweets by independently coding the tweets according to the codebook. Once the team finished their coding, the codes were compared with a coding example sheet that JDB and MEO developed. Following this pilot test, a group coding workshop was held to collectively pilot-code 50 tweets and discuss any inconsistencies in the interpretation of the codes. During this workshop, group discussion resolved coding uncertainties and disputes, leading to the refinement of the codebook (eg, overlapping codes or unused codes). The final version of the codebook consisted of 9 codes including (1) death, (2) fear for person with dementia's health and well-being, (3) challenges and unmet needs, (4) separation or restricted visiting, (5) formal care provider challenges, (6) supports described, (7) informal caregiver's health and well-being, (8) stories of survival, and (9) user identifies as a person with dementia (used as a second tag vs a primary code).

The tweets (n=5063) were then divided among the seven authors (approximately 723 tweets each) for descriptive analysis, with JDB managing intercoder consistency throughout the coding process. For 7 consecutive days, each coder completed approximately 100 codes per day and sent them to JDB. Coders flagged any tweets of which they were unsure or uncertain for JDB to review. In addition to reviewing the flagged tweets, the JDB randomly reviewed 10% of each coder's work and provided feedback (eg, flagged tweets or any inconsistencies) for each day of coding. Throughout the coding process, JDB worked in direct collaboration with the MEO to discuss any discrepancies or uncertainties within the data. Once the coding was completed, two team meetings were held to identify and discuss the key themes arising from the data.

Results

From the 5063 tweets analyzed, we identified 4 main themes including (1) separation and loss; (2) COVID-19 confusion, despair, and abandonment; (3) stress and exhaustion; and (4) risks of exposure and personal sacrifices faced by formal care providers. Illustrative tweets are provided and are unedited for grammar.

Separation and Loss

This theme captures the psychological sense of loss due to physical barriers that create separation. Many personal descriptions included discussion of the physical separation, which includes separation due to death, separation during the process of dying during the COVID-19 pandemic, and separation due to visitation bans because of COVID-19. Underlying these

descriptors of physical separation is a clear psychological disconnection accompanied by feelings of loss. Separation creates a psychological sense of loss. A notable subtheme in separation and loss is the expression of the sense of loss expressed by care partners at the acceleration of decline perceived in persons with dementia during COVID-19, which was frequently blamed on the visitation bans and imposed lockdowns in care homes and health facilities. The intersection of the multiple dimensions of loss and separation are highlighted in the following illustrative quotes:

> *Yesterday I lost my mom. Due to covid [sic] I was unable to see her for the last few months. I did get to FaceTime twice and we did chat on the phone until her dementia made it difficult for her to do so. There will be no memorial until it is cleared to do so. My heart is broken.*

> *...My husband passed away a few days ago, victim of Covid [sic] protocol! He had dementia, didn't understand why I couldn't visit him. He lost hope, 36 lbs in 23 days; could not be saved. This is so cruel to do to our seniors/he was a veteran!!! WRONG!!!*

> *...Dad had dementia and was otherwise healthy. He had daily visitors even though he had little memory of who they were. Covid [sic] closed the nursing home to visitors and he stopped eating. He lost 40lbs and died in June. It's another aspect of the Covid [sic]. Dying Alone.*

> *Let me tell you what this covid [sic] lockdown did, it killed my daddy. He had dementia and he was still doing good, then the lockdown, we weren't there to hold him and to help feed him. When we went to see him, he was a shell, there was nothing left of him. I am so angry.*

COVID-19 Confusion, Despair, and Abandonment

Another predominant theme was feelings of despair and abandonment among people with dementia from COVID-19 confinement and visitation bans. Many tweets described difficulties understanding COVID-19 displayed or experienced by persons with dementia and negative psychological consequences due to this confusion about COVID-19. Many reported that people with dementia could not understand the changes necessitated by the pandemic response; they required constant teaching, reminders, and reassurance. For some, this lack of understanding of COVID-19 led to challenges (described or implied) of living with the new policies for social distancing, mask wearing, and other sanitary precautions, which engendered feelings of hopelessness and despair. For many others, the lack of understanding the physical distancing restrictions due to COVID-19 led to feelings of abandonment and subsequent despair. For example, many described that their loved one could not understand why visits were no longer being made and why they could not have physical contact. The following tweets illustrate these issues:

> *Or live alone with dementia and all the trouble I have. I can't even drive myself to a doctor. I don't remember all the rules myself. I'm terrible at wearing a mask. Someone pointed out I had it inside out at the covid [sic] testing place. Im gonna [sic] die, I hope. Im [sic] tired of life.*

> *You are told your Covid [sic] positive Mum is being discharged to you Covid [sic] negative dad. She has dementia. He is told to keep 2m away in their 3 bed bungalow. Is this NHS policy?*

> *I've lost count of how many times I've been on the phone with my grandmother telling her that it's not safe for her to leave the house because of COVID-19. Life with a loved one who has dementia right now is frustrating. Constantly re-teaching and remaining patient.*

> *Hardest thing to hear is my mom trying to explain to my grandmother, who has Alzheimer and dementia, that we can't see her because of the corona [sic]. My grandmother repeating that she is in jail. Asking where we are.*

Stress and Exhaustion Exacerbation

Care partners described stress and exhaustion (eg, mental, emotional, and physical) related to providing care for people with dementia in the context of the COVID-19 pandemic. Increased workload, disruption to routine, financial strain, mental health issues, social isolation, and loneliness were common features described.

COVID-19 confinement and lockdown measures substantially increased the workload of informal care partners by limiting or terminating access to support services such as day care programs, home care, respite, meal programs, medical specialists, and adequate care home options. As such, many described the difficulty of dealing with household chores, social isolation, and the increasing workload, which often led to feelings of mental, emotional, and physical exhaustion. Moreover, care partners described difficulties managing behavioral changes and worsening neuropsychiatric symptoms (eg, anxiety, agitation, anger, and depression) of their loved ones with dementia.

Care partners also discussed stress related to the fear of COVID-19 exposure and concern for the person with dementia's health and well-being. This fear was especially apparent among care partners with loved ones staying in care homes or hospitals. Others noted that COVID-19 precautions were confusing to people with dementia and made appointments and outings more difficult not only for the person with dementia but also for the care partner. Some reported balancing decisions on whether to pursue health services based on how distressing the experience would be for their loved one (eg, due to being alone without care partner support). Many reported strain due to financial pressures related to losing work coupled with unease for the future of their loved one. Difficulty obtaining care services or relocation to long-term care due to the pandemic were noted. Further, some care partners described feeling a need to bring people with dementia home from long-term care to ensure their well-being. The following tweets highlight the challenges faced by informal care partners:

I've lost some income but the hardest part is being stuck 24/7 in the house with my Mom who has severe dementia. It is hell! She had a daycare but it closed. I can't get respite bc [sic] I'm terrified of exposing her to covid [sic]. I fight loneliness, depression and boredom everyday [sic]!

The services for people with dementia have had to fall into line with COVID rules and there are of course personal restrictions. A devastating combination for people who need safety, routine and gentle stimulation.

Another horrifying day. We are in isolation with my beloved 93 yo [sic] Mom. She has descended into terrifying hallucinations and extreme anger because of dementia. We can't get her into nursing care because of a Covid [sic] outbreak. Just getting thru [sic] each hour.

Unpaid Sacrifices by Formal Care Providers

Formal care providers identified numerous sacrifices beyond their paid jobs. Formal care providers commonly expressed emotional connection to people with dementia and a sense of duty related to care, noting that this was more than simply a job. Formal care providers also described making personal sacrifices to work and provide care during the COVID-19 pandemic. For example, care providers discussed sacrificing their participation in family gatherings, parenting responsibilities, and social activities to help protect their patients and family members from potential exposure to the virus. Consequently, many expressed concern for the health of their families due to exposures at work and made trade-offs to help ensure the safety of their patients or residents, such as limiting their outside contacts. They also noted that caring for people with dementia involved a sacrifice of their own safety because of the lack of personal protective equipment (eg, gowns, gloves, masks, eye protection, and face shields), leading to stress of exposure. Finally, they reported their frustration with the reduced ability to support quality of life for people with dementia in the face of an increased workload due to COVID-19.

The workforce challenges experienced by formal care providers are captured in the following tweets:

People were discharged from hospital with covid [sic] and placed directly into my work. Trying to isolate a dementia patient with covid [sic] is impossible in a care home, they've already wandered down the corridor before we could even get our gloves on

I'm a mental health nurse working in a dementia specialist nursing home. My fight is to keep corona [sic] out of the building. There are many of us who will be in hiding to protect our residents…

I'm a nurse with COVID, probably from reusing dirty N95s and working with dementia patients who simply could not grasp the need to wear a mask and social distance. I worked so hard to try not to get COVID.

Discussion

Principal Results

Using Twitter, the aim of this study is to understand the COVID-19 experiences of people with dementia and their care partners. People with dementia are among the most vulnerable to the pandemic in terms of exposure risk, social isolation, hospitalization, and mortality [4]. Understanding the impact of COVID-19 is urgently needed to reduce mortality and improve the quality of life for people with dementia and their care partners during the pandemic. Given the current COVID-19 context, Twitter provided a valuable means to support timely and innovative research during the pandemic.

In analyzing the 5063 tweets, this study found that people with dementia are experiencing substantial burden from the COVID-19 pandemic. For example, separation and institutional visiting bans were described as having a detrimental impact on people with dementia. Numerous tweets identified the effects of visitation bans on people with dementia, such as despair, loss, abandonment, social isolation, not eating, losing the will to live, and dying alone. Tweets also identified challenges faced by informal care partners, such as financial struggles, mental health issues, lack of formal supports, inadequate care home options, fear of COVID-19 exposure, and difficulties explaining COVID-19 (eg, quarantine, self-isolation, social distancing, and protective equipment) to people with dementia. In addition, tweets addressed workforce issues experienced by formal care providers, ranging from insufficient access to personal protective equipment to understaffing and having to sacrifice family responsibilities to provide formal care.

This study has significant implications for COVID-19 policy and practice. For example, findings from this study suggest that prohibitive visitation policies (eg, visitation bans and institutional lockdowns) in care homes and health facilities may not be advantageous or acceptable for people with dementia. Numerous tweets emphasized the issue of separation on mortality for people with dementia. Emerging data from the United Kingdom showed that, in care homes, more people have died from dementia than from COVID-19 [2]. Similarly, data from Canada [17,18] and the United States [1] mirror this trend, documenting thousands of excess dementia deaths in care homes throughout the pandemic. These findings suggest that secondary effects of the COVID-19 pandemic (eg, social isolation) may be causing rapid deterioration and mortality of people with dementia. Consequently, COVID-19 policies (eg, visitation bans and institutional lockdowns) that were initially intended to protect people from the virus may be causing significant harm to people with dementia. Accordingly, there is an imminent need for governments to rethink using a one-size-fits-all response to COVID-19 policy and use instead a collaborative approach to support people with dementia and their care partners. In moving forward, collaboration and partnerships with people with dementia are essential to developing targeted policies to protect people with dementia and their care partners.

Formal care providers desperately need additional resources (eg, allocated funding, personal protective equipment, adequate staffing, and mental health supports) to support people with

dementia during the pandemic. Findings from this study identify a range of workforce challenges such as understaffing and lack of adequate personal protective equipment. Formal care providers in care homes and health facilities cannot provide optimal care and prevent COVID-19 exposure without having access to required resources and supports. Consequently, additional resources are needed to provide safeguards to protect both formal care providers and people with dementia during the pandemic.

Research is needed on the COVID-19 impact from the perspective of people with dementia and their care partners. Although several editorials, letters to the editor, and commentaries have discussed anticipated challenges of COVID-19 for people with dementia [8-10,19-21], few studies have involved people with dementia. Research is needed to examine the lived experiences of COVID-19 among people with dementia. Accordingly, more evidence-informed research is required to reduce mortality and understand the impact of COVID-19 on people with dementia and their care partners.

Limitations

Twitter has a 280-character limit for each tweet. Given this limit, the user's story and experience is confined to these restrictions. For example, important information and relevant details (eg, context, background, and confounding factors) may not be captured in the tweet. Consequently, qualitative interviews may provide a more comprehensive and in-depth perspective of the COVID-19 impact on people with dementia. In addition, given that Twitter is in the public domain, people may not feel comfortable sharing their full perspectives and lived experiences. Future research requires collaboration and partnerships with people with dementia to develop more in-depth knowledge on the impact of COVID-19 on people with dementia and their care partners.

In addition, there are some limitations related to the generalizability of our findings from Twitter. For example, no demographic information was collected in this study, and findings from Twitter may not be fully generalizable or representative of the general public living with dementia and their care partners (eg, age, gender, ethnicity, education, income, or employment background). However, existing data show that Twitter users are 56% male and 44% female, with the largest age groups of users being in the categories of 18-29 years (38%), 30-49 years (27%), and 50-64 years (17%) [22]. Since no demographic information was collected, another study limitation relates to sex and gender. Without any demographic information, it is impossible to make any inferences or draw specific conclusions regarding the impact of COVID-19 in relation to sex or gender. As such, more research is needed to examine the impact of COVID-19 in relation to the sex and gender of people with dementia and their care partners.

A final limitation of these data is the cross-sectional nature of our analysis and geographically blind nature of the data. It is possible that experiences of people with dementia and their care partners will vary over time, particularly over waves of the pandemic. We believe these current data captured what might be described as wave one of the pandemic. It is likely, however, that any temporal variability in experiences with COVID-19 and dementia will be related to geography. It is clear that there are geographic differences in the experiences of the pandemic. Future research to compare temporal variability in experiences of COVID-19 and dementia with publicly available databases detailing country-level COVID-19 disease burden and mitigation strategies is needed.

Conclusions

The purpose of this study was to use Twitter to understand the COVID-19 experiences of people with dementia and their care partners. Through an analysis of 5063 tweets, this study found that people are experiencing substantial burden from the COVID-19 pandemic. Specifically, four main issues were identified, including separation and loss, despair and abandonment, informal care partner challenges, and workforce issues experienced by formal care providers.

There is an imminent need for governments to rethink using a one-size-fits-all response to COVID-19 policy and use a collaborative approach to support people with dementia. More specifically, collaboration and partnerships are essential to developing effective COVID-19 policies to support people with dementia and their care partners. Moreover, there is a critical need for additional resources (eg, personal protective equipment, adequate staffing, safeguards, and mental health supports) to address workforce challenges and support formal care providers of people with dementia during the pandemic. Research is needed on the impact of COVID-19 from the perspective of people with dementia. Collaboration and more evidence-informed research are essential to reducing COVID-19–related mortality and improving the quality of lives for people with dementia and their care partners.

Acknowledgments

JDB is a postdoctoral fellow, KG is a doctoral student, and MA and SG were research assistants whose salaries were partially funded by Team 15 in the Canadian Consortium on Neurodegeneration in Aging (CCNA). CCNA is supported by a grant from the Canadian Institutes of Health Research with funding from several partners including the Saskatchewan Health Research Foundation, the Centre for Aging and Brain Health, and the Alzheimer Society of Canada (ASC). The ASC COVID Task Force (of which MEO, LP, and SS are members) was a particular catalyst for this study.

Authors' Contributions

MEO conceived the idea with LP. MEO, MA, and RJS devised the Twitter scraping approach, and MA scraped Twitter. MEO and JDB devised the codebook. MEO, AC, MA, KG, LP, SG, and RJS coded tweets, JDB double-coded a random sample of

these for quality control, and MEO was the final arbiter. All authors contributed example tweets. MEO and AC performed the thematic analysis. JDB wrote the first draft of the manuscript, and all authors revised the manuscript.

Abstract

Background: During the COVID-19 pandemic, growth in citizen engagement with social media platforms has enabled public health departments to accelerate and improve health information dissemination, developing transparency and trust between governments and citizens. In light of these benefits, it is imperative to learn the antecedents and underlying mechanisms for this to maintain and enhance engagement.

Objective: The aim of this study is to determine the factors and influencing mechanisms related to citizen engagement with the TikTok account of the National Health Commission of China during the COVID-19 pandemic.

Methods: Using a web crawler, 355 short videos were collected from the Healthy China account on TikTok (with more than 3 million followers throughout China), covering the period from January 21, 2020, to April 25, 2020. The title and video length, as well as the number of likes, shares, and comments were collected for each video. After classifying them using content analysis, a series of negative binomial regression analyses were completed.

Results: Among the 355 videos, 154 (43.4%) related to guidance for clinicians, patients, and ordinary citizens, followed by information concerning the government's handling of the pandemic (n=100, 28.2%), the latest news about COVID-19 (n=61, 17.2%), and appreciation toward frontline emergency services (n=40, 11.3%). Video length, titles, dialogic loop, and content type all influenced the level of citizen engagement. Specifically, video length was negatively associated with the number of likes (incidence rate ratio [IRR]=0.19, *P*<.001) and comments (IRR=0.39, *P*<.001). Title length was positively related to the number of shares (IRR=24.25, *P*=.01), likes (IRR=8.50, *P*=.03), and comments (IRR=7.85, *P*=.02). Dialogic loop negatively predicted the number of shares (IRR=0.56, *P*=.03). In comparison to appreciative information, information about the government's handling of the situation (IRR=5.16, *P*<.001) and guidelines information (IRR=7.31, *P*<.001) were positively correlated with the number of shares, while the latest news was negatively related to the number of likes received (IRR=0.46, *P*=.004). More importantly, the relationship between predictors and citizen engagement was moderated by the emotional valence of video titles. Longer videos with positive titles received a higher number of likes (IRR=21.72, *P*=.04) and comments (IRR=10.14, *P*=.047). Furthermore, for short videos related to government handling of the pandemic (IRR=14.48, P=.04) and guidance for stakeholders (IRR=7.59, *P*=.04), positive titles received a greater number of shares. Videos related to the latest news (IRR=66.69, *P*=.04) received more likes if the video title displayed higher levels of positive emotion.

Conclusions: During the COVID-19 pandemic, videos were frequently published on government social media platforms. Video length, title, dialogic loop, and content type significantly influenced the level of citizen engagement. These relationships were

moderated by the emotional valence of the video's title. Our findings have implications for maintaining and enhancing citizen engagement via government social media.

KEYWORDS

government social media; citizen engagement; public health crisis; TikTok; emotion valence; dialogic loop; COVID-19

Introduction

Background

Citizen engagement on social media during times of public health crises, such as that experienced during the COVID-19 pandemic, provides governments with a valuable tool for communicating with and understanding the concerns and priorities of their citizens [1]. Citizen engagement highlights the active role citizens play in public affairs, including public communication, public consultation, and public participation, which have the potential to influence government decision making [2]. With citizen engagement, governments can solicit public concerns and respond accordingly, improving the quality and efficiency of public services delivered [3]. Due to the popularity and communicative nature of social media, it has been employed widely by governments during public health crises, creating new opportunities for citizens to voluntarily participate in government activities [4-8]. However, the practice of engaging citizens is relatively underdeveloped. Strategies for citizen engagement via social media platforms have not been adequately deployed, although the importance of citizen engagement is widely acknowledged by government agencies. The use of social media by governments during public crises is hampered by both internal and external factors, such as insufficient resources, the digital divide, ethical considerations, and accountability [9,10]. Government agencies thus prefer to broadcast information and improve disease surveillance through social media, rather than initiate public conversation and engagement [11-13]. Considering its benefits, it is imperative to better understand the antecedents and underlying mechanisms of citizen engagement with government social media during public health emergencies to maintain and enhance citizen engagement.

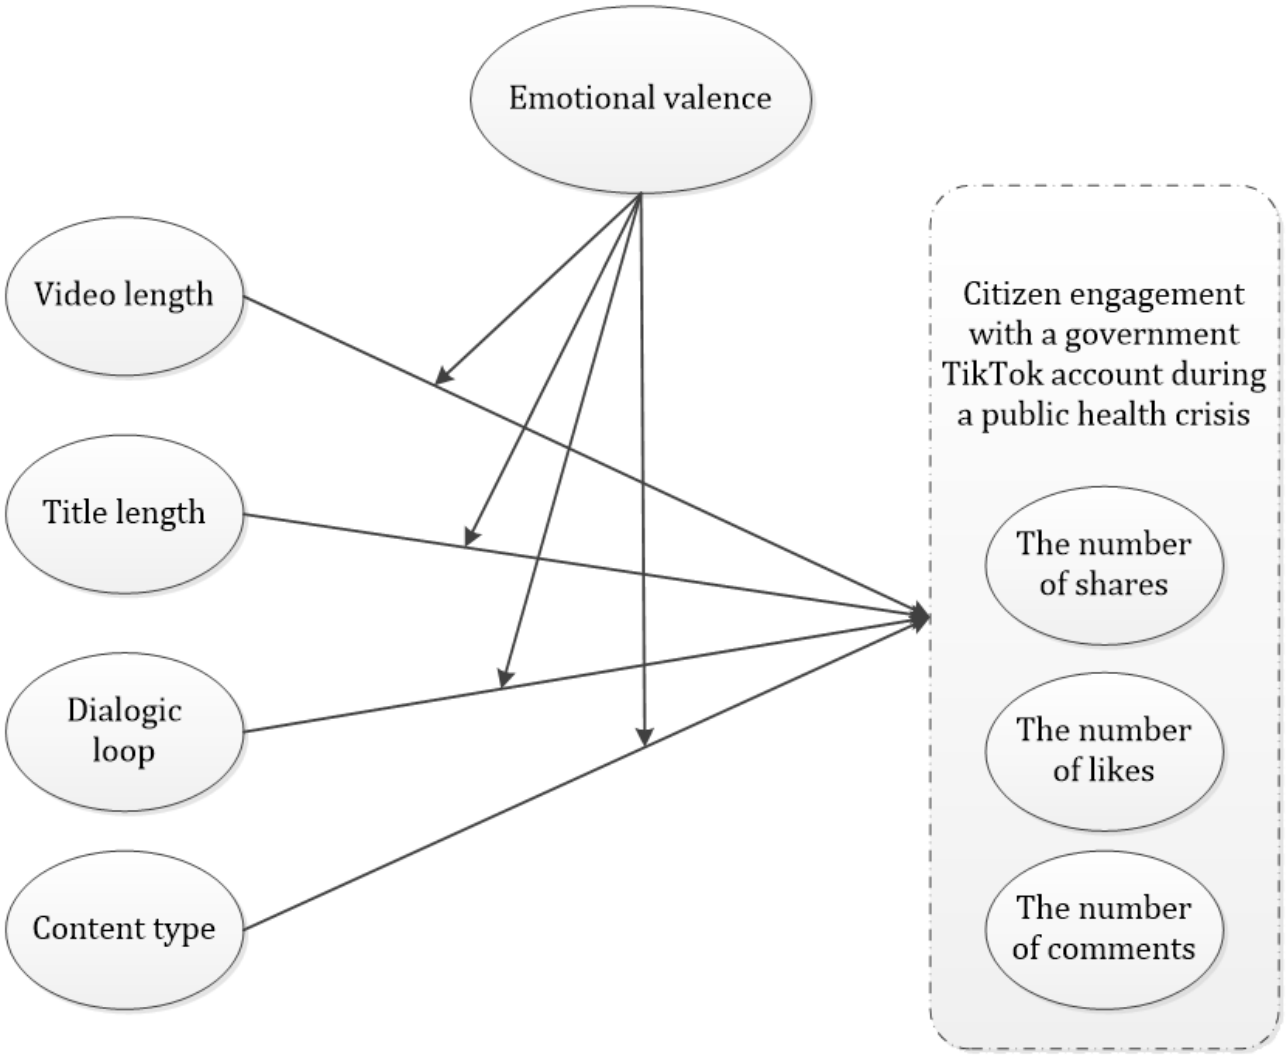
Although some studies have examined the relationship between government agencies' use of social media and citizen engagement during public health crises, there are several obvious gaps that deserve further investigation. First, existing studies have paid extensive attention to more traditional social media, including Sina Weibo [1,8], Twitter [4,14], and Facebook [7]. Chen and colleagues [14] identified the tweeting patterns of the Centers for Disease Control and Prevention during different phases of the Zika epidemic. However, their studies focused on text-dominated social media exclusively, with little attention paid to emerging social media platforms. For example, TikTok, which launched in 2016, is a video-sharing platform that allows users to create, upload, repost, and write comments on short videos, ranging from a few seconds to minutes. Since its creation, the popularity of TikTok has increased rapidly, with more than 800 million active users in 2020 [15]. During the COVID-19 pandemic, TikTok became an indispensable source of information and communication channel for the general public and between government organizations and citizens [16]. Second, extant studies have predominantly explored possible influencing factors through the lens of media type, government type, content type, media richness, message style, and interactive features, with limited effort paid to specific influencing mechanisms [1,4,8]. Guidry et al [4] explored the Ebola-related social media posts published by three major health organizations on Twitter and Instagram, and found that messages with solutions, visual imagery, and acknowledgment of public concerns are the most effective risk communication strategies. By investigating the People's Daily Sina Weibo account during COVID-19, Ngai et al [8] found that disease prevention content posts in a narrative style generated more public engagement, and further revealed an interaction effect between content and style.

This study aims to address the above gaps by exploring the factors that drove citizen engagement through the TikTok account of the National Health Commission of China (NHCC) during the COVID-19 pandemic, in the context of China. Chinese governments, across different levels, have now started to realize the potential of TikTok for public participation, leveraging the platform for routine administration tasks. According to the latest report by the China Internet Network Information Center (CNNIC), the number of verified government TikTok accounts is 25,313, implying wide employment in the Chinese public sector [17]. In this study, we develop a conceptual model, including video length, title length, dialogic loop, and content type, to empirically examine the driving factors of citizen engagement with TikTok accounts operated by Chinese government agencies. Citizen engagement through the official TikTok account of the NHCC consists of three dimensions: comments, likes, and shares [18]. For each video uploaded to TikTok, data on its number of comments, likes, and shares are publicly available. Importantly, we take the emotional valence variable as a moderator to unravel potential influencing mechanisms.

Research Hypotheses and Conceptual Model

Based on the characteristics of TikTok videos, our study built a moderated model that unraveled the moderating role of emotional valence among the differentiated effects of video length, title length, dialogic loop, and content type on the three dimensions of citizen engagement, namely the number of shares, likes, and comments (Figure 1).

Figure 1. The research model of the study.



Video length refers to the duration of a video. Although several studies have examined the length of popular videos, few have investigated the impact of video length on citizen engagement on TikTok. For example, Zhu et al [19] analyzed the 100 most-liked videos on TikTok published by 31 provincial Health Committees in China, and found that 98% of them lasted under 60 seconds. Our study suggests that video length is negatively associated with the number of likes, shares, and comments received from the public. Shorter videos usually have better content because they require detailed planning to explain the content concisely [20]. Guo et al [20] analyzed a big data set comprising 6.9 million Massive Open Online Course (MOOC) videos and confirmed that shorter videos had a perceived higher quality, thus leading to increased engagement. In addition, shorter videos align better with the information consumption habits of social media users. Users usually watch TikTok videos on mobile devices during fragmented periods. If a video is too long, it will not only consume more mobile data and battery power, but also fail to meet the demands of individuals' allotted time.

Therefore, hypothesis 1 is as follows: video length negatively affects the three dimensions of citizen engagement via the official TikTok account of the NHCC, as measured by the number of likes, shares, and comments.

Title length refers to the total number of words summarizing the video's content in the title of an uploaded video. During times of crisis, citizens are usually motived by utility, craving information that relieves anxiety and eases panic [21]. Longer titles typically contain richer information, promoting a better understanding of the video, thereby increasing citizen engagement [21,22]. For example, Xu and Zhang [22] examined 13,322 tweets related to Malaysia Airlines Flight 370 and found that the more words a tweet had, the more likely it was to be retweeted. Specific to video-sharing platforms, Halvey and Keane [23] analyzed 4.25 million YouTube videos and identified that a longer video title increased the number of video views. We argue that the longer the title length, the more likely citizens are to share, comment, and like COVID-19–related TikTok videos.

Therefore, hypothesis 2 is as follows: title length positively affects the three dimensions of citizen engagement via the official TikTok account of the NHCC, as measured by the number of likes, shares, and comments.

Dialogic loop emphasizes the importance of providing an interactive feedback loop, facilitating mutual communication between organizations and citizens [1]. Organizations allow the general public to directly ask questions, post comments, make

suggestions, and provide feedback on relevant issues pertaining to the organization [24]. Dialogic loop is beneficial for promoting mutual conversation through question posing and answering [1]. However, few studies have investigated the effect of dialogic loop on citizen engagement via social media. Gálvez-Rodríguez et al [25] analyzed 137 Latin American local governments' Facebook accounts and revealed that dialogic loop can increase the level of citizen engagement (weighed calculation based on the number of likes, comments, shares, and posts). Specific to public health crises, Chen et al [1] studied the official Sina Weibo account of the NHCC and verified that dialogic loop positively influences citizen engagement (sum of number of likes, comments, and shares).

Therefore, hypothesis 3 is as follows: dialogic loop positively affects the three dimensions of citizen engagement via the official TikTok account of the NHCC, as measured by the number of likes, shares, and comments.

Extant studies into health communication have identified that different content types have varying effects on citizens' social media engagement behaviors. According to the Use and Gratification Theory, the degree to which media content gratifies individuals' differential needs directly influences their media selection and usage behavior [26]. Analyzing 203,191 COVID-19–related posts on Sina Weibo, Wang et al [27] concluded that posts on the domestic epidemic were retweeted the most, while posts about quarantine and investigations received the most likes. Short videos related to COVID-19, posted by the official TikTok account of the NHCC during the pandemic, will satisfy public demands to different degrees, thus promoting citizen engagement at different levels. Research that analyzed 4221 tweets posted by the health departments of 39 states in the United States showed that acknowledging the events of other organizations and expressing gratitude and providing recognition improved citizen engagement [28]. Park et al [29] examined 1583 tweets posted by three American health organizations and found that personal health–related information and actions received more shares and likes. In relation to public health crises, Chen et al [1] determined that posts about the latest news and government disposition facilitated citizen engagement via government Sina Weibo accounts, while posts providing guidance for stakeholders had no effect.

Therefore, hypothesis 4 is as follows: content type has significant differential effects on the three dimensions of citizen engagement via the official TikTok account of the NHCC, as measured by the number of likes, shares, and comments.

Emotional valence refers to the positive and negative feelings triggered during an individual's consumption of information [1,18]. Emotional expression in social media content can attract public attention, promote dialogue, and drive engaged feedback [18]. Emotions possess the function of physiological arousal, which can contribute to information-sharing behavior [30]. High emotional traits can trigger the viral spread of social media content [22]. Citizens regulate their emotional status through actions such as reposting, liking, and commenting when receiving emotional information via social media [1]. Empirical evidence indicates that emotional posts often promote citizens' social media engagement [18,31,32]. However, few studies have investigated the moderating effect of emotional valence [33]. Tang et al [34] studied the official Sina Weibo accounts of 30 provincial police departments in China and identified that emotional valence moderated the influence of content type on reposting behavior. Child-friendly content with positive emotion increased reposting the most. Current research has also confirmed that emotional valence moderates the effects of dialogic loop, media richness, and content type on citizen engagement via government Sina Weibo accounts during public health crises [1].

Therefore, hypothesis 5 is as follows: emotional valence will moderate the effects of video length, title length, dialogic loop, and content type on the three dimensions of citizen engagement via the official TikTok account of the NHCC, as measured by the number of likes, shares, and comments.

Methods

Data Collection

For this study, we collected data from the official TikTok account of the NHCC, "Healthy China." The official account was created on May 4, 2018, to help more widely disseminate health-related information. By May 12, 2020, the account had posted 576 short videos, had 3 million followers, and had received more than 8 million likes. Since the outbreak of COVID-19 in December 2019, the NHCC has actively uploaded relevant short videos. We used a web crawler tool to capture all videos uploaded to the official account from January 21, 2020, to April 25, 2020. In total, 364 videos were obtained. After manual checking, 355 were found to be related to the COVID-19 crisis. In addition, data about the video's length, title text, number of likes, number of shares, and number of comments were collected.

Operationalization of Variables

Citizen engagement through the official TikTok account of the NHCC includes three dimensions: sharing, liking, and commenting behaviors [18]. We captured this objective data using web crawlers.

Video length is the duration of the video. The length of all 355 videos was captured from the "Healthy China" account using a web crawler.

Title length relates to the number of words included in a video's title. This study first collected the complete texts of 355 video titles using web crawlers, and then automatically counted the number of words in each text using Microsoft Excel (Microsoft Corp).

Dialogic loop is measured by two indicators: posing and answering questions [35]. If a question or answer appears in a short video title, it is marked as 1, otherwise it is marked as 0. The dialogic loop score was the sum of the scores of the two indicators.

Content type includes 4 categories, namely the following: the latest news about the COVID-19 crisis, the government's handling of the pandemic, appreciation for frontline emergency services, and guidance for stakeholders [1]; the codebook in Table 1 contains examples.

Table 1. Codebook examples of content categories.

Categories	Example posts
The latest news about the COVID-19 crisis	[Authoritative Release] The latest situation of COVID-19 crisis as of 24:00 on April 11#Action to defeat COVID-19
The government's handling of the crisis	Covid-19 prevention, control and medical treatment work in Hubei, from the press conference of the State Council Information Office. #Action to defeat COVID-19
Appreciation of frontline emergency services	Thank you, Sichuan Provincial Medical Aid Team, tribute heroes triumphantly! #Action to defeat COVID-19 #Warm doctor moment
Guidance for stakeholders	Parents look out! How can children prevent COVID-19? #Action to defeat COVID-19

Emotional Valence

We measured this variable by calculating the emotional valence of each short video's title based on a sentiment lexicon and Python (Python Software Foundation). Initially, title information was split into three categories (sentimental words, negative words, and degree adverbs) using the Jieba database. Upon word separation, the words were annotated using BosonNLP, while machine learning enabled word processing to assign values for sentimental words. By combining the review of the rest of the words with preassigned values, the emotional value for each title was determined based on a weighted approach. Each title was assigned a value ranging from 0 to 1, with 0.5 being neutral emotion. The closer the value was to 0, the more negative the emotion was considered, and vice versa.

Intercoder Reliability and Data Analysis

This study obtained the analysis data of dialogic loop and content type by manually coding the content of the video titles. We employed two graduate students to carry out the coding of the 355 short videos. Before beginning, the students were provided with operation training and an explanation of the coding scheme to ensure a good coding standard. To examine the interreliability, 30% of the sample was randomly selected, and 106 short videos were precoded. Both coders worked independently, and the results are as follows: the κ values for the content categories, "posting a question," and "responding to a question" were 0.918, 0.941, and 0.795, respectively. This indicated that the interreliabilities were high enough and acceptable.

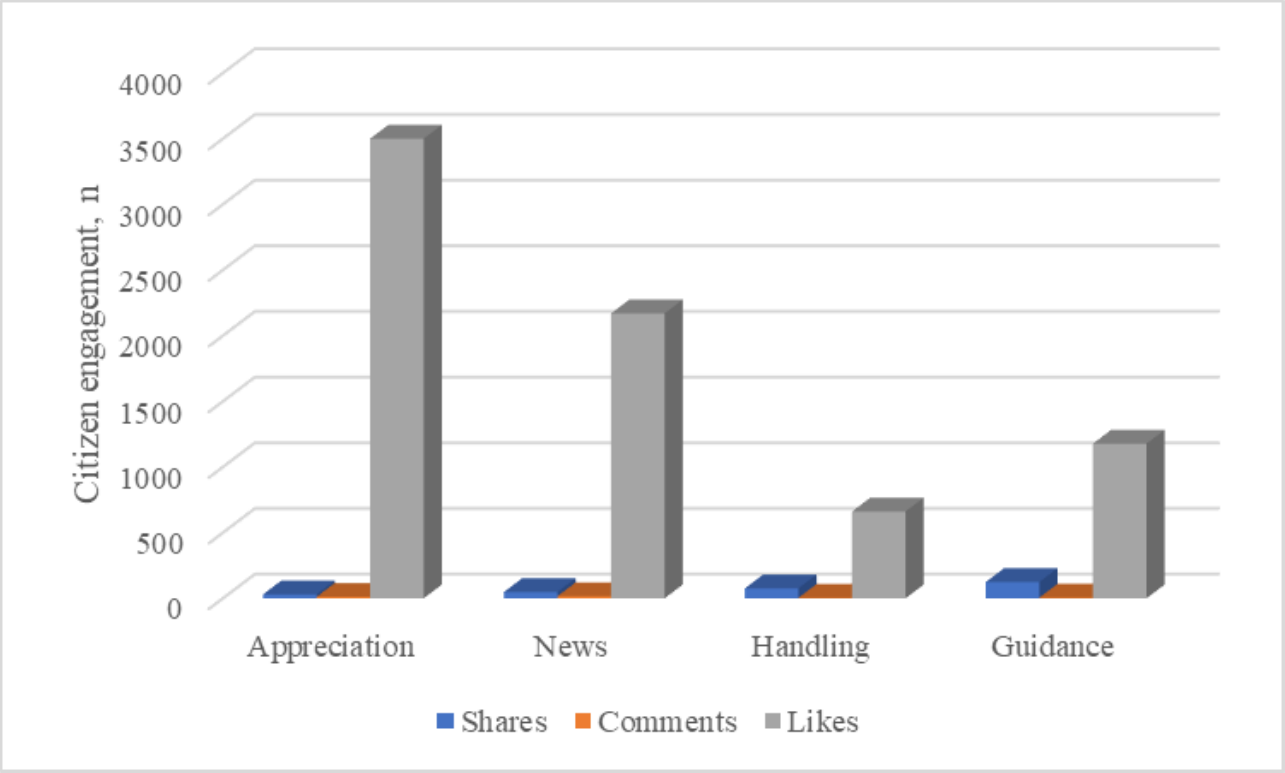
Our dependent variables are all count measures that exhibit overdispersion (shares: mean 86.94 [SD 492.71], skewness=11.36, kurtosis=140.27; likes: mean 1464.22 [SD 4772.29], skewness=6.94, kurtosis=57.85; comments: mean 7.57 [SD 13.22], skewness=4.10, kurtosis=26.07). A significant number of short videos rarely received shares, likes, or comments, while others received a high number in comparison. To deal with this overdispersed count data, we modelled the number of shares, likes, and comments using negative binomial regression. We first estimated the impact of video length, title length, dialogic loop, and content type on different types of citizen engagement. We then explored whether the impacts were contingent upon the emotional valence of each video's title. All analyses were conducted using STATA (Version 15.0; StataCorp LLC).

Results

Descriptive Analysis

The 355 collected short videos had large variations in the level of citizen engagement. Overall, 32.1% of videos (n=114) had less than 10 shares, while 9.9% of videos (n=35) were shared more than 100 times. The gap in the number of likes was also significant, with 56 videos (15.8%) receiving less than 100 likes and 10 videos (2.8%) receiving more than 10,000 likes. For comments, 8 videos received more than 50 comments, while 18.9% of videos (n=67) did not receive any comments. Among all videos, 154 (43.4%) were related to guidance for clinicians, patients, and ordinary citizens, followed by information concerning the government's handling of the pandemic (n=100, 28.2%), and the latest news about COVID-19 (n=61, 17.2%). Posts about appreciation toward frontline emergency services only represented about 11.3% (n=40) of posts. On average, the appreciation posts received the highest number of likes (mean 3500.28 [SD 8086.11]), while guidance and government handling information received the least (mean 660.97 [SD 1493.57] and mean 1177.60 [SD 3952.23], respectively; Figure 2). Moreover, videos related to guidance information experienced the highest level of sharing (mean 124.12 [SD 624.95]), while videos pertaining to the latest news had the highest number of comments (mean 16.07 [SD 21.44]). Of the other characteristics of videos, the length of all videos collected ranged from 11 seconds to 493 seconds (mean 96.53 [SD 81.78]). Furthermore, the average length of video titles was 34.75 characters (SD 6.79; range 15-54). For dialogic loop, 203 videos (57.2%) either raised or answered questions to deliver information. Further, the emotional valence of video titles was positive on average (mean 0.71 [SD 0.30]).

Figure 2. Average amount of citizen engagement in the form of shares, likes, and comments, grouped by content type.



Hypothesis Testing

Table 2 shows estimates of the negative binomial regression models that predicted the number of likes, shares, and comments for each coded short video uploaded during the COVID-19 pandemic. Hypothesis 1 posited that longer videos were less likely to attract citizen engagement. Models 2 and 3 in Table 2 show that video length has a negative and statistically significant association with the number of likes (incidence rate ratio [IRR]=0.19, *P*<.001) and comments (IRR=0.39, *P*<.001) received. The IRR value shows that a one-unit increase in video length leads to a decrease in the number of likes and comments by a factor of 0.19 and 0.39, respectively. However, the relationship between video length and number of shares is not significant. Thus, hypothesis 1 was partially supported.

Table 2. Predicting citizen engagement with government social media.

Variables	Shares (Model 1)		Likes (Model 2)		Comments (Model 3)	
	Incidence rate ratio	*P* value	Incidence rate ratio	*P* value	Incidence rate ratio	*P* value
Video length	0.81	.59	0.19	<.001	0.39	<.001
Title length	24.25	.01	8.50	.03	7.85	.02
Dialogic loop	0.56	.03	0.67	.07	0.68	.07
Content type (reference: appreciation)

[a]N/A: not applicable.

Hypothesis 2 proposed that a longer video title increases the level of citizen engagement. According to Table 2, title length indeed plays an important role in predicting the number of shares (IRR=24.25, *P*=.01), likes (IRR=8.50, *P*=.03), and comments (IRR=7.85, *P*=.02). A one-unit increase in title length can result in a 2325% increase in the number of shares, a 750% increase in the number of likes, and a 685% increase in the number of comments. Thus, hypothesis 2 was supported.

Hypothesis 3 proposed that videos with multiple dialogic features were more likely to attract citizen engagement. Model 1 in Table 2 shows that dialogic loop is negatively associated with the number of shares (IRR=0.56, *P*=.03). This means that dialogic loop decreases willingness to share by about 44%. In addition, Models 2 and 3 show that dialogic loop is not associated with the number of likes and comments received. Thus, hypothesis 3 was not supported.

Hypothesis 4 proposed that the degree of citizen engagement was influenced by the content shown in the videos. Since content type is a categorical variable, we treated appreciative posts as the reference group. Model 1 in Table 2 shows that government handling information (IRR=5.16, *P*<.001) and guidelines information (IRR=7.31, *P*<.001) were positively correlated with the number of shares. The IRR values mean that, compared to appreciative information, handling information would result in a 416% increase in the number of shares, while guideline information would lead to a 631% increase. Videos about the latest news were found to be negatively related to the number of likes (IRR=0.46, *P*=.004), which means that posts about the latest news would result in a 54% decrease in the number of likes received, compared to posts about appreciative information. Interestingly, the number of comments did not vary significantly across different types of video content. Thus, hypothesis 4 was partially supported.

We investigated the conditional impacts of the predictors by entering emotional valence and interaction variables into the negative binomial regression model. As seen in Table 3, the relationship between video length and citizen engagement is moderated by the emotional valence of a video's title. The interaction between video length and emotion is positively related to the number of likes (IRR=21.72, *P*=.04) and comments (IRR=10.14, *P*=.047; see Models 2 and 3). As Figure 3 shows, the gap in the number of likes between videos with positive emotion and negative emotion is only significant when the video length is long. The more negative the emotion in the video's title, the lower the number of likes received. This pattern is almost the same for the number of comments (Figure 4). The lowest number of comments occurred when the video was long and had negative emotion. Emotion also moderates the relationship between content type and the number of shares. As shown in Table 3 (Model 2), for guidelines (IRR=7.59, *P*=.04) and government handling (IRR=14.48, *P*=.04) information, the more positive emotion a video's title had, the higher the number of shares the video received, in comparison to appreciative news. Videos related to the latest news (IRR=66.69, *P*=.04) received more likes when their titles had higher levels of positive emotion. Interestingly, the title's emotional valence has a weak effect or no effect on the relationship between content and other types of engagement behavior. Overall, emotion plays a moderate role in the relationship between video length, content type, and citizen engagement, but patterns vary across different types of engagement.

Table 3. The moderating role of emotional valence in predicting citizen engagement.

Variables	Shares (Model 1)		Likes (Model 2)		Comments (Model 3)	
	Incidence rate ratio	*P* value	Incidence rate ratio	*P* value	Incidence rate ratio	*P* value

Discussion

Principal Findings

This pioneering study is the first to attempt to reveal how to promote citizen engagement with official government TikTok accounts during the COVID-19 crisis. To reveal the specific mechanisms of engagement, we proposed a moderated model, which investigated the moderating role of emotional valence on the effects of video length, title length, dialogic loop, and content type on the three dimensions of citizen engagement with the official TikTok account of the NHCC.

First, we found that shorter videos and videos with longer titles generate greater engagement in general. On the one hand, video length negatively and significantly influenced the number of likes and comments received. This conclusion confirms the findings of Zhu et al [19], who found that citizens prefer shorter TikTok videos. We extend their findings in the context of public health crises. Shorter videos can better satisfy public demands for timely consumption and relaxation during fragmented time and promote the public's continuous use of TikTok videos, including increasing sharing, liking, and commenting behaviors, thereby improving engagement [1,26]. On the other hand, videos with longer titles generate greater levels of sharing, liking, and commenting, simultaneously. This is consistent with the findings

of Halvey and Keane [23], who established that YouTube videos with longer titles receive more views. Longer video titles help to enhance the logical and interactive elements of expression but can also deliver more information. In contrast, shorter titles may compromise the integrity and accuracy of video content cues. Hence, the longer the video title is, the more accurately and effectively the core content can be presented, which increases the likelihood of receiving likes, shares, and comments. However, this conflicts with the result of a recent study on YouTube marketing, in which video titles with a lot of information were associated with a lower number of video views [36]. This discrepancy may be due to the evolving functionalities of YouTube, the increasing large volume of available videos, and the changing demographics of YouTube users. With the surge of new videos, the younger generation's attention is precious and they are more likely to be attracted by videos with shorter titles. It remains to be seen whether this change also applies to TikTok.

Second, this study found that content related to the government's handling and guidance for stakeholders promotes citizens' reposting behavior, while information related to the latest news about the crisis reduces the number of likes received. This further expands on the conclusion of Chen et al [1], who found that posts related to the government's handling of information (released by the official Sina Weibo account of the NHCC) promoted citizen engagement on the TikTok platform. This suggests that, whether it is a general social networking platform or one focused on video sharing, the public are concerned about the government's handling of the crisis, which increases the level of citizen engagement. However, compared with Sina Weibo users, content related to the latest news about the COVID-19 crisis has very limited attraction for TikTok users. This may be because short videos that are related to the latest news about the COVID-19 crisis are mostly a combination of plain text and pictures, which are rougher and less interactive.

Interestingly, this study discovered that higher levels of dialogic loop significantly reduce the number of shares received. This conflicts with existing studies that examine how dialogic loops affect citizen engagement [1,25,37]. It is worth noting that previous studies that support the positive impact of dialogic loop on citizen engagement were all concentrated on nonvideo social media platforms, such as Facebook, Twitter, and Sina Weibo, while this study focused on TikTok, a short video-sharing platform. This indicates that the effect of dialogic loop on citizen engagement may vary depending on the type of social media platform. This study measured dialogic loop by video title. Although a video's title is a concentrated expression of the content displayed, it is not completely equivalent to the interactivity of the video itself. In addition, this inconsistency may also be due to different measurements of dialogic loop. In fact, researchers have not reached a consensus on how to evaluate dialogic loop on social media platforms [1]. For example, Men et al [37] measured the dialogic loop of chief executive officers' Facebook accounts from three dimensions, namely replying to comments, liking user comments, and launching surveys. Chen et al [1] adopted 5 dimensions, including using hashtags and mentions, launching surveys, asking users questions, and answering users' questions, to assess the dialogic loop of government social media. Both studies found that dialogic loop is positively associated with social media engagement. A study by Wang and Yang [35] used questions and answers published by nonprofit and for-profit organizations on Twitter to measure dialogic loop. Interestingly, our findings are comparable in that responding to questions resulted in the lowest numbers of likes and retweets, while asking questions had little effect on the number of likes and shares received [35].

Most importantly, this study confirmed that emotional valence can moderate the impact of video length and content type on citizen engagement, although the moderating effects vary in the three dimensions of citizen engagement. For longer videos, the more negative emotion the video's title displays, the lower the number of likes that the video would receive. This pattern is almost the same for the number of comments. This means that longer videos with positive titles receive higher numbers of likes and comments. For short videos related to the government's handling of the pandemic and guidance for stakeholders, positive titles received more shares. Videos about the latest news received more likes if the title had a higher level of positive emotion. This demonstrates the important role of the emotional valence of video titles in promoting citizen engagement through government TikTok accounts. This can be explained by The Social Sharing of Emotion Theory (SSET), which was proposed by Rimé and colleagues in the 1990s. The SSET posits that emotion is a critical motivator for information sharing and social interaction. In our daily life, emotional events can happen anywhere and at any time, and those who experience emotional events are likely to talk about them and the feelings experienced [38]. Through this social sharing of emotion, individuals can express their emotional state and facilitate the establishment of interpersonal relationships [38]. Considering the existence of positivity bias, information with positive emotion creates a good experience for the receiver, and builds a positive image of the information sender [39]. Compared to negative emotion, positive emotion can activate individuals' desire to seek and share information [40]. Therefore, when individuals encounter emotional content from the title of a TikTok video, they will have an urgent need to share this emotional experience. Further, positive emotion will strengthen this behavior, facilitating public engagement on TikTok, enhancing likes, shares, and comments.

Contribution and Implications

This research makes the following contributions. First, we not only empirically examined how governments have used new video-based social media platforms for public engagement in the context of a public health crisis, but also built a model with emotional valence as a moderator to explain the underlying mechanism of how video length, title length, dialogic loop, and content type affects public engagement with government TikTok accounts. Second, we reveal that although shorter videos are likely to attract more likes and comments, for longer videos, the emotional valence of the title is of critical importance. For long videos, the more positive the title, the more likes and comments it receives, and vice versa. Third, our study found that emotional valence displayed in the title plays a critical role in the impact of content type on public engagement. For videos

focused on guidance and the government's handling of the crisis, the more positive the emotion displayed in the video title, the higher the number of shares it received. In addition, videos related to the latest news received more likes when the title had higher levels of positive emotion. Fourth, our study found that dialogic loop is likely to reduce certain types of public engagement.

This study has several practical implications. First, TikTok has become an indispensable channel for government-citizen communication, and governments should actively embrace this new method of communication. Second, for government entities producing videos for TikTok, shorter video length is preferred. If the video length is relatively long, it is better to have a title with positive emotion rather than negative emotion. Third, after the public health crisis, governments are advised to publish more information about their handling of the crisis, provide further guidance for stakeholders, and upload videos with positive emotion in the title to facilitate delivery.

Limitations and Future Recommendations

This study has several limitations. First, we focused on the official TikTok account of the NHCC. Whether the results of this research are equally applicable to local health departments is worthy of investigation. Second, it is worth exploring if the conclusions are similar in Western countries. There are notable differences between TikTok and YouTube [41]; although both of them are video-based social networking platforms, TikTok videos are much shorter than those on YouTube, and there are various easy-to-use templates. The typical length of a TikTok video may be just 30-40 seconds, while YouTube videos can be more than 15 minutes long. In addition, TikTok is a mobile-only social media app, while YouTube operates via both a website and mobile app. Their functionalities also differ; for example, YouTube has a dislike button, while TikTok does not. Furthermore, compared with the individualism advocated by Western countries, China emphasizes collectivism. Moreover, the number of comments found by our study could be influenced by the presence of censorship in China. Third, due to the constraints of the content analysis methods, some important variables were not employed in our research model (eg, camera view). Wang [42] found that the camera view of short videos on TikTok significantly affects the audience's immersion and social presence, which are important elements in promoting citizen engagement. We attempted to use content analysis to determine the type of camera view but it was difficult for the encoders to reach consensus and the interreliability was relatively low. Fourth, the significant negative impact of dialogic loop on reposting behavior deserves further investigation, although we infer that this may be due to differences between TikTok and other non-video–related social media platforms. In addition, our study did not obtain information from NHCC regarding their video and post creation process. Future research could use a qualitative approach to find out how the government TikTok operates in terms of content selection, rules, and strategies during a health crisis. Data from TikTok users could also enrich future studies [43,44].

Conclusions

It is evident that fostering engagement through video sharing on TikTok provides public health departments with the ability to promote citizen engagement and accelerate the dissemination of health information. Nonetheless, how to sustain this positive effect is still unclear. Through analysis of 355 COVID-19–related TikTok videos scraped from the official NHCC account, this study addresses this knowledge gap by considering emotional valence as a moderator that determines the effect that video length, title length, dialogic loop, and content type have on the three dimensions of citizen engagement. In general, shorter videos and longer video titles elicit greater citizen engagement. Citizens prefer to view content about the government's handling of the pandemic and guidance for stakeholders, and actively repost these TikTok videos. We confirmed the important role of emotional valence as a moderator and discovered the specific moderating mechanisms. Longer videos with positive titles received higher numbers of likes and comments. For short videos related to government handling and guidance for stakeholders, positive titles received more shares. Videos related to the latest news received more likes when the title had a higher level of positive emotion. Public health departments should create shorter videos with longer titles, with content focused on the government's handling of the crisis and guidance for stakeholders. Moreover, in the future, video producers should consider the emotional valence of titles and align it with the content type and video length.

Abstract

Background: The rapid spread of the COVID-19 pandemic in the United States has made people uncertain about their perceptions of the threat of COVID-19 and COVID-19 response measures. To mount an effective response to this epidemic, it is necessary to understand the public's perceptions, behaviors, and attitudes.

Objective: We aimed to test the hypothesis that people's perceptions of the threat of COVID-19 influence their attitudes and behaviors.

Methods: This study used an open dataset of web-based questionnaires about COVID-19. The questionnaires were provided by Nexoid United Kingdom. We selected the results of a questionnaire on COVID-19–related behaviors, attitudes, and perceptions among the US public. The questionnaire was conducted from March 29 to April 20, 2020. A total of 24,547 people who lived in the United States took part in the survey.

Results: In this study, the average self-assessed probability of contracting COVID-19 was 33.2%, and 49.9% (12,244/24,547) of the respondents thought that their chances of contracting COVID-19 were less than 30%. The self-assessed probability of contracting COVID-19 among women was 1.35 times that of males. A 5% increase in perceived infection risk was significantly associated with being 1.02 times (OR 1.02, 95% CI 1.02-1.02; P<.001) more likely to report having close contact with >10 people, and being 1.01 times (OR 1.01, 95% CI 1.01-1.01; P<.001) more likely to report that cohabitants disagreed with taking steps to reduce the risk of contracting COVID-19. However, there was no significant association between participants who lived with more than 5 cohabitants or less than 5 cohabitants (P=.85). Generally, participants who lived in states with 1001-10,000 COVID-19 cases, were aged 20-40 years, were obese, smoked, drank alcohol, never used drugs, and had no underlying medical conditions were more likely to be in close contact with >10 people. Most participants (21,017/24,547, 85.6%) agreed with washing their hands and maintaining social distancing, but only 20.2% (4958/24,547) of participants often wore masks. Additionally, male participants and participants aged <20 years typically disagreed with washing their hands, maintaining social distancing, and wearing masks.

Conclusions: This survey is the first attempt to describe the determinants of the US public's perception of the threat of COVID-19 on a large scale. The self-assessed probability of contracting COVID-19 differed significantly based on the respondents' genders, states of residence, ages, body mass indices, smoking habits, alcohol consumption habits, drug use habits, underlying medical conditions, environments, and behaviors. These findings can be used as references by public health policy makers and health care workers who want to identify populations that need to be educated on COVID-19 prevention and health.

COVID-19; perceived threat of disease; environment; behavior; America

Introduction

Background

COVID-19 is an acute infectious respiratory disease that is caused by the novel SARS-CoV-2 virus [1]. It was first detected on December 2019 in Wuhan, China. SARS-CoV-2 is a novel coronavirus that has not been previously identified in humans. It also has a stronger ability to spread and a longer incubation period than the severe acute respiratory syndrome coronavirus. Therefore, SARS-CoV-2 poses a greater epidemic risk [2]. In January 29, 2020, 7711 COVID-19 cases were confirmed in China, and 98 cases were confirmed in 18 other countries [3,4]. As a result, the World Health Organization (WHO) declared the COVID-19 epidemic a public health emergency of international concern on January 30, 2020, and called on all countries to collaborate and prevent the spread of the COVID-19 epidemic [5]. At the beginning of the outbreak, the Chinese government immediately initiated rigorous and intensive prevention and control measures to contain the spread of SARS-CoV-2. Such measures included implementing effective medical treatments, initiating precautionary measures, conducting comprehensive testing, and reducing social mobility and social contact by implementing travel restrictions, banning large gatherings, closing public places, and issuing a stay-at-home order [6,7]. However, due to the strong human-to-human transmissibility of the SARS-CoV-2 virus, the COVID-19 epidemic spread rapidly around the world. On March 11, 2020, the WHO declared the COVID-19 epidemic a worldwide pandemic.

The United States announced the first confirmed case of COVID-19 on January 21, 2020, and the SARS-CoV-2 virus spread to all 50 states by mid-March. As of April 28, 2020, the cumulative number of confirmed cases in the United States has exceeded 1,000,000 [8]. To control the development of the COVID-19 epidemic, the US government implemented a number of measures, including enhancing detection capacities, increasing investments in medical resources, limiting social activities, and providing economic assistance. However, the number of confirmed cases is still rapidly growing at a rate of more than 20,000 new cases per day. The continuous development of the COVID-19 epidemic has seriously affected the physical and mental health of the US public. In terms of coping with large-scale epidemics, the effects of policy implementation are usually influenced by group behaviors. People's methods for coping with large-scale epidemics depend on each individual's perception of the risk of contracting the disease and each individual's ability to adjust their behavior when adapting to environmental changes, to a certain extent [9]. To ensure ultimate success in the fight against COVID-19, it is necessary for the public to adhere to the control measures that have been proposed by the government. However, compliance with control measures depends on the perceived threat level of COVID-19. Therefore, to control the pandemic and quickly reduce the impact of the epidemic on the US economy and society, we must understand the US public's perception of the threat of COVID-19. This will provide the health sector with useful information on increasing disaster preparedness and improving countermeasures.

Risk Perception During the COVID-19 Epidemic

Risk perceptions refer to people's intuitive evaluations of hazards that they are or might be exposed to [10]. Risk perception is influenced by multiple individual and societal factors, such as different social, cultural, and contextual factors. Risk perceptions act as triggers for precautionary action [11]. When individuals and communities deem risks as unsafe, unacceptable, or something to be feared, their responses and adherence to important public health measures for risk mitigation will be influenced [12]. For example, risk perceptions may shape the public's willingness to accept and adhere to COVID-19 risk mitigation strategies, such as social distancing and the use of face masks [13]. As the number of COVID-19–related deaths rises around the world, understanding the public's risk perceptions becomes increasingly more important [14].

Researchers around the world have been actively conducting COVID-19 surveys. Research on the perception of COVID-19 risk mainly focuses on the following 3 aspects: (1) the influencing factors of risk perception (eg, personality characteristics, knowledge level, and health and economy status) and their relationship with protective behaviors [15-17]; (2) the risk perceptions of COVID-19 among special populations, such as college students under quarantine, medical students, patients with COVID-19, health care professionals, and pregnant women [18-22]; and (3) the impact of risk perception on social distancing and the mental health of the public or health workers (eg, anxiety and distress) [23-27]. However, there are few studies on the American public's risk perception of COVID-19. For instance, Wise et al [28] investigated risk perceptions and self-reported protective behaviors among 1591 individuals who lived in the United States during the first week of the outbreak. Furthermore, Niepel et al [29] discussed the risk perception of COVID-19–related fatality among adult US residents. However, there is limited scientific evidence for personality characteristics, risk perceptions, attitudes, and behavior patterns among the American public, especially with regard to the attitudes and behaviors of cohabitants. In addition, most research on the United States is based on adults; there is a lack of research on the risk perceptions of COVID-19 among American people aged <18 years. Moreover, the sample sizes of existing surveys have been limited (ie, generally hundreds or thousands of samples), which has led to certain limitations with regard to the interpretation of the results. Additionally, there have been no COVID-19 surveys that target American people of all ages and have a very large sample size (ie, tens of thousands of samples).

This paper describes a cross-sectional web-based survey that was designed to gauge the US public's perception of the threat posed by COVID-19. This study is one of the first attempts to conduct a large-scale survey for determining the US public's perception of the health threat of COVID-19, and the characteristics that influence the US public's environment and behaviors toward COVID-19.

Methods

Participants

The dataset for this cross-sectional study came from the COVID-19 (Coronavirus) Survival Calculator project [30]. This project was created and managed by the data research team at Nexoid United Kingdom, which is a software company that is located in London, United Kingdom and specializes in research, analysis, and computer science. The COVID-19 (Coronavirus) Survival Calculator is a website that was posted on Reddit (ie, a discussion-based platform) under the subreddit r/Coronavirus_PH. The website was launched to measure participants' risk rates of SARS-CoV-2 infection [30]. The website is available in 49 languages, such as English, Spanish, Portuguese, Russian, and French, and it asks participants certain questions in a survey-like manner (ie, participants can choose the following 3 answers: disagree, neutral, or agree). The dataset is protected by the Creative Commons Attribution 4.0 International (CC BY 4.0) License. The dataset is available for everyone to download, but its respondents remain anonymous for privacy and safety reasons.

On April 20, 2020, Nexoid United Kingdom released the original data of 682,793 surveys. Data were collected from March 24 to April 20, 2020. This open dataset contains the longitude and latitude data of participants' Internet Protocol (IP) addresses. To find respondents who participated in the survey in the United States, we used the Baidu Map geocoder to parse and convert latitude and longitude data, so that we could obtain information on participants' locations. However, to protect participants' privacy, Nexoid United Kingdom does not publish participants' IP addresses. As such, our IP address location data were accurate up to 5 km. Therefore, there may have been several errors in participants' location information in this study.

The dataset initially included 566,122 respondents from the United States. However, we excluded participants who had missing values in the "chance of getting COVID-19" field and participants whose gender was labelled as "other." Furthermore, we conducted stratified random sampling so that the distribution of participants in the age and gender subgroups matched that of the general population, as per the US Census Bureau's methodology when they reported demographic data for the 2019 US census [31]. The respondents participated in this cross-sectional study from March 29 to April 20, 2020. This study was performed 10 weeks after the first COVID-19 case was confirmed in the United States. This survey period corresponds to the rapid spread of the COVID-19 outbreak in the United States.

Data Availability

The data supporting this study is openly available in the Population Health Data Archive [32].

Measures

The COVID-19 (Coronavirus) Survival Calculator is rich in content, such as demographic characteristics, environmental factors, behavioral factors, governmental factors, and health-related factors. In addition, the calculator includes 2 questions about people's perceptions of the threat posed by COVID-19. These questions assessed a respondent's chance of contracting COVID-19 and a respondent's chance of dying from COVID-19. Before participants accessed the survey, Nexoid United Kingdom provided a data and privacy statement, which informed participants that the calculator would record the data that they enter on the page and their locations (ie, locations derived from participants' IP addresses). In addition, participants were informed that the survey was anonymous, the collected data would be added to a freely accessible dataset, and the dataset would be shared.

For the purposes of this study, we selected specific data from the COVID-19 (Coronavirus) Survival Calculator, such as demographics, environmental factors, behavioral factors, and the people's chances of contracting COVID-19. Demographic characteristics included gender, the place of current residence, age, body mass index (BMI), smoking status, alcohol consumption status, nonprescription/recreational drug use (ie, cannabis, amphetamines, cocaine, lysergic acid diethylamide, and 3,4-methylenedioxymethamphetamine use), and underlying medical conditions. Several questions had too many answer options in the original questionnaire, which is not conducive to the analysis of practical problems. Therefore, we regrouped the answer options for several questions.

As per the classification criteria of the Centers for Disease Control and Prevention (CDC), participants' areas of residence were divided into the following six categories, based on the number of confirmed COVID-19 cases that were reported by participants' state of residence: 0-1000 cases, 1001-5000 cases, 5001-10,000 cases, 10,001-20,000 cases, 20,001-40,000 cases, and ≥40,001 cases. Participants were also divided into the following four age categories: 0-20 years, 20-40 years, 40-60 years, and >60 years. Furthermore, participants were divided into the following weight categories based on the WHO BMI criteria: underweight (BMI<18.5 kg/m^2), normal weight (BMI=18.5-24.9 kg/m^2), preobesity (BMI=25-29.9 kg/m^2), and obesity (BMI≥30 kg/m^2). In addition, smoking status was divided into four categories (ie, never, quit, vape, and yes), and alcohol consumption status (ie, never, none in last 14 days, and some in last 14 days) and drug use status (ie, never, none in last 28 days, and some in last 28 days) were divided into three categories. Underlying medical conditions included asthma, carcinoma, chronic kidney disease, compromised immune system, coronary heart disease, chronic obstructive lung disease, diabetes, HIV disease, hypertension, or other chronic illness. We categorized participants' underlying medical condition status as either "have" or "none."

The questionnaire in this study contained seven questions (Table 1). Of these 7 questions, 3 pertained to environmental factors, 3 asked about behavioral factors, and 1 addressed people's perceptions of the threat posed by COVID-19. The question that addressed people's perceptions of the threat posed by COVID-19 provided participants with the following 10 answer options: 0%-10%, 10%-20%, 20%-30%, 30%-40%, 40%-50%, 50%-60%, 60%-70%, 70%-80%, 80%-90%, and 90%-100%. The questionnaire used the median of each probability range as participants' final results (eg, 5%, 15%, and 25%).

Table 1. Questionnaire on the environmental and behavioral factors that affect people's perceptions of the risk of contracting COVID-19.

Topic, question, and options	Value
Environment	
How many people were you in close contact with in the last week, including partners, children, work colleagues, customers, patients, etc? (number of close contacts), mean (SD)	6.9 (6.6)
<10 people, n (%)	19,772 (80.5)
>10 people, n (%)	4774 (19.5)
How many people live in your house/apartment? (number of cohabitants), mean (SD)	3.1 (1.6)
<5 people, n (%)	22,741 (92.6)
>5 people, n (%)	1806 (7.4)
Do you travel to work/school?	
Home (I always worked/studied from home), n (%)	1439 (5.9)
Never (I did not go to work/school before), n (%)	5003 (20.4)
Stopped (I have stopped going to work/school), n (%)	10,469 (42.6)
Critical travel (I still go to work; critical job fields include health care, utilities, military, etc), n (%)	5703 (23.2)
Noncritical travel (ie, I still go to work/school), n (%)	1933 (7.9)
Behaviors	
I am taking steps to reduce my risk (eg, social distancing, washing hands, etc)	
Disagree, n (%)	397 (1.6)
Neutral, n (%)	3133 (12.8)
Agree, n (%)	21,017 (85.6)
The people I live with are taking steps to reduce my risk (social distancing, washing hands)	
Disagree, n (%)	740 (3)
Neutral, n (%)	4956 (20.2)
Agree, n (%)	18,851 (76.8)
Do you wear a mask when outside of your house/flat?	
Rarely, n (%)	14,053 (57.2)
Sometimes, n (%)	4981 (20.3)
Usually, n (%)	5513 (22.5)
Opinion of infection (% chance), mean (SD)	33.2 (21.8)
What do you think are your chances of getting COVID-19?	
0%-10%, n (%)	4236 (17.3)
10%-20%, n (%)	3865 (15.7)
20%-30%, n (%)	4143 (16.9)
30%-40%, n (%)	3061 (12.5)
40%-50%, n (%)	3434 (14)
50%-60%, n (%)	3110 (12.7)
60%-70%, n (%)	1195 (5.9)
70%-80%, n (%)	868 (3.5)
80%-90%, n (%)	355 (1.4)
90%-100%, n (%)	280 (1.1)

Statistical Analysis

We described the frequency of participants' demographic characteristics and various environmental and behavioral factors. Independent samples 2-tailed *t* tests, one-way analysis of variance tests, or Chi-square tests were used to compare the differences between groups of categorical variables, as

appropriate. Furthermore, we used Bonferroni-corrected *P* values for multiple comparisons. In our logistic regression analysis, all demographic, environmental, and behavioral variables were used as independent variables, and participants' self-assessments of their chances of contracting COVID-19 were used as the outcome variable. The logistic regression analysis was conducted to identify factors that were associated with participants' perceptions of the threat of contracting COVID-19. We conducted binary logistic regression analyses to identify factors that were associated with environmental factors and behaviors. Factors were selected by using the backward stepwise method. Odds ratios and their 95% confidence intervals were used to quantify the associations among variables, estimated probabilities of infection, environmental factors, and behaviors. Results were considered statistically significant when $P<.05$. All analyses were conducted from May 2020 to June 2020 with SPSS version 23.0 (IBM Corp).

Results

After excluding 97,883 respondents who had missing values in the "chance of getting COVID-19" field, 1742 respondents whose gender was labelled as "other," and 441,950 respondents due to stratified random sampling, the final sample consisted of 24,547 participants. These respondents lived in all 50 states in the United States. Of the 24,547 respondents in the final sample, 12,465 (50.8%) were women, 6100 (24.9%) were aged <20 years, 6677 (27.2%) were aged 20-40 years, 6191 (25.2%) were aged 40-60 years, and 5579 (22.7%) were aged >60 years. Furthermore, the average BMI of the respondents was 29.41 kg/m^2 (SD 7.74 kg/m^2; range 11.6-87.6 kg/m^2), and 39.2% (9617/24,547) of the respondents were obese (BMI≥30 kg/m^2). Additionally, 56.7% (13,919/24,547) of the participants reported that they never smoked, 51.5% (12,632/24,547) reported that they drank alcohol in the last 14 days before taking the survey, and 47.3% (11,621/24,547) reported that they never used drugs. In terms of medical conditions, 61% (14,983/24,547) of participants did not have the underlying medical conditions that were described in this study. Additional demographic information is included in Table 2.

Table 2. Participants' demographic characteristics and self-assessment results for their risk of contracting COVID-19, stratified by demographic variables (N=24,547).

Demographic characteristics	Number of participants, n (%)	Opinion of infection (% chance), mean (SD)	*t* test (df) or *F* test (df)	*P* value
Gender			10.99[a] (24,464.28)	<.001

[a]A 2-tailed *t* test value.

[b]An *F* test value.

[c]BMI: body mass index; participants had a mean BMI of 29.41 kg/m^2 (SD 7.74 kg/m^2).

[d]The total number of participants in this category does not equal 24,547 due to missing data.

In terms of environmental factors, the average number of people that the respondents had close contact with in the week before taking the survey was 6.9 people (SD 6.6 people) (Table 1). In addition, 19.5% (4774/24,547) of participants reported that they had close contact with more than 10 people. In our sample, an average of 3.1 people (SD 1.6 people) lived together in 1 house/apartment, and 92.6% (22,741/24,547) of the respondents reported that less than five people lived in their houses/apartments. Furthermore, 42.6% (10,469/24,547) of the participants stopped working and going to school, while 7.9% (1933/24,547) were still in school or engaged in noncritical work.

In terms of behaviors, most participants (21,017/24,547, 85.6%) were willing to take measures to reduce the risk of infection, but 1.6% (397/24,547) of participants reported that they were not willing to take risk reduction measures. Additionally, 76.8% (18,851/24,547) of the respondents stated that their cohabitants were also taking steps to reduce the risk of infection. However, 57.2% (14,053/24,547) of the respondents reported that they rarely or never wore a mask, and only 22.5% (5513/24,547) stated that they often wore masks.

The average self-assessed probability of COVID-19 infection was 33.2% (SD 21.8%; range 5%-95%); 33% (8101/24,547) of the respondents thought their chances of contracting COVID-19 were <20%, but 2.5% (635/24,547) thought they had a >80% chance of contracting COVID-19 (Table 1). Moreover, participants' perceptions of the threat posed by COVID-19 significantly differed across genders (P<.001), places of residence (P<.001), ages (P<.001), BMI categories (P<.001), smoking statuses (P<.001), alcohol consumption statuses (P<.001), nonprescription/recreational drug use statuses (P<.001), and underlying medical condition statuses (P<.001) (Table 2).

The logistic regression analysis results suggested that there were several important relationships between variables (Table 3). Women thought that their chances of contracting COVID-19 was 1.35 times (OR 1.35, 95% CI 1.28-1.41) that of males. The self-assessed probabilities of contracting COVID-19 for participants who lived in states with 5001-10,000, 10,001-20,000, and 20,001-40,000 COVID-19 cases were 22% (OR 0.78, 95% CI 0.70-0.88; OR 0.78, 95% CI 0.70-0.87; OR 0.78, 95% CI 0.70-0.87, respectively) lower than those of participants who lived in states with >40,000 cases. The self-assessed probabilities of contracting COVID-19 for participants aged 0-20 years, 20-40 years, and 40-60 years were 1.32 times (OR 1.32, 95% CI 1.22-1.43), 1.68 times (OR 1.68, 95% CI 1.56-1.81) and 1.55 times (OR 1.55, 95% CI 1.44-1.66) higher than those of participants aged >60 years, respectively. The self-assessed infection probabilities of participants with a normal BMI were 6% (OR 0.94, 95% CI 0.88-0.99) lower than those of participants who were obese. The self-assessed probabilities of contracting COVID-19 for participants who did not smoke or quit smoking were 8% (OR 1.08, 95% CI 1.00-1.16; OR 1.08, 95% CI 1.00-1.18) higher than those of participants who smoked cigarettes. The self-assessed probabilities of participants who did not drink and did not take drugs were 13% (OR 0.87, 95% CI 0.82-0.92) and 23% (OR 0.77, 95% CI 0.72-0.82) lower than those of participants who did drink and take drugs, respectively. Moreover, participants without underlying medical conditions were 32% (OR 0.68, 95% CI 0.65, 0.72) less likely to contract COVID-19 than participants with these conditions, as per their self-assessment results. Furthermore, compared to participants who had close contact with more than 10 people, participants who were in close contact with less than 10 people had a 43% (OR 0.57, 95% CI 0.53, 0.61) lower self-assessed probability of contracting COVID-19. Participants who engaged in critical work assessed that their probability of contracting COVID-19 was 1.50 times (OR 1.50, 95% CI 1.37-1.65) higher than those of participants who engaged in noncritical work. In addition, participants who were neutral about taking steps to reduce their infection risk thought that they were 21% (OR 0.79, 95% CI 0.73, 0.85) less likely to contract COVID-19 compared to those who agreed with taking steps to reduce their infection risk.

The self-assessed probability of contracting COVID-19 for participants who lived with people that did not take steps to reduce their infection risk were 1.56 times (OR 1.56, 95% CI 1.36-1.79) higher than those of participants who lived with people that did take measures for reducing their infection risk. Respondents who rarely wore masks assessed that their probability of contracting COVID-19 was 34% (OR 0.76, 95% CI 0.72-0.81) lower than that of participants who frequently wore masks.

Table 3. Results of the logistic regression analysis of factors that were associated with participants' self-assessed probability of contracting COVID-19.

[a]Bonferroni *P* values are used to correct for multiple comparisons. Statistical significance was set to a level of *P*<.05.

[b]These parameters were set to 0 because they were redundant.

[c]N/A: not appliable.

[d]BMI: body mass index.

The binary logistic regression analysis results revealed several predictors among the environmental factors (Table 4). When participants' self-assessed risks of contracting COVID-19 increased by 5%, they were 1.02 times (OR 1.02, 95% CI 1.02-1.02) more likely to report that they had close contact with more than 10 people, while their odds of reporting a cessation of work/school decreased by 1% (OR 0.99, 95% CI 0.99-0.99). The odds of having close contact with more than 10 people increased by 82% (OR 1.82, 95% CI 1.52-2.18), 89% (OR 1.89, 95% CI 1.57-2.28), 58% (OR 1.58, 95% CI 1.32-1.89), and 45% (OR 1.45, 95% CI 1.21-1.73) for participants who lived in states with 1001-5000, 5001-10,000, 10,001-20,000, and 20,001-40,000 COVID-19 cases, respectively, compared to those who lived in states with >40,001 confirmed COVID-19 cases. The odds of reporting a cessation of work/school decreased by 34% (OR 0.66, 95% CI 0.58-0.75), 32% (OR 0.68, 95% CI 0.59-0.78), 22% (OR 0.78, 95% CI 0.68-0.88), and 26% (OR 0.86, 95% CI 0.74-0.95) for participants who lived in states with 1000-5000, 5001-10,000 cases, 10,001-20,000, and 20,001-40,000 COVID-19 cases, respectively, compared to those who lived in states with >40,001 COVID-19 cases. Compared to participants aged 20-40 years, participants aged 40-60 years were 30% less likely (OR 0.70, 95% CI 0.64-0.76) to have close contact with more than 10 people in the week before taking the survey, and 14% less likely (OR 0.86, 95% CI 0.75-0.99) to live with more than five people. Participants aged <20 years were 1.68 times (OR 1.68, 95% CI 1.56-1.81) more likely to report that they ceased to go to work/school compared to those aged 20-40 years. Participants who were obese were 1.28 times more likely (OR 1.28, 95% CI 1.18-1.39) to have close contact with more than 10 people compared to participants with a normal BMI. Participants who smoked electronic cigarettes and cigarettes were also 1.41 times (OR 1.41, 95% CI 1.26-1.58) and 1.68 times (OR 1.68, 95% CI 1.52-1.86) more likely to have close contact with more than 10 people compared to nonsmokers, respectively. Participants who

drank alcohol within 14 days before taking the survey were 1.30 times more likely (OR 1.30, 95% CI 1.19-1.42) to have close contact with more than 10 people compared to participants who never drank alcohol. However, participants who were obese were 24% less likely (OR 0.76, 95% CI 0.71-0.81) to stop going to work/school compared to participants with a normal BMI, and participants who smoked cigarettes were 42% less likely (OR 0.58, 95% CI 0.53-0.63) to report that they stopped going to work/school compared to nonsmokers. Compared to participants who never used drugs, participants who used drugs in the last 28 days before taking the survey were 21% less likely (OR 0.79, 95% CI 0.72-0.87) to have close contact with more than 10 people. Participants who never used drugs were also 18% more likely (OR 1.18, 95% CI 1.09-1.27) to cease going to school/work compared to participants who did use drugs. Participants who had underlying medical conditions were 16% less likely (OR 0.84, 95% CI 0.79-0.91) to have close contact with more than 10 people and 9% more likely (OR 1.09, 95% CI 1.03-1.15) to stop going to school/work compared to participants who did not have underlying medical conditions.

Table 4. Results of the binary logistic regression analysis of factors that were significantly associated with environmental factors.

The binary logistic regression analysis results revealed several predictors among behaviors (Table 5). When participants' self-assessed risks of contracting COVID-19 increased by 5%, they were 1.01 times (OR 1.01, 95% CI 1.01-1.01) more likely to report that their cohabitants disagreed with taking steps to reduce the risk of contracting COVID-19, and their odds of reporting that they rarely wore masks decreased by 1% (OR 0.99, 95% CI 0.99-0.99). The odds of women disagreeing with taking measures to reduce their infection risk and rarely wearing masks were 40% (OR 0.60, 95% CI 0.49-2.74) and 25% (OR 0.75, 95% CI 0.71-0.79) lower than those of males, respectively. Compared to those who lived in states with >40,001 confirmed COVID-19 cases, participants from states with 1001-5000 cases and 5001-10,000 cases were 1.98 times (OR 1.98, 95% CI 1.73-2.25) and 1.80 times (OR=1.80, 95% CI: 1.57-2.06) more likely to report that they rarely wore masks, respectively. Compared to participants aged 20-40 years, participants aged <20 years were 2.96 times (OR 2.96, 95% CI 2.27-3.88), 2.04 times (OR 2.04, 95% CI 1.68-2.47) and 1.48 times (OR 1.48, 95% CI 1.36-1.60) more likely to report that they did not take protective measures, their cohabitants did not take protective measures, and they rarely wore masks, respectively. Participants who were obese were 1.14 times (OR 1.14, 95% CI 1.06-1.21) more likely to report that they rarely wore masks compared to participants with a normal BMI. Compared to nonsmokers, participants who smoked cigarettes were 2.22 times (OR 2.22, 95% CI 1.65-2.99), 1.57 times (OR 1.57, 95% CI 1.25-1.96) and 1.11 times (OR 1.11, 95% CI 1.02-1.21) more likely to report that they did not take protective measures, their cohabitants did not take protective measures, and they rarely wore masks, respectively. Participants who drank alcohol were 1.18 times (OR 1.18, 95% CI 1.10-1.27) more likely to report that they rarely wore masks compared to participants who never drank alcohol. Participants who used drugs within 28 days before answering the survey were 1.47 times (OR 1.47, 95% CI 1.20-1.81) more likely to report that their cohabitants did not agree with taking measures to reduce infection risk compared to participants who never used drugs. Additionally, participants who had underlying medical conditions were 1.31 times (OR 1.31, 95% CI 1.12-1.53) more likely to report that their cohabitants did not agree with measures to reduce infection risk compared to participants without these conditions.

Discussion

Principal Results

This study analyzed the US public's perception of the threat posed by COVID-19 during the rapid spread of the COVID-19 pandemic. Individuals' risk perceptions affect their protective behaviors during the early stages of a pandemic [28,33]. By extending this idea to the COVID-19 epidemic, we hypothesized that when people believe that they have an increased chance of contracting COVID-19, they will be more willing to follow public health recommendations. This study showed that a high self-assessed probability of contracting COVID-19 was related to the following factors: having close contact with more than 10 people, working at a critical job, having cohabitants that disagreed with taking steps to reduce infection risk, and sometimes wearing masks outside the house. In addition, this study also analyzed environmental factors, behaviors, and their associations with people's self-assessed probabilities of contracting COVID-19. We also identified several demographic factors that were associated with environmental factors, behaviors, and people's self-assessed probabilities of contracting COVID-19. These findings can be used as references by public health policy makers and health care workers who want to identify populations that need to be educated on COVID-19 prevention and health education.

The sample's average self-assessed probability of contracting COVID-19 was 33.2%, and 49.9% (12,399/24.547) of the participants believed that their chances of contracting COVID-19 were less than 30%. This indicated that most respondents were optimistic about the COVID-19 pandemic. Moreover, participants' self-assessed probabilities of contracting COVID-19 differed significantly across respondents' genders, participants' states of residence, ages, BMIs, smoking statuses, alcohol consumption statuses, drug use statuses, underlying disease statuses, environments, and COVID-19–related behaviors. Participants who were obese, were aged 20-40 years, consumed alcohol in the last 14 days before taking the survey, took drugs in the last 28 days before taking the survey, and had underlying medical conditions thought that they had a higher chance of contracting COVID-19. These findings are in line with those of other literature about controversial scientific topics [34-36].

In this study, women felt that they had a higher chance of contracting COVID-19 than men. Women's risk perceptions of COVID-19 also affect their protective behaviors. Women pay more attention to self-protection methods, such as agreeing with taking measures to reduce the risk of contracting COVID-19 and wearing masks, compared to men. However, Chen et al [37] found that more men contracted COVID-19 than women. Studies have also shown that the mortality rate of men is higher than that of women [38]. Nonetheless, in this study, male participants were more reluctant to take measures for reducing their infection risk and less willing to wear masks compared to female participants. These environmental factors and behaviors greatly increase the chance of contracting COVID-19.

We also found that young people (ie, aged <20 years) were more reluctant to wear masks and take measures for reducing the risk of contracting COVID-19 compared to older people. Although the vast majority of COVID-19–related deaths occur in older patients and those with underlying health conditions, this does not mean that young people cannot be infected with SARS-CoV-2. Studies have shown that anyone can become severely ill from contracting COVID-19. The SARS-CoV-2 virus has been infecting young people, and this has resulted in young people spreading COVID-19 [39].

In this study, cigarette smokers reported that their chances of contracting COVID-19 were lower than those of nonsmokers. Although there are no peer-reviewed studies that have evaluated the association between the risk of SARS-CoV-2 infection and smoking, available research suggests that smokers are at a high risk of developing severe COVID-19 outcomes and dying [40,41]. Therefore, it may be necessary to strengthen COVID-19–related prevention and health education for men, young people, and smokers, to increase their understanding of COVID-19.

In general, participants who lived in states where the epidemic was more severe thought that they had a high chance of contracting COVID-19. Therefore, they also paid more attention to maintaining social distance and taking protective measures. These participants were more likely to stop going to work/school and often wear masks. It is worth noting that although the outbreak was less severe in states with 1001-5000 confirmed COVID-19 cases, participants in these states paid less attention to maintaining social distance, were the least likely to stop going to school/work, and were the least willing to take protective measures and wear masks. In addition, these participants thought

they were less likely to contract COVID-19 than those who lived in states with more than 40,001 cases. Environmental factors and people's behaviors toward COVID-19 are likely to result in an increased number of confirmed cases in states with 1001-5000 COVID-19 cases. According to the data provided by USA Facts [8], in April 20, 2020, the states with 1001-5000 reported cases were Arkansas, Delaware, Idaho, Iowa, Kansas, Kentucky, Minnesota, Mississippi, Nebraska, Nevada, New Hampshire, New Mexico, Oklahoma, Oregon, South Carolina, South Dakota, Utah, and Wisconsin. A week later, the number of confirmed cases in Arkansas, Delaware, Iowa, Kansas, and Nebraska increased by more than 50%, and the number of cases in Nebraska increased by 122.74%. In addition, the number of COVID-19 cases in Iowa, Mississippi, South Carolina, and Wisconsin exceeded 5000. Therefore, to avoid a resurgence of COVID-19, people who live in low-risk areas cannot ignore daily preventive measures.

Limiting face-to-face contact with others is the best way to reduce the spread of COVID-19. During the COVID-19 outbreak (ie, March 29 to April 20, 2020) 42.6% (10,469/24,547) of participants stopped going to work/school. This was related to the closure of many schools and businesses in the United States on March 2, 2020 [8]. However, 19.5% (4774/24,547) of the participants reported that they had close contact with more than 10 people in the week before taking the survey. This went against the White House's recommendation on March 16, 2020 (ie, this survey was conducted between March 29 and April 20, 2020) [42]. Those who lived in states with 5001-10,000 cases, were aged 20-40 years, were obese, and smoked had a greater chance of reporting that they had close contact with more than 10 people. In the 2 weeks after the lockdown in Hubei Province, China, only 3.6% of people reported that they went to crowded places [43]. It is possible that China's stringent isolation measures and the Chinese government's strong enforcement of these measures motivated Chinese citizens to comply with government orders. Unlike in China, there is still some debate between the federal US government and the state governments about the need to implement stay-at-home orders and similar measures. Stay-at-home orders are predominantly issued by state governments rather than the federal government. On March 19, 2020, California was the first state to issue a stay-at-home order. As of March 29, 2020, 26 states, such as Illinois, New Jersey, New York, and Washington, have issued similar orders [44]. More than half of Americans are required to stay at home to maintain social distance and reduce close contact with each other. Moreover, between March 29 and April 20, 2020, an additional 17 states and Washington, D.C. issued stay-at-home orders. This may have led the population to change their behaviors toward crowds.

Health care workers are among the most vulnerable groups because of their proximity to patients with COVID-19. In our sample, participants who had critical jobs (eg, health care jobs, utilities jobs, military jobs, etc) also thought they had a high probability of contracting COVID-19 (mean 40.81%, SD 23.05%; Multimedia Appendix 1). In spite of this, only 20.2% (1151/5703) of participants with critical jobs reported that they wore masks regularly, and 57.3% (3267/5703) reported that they rarely wore masks. The lack of protective equipment has further increased the risk of infection in people with critical jobs. According to a report from The Hill [45], on March 19, 2020, health care workers were forced to reuse single-use masks and protective equipment due to shortages caused by the COVID-19 epidemic. The US Department of Health and Human Services have reported that there was a serious shortage of new COVID-19 tests for medical staff and a shortage of protective equipment on a large scale. During the COVID-19 pandemic, the strong risk of infection and the shortage of protective equipment have caused great stress, anxiety, fear and other strong emotions in people with critical jobs. Studies have shown that hospital medical staff who are in charge of patients with COVID-19 have a higher incidence of mental symptoms, such as somatization, obsessive-compulsive behavior, anxiety, hostility, and paranoia, than the general public. Furthermore, hospital medical staff have been experiencing obvious psychological, behavioral, and emotional problems [46,47]. Therefore, in addition to increasing the supply of protective equipment, psychological interventions and counseling should be provided to people with critical jobs, to address their psychological needs.

In this study, participants had different attitudes toward social distancing, washing hands, and wearing a mask. We found that 85.6% (21,017/24,547) of participants agreed with taking steps to reduce the risk of contracting COVID-19 (eg, social distancing and washing hands), while only 22.5% (5513/24,547) usually wore masks. In China, only 2% of people have reported that they do not wear masks outside of home [43]. This is not only related to the personality of US citizens, but also to the decisions of the US government. In China, people have been encouraged—and even mandated—to wear masks outside of home. The CDC has encouraged people to wash their hands frequently and avoid close contact with people. However, the CDC has also recommended that healthy people should not use masks, to ensure that masks are available for frontline health care workers [48]. In Western countries, people do not need to wear a mask unless they are sick. The use of masks is still an evolving process. Many studies and practices have shown that wearing masks is important for slowing the spread of SARS-CoV-2 [49-51]. On April 3, 2020, the CDC revised its guidelines for wearing masks, and recommended that people should wear cloth face coverings in public settings where other social distancing measures are difficult to maintain. Since then, the proportion of US residents who wear masks has rapidly increased.

Limitations

This study has several limitations. First, the scope of our investigation was limited. The recruitment of participants was based on their willingness to participate and access to social networking sites. As such, our participants are not representative of the entire American public. Furthermore, participants were not compensated for participating in this survey. This may reflect participants' prior concerns about contracting COVID-19. Therefore, the respondents may have a higher self-assessment risk of contracting COVID-19 compared to that of the general population. However, we conducted stratified random sampling to achieve a distribution of participants that matched the general population in terms of age and sex, thereby reducing selection

bias to a certain extent. Second, people's perceptions of the threat posed by COVID-19 are influenced by many factors, and these factors are constantly changing. The questionnaire in this study asked participants to answer very specific questions that could not comprehensively cover the complex situations surrounding participants' awareness of their chances of getting COVID-19. For example, the content of the Nexoid United Kingdom questionnaire was updated on April 25, 2020; Nexoid United Kingdom added factors such as private health insurance, income, and race. However, these factors are not included in this study.

Conclusions

In summary, this survey is the first large-scale attempt to describe the determinants of the US public's perception of the threat posed by COVID-19. We also describe COVID-19–related environmental factors and behaviors in the United States, and their relationship with the public's perceptions. Our findings suggest that the US public is generally optimistic; they believe that they have a relatively low chance of contracting COVID-19 during the rapid spread of the COVID-19 outbreak. People, especially women, who live in high-risk areas, are obese, smoke, drink, take drugs, and have chronic or immune-related diseases think that they have a high risk of contracting COVID-19. These people are also more anxious. The struggle to control the spread of COVID-19 will be long and drawn out. Considering the likely future resurgence of COVID-19, it is important to consider implementing specific policies and programs for those who are severely affected by the pandemic, to control the epidemic as soon as possible. Due to the limited questionnaire content, it is necessary to conduct more research on other factors (eg, income and race) that affect the US public's assessment of their chances of contracting COVID-19.

Abstract

Background: The COVID-19 outbreak has affected the lives of millions of people by causing a dramatic impact on many health care systems and the global economy. This devastating pandemic has brought together communities across the globe to work on this issue in an unprecedented manner.

Objective: This case study describes the steps and methods employed in the conduction of a remote online health hackathon centered on challenges posed by the COVID-19 pandemic. It aims to deliver a clear implementation road map for other organizations to follow.

Methods: This 4-day hackathon was conducted in April 2020, based on six COVID-19–related challenges defined by frontline clinicians and researchers from various disciplines. An online survey was structured to assess: (1) individual experience satisfaction, (2) level of interprofessional skills exchange, (3) maturity of the projects realized, and (4) overall quality of the event. At the end of the event, participants were invited to take part in an online survey with 17 (+5 optional) items, including multiple-choice and open-ended questions that assessed their experience regarding the remote nature of the event and their individual project, interprofessional skills exchange, and their confidence in working on a digital health project before and after the hackathon. Mentors, who guided the participants through the event, also provided feedback to the organizers through an online survey.

Results: A total of 48 participants and 52 mentors based in 8 different countries participated and developed 14 projects. A total of 75 mentorship video sessions were held. Participants reported increased confidence in starting a digital health venture or a research project after successfully participating in the hackathon, and stated that they were likely to continue working on their projects. Of the participants who provided feedback, 60% (n=18) would not have started their project without this particular hackathon and indicated that the hackathon encouraged and enabled them to progress faster, for example, by building interdisciplinary teams, gaining new insights and feedback provided by their mentors, and creating a functional prototype.

Conclusions: This study provides insights into how online hackathons can contribute to solving the challenges and effects of a pandemic in several regions of the world. The online format fosters team diversity, increases cross-regional collaboration, and can be executed much faster and at lower costs compared to in-person events. Results on preparation, organization, and evaluation of this online hackathon are useful for other institutions and initiatives that are willing to introduce similar event formats in the fight against COVID-19.

(J Med Internet Res 2021;23(2):e25283) doi:10.2196/25283

Introduction

The COVID-19 outbreak is first and foremost a human tragedy, affecting the health of millions of people and overwhelming health care systems and the global economy [1]. This devastating pandemic has brought together communities across the globe to tackle this issue in an unprecedented manner.

Hackathons are collaborative multiday events that bring people from different professional and personal backgrounds face to face in a venue to work on specific challenges. Previous publications have shown how health hackathons work as an effective model of interdisciplinary collaboration, capable of forwarding recommendations and viable solutions effectively [2-36]; however, they often require several months of preparation and considerable financing [6,34].

Little is so far known about how health hackathons can be executed remotely and in quick response to ongoing circumstances, as well as how they can contribute to solving challenges related to the COVID-19 pandemic, considering the amount and fast pace of evidence gathered on its impact and possible solutions [37-48].

The following case study describes the execution of an online hackathon dedicated to the challenges of the COVID-19 pandemic and participant experience, which will be useful to other organizations and institutions in the health care sector.

Methods

Study Setting

Hacking Health is a global nonprofit organization that pairs innovators with health care experts [6]. Its Berlin chapter organized its first online hackathon in partnership with Charité – Universitätsmedizin Berlin (the largest university hospital in Europe), the Berlin Institute of Health, Diabetes Center Berne, and Data Natives (an online community of data scientists and developers). The event, called EasterHack [49], ran from Friday evening to Monday afternoon over the Easter weekend in 2020. Participants included physicians, health care professionals, researchers, patients, entrepreneurs, engineers, designers, developers, etc. Participation was open to everyone worldwide and was free of charge.

Challenges

The most critical issues caused by, or associated with, COVID-19 and the current state of possible solutions were reviewed and discussed in a series of five virtual meetings held across the interdisciplinary Hacking Health Berlin community in cooperation with the hospital's executive board and different departments of Charité – Universitätsmedizin Berlin.

A summary of this review was sent to, and discussed with, frontline clinicians and researchers for consideration, to ponder on its relevance, and to raise other questions related to the most pressing issues in their line of work. It was highly relevant for identifying unmet needs and urgent problems among health care professionals, vulnerable patient groups, and more generally on a population level, rather than ideas for solutions. Thereafter, a total of six challenges were identified by the Hacking Health Berlin team (Table 1) in close cooperation with the university hospital's executive board and other institutes and departments (Institute of Hygiene and Tropical Medicine, Department of Anesthesiology and Intensive Care Medicine, Department of Psychosomatic Medicine, Department of Paediatric Endocrinology and Diabetes of Charité – Universitätsmedizin Berlin) and the open-source initiative CoEpi.org, an international online community of volunteers with different skillsets working on open-source solutions for privacy-first contact tracing. Participants were allowed to use their choice of technology to solve these challenges, without constraint or limitation.

Table 1. Overview of the hackathon's challenges. A total of six COVID-19–related challenges were identified in close cooperation with frontline physicians and researchers.

Challenge	Questions/considerations
1. Protect high-risk populations	• How can we better support the medical needs of high-risk populations (eg, people with pre-existing conditions such as cancer, diabetes, and immunodeficiencies)? • How can we identify high-risk patients and isolate them from the general population? • How can we support high-risk patients with preventive ambulatory treatment? • How can we deliver care for people with chronic conditions during a pandemic?
2. Protect health care workers	• How can we prevent medical staff from getting infected with SARS-CoV-2 in health care facilities? • How can we manage the increasing demand for personal protective equipment in patient care?
3. Privacy-first contact tracing and digital epidemiology	• What can we build on top of open-source solutions (such as CoEpi.org and COVID-watch.org) to allow users to opt in to disclose anonymous, nonidentifiable information that public health officials would find useful? • How can we authenticate positive COVID-19 tests without requiring public health authorities to do extra work to authenticate them for us? • How can we collect more information on Bluetooth low-energy proximity contact event duration and distance to inform risk scores? • How can we automate the provisional diagnosis of COVID-19 based solely on self-reported symptoms and self-collected data?
4. Improve intensive care	• How can mechanical ventilation be improved to reduce long-term damage to the lungs? • How can we ease prone positioning in ventilated patients? • How can we reduce the formation of aerosols? • How can we visually monitor agitated and hyperactive patients in the ICU[a] to prevent them from extubating or hurting themselves? • How can we give confused ICU patients in-room, time, and situation orientation? • How can we make the ICU a more natural and pleasant environment? • How can we apply evidence-based medicine in all ICUs by tele-ICU? • How can we prevent long-term complications following ICU treatment such as controlled cortical impact and postintensive care syndrome?
5. Protect our mental health	• How can we support health care workers in dealing with the stress and trauma that they might experience during a pandemic? • How can we identify and offer support to people, families, friends, and/or coworkers who are running into mental health issues? • How can we predict critical mental states through early detection?
6. Your idea	• Find a novel solution for your individual COVID-19 challenge, if it has not been listed above

[a]ICU: intensive care unit.

Preparation

The core organizing team consisted of 7 volunteers to set up digital tools; scheduling; marketing outreach strategy for recruitment of participants, cooperating partners, participant and mentor communication; and coordination. An implementation strategy previously designed and used for in-person hackathons by Charité – Universitätsmedizin Berlin and Hacking Health Berlin [6] was adjusted accordingly.

Due to the novelty and urgency of the topic, organization of the hackathon began only 2 weeks prior to the event being completely prepared and executed online, which is different from former hackathons. In April 2020, travel and assembly restrictions, as well as social distancing recommendations, did not allow in-person meetings in Europe. However, the online nature of the event allowed participants and mentors from all over the world to participate regardless of their location, avoiding traveling costs and time.

Participant Engagement

Recent innovation studies have demonstrated interdisciplinarity among participants and within-team compositions are essential for the success of hackathon projects [50,51]. Therefore, it is essential to recruit participants from various relevant fields of expertise such as biomedical research, health care, psychology, education, design, economics, data science, computer science, engineering, social sciences, and politics. Future end-users of the solutions created at a hackathon should be included as early as possible to actively contribute to the cocreation process.

To attract and recruit a diverse and interdisciplinary group of participants, previously existing multidisciplinary networks on LinkedIn [52] and Slack [53] actively engaged in health care innovation, and cooperating with Hacking Health Berlin, were targeted. This provided a great opportunity to reach participants, mentors, and cooperation partners who supported organizers and participating teams in developing projects before, during, and after the hackathon. As one of the largest local networks of innovation in health care, Hacking Health Berlin was able to recruit a large number of interdisciplinary skilled participants

within only 5 days. Professionals working in relevant fields and interested in digital health were also targeted through promotional campaigns using LinkedIn, Facebook, Meetup, and other social media channels.

Participants and mentors were able to sign up via an online form, where they provided information on their skillset, shared their experience level and accomplishments from previous hackathons, their motivations to participate, their desired team role during the hackathon, and a brief outline of their project idea.

Online Tools

To prepare for the hackathon, the organizers used Airtable [54] to arrange schedules, responsibilities, marketing, registration procedures, jury criteria definition, and the collection and structuring of all information provided to the teams before, throughout, and after the event. The Hacking Health Berlin team and external co-organizers had access to this platform.

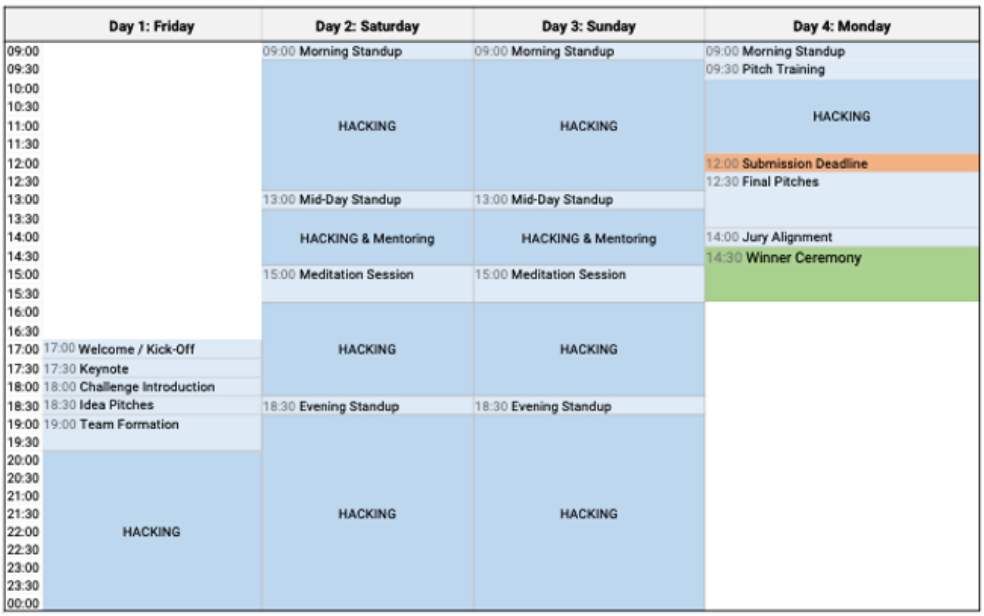
The online instant messenger tool Slack [53] was used for communication during the event to coordinate actions and share data via text and video. Public and closed subchannels were created for the organizing team, mentors, judges, and participants to communicate and execute activities. Additionally, participating teams created their private subchannels on Slack to communicate internally.

Mentoring sessions were coordinated and held on the Mentornity platform [55], as described in a subsequent point. For the opening and closing ceremonies, moderations, pitches, and prototype showcasing sessions, video conferences were held via Zoom and live streamed to the public on Facebook and YouTube.

The Hackathon

The hackathon was conducted over a period of 4 days, from Friday to Monday afternoon. An example schedule is shown in Figure 1.

Figure 1. Activities and schedule of a 4-day online hackathon.



A keynote from the director of the interoperability unit of the Berlin Institute of Health opened the event, motivated the teams, and pointed out the importance of this online hackathon to create solutions for the challenges of the COVID-19 pandemic.

Following the opening ceremony, individual participants and pre-existing teams pitched their ideas for the challenges they selected. Additional participants joined the team of their choice. Team composition is a crucial part of hackathons. As previous research shows, highly diverse and multidisciplinary teams are more likely to be effective in developing creative and sustainable solutions [50,51]. This is particularly relevant in the complex field of digital health, where experts from different fields and areas are needed for development such as health care workers, patients and caregivers, developers, engineers, data scientists, designers, and experts in economics, legal and regulatory affairs. Team building was supported by volunteers from the Hacking Health Berlin team to foster interdisciplinary and international cooperation. A maximum of 6 people per team was recommended.

After teams were formed, the idea and prototype were developed collaboratively over the course of 4 days aided by mentoring sessions. Daily morning and evening stand-up sessions were held virtually, open to all organizers, mentors, and participants.

On day 4, solutions and prototypes were presented to the public and evaluated by an interdisciplinary jury entitled to award the most elaborate and promising solutions based on the criteria described below.

Mentoring

Mentors provided participants with valuable expert knowledge about medicine, design, business, IT (information technology), and other areas of expertise. They indicated their availability for mentoring within the 48-hour span of days 2 and 3. This setting was well embraced, especially by health care

professionals—despite the pressing pandemic situation—and other professionals working from home.

One week prior to the hackathon event, mentors with previous mentoring experience at Hacking Health Berlin events were recruited via email. New mentors were recruited through various local and international networks with the use of social media campaigns and direct messaging via networking platforms. In both cases, mentors were asked to fill in an online form indicating fields of expertise and availability (ie, convenient time slots). This information was transferred to the online platform Mentornity. The platform showed each mentor's profile and facilitated video call sessions for each team. Simultaneously, participants created team profiles for their project, searched mentors by expertise area, and booked at least one mandatory mentoring session made available by the mentor. The platform's analysis feature tracked the number of mentoring sessions held by every mentor and team. Likewise, mentors were encouraged to sign up for Slack—the hackathon's communication platform—to keep everyone informed on sessions prior to and during the event.

Two experts in the field of communication and public speaking offered dedicated pitch training to help teams develop focused final pitches that adhered to the 3-minute time limit.

Jury and Project Evaluation

The interdisciplinary jury was composed of 10 members: a professor of anesthesiology and computer science, a pediatrician and hospital executive board member, a professor of medical informatics, an entrepreneur with a background in open-source technology, a medical doctor and high-risk patient, a senior doctor in hygiene, a digital health connector, a designer, a chief information and digital officer, and the managing director of a research institution.

During the final presentations, teams were asked to first name the challenge or problem intended to be solved, then showcase the solution developed, and how it can be integrated into health care systems. The winning teams were awarded monetary prizes of 5000 EUR (US $6059) in total following the evaluation criteria shown in Table 2.

Table 2. Evaluation criteria for the projects presented in the final pitch session at the end of the hackathon.

Criterion	Considerations
Innovation	How innovative is the idea? Does the approach stand out from solutions that are available so far?
Impact	How high is the benefit for the patient and other stakeholders of the health care system? Does the solution generate impact for our society? How viable is the idea?
Applicability	How user-friendly is the solution? Is the solution convenient to use? How viable is the solution?
Feasibility	How realistic is the implementation of the idea? Can the solution be brought to life by further research projects or by founding a company?
Execution	How sophisticated and well-made is the technical implementation?

Data Collection and Analysis

Two online surveys were designed by the Hacking Health Berlin team, one survey targeting participants and another one for mentors of the hackathon (Multimedia Appendices 1 and 2). The research team members comprised health care professionals, scientists, and entrepreneurs with backgrounds in anesthesiology, intensive care medicine, pediatrics, psychology, microbiology, medical informatics, neuroscience, human factors, health care building design, human-centered design, and marketing. Google Forms was used to collect responses. CHERRIES (Checklist for Reporting Results of Internet E-Surveys) was used to guide survey development (Multimedia Appendix 3) [56].

The participant survey comprised 17 plus 5 optional items (using branching logic, dependent on responses to previous questions). The questions assessed quality experience throughout the online hackathon, including the mentorship sessions and future plans regarding the projects presented. Furthermore, mentors provided feedback to the organizers via an online survey through Mentornity subsequently to each session (Multimedia Appendix 1). All data were collected during a single event with surveys being distributed to mentors and participants at the end of the hackathon. Surveys were anonymous and voluntary and included electronic consent. Participant responses were collected, managed, and analyzed using Google Forms. A thematic hackathon T-shirt was offered as a reward for completing the surveys.

Results

Participants

In total, 171 participants, of whom 42% (n=72) were female, expressed their interest and preregistered online within 5 days prior to the hackathon. Of the total, 84 participants had joined the Zoom event for the opening ceremony, 62 of whom formed 23 different teams. Finally, 14 teams comprising 48 members pitched their completed projects at the end of the hackathon.

Participants based in at least 8 countries participated, including Germany (n=25, 52%), the United States (n=5, 10%), Bosnia and Herzegovina (n=3, 6%), Canada (n=3, 6%), and others (n=5, 10%) like Belgium, Sri Lanka, Switzerland, and the United Kingdom, as well as 7 participants (15%) from unknown locations. Various professional backgrounds were represented, with IT (n=8, 17%), research (n=5, 10%), project management (n=4, 8%), and software engineering (n=4, 8%) being the most frequent work fields. Other backgrounds (n=27, 56%) included business development, data science, entrepreneurship, health care, human resource management, mechanical engineering, quality management, education, and UI/UX (user interface/user

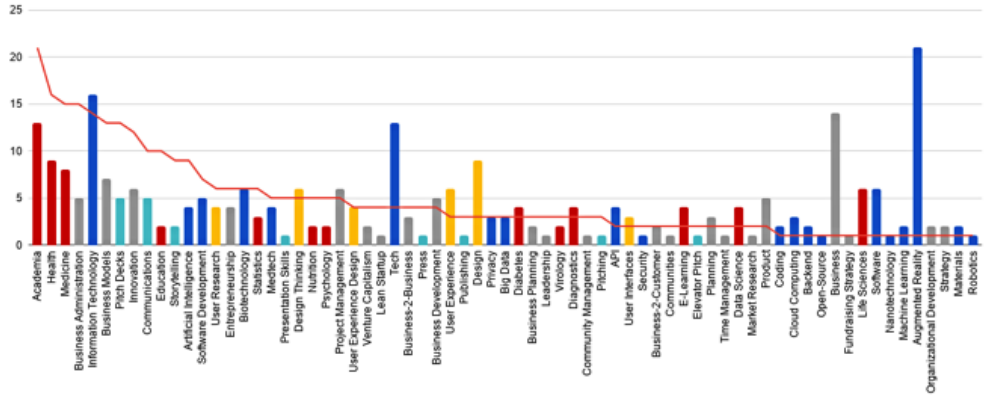
experience) design. Half of the participants (n=24) had never joined a hackathon before.

Mentoring

A total of 60 mentors preregistered online over a period of 6 days prior to the hackathon. Of them, 52 completed their profiles and became active on the Mentornity platform, of whom 46 joined Slack to communicate with teams and organizers. A briefing session was held to inform mentors about the online hackathon concept and how to offer expertise and express their availability to participants. In total, 75 video mentoring sessions took place on Mentornity where 35 mentors and 19 teams interacted. The actual number of video sessions is estimated to have been higher since it was known that other video conference platforms such as Zoom, Slack, and Skype were used and not tracked by Mentornity.

Of all mentors, 24 had no previous experience mentoring, 12 had experience from a previous Hacking Health Berlin hackathon, and the remaining 16 had experience mentoring but were new to Hacking Health Berlin events. The group of mentors had broad professional backgrounds as shown in Figure 2. The top fields of expertise comprised business, medicine, and software development. Along those lines, the most booked mentoring sessions reflected a high interest in these fields.

Figure 2. Sessions booked in the different fields of expertise available for mentorship (red line) and the number of mentors with knowledge in the respective disciplines (bars). Participants booked mentoring sessions in the field of tech (blue bars); health care, research, and education (red bars); entrepreneurship and management (gray bars); public speaking and public relations (teal bars); user research and design (yellow bars). API: application programming interface.



Feedback forms (Multimedia Appendix 1) were automatically created on Mentornity for each mentoring session conducted. Of the mentors, 13 completed the feedback forms, covering a total of 25 mentoring sessions involving 13 teams. The feedback showed that mentors were largely satisfied with the online mentoring experience despite the new format. Of 25 mentoring sessions, 22 took place and were evaluated with ratings ranging from 3 to 5, scoring an average of 4.68 (SD 0.57). Three surveys indicated that the mentoring session did not occur for various reasons: cancellation of the meeting, difficulties with the platform, or the teams did not attend the scheduled mentoring session. The teams that received mentoring reported gaining valuable insights, although they also highlighted that online mentoring was a new format and brought interaction and scheduling challenges. A number of positive comments by mentored teams reflected appreciation for mentors' willingness to share their experience, which enabled them to take a broader perspective of their project. However, during the hackathon, some teams and mentors reported difficulties in scheduling sessions or connecting via the platform, resulting in some frustration.

Projects

A total of 14 projects were developed and presented to the jury and public audience. The scope of the created solutions included telemedicine services, personal risk assessment tools, trackers for COVID-19–specific symptoms and mental health impairments, tracers for population density and risk contacts, immunity passports, hardware for safe reuse of personal protective equipment, platforms for sharing food and other essential products, and educational tools.

The *most innovative* solution [57] consisted of a mobile app for knowledge transfer between researchers, the public, and health care workers during and after the pandemic. It tackled the need to access clear and timely COVID-19 scientific evidence for researchers and practitioners to have a clear picture of the situation. App users were able to share information through short videos and visual graphics, aided by curated information and deep learning. The team presented a functional website presenting an novel artificial intelligence–based tool where users could enter specifics about their professional background and their individual research question in a free-text field to obtain summarized research findings from peer-reviewed scientific literature.

The *most impactful* solution [58] was a service platform with a video-based hotline to provide instant psychological support for health care professionals exposed to stress, a high workload, and moral dilemmas during the pandemic. With restricted time, health care workers lack the capacity to reach out to existing psychosocial support structures. By bringing psychological support to health care professionals directly via a video chat hotline, the instant psychological support was made possible by the voluntary commitment of a broad network of psychotherapists. With a well-planned concept presented on a functional website, the project straightforwardly addressed an imminent user need as identified by frontline health care professionals and outlined in challenge 5.

The *most applicable* solution [59] consisted of an app that allowed frontline health care workers involved in COVID-19 patient care to perform regular virtual health self-checks and seek support to ensure their mental, as well as physical health, was prioritized. The presented mock-up of the app had a simple user interface, self-checks required very little time, and support tools were easy to access.

The app rated as *most feasible* [60] helped to redistribute critical resources and services. As the pandemic has disrupted supply chains around the world, at the time plenty of resources available were not arriving at locations where needed. The platform solved the issue by allowing people to easily know what was needed, indicate where to send these resources, and track the resource shipping progress. A web portal ready for immediate implementation and use, as well as an outline of short and long-term goals of the project, was presented.

The *best executed* solution [61] focused on privacy-first contact tracing and digital epidemiology. It created a multiservice platform connecting patients to self-assessment tools, dashboards, and personal analytics. Users would be able to easily track their logins on their mobile phones and see how symptoms changed. The secure and anonymous contact tracing would allow patients to be aware in their residential area and avoid potential high-risk areas. Finally, information like location, age, and test results would be collected and anonymized into a large database for further analyses and data modeling. The team presented a working web app prototype with 3 features (self-assessment for tracking COVID-19–specific symptoms, contact tracing, warning function for population-dense areas) with a user-friendly and professional-looking user interface, as well as a clear roadmap for the future implementation of their product.

Approaches by other teams included sterilization methods to reuse protective equipment for health care workers, virtual reality visualizations of epidemiological data, and tools to support social distancing in public spaces. The results presented varied from concepts and click dummies to working prototypes of mobile apps.

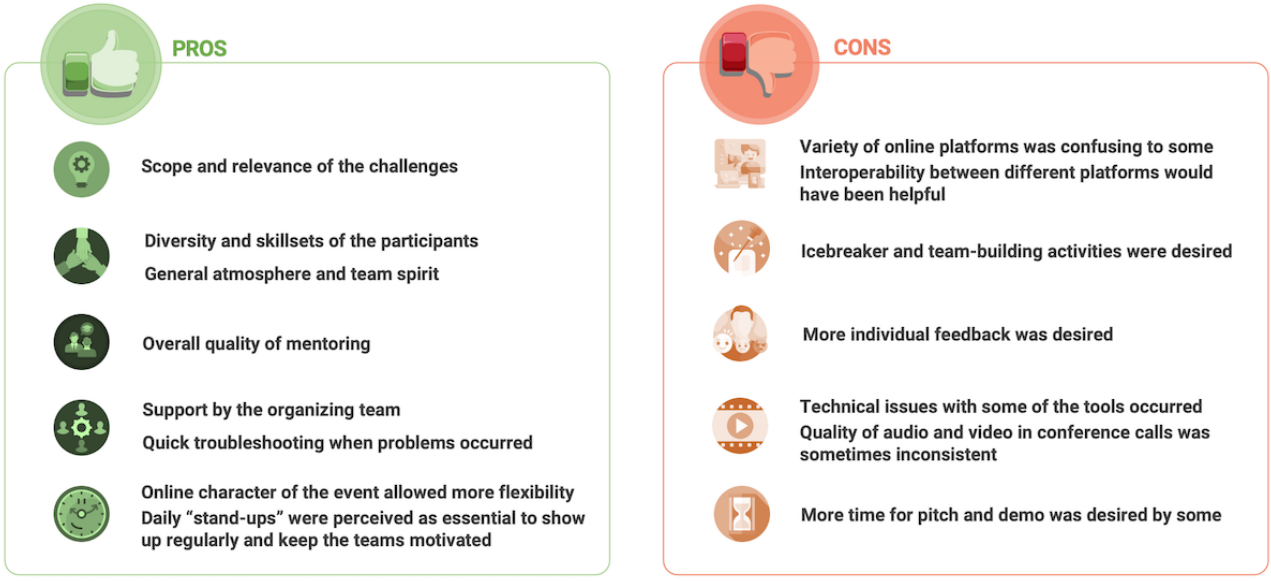
Hackathon Experience

According to the feedback (n=30), participants were made aware of the event by word of mouth (n=14, 47%), social media (n=12, 40%), event platforms (n=3, 10%), email, and postings on Hacking Health Berlin's and Data Natives' existing online communication channels on Slack (n=4, 13%).

Participants were overall satisfied with the execution of the remote hackathon, evaluating the experience with 4.23 points out of 5 on average. They appreciated the general atmosphere and team spirit, diversity and skillsets of the participants and mentors, the flexibility permitted by the remote nature of the event, and felt that occurring problems could be quickly resolved by the organizing team. However, the variety of online platforms that were used was perceived to be overwhelming to some, and technical issues with the tools were reported. Furthermore, icebreaker and team-building activities at the beginning of the event were desired to get familiar with the general concept of online hackathons and to get to know the other participants (Figure 3). Most participants (n=21, 70%) felt that it was an advantage that the hackathon was held over a long holiday weekend, but opinions were mixed about whether an in-person event of a longer duration than the usual 48 hours would be desirable, with 40% (n=12) in favor of the idea.

Before the hackathon, participants rated their confidence in starting a digital health venture or research project with 2.6 points out of 5 on average. After the hackathon, the participants' confidence increased significantly to 3.7 on average. Of the participants, 60% (n=18) would not have started their projects without attending this hackathon, and agreed that it enabled them to progress faster by (1) offering new insights and feedback provided by the mentors, (2) creating a functional prototype, and (3) finding the right members for their team.

Figure 3. Experiences of participants specifically regarding the remote and online nature of the hackathon.



Discussion

Main Findings

This case study demonstrates the feasibility and effectiveness of remote hackathons as an approach to combat the challenges of the COVID-19 pandemic. The event was prepared in a much shorter time and conducted entirely online at significantly lower costs, with similar results as health hackathons held in person. To our knowledge, this is one of the first studies to report and critically discuss experiences of, and provide guidance on, online hackathons and hackathons specifically targeted to solve the challenges around COVID-19, as well as to report on the impact of expert mentoring during health hackathons.

Cultural Change and Opportunities of Online Collaborations

The circumstances of the COVID-19 pandemic and the necessity for social distancing have led to a cultural change in work settings, communication, and collaboration. As a consequence, professional meetings and conferences are more likely to take place in an online setting. Based on the high number of participants and mentors, the medical and scientific way in which the challenges were addressed, and the feedback from participants who had experience in face-to-face hackathons, we can conclude that remote online hackathons are feasible and resemble some of the dynamics and synergies of the in-person ones. Online hackathons effectively bring people together at a significantly lower cost in comparison to a conventional in-person hackathon. The EasterHack event enabled participants not only to collaborate in an interdisciplinary manner but also across diverse geographic locations, avoiding the possible inconveniences and costs of travel. The transition toward an online and federated event allowed for a more diverse and global audience. There is substantial research showing a relation between increased diversity in teamwork leads and benefits, such as increased creativity and better problem-solving abilities [50,51].

Since the first online hackathons to fight COVID-19 were launched in March 2020, more than 50 online events summing up to 28,000 participants [62-67] have been held. The impact is evident in terms of a higher participation level and number of collaborating partners, which brings a multibeneficial bottom line of fewer logistical, financial, geographical, and time constraints, and reduced carbon dioxide output.

The Impact of Expert Mentoring

In recent years, mentoring has been shown to have a positive impact on the way participants gain insights, interact, execute multidisciplinary tasks, and build their prototypes during hackathons [3,6,8,28,36]. They act as guiding lights during the process by encouraging exploration and providing information in areas where participants have questions and interests. The main benefit is reflected in the holistic and complementary nature of each hack, often embracing different disciplines and resulting in outstanding solutions and pitches with a strong technical background (software or hardware); addressing health-related challenges pragmatically; and putting the whole idea into a well-polished business plan. On those grounds, the recruitment of expert mentors takes place depending on the scope of the hackathon.

In general, challenges tackling the COVID-19 pandemic are complex and require critical advice from biomedical experts and frontline health care professionals. These hurdles can be tackled through expert mentorship, complemented with knowledge from specialists for additional areas of expertise aiming to increase the feasibility and applicability of solutions. Availability of mentors is important; for example, health care staff and other essential workers may have commitments directly related to the pandemic, which limits their availability. With online mentoring programs, mentors can help participants with flexible and short mentorship sessions without altering their working schedules and personal time. Likewise, mentors located in different regions and time zones were able to support participants, which in an in-person format would not have been the case. The interdisciplinary nature and outcome of the event was reflected in the diversity of sessions booked; this also confirms the relevance of mentoring and our endeavor to have medical expertise as the backbone. For these reasons, we strongly recommend online mentorship to be considered in both virtual and on-site hackathons.

Challenges of Conducting Hackathons Remotely

Online hackathons might have some limitations such as data security concerns when it comes to personal information, especially with video conference tools, communication breakdowns, technical issues, and access to essential hardware including microphones and cameras. Only recently, the video conference service Zoom reported security issues concerning unwanted guests who disturbed some virtual meeting rooms [67-69]. While the preparation time for online hackathons can be relatively short, all tools and technical solutions need to be tested thoroughly in advance to avoid frustration among organizers, participants, and mentors. Technical glitches may also affect the ability to communicate properly, share announcements, recruit survey participants, and marketing. Furthermore, participants who work remotely might become distracted more easily with the screen being the only visual feedback platform and other work-related and personal commitments at the same time. Therefore, a certain level of media competence is recommended. Online team building activities require different approaches compared to events in physical presence. In addition, the dynamics of networking and small talk might be different. Although participants of EasterHack reported positive experiences regarding group synergies and team spirit during the event, there were 14 individuals who did not complete their projects. Further research should address drop-out reasons and challenges of attending online hackathons from the participant perspective, and elaborate on how these challenges might be resolved.

Limitations

This case study was based on data that were captured in a single online event and not directly compared with in-person events. Although participants were from various geographical locations, the sample size of 48 participants limits broad generalizations. Further studies in the course of online hackathons should be conducted to validate the stated findings.

Conclusions

Online hackathons offer an ideal setting for rapid and goal-oriented collaborative work, and a format to react quickly to urgent and unknown situations like the COVID-19 pandemic.

EasterHack participants generally reported a positive experience during the online hackathon format, increased confidence, and a higher likelihood of continuing to work on their projects. Despite remotely held events posing challenges to organizers, participants, and mentors, they can be executed much faster and at lower costs compared to in-person meetings, as well as foster team diversity and increase cross-regional collaboration. Setting up a research project and creating IT solutions within health care or research facilities can be a time-consuming and onerous process; however, concept-to-solution processes can be achieved during a single online hackathon weekend. As highlighted by an avid supporter of hackathons [70]:

> *Governments need to change. Institutions need to change. But, in the meantime, we have hackathons, where you can rapidly prototype. [...] Do you get a perfect solution? No. But anything is better than nothing. Done is better than perfect.*

Acknowledgments

Our thanks and appreciation go out to the volunteers of Hacking Health Berlin, Data Natives, and Charité – Universitätsmedizin Berlin, as well as to our mentors and judges, who have greatly contributed to this event. The hackathon received funding from the Berlin Institute of Health, Diabetes Centre Berne, and Paul Hartmann. We further acknowledge support from the German Research Foundation and the Open Access Publication Funds of Charité – Universitätsmedizin Berlin for the publication of this paper.

Authors KB and A-SP are fellows of the Charité Digital Clinician Scientist Program funded by the Charité – Universitätsmedizin Berlin and the Berlin Institute of Health. This program was initiated and led by Prof. Dr. Duska Dragun to enable resident physicians to pursue a career in digital health and academic research. With great sadness we have received the news that Prof. Dragun passed away on December 28th of 2020. This publication is dedicated to her as a mentor, friend, role model and stellar scientist.

Authors' Contributions

KB, ASP, and JH performed the literature search. KB, AL, and PDR designed the surveys and collected the data. KB analyzed the data. KB, AVS, JH, ASP, PDR, and AL wrote the initial draft of the paper, supported by ST, FB, SL, and VK. All authors have critically revised the paper and approved its final version.

Abstract

Background: The main German-speaking countries (Germany, Austria, and Switzerland) have implemented digital contact tracing apps to assist the authorities with COVID-19 containment strategies. Low user rates for these apps can affect contact tracing and, thus, its usefulness in controlling the spread of the novel coronavirus.

Objective: This study aimed to assess the early perceptions of people living in the German-speaking countries and compare them with the frames portrayed in the newspapers during the first wave of the COVID-19 pandemic.

Methods: We conducted qualitative interviews with 159 participants of the SolPan project. Of those, 110 participants discussed contact tracing apps and were included in this study. We analyzed articles regarding contact tracing apps from 12 newspapers in the German-speaking countries.

Results: Study participants perceived and newspaper coverage in all German-speaking countries framed contact tracing apps as governmental surveillance tools and embedded them in a broader context of technological surveillance. Participants identified trust in authorities, respect of individual privacy, voluntariness, and temporary use of contact tracing apps as prerequisites for democratic compatibility. Newspapers commonly referenced the use of such apps in Asian countries, emphasizing the differences in privacy regulation among these countries.

Conclusions: The uptake of digital contact tracing apps in German-speaking countries may be undermined due to privacy risks that are not compensated by potential benefits and are rooted in a deeper skepticism towards digital tools. When authorities plan to implement new digital tools and practices in the future, they should be very transparent and proactive in communicating their objectives and the role of the technology—and how it differs from other, possibly similar, tools. It is also important to publicly address ethical, legal, and social issues related to such technologies prior to their launch.

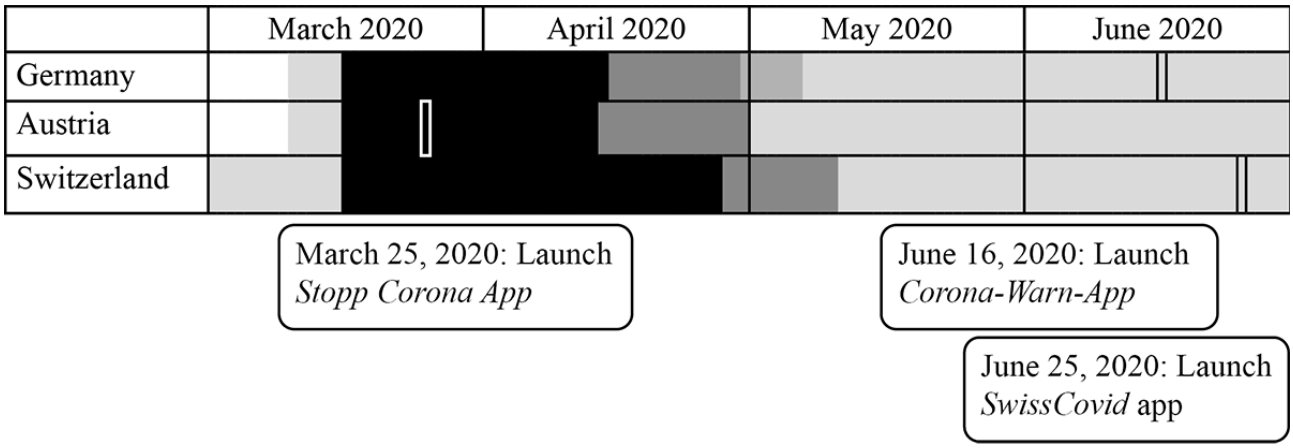
Introduction

During the COVID-19 pandemic, several country-specific contact tracing apps were introduced to assist and supplement analog contact-tracing. In Austria, Red Cross launched the Stopp Corona app on March 25, 2020; Germany launched the Corona-Warn-App on June 16, 2020; and Switzerland launched the SwissCovid app on June 25, 2020 (Figure 1). All these free

apps use Bluetooth Low Energy technology to measure the distance and the duration of contact between smartphones that have the app installed. If the tracking function is enabled, random encrypted codes are automatically exchanged and directly saved on the devices whenever a person encounters another user. These random codes do not reveal any names or identities of people or exact locations, and the codes are erased from the smartphones after 14 days. If a person using the app tests positive for COVID-19, they can voluntarily choose to make their random codes anonymously available so that other users who may have come into contact with the infected person can be notified and asked to contact their local health authorities for further instructions.

Figure 1. Comparative timeline of COVID-19–related restrictions and contact tracing smartphone apps released from March to June 2020. Black: lockdown period; grey: step-wise easing of restrictions.



Although these apps have the same basic functions, there are some important differences among them. First, there are differences concerning the institution that launched the apps—the Swiss and German contact tracing apps were launched by the respective federal governments, whereas the Austrian app was launched by Red Cross Austria, a national nongovernmental organization. Second, the apps differ in the way in which users can report infection. For instance, German app users need to call a hotline after having received a positive COVID-19 test result [1]. Swiss app users receive a code from health authorities that needs to be entered into the app [2]. Austrian app users can alert their contacts directly without contacting any authority, but they need to register their phone numbers to avoid misuse [3]. The Austrian app also includes a symptom checker that allows for a direct alert if symptoms indicative of COVID-19 are entered [3]. Third, there are differences concerning the warning levels: the Swiss and Austrian apps have 2 warning levels (“no warnings” or “potential infection”), whereas the German app has an additional option called “unknown risk,” which is useful in cases wherein the app was not activated long enough to make an assessment. Finally, there are also differences in the management systems used by these apps. In Europe, key management systems for such contact tracing apps include Pan-European Privacy-Preserving Proximity Tracing (PEPP-PT) [4] and Decentralized Privacy-Preserving Proximity Tracing (DP-3T) [5]. PEPP-PT aimed for a centralized data storage system, whereas DP-3T foresaw a decentralized data storage approach on individual phones, thereby aiming to increase data security and privacy [6,7]. The final versions of all 3 apps used the decentralized approach as promoted by DP-3T.

However, it appears that very few people have downloaded and are using these apps. Although surveys conducted in Spring 2020 reported acceptance rates of up to 70% for hypothetical contact tracing apps in Germany and Switzerland [8,9], only 25% and 31% of the total populations in Germany and Switzerland, respectively, had downloaded the app by October 30, 2020, with active user estimations ranging around 21% in both countries [2,10]. On the other hand, only 12% of the population in Austria had downloaded the Stopp Corona App by mid-April 2020 [11,12], and download rates only increased marginally to 12.4% until October 2020 [13]. Modeling studies estimated that for contact tracing apps to be effective, the user rate needed to be at least 56% of the overall population [14] and that uptake rates need to be higher for decentralized data storage systems than for centralized ones [15]. Nevertheless, even lower user rates can have an impact on contact tracing and, consequently, on the ability of the system to control the spread of COVID-19 [16]. Contrary to those estimates, Maccari and Cagno [17] argued that Bluetooth-based, privacy-preserving contact tracing apps are of limited benefit due to potentially high false-positive rates and low sensitivity. Similarly, Rowe et al [18] contended that the French contact tracing app was implemented very quickly without taking into account the available evidence on viral spread. Overall, robust evidence on the actual effectiveness of contact tracing apps is lacking [19].

A large body of the existing literature has assessed users’ perceptions, motivations, and barriers to using mobile health (mHealth) apps, particularly those related to chronic diseases and behavioral interventions [20-22]. Previous research on peoples’ motivation to use mHealth apps suggests that user’s perceived personal value is a crucial motivating factor [23-27], but other factors such as convenient use [26], high quality, trustworthy information provided through the apps [28], and previous experience and training with mobile technology particularly among older adults [27,29] are also mentioned. Stach et al [30] recently suggested a framework to evaluate mHealth apps, including user engagement, app functionality, aesthetics, information quality, therapeutic gain, users’ subjective quality ratings, and perceived impact. Although

research on mHealth apps generally focuses on individual usability, including the specific needs of patients with chronic conditions [22,31] or lifestyle support for a healthy diet or physical activity [32,33], contact tracing apps for pandemic control have an additional societal component. Accordingly, in the German context, Trang et al [34] found that appeals to the societal rather than personal benefit of contact tracing apps were most helpful to maximize uptake, particularly if the majority of the population was critical of the apps or undecided about using them. Other survey studies on the willingness to use contact tracing apps indicated that perceived benefit, expected performance, trust in government, and social influence were important motivating factors for using contact tracing apps, whereas privacy concerns were identified as the main hindering factor [8,35-40]. In line with these surveys, Keshet [41] identified a dichotomy in the comments related to Israeli news websites between supporters of contact tracing apps who see them as a protective measure for containment and opponents who see their civil rights violated. Despite issues pertaining to privacy and other civil rights being the most important concern against the use of contact tracing apps [34,42,43], the privacy policies of these apps are not comprehensible by the average individual owing to their complexity [44]. Lack of privacy policies have also been identified for other mobile health apps [45], mHealth apps [46] and privacy concerns, including data safety and confidentiality, are known to negatively affect the uptake of mHealth apps in general [20,46-48].

How digital contact tracing apps are perceived will ultimately be a key factor in people's willingness to download and use them. Therefore, there is a need to better understand people's views on the use of digital technology to support COVID-19 contact tracing. The COVID-19 pandemic has been widely covered in the media, mirroring the immense public interest, with traditional mass media, including print and online news media, considered to be one of the preferred information sources [49,50]. The dynamic and uncertain situation at the beginning of the pandemic made people particularly reliant on such information sources. Previous studies have used media content analyses to assess public debates during the COVID-19 pandemic [18,50], as well as other issues that affect population health [51,52]. Some other studies have combined media content analyses with surveys and interviews [53,54].

This study aimed to examine the early perceptions of people living in Germany, Austria, and German-speaking Switzerland toward digital contact tracing apps and compare them with frames as portrayed in the newspapers during the first wave of the COVID-19 pandemic. More specifically, the following research questions were addressed: (1) How did people living in Germany, Austria, and German-speaking Switzerland conceptualize and evaluate digital contact tracing apps during the COVID-19 lockdown in April 2020? (2) How were such apps portrayed in the newspapers, and were there any country-specific differences observed? (3) How did people's concepts and assessments intersect with the ongoing public debates and policies in April 2020? The countries investigated in this study are quite similar in terms of their culture (eg, language and a strong emphasis on privacy) and have democratic federalist political systems. By comparing data from similar countries, the observed differences can be interpreted in a more precise way [55]. In this context, one relevant difference is the circumstance that Austria had already launched a contact tracing app at the time of the interviews of this study, whereas Switzerland and Germany had not.

Methods

Qualitative Interviews

As part of the qualitative, longitudinal, and multinational SolPan (Solidarity in Times of a Pandemic) study [56], qualitative interviews were conducted with 159 individuals in Germany, Austria, and German-speaking Switzerland during the first COVID-19–related lockdown of April 2020. The SolPan Consortium includes 9 European countries (Austria, Belgium, Germany, France, Ireland, Italy, The Netherlands, German-speaking Switzerland, and the United Kingdom). It aims to explore peoples' experiences during the COVID-19 pandemic, particularly how people describe practices relating to solidarity. Interviews were conducted between April 6 and May 6, 2020, during which country-specific measures were in place to flatten the infection curve. This included various restrictions on movement and contact with other individuals, and the closure of schools, nonessential businesses, and public institutions.

Participants were recruited through online advertisement via university websites, social media networks, convenience sampling, and snowballing. To enable a variety of perspectives, participants were recruited with attention to a range of different demographics, including age, gender, income, household structure, geographic area, education, and employment. Participants received a study information leaflet prior to the interview, and verbal consent was obtained directly before the interview. A researcher-developed interview guide was used to guide the interview, which included a question regarding the use of mobile phones to assist in contact tracing (see Multimedia Appendix 1 for the interview guide). Interviews ranged from 25 minutes to 80 minutes in length; they were conducted online or by telephone and recorded on a digital recorder or using a video chat recorder compliant with the European General Data Protection Regulation. Only audio material was stored. The interviews were transcribed and subsequently pseudonymized. The study was approved by the ethics committees of the Technical University Munich (no. 208/20 S) and the University of Vienna (no. 00544). Interview transcripts were coded by all researchers by using an inductively generated coding scheme developed through the broader SolPan Consortium, using the ATLAS.ti 8.0 software (ATLAS.ti Scientific Software Development GmbH). Coding was checked by a second researcher for consistency. Relevant text passages were extracted using the Atlas.ti query function, analyzed inductively, and summarized in a memo by the first author (BZ), thereby aiming to gain a higher level of abstraction by building concepts and categories. This analysis was performed separately for each country, and 2 authors (SM for Germany and Switzerland, and BP for Austria) double-checked and supplemented the analysis. Then, the concepts and categories were compared between the 3 countries and discussed among the researchers. Interviews

were analyzed in German, but memos were written in English. Illustrative quotes were translated from German to English by a native German speaker (BZ) and double-checked by a native English speaker with good German skills (SM).

Content Analysis of Newspaper Coverage

In parallel to the interview analysis, a newspaper content analysis was conducted to assess what concepts, topics, and concerns were predominant at the time of the interviews across the countries. These insights were used to create a comparative framework analysis for country-specific interpretations and intercountry comparisons. The newspaper content analysis included articles published between March 15 and May 6, 2020, which includes the interview study period, and 3 weeks before the first interviews were conducted.

Three quality newspapers with a national readership and one tabloid from each country were included in the analyses. The selected newspapers are among those with the highest readership and were chosen based on equivalent functions in the respective national media systems [57], to allow for meaningful comparison. Newspapers were included to represent the mass media landscape of public debates for several reasons. First, even though newspapers lose readers to other channels, they still have considerable influence on coverage of other mass media, including social media for long-lasting issues [58]. Moreover, particularly large, high-quality newspapers are still considered a trustworthy source for reliable background information on health-related issues [25]. Finally, the publication format is reliably accessible. Accordingly, the Factiva database (Dow Jones Professional) [59] was used for a systematic search of articles that covered issues related to digital contact tracing. This database was selected because it covered the relevant newspapers, thus allowing for a unified search strategy, and was accessible to the research team. Relevant articles were retrieved with the following search algorithm using full-text search (in German): "(app OR technologie) AND (tracing OR tracking) AND (corona* OR covid-19)." Articles that reported on technology-based tracking or tracing in the context of COVID-19 were included in the study.

A codebook for the media content analysis was developed to collect the following variables: date of publication, medium, importance of topic (ie, contact tracing apps) in the article, country reference, article topics, app evaluation, and stakeholders cited (see Multimedia Appendix 2). The codebook was adapted from a previous study investigating newspaper coverage of medico-scientific issues [51]. Three coders collected these variables; they were trained in 2 online sessions wherein the codebook was discussed and tested in the team and refined upon discussion to make categories exclusive and intersubjectively understandable. For this aspect, 10 articles from each country were double-coded to identify the remaining ambiguities in the codebook. Since all instances of discordant coding could be easily resolved and were assignable to a source of uncertainty that was removed by clarifying the codebook, and because this analysis was used to supplement the qualitative analysis of the interviews, no formal reliability test was conducted. Descriptive statistics were calculated using Excel (Microsoft Corp). To identify key events, the distribution of articles over time as well as information from policy analyses were qualitatively linked to the collected variables. Key events were identified when several newspapers covered the same topic on the same day and/or when a topic was followed-up on several subsequent days.

Results

In German-speaking countries, both interview participants and newspaper coverage perceived and framed contact tracing apps predominantly as governmental surveillance tools. In the following sections, we first report the findings of the interviews, followed by results of the newspaper content analysis.

Participants' Perceptions of Contact Tracing Apps

In the 159 interviews conducted, more than two-thirds (110/159, 69.2%) of the participants commented on contact tracing apps and were included in this analysis (Germany n=29, Austria n=56, and Switzerland n=25). Table 1 presents the demographics of the study participants.

Table 1. Demographic distribution of study participants.

Characteristic	Value, n (%)		
	Germany (n=29)	Austria (n=56)	Switzerland (n=25)
Age (years)

[a]Investigator observed.

[b]Self reported; categories were adjusted based on country-specific income levels.

Most participants stated that they had heard about the option of mobile phone–based contact tracing, but several participants seemed to be uncertain about the function and scope of contact tracing apps or lumped together different technologies. For instance, the concept of individual contact tracing was sometimes confused with population surveillance measures, such as anonymous mobile phone tracking to analyze population behavior during restrictions. These different conceptions of how

contact tracing could be employed were also a source of confusion and uncertainty about what mobile phone–based tracing would actually entail.

> *What I don't quite understand here is whether it´s about who is positive or simply controlling masses of people, such as [navigation systems] in traffic. That uses data to control traffic volume. I don't know exactly how it is supposed to work, that the people who are positive sign up themselves, so to say, or whether the database is maintained and you don't even know whether you are in it or not.* [Swiss participant 15]

A few participants also stated that they were not well informed about the topic at the time of the interview, indicating that they were not sure whether they could endorse the use of digital tracking tools due to their limited understanding or stating that they were aware of the tools but had not yet formed an opinion on their use.

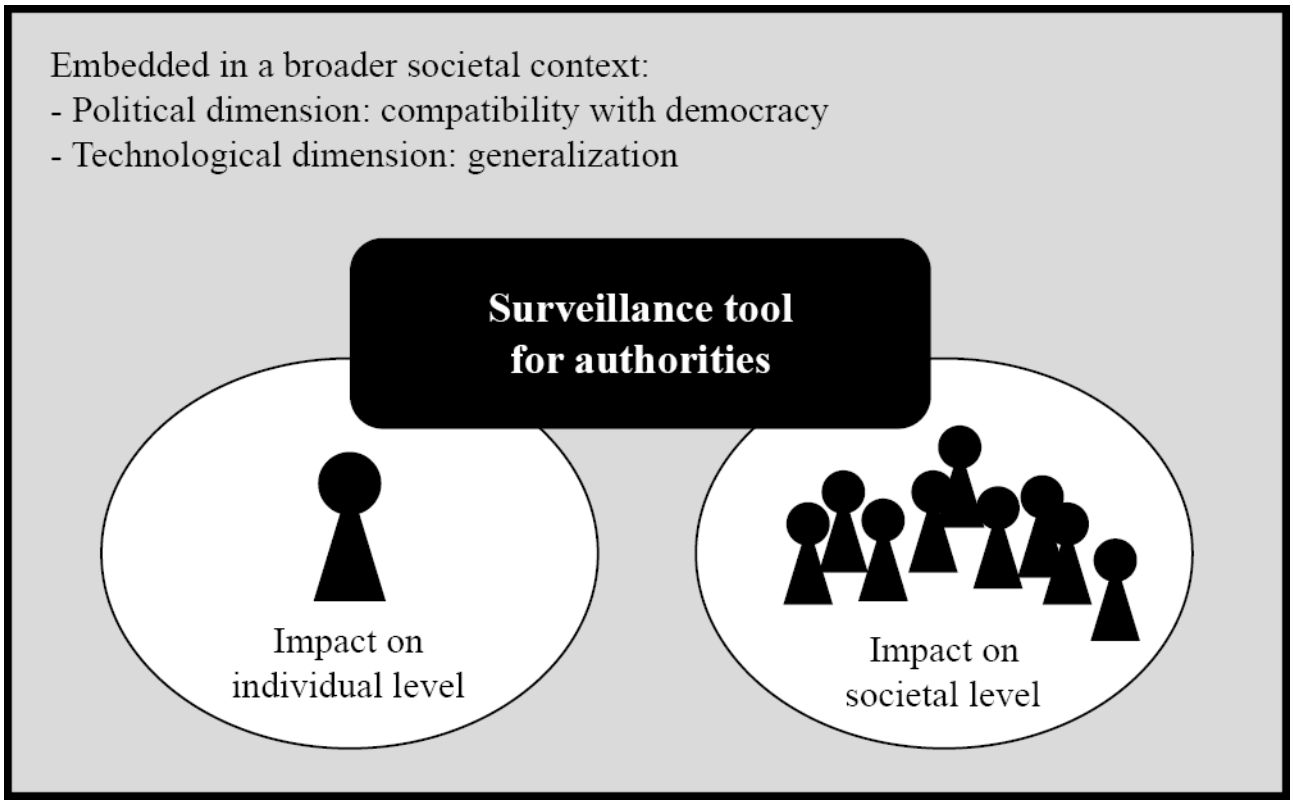
Perceiving Contact Tracing Apps as Governmental Surveillance Tools

Participants perceived contact tracing apps as governmental surveillance tools and embedded them in a broader societal context (Figure 2). However, “surveillance” was framed by participants in different ways. Some participants viewed such surveillance as a mechanism that empowers the authorities to control individual compliance with measures, which provoked negative sentiments. By contrast, other participants justified such contact tracing apps as surveillance tools for authorities that helped contain the pandemic without too many further restrictions. Yet other participants balanced the perils of surveillance against the specific needs to contain the pandemic:

> *Controlling is not necessarily a threat.* [German participant 7]

Although German and Swiss participants generally spoke about contract tracing apps only when asked about them specifically, approximately 20% of Austrian participants brought up the topic spontaneously, and their responses were also often more elaborate in length than the responses from Swiss and German participants.

Figure 2. Illustration of interview participants’ perceptions of digital contact tracing apps during the first wave of the COVID-19 pandemic (data collected in April and early May 2020).



Compatibility With Democracy

In all three countries, participants related contact tracing apps to Asian countries, such as China, which had already been using digital contact tracing technology for viral containment when the interviews were conducted. Although a few participants referred to the success of Asian countries in virus suppression as proof of the usefulness of these applications, most others used a comparison with “totalitarian states” as an argument against contact tracing apps, stating that the tools were incompatible with democratic values and rights.

> *Yes, I've heard about [the idea of contact tracing apps] and I completely reject it, I must say because my own data is simply too insecure, not protected and I don't want the state or whoever evaluates this data to know exactly where I was, what I did. And it also has a touch of the Chinese state or something [sic].*

> *In Asia, it is already being practiced without people critically questioning it. But I am absolutely against it.* [German participant 41]

By contrast, some participants framed contact tracing apps as tools that support authorities to control the viral spread:

> *I really believe in these apps because I think that if they are handled consistently, they can really reveal a lot of information to the authorities to develop certain measures or to react to the course of the disease [sic].* [German participant 3]

Participants also indicated a list of prerequisites that they considered crucial for a contact tracing app to be compatible with democracy: trust, privacy, voluntariness, and a time limit on data retention and use. The first prerequisite concerned the level of trust in national and local authorities. Since contact tracing apps were perceived as a surveillance measure of authorities, the level of trust towards these authorities was an important factor for people's willingness to participate. Participants in all three countries expressed the fear that the pandemic could be exploited by governments to install long-term surveillance systems, weighing the possible benefits of virus containment against the erosion of human rights:

> *I understand, of course, that this can be used to do contact tracing and potentially contain virus spread and I can see its usefulness. It's just, I'm struggling with the question of how much a crisis justifies intervening in basic human rights? And I think the problem is, if there is no pushback, then you might end up in a situation. I mean, I think that is what happened after the terrorist attacks in London and the US, that suddenly the NSAs of the world are created. And then nobody really knows what kind of information they actually have. And that shouldn't be the case in a democracy. So I think that citizens should be aware that some things are very difficult to undo later on.* [German participant 42]

The distrust of authorities was expressed most prominently by Austrian participants, who repeatedly called for more transparent communication about the app. They criticized a lack of clarity in communication surrounding how location and movement data were analyzed, possible extensions regarding the functionality of the app, or the role of the Austrian government in an app that was originally launched by Red Cross Austria, a nongovernmental organization. Austrian participants also seemed to be uncertain whether the app could be used for personalized tracking later on. They feared penalties for noncompliance or expressed concerns about a creeping loss of privacy. Others indicated skepticism surrounding a lack of clarity of how data would be used from the app.

> *So on the one hand the minister says: "Watch out because of this data on Facebook or whatever, or with people that want to call you or steal your login." On the other hand, he says we should use the Red Cross app. But they don't say what happens to the app or your data in the background [i.e. for other than contract tracing purposes], do they? I don't quite believe them, unfortunately. That's the only thing I don't really believe, to be honest.* [Austrian participant 46]

In the second prerequisite, many participants stressed the need to develop contact tracing apps that were compatible with existing privacy and data protection regulations:

> *I have heard about it [contact tracing apps] and I know that there are different models. So for me, it's just that I'm generally quite skeptical, that such things could be abused. For example, I don't do anything with YouTube or Facebook or whatever. I'm a bit old-fashioned in that sense. But last night I heard that someone in Switzerland has now created a program where data wouldn't go into any server anywhere, that it would just stay in your own smartphone and one wouldn't know any phone numbers of the people you met. And it wouldn't be stored anywhere. If that were so, I could say, yes, let's do it.* [Swiss participant 31]

Third, many participants believed that voluntariness was a key prerequisite for contact tracing apps to be compatible with democratic values and human rights. Although participants in all three countries mentioned this topic, we found it most predominantly mentioned in the Austrian data. Some Austrian participants even envisaged the possibility of "class action lawsuits" [Austrian participant 25] against the government and considered "strategies how to defend" themselves [Austrian participant 27] in case of the possibility of compulsory app use. Two Austrian participants even stated that they would rather die than be monitored by the government.

Finally, participants also thought that these tracing apps should be used temporary and only in the context of special circumstances such as the COVID-19 pandemic. Some participants suggested that the data should be erased when it was no longer needed, whereas others reiterated their concern that the data should only be used for the purposes indicated and not to build a surveillance state. One participant noted that although it made sense to use the app now, they intended to uninstall it by the end of the year, whereas another participant noted that these apps would no longer be justified when vaccines or other treatments are available.

Embedding Contact Tracing Apps in a General Technological Context

Participants from all countries linked tracing apps to other applications that collect data, such as social media, credit cards, or shopping cards, with the underlying concern that their data might be misused. The idea that others might be able to watch over one's actions and whereabouts was unnerving for some participants, particularly concerning uncertainty to where the data would be stored, who would have access to data for how long, and whether the crisis would erode privacy principles that would later be hard to re-establish:

> *I don't know, with technology, I always get the impression that these things creep in like crazy. Like we accept everything with every normal app because we only have the [binary] option not to use it or to accept the terms of use.* [Austrian participant 45]

Others were specifically concerned about the way the government or other powerful actors might use the information in the future:

> *We reveal so many things but we don't know yet how this could be used against us in the future […] So people should be careful and I believe that the state has far too much power over us in that context.* [Austrian participant 5]

Some participants seemed generally suspicious of surveillance technologies because of their potential for abuse, extending their suspicion of platforms such as YouTube or Facebook to digital tracking tools. Others said that their smartphones were already tools for individual surveillance. They suggested leaving smartphones at home to avoid being traced, or jokingly noted that they speak in dialect so that those "listening" will not understand:

> *I have a Huawei phone and I believe that the data will be delivered to China. That is why I always speak dialect because then the Chinese cannot understand me [laughing] [sic].* [Austrian participant 6]

Moreover, some participants worried that this technology could negatively affect not only their own lives but also how people relate to each other:

> *For me, it is not an option for everybody to be so high-tech. That's what it's all about. That you can see where somebody is. Who has been with whom in some way and so on. I find that threatening. I find that threatening. And I don't really want that.* [Swiss participant 22]

Embedding contact tracing apps in their general attitude towards technology led some to generally reject contact tracing apps. For others, by contrast, such consideration relativized their privacy concerns. For instance, one participant noted that they had already been recorded a hundred times on camera when driving into the city. Other participants suggested and expressed acceptance that people had long lost control over their data and their lives.

Impact on the Societal Level

Some participants framed contact tracing apps as a resource for the common good, stressing their function to help contain the viral spread and protect at-risk individuals. This was particularly pronounced in Germany and Switzerland, whereas only very few Austrian participants articulated this stance. One participant even felt that it was a duty to use the available technology to fight the risk of infection:

> *But I think that's good, I'm not concerned that [contact tracing apps restrict] freedom and privacy issues, instead I see the benefits. And in South Korea, [digital contact tracing] has really helped to reduce the number of infected people. And I believe that there is a duty to support this.* [German participant 35]

Others perceived tracing apps as a fast-track back to normality, increasing people's "freedom to move around" [German participant 26] and as a tool that "makes us all, as a society, more flexible" [Swiss participant 17]. By contrast, a few participants (particularly those in Austria) expressed fears of social pressure, stigma, and panic. One Austrian participant compared the app to the Star of David during the National Socialist Regime that singled out Jewish people. In a similar manner, this participant argued, the app stigmatizes infected people and makes them visible to everyone. It should be noted here that neither of the apps we report on here actually includes the function of making infected individuals visible to others.

Impact on the Individual Level

Some participants also focused on the impact the app might have on the individual level. Some of them focused on the potential personal benefit when using the app by framing contact tracing apps as a useful individual warning and information tools to proactively avoid COVID-19 infection. They hoped to get warnings to avoid risky situations, thereby decreasing personal uncertainty and providing orientation: "My wife and I, we would download and use it [contact tracing app] immediately and hope to be warned if someone comes too close. Or has come too close" [German participant 12]. This view was mainly taken by participants without practical experience with these apps, as none of the apps include such an immediate warning function. Moreover, contact tracing apps were framed as tools that affect individual responsibility. A few individuals perceived them as a tool that enables them to take individual responsibility: "I would probably also install the app on my cell phone, just because I find it helpful for me to know that if I picked up the virus somewhere, I could inform people, hey, watch out and stuff." [Austrian participant 15]. One participant said that they wished people would behave more responsibly, indicating that they felt contact tracing apps were only necessary because people were not acting responsibly enough.

Many of those participants who were skeptical of tracing apps were concerned about their privacy, expressing uneasiness about such tools "lying on the bedside table" [German participant 4] and comparing mobile phones to "personal diaries" [German participant 22] that they considered very private. Participants also expressed concerns about data protection in connection with contact tracing apps. To protect their data safely, some advocated for local data storage and against data silos.

Comparative Content Analysis of Newspaper Coverage

To further contextualize our participants' perceptions of contact tracing apps, we also performed a content analysis of newspaper coverage on contact tracing apps during the interview period (April 6 to May 6, 2020). By quantitatively and qualitatively comparing coverage from the four most-read newspapers of each country, we identified country-specific differences that laid out the basis for comparative interpretation as presented later in the discussion.

A total of 194 newspaper articles from 12 newspapers of the three German-speaking countries were included in the media content analysis (see Table 2). The nature of newspaper coverage regarding tracing apps was similar in the three countries studied, but Germany tended to have longer articles than the other two countries (see Multimedia Appendix 3).

Table 2. Sampling of newspapers and articles.

Country and newspaper	Genre	Publisher	Number of included articles
Switzerland

Frames and Country-Specific Key Events

From the end of March to the beginning of April, German-language newspapers in all three countries reported geolocation or Wi-Fi–based tracking apps used for the anonymous analysis of population mobility or individual surveillance. Articles reported anonymous mobile phone data analysis to assess population mobility during the lockdown in all three countries. German and Austrian newspapers critically reported political discussions to use nonanonymous data for individual surveillance and raised fundamental concerns regarding basic human rights and democratic legitimacy. Swiss newspapers reported predominantly positive aspects and did not raise such concerns. In Austria, newspapers focused those concerns directly on the Austrian app, which was launched in March. In this context, the president of the first chamber of the Austrian Parliament, Wolfgang Sobotka, speculated publicly about making the Austrian app mandatory in an interview with the Austrian news magazine profil. This fueled already-existing concerns about civil rights and privacy violations in that context.

Similarly, the German health minister Jens Spahn attracted much critical coverage when, on March 25, 2020, he publicly considered including new options for tracking and surveillance in the updated German Epidemic Law. Even though newspapers in Germany reacted with similar concerns as those in Austria, the topic did not stay in the news as long as in Austria. Nevertheless, the launch of Robert Koch-Institut's "data donation app" on April 9, 2020, was accompanied by predominantly critical coverage about lack of transparency and insufficient data protection.

Starting at the end of March, the Swiss and German newspaper coverage discussed proximity tracing (meaning registering close contacts rather than using location data) as a possible assistance tool for contact tracing after the so-called lockdown period. Even though data protection and privacy issues were discussed, proximity tracing was introduced to potentially overcome these issues. To that end, the German and Swiss newspapers evaluated such applications more positively than Austrian newspapers, which were predominantly critical towards the potential privacy implications of the Austrian app. In mid-April, German and Swiss media picked up disagreements on data storage mechanisms within the PEPP-PT research consortium. Swiss coverage focused on the Swiss epidemiologist Marcel Salathé who argued for a decentralized data storage system. In that context, Swiss newspapers reported supportively about the Swiss contact tracing app in development. In Germany, where researchers had initially favored a centralized data storage system, the same éclat caused discussions about data protection requirements. On April 27, 2020, the German government announced that they had decided on a decentralized data storage system. This was evaluated positively in the newspapers. All three countries also compared nationally discussed solutions of contact tracing apps with international applications, especially those in active use in Israel, China, and South Korea, and criticized those as being largely inconceivable in Western European democracies. Country-specific framings and key events are presented in detail in Multimedia Appendix 4.

National and International Views on Coverage

In Swiss and German coverage, the international collaboration of researchers involved in research needed for the development of such an app was mentioned more often than in Austria (see Table 3).

Table 3. Stakeholders cited in newspaper articles.

Stakeholders cited	Mentions, n (%)		
	Germany (n=67)	Austria (n=62)	Switzerland (n=65)
Governmental actors or politicians	28 (42)	30 (48)	36 (55)
Nongovernmental actors	9 (13)	11 (18)	1 (2)
Scientific and medical experts	22 (33)	5 (8)	32 (49)
Legal experts	4 (6)	18 (29)	9 (14)
Experts from humanities or social sciences	9 (13)	1 (2)	2 (3)
Celebrities or VIPs	1 (1)	1 (2)	0 (0)
Civil society	2 (3)	0 (0)	2 (3)
Private companies	4 (6)	3 (5)	4 (6)
Other	0 (0)	1 (2)	0 (0)

In general, Austrian coverage tended to focus more on a national perspective than Swiss and German coverage, where newspapers repeatedly referred to the international PEPP-PT research initiative. This, in turn, led to coverage on the topic of centralized versus decentralized data storage in these two countries, which did not come up as frequently in Austrian newspaper coverage (see Table 4). In all three countries, tracing and tracking applications were repeatedly connected to totalitarian surveillance states, such as China, or even Asian democracies such as South Korea, where surveillance apps were used as containment strategies.

Table 4. Topics mentioned in newspaper articles.

Topic	Germany (n=67)		Austria (n=62)		Switzerland (n=65)	
	Topic total, n (%)	Main topic[a], n (%)	Topic total, n (%)	Main topic, n (%)	Topic total, n (%)	Main topic, n (%)
GPS motion tracking at population level (anonymized)	3 (4)	2 (3)	4 (6)	0 (0)	16 (25)	6 (9)
GPS motion tracking on an individual level	12 (18)	4 (6)	13 (21)	6 (10)	4 (6)	1 (2)
“Datenspende” app (Robert Koch-Institut)	8 (12)	5 (7)	0 (0)	0 (0)	0 (0)	0 (0)
Development of contact tracing apps	14 (21)	10 (15)	20 (32)	11 (18)	26 (40)	9 (14)
Functioning of contact tracing apps	19 (28)	9 (13)	18 (29)	6 (10)	24 (37)	4 (6)
Centralized vs decentralized data storage	12 (18)	4 (6)	1 (2)	1 (2)	7 (11)	0 (0)
Legal or ethical issues regarding tracing apps	5 (7)	3 (4)	38 (61)	19 (31)	33 (51)	15 (23)
Other relevant topics	4 (6)	4 (6)	0 (0)	0 (0)	0 (0)	0 (0)
Tracking/tracing technology that not the main topic	25 (37)	N/A[b]	17 (27)	N/A	29 (45)	N/A

[a]A topic was defined as the “main topic” if it was mentioned in the title or the first paragraph of the article. There was only one main topic per article but otherwise an indefinite number of topics could be coded if necessary.

[b]Not applicable.

Discussion

Even though policymakers in Germany, Austria, and Switzerland framed contact tracing apps as safe and helpful tools to contain the viral spread, most participants perceived contact tracing apps as governmental surveillance tools. This perception was represented in all interviews and across all three countries. What varied, however, was how people framed and assessed this form of governmental surveillance. Many participants reflected on the compatibility of contact tracing apps with Western democracies. Newspaper coverage periodically framed these apps in a similar fashion by using three frames that were predominantly covered in April 2020: (1) critical examination of the impact of contact tracing apps on individual privacy and the compatibility with existing data protection regulations; (2) simultaneous framing and comparison with digital surveillance tools used in Asian countries, especially China, provoking a contrasting view to Western democracies; and (3) periodical focus on country-specific political and scientific stakeholders.

Privacy issues were a predominant concern expressed by participants and in newspaper coverage; these issues also mirror the early concerns expressed in the literature [43,60]. People were concerned about the impact of contact tracing apps on individual freedom and privacy, in line with concerns commonly

expressed in the newspaper articles reviewed in this study. Participants emphasized that it was a matter of principle for them: The use of a digital tool that was perceived to be so intrusive in people's privacy should never be made mandatory. Indeed, the voluntariness of contact tracing apps is also debated and emphasized by experts, including what voluntariness means in this context [61-63]. Nevertheless, ethicists have more recently criticized this emphasis on privacy and pointed to other ethical issues that were left aside in app development, such as safety and effectiveness [60,64], social justice issues [65,66], or the potentially problematic policy influence of Apple and Google in that context [18,67].

Possible Explanations for Low Uptake Rates

At the time of writing this manuscript, over half a year after the launch of the respective contact tracing apps, app developers and authorities were facing lower user rates than initially expected [8,9]. This constitutes some tension with other government measures that also limited people's freedom but were readily accepted; for example, the majority of people in Germany and Austria supported compulsory face mask use a few months later [12,68,69].

One reason for this might be that the early perception as a surveillance tool for authorities left many people reluctant to use contact tracing apps. The observed tendency to put these contact tracing apps into a broader context of technological surveillance tools and privacy concerns might have triggered general concerns of privacy that are known to be particularly important in the German-speaking areas [70], and the same has been reported in the French context [18]. Newspapers reporting the use of contact tracing and tracking apps in Asian countries might have further deepened the impression that these applications are not aligned with democratic principles of individual privacy and freedom since these applications were considered by interview participants and newspapers alike to be not compatible with privacy regulations and democratic principles as understood in the European context.

The broad contextualization of contact tracing apps makes factual information about the app itself (such as it contributes to controlling the pandemic, data is anonymized, and location tracking impossible) less effective, as people tend to use pre-existing concepts from other technologies to avoid cognitive dissonance, which occurs when expectations and performance contradict each other [71]. Thus, even though the performances of the apps are privacy-friendly, those who are generally skeptical towards digital tools and surveillance still expect them to be dangerous, despite the crucial efforts of app developers and policymakers. This points to the underlying and unsolved issues of regulating digital tools, data ownership, and nontransparent use and economization of data [67].

Likewise, Barth and Jong [72] suggested that the privacy paradox, in which people share some information willingly but are reluctant to share information with others, was relying on risk-benefit assessment (see also [60]). It is plausible that a subset of people considers contact tracing apps to have more privacy-related risks than benefits. Indeed, the currently available contact tracing apps have little personal benefit but promise to serve the common good by contributing to pandemic containment. Proof of effectiveness has been difficult to demonstrate thus far because user rates have been lower than originally suggested [14], so potential benefits could not unfold, and it is challenging to collect relevant data for quality control due to privacy constraints. Showing the benefits of contact tracing apps on an individual and a societal level might increase the uptake, but would need to be reliable, ideally through direct empirical evidence of effectiveness.

Public Trust and Transparent Communication

Particularly in Austrian interviews, people criticized what they perceived to be the absence of transparent political communication. For example, the public speculation of the president of the first chamber of the Austrian parliament, Wolfgang Sobotka, that the use of the Austrian app may become mandatory seemed to undermine people's trust. It also influenced participants' responses in the days following this particular event. Although most Austrian participants trusted the Red Cross, the fact that Red Cross launched the app was often considered less relevant than the function of the app as a surveillance tool for authorities. Trustworthiness was generally a less dominant topic in Swiss and German interviews. In both countries, epidemiologists and app developers were frequently given a voice in newspapers. For instance, newspaper coverage followed discussions of app developers about centralized or decentralized data storage, or it critically reflected on political considerations connected to voluntariness and whether to introduce a legal basis for surveillance measures. These issues were publicly discussed and addressed prior to the release of contact tracing apps in June, and upon their launch, it was already legally binding that apps could not become compulsory and needed to employ decentralized storage systems. This is in sharp contrast with other examples, such as in France, where a centralized storage system was implemented despite privacy concerns [18]. Such discussions prior to launch might have promoted public trust in authorities and could be a possible reason for the higher relative uptake numbers in Germany and Switzerland as compared with those in Austria. This is further supported by our finding that German and Swiss newspapers framed the discussion, particularly the scientific discussion behind app development, from a more international perspective, whereas Austrian newspapers focused on the national issues of the already-released app. In line with our findings, recent ethical inquiries have also identified public trust as the most critical element for the uptake of contact tracing apps [18,40,73-75].

Conflation of Different Mobile Phone–Based Tracing and Tracking Apps

Newspapers and interview participants alike often conflated different tracking applications (anonymous geolocation or Wi-Fi data population analysis vs. real-time personal GPS tracking versus Bluetooth-based proximity tracing). This seems to have confused people and may have solidified concerns surrounding the possibility of ubiquitous surveillance because instances where de-identified information was collected were interpreted as personalized tracking. These uncertainties and misconceptions seemed to be associated with uneasiness and general skepticism. These findings highlight the difficult task for governments to communicate about the apps they plan to introduce transparently,

clearly, and simply, while including sufficient information to allow people to distinguish between different applications [76,77].

Limitations

This study did not assess the exact prevalence of specific views on, or experiences with, contact tracing apps in the general population in the three countries or regions examined. Instead, we sought to explore how people describe their practices regarding contract tracing apps where they have had personal experience, and their normative, factual, and emotional reference points when discussing the design, utility, and effect of digital contact tracing. To contextualize the data obtained from the large-scale interview study, we also carried out an analysis of mainstream news media in the three countries or regions that was limited by the fact that newspapers were the only format examined and other mass media (such as television, radio, and social media) were excluded. No reliability testing was conducted because we interpreted the data relationally and qualitatively, looking for relationships rather than statistical significance. As such, this article provides context-specific insights into digital tracking tools during a specific period in the COVID-19 pandemic. Even though we sought a balanced demographic distribution, the final sample of interview participants is slightly skewed towards people with higher educational levels (more than 10 years), those who are under 70 years of age, and those in the Austrian sample living in urban areas. However, because this is a qualitative analysis not aiming for statistical representativeness, every view was considered independent of how many participants had stated this view. Given that several interviewees supported every view we report and that we were able to draw what in the grounded theory approach is called a "middle-range theory," we conclude that we have reached satisfying theoretical saturation [78]. Although we did report when issues were mentioned particularly frequently or particularly rarely, any quantification in terms of how many citizens support these views is subject to further quantitative inquiries, such as follow-up surveys, which go beyond the scope of this paper. In the Swiss context, only the German-speaking part is covered both in terms of newspaper coverage and interview participants. Since there are considerable cultural differences between Swiss language regions [79], our findings are limited to the German-speaking part of Switzerland.

Conclusions

Newspapers from and people living in German-speaking countries perceived digital contact tracing apps as surveillance tools popularized by authorities during the first wave of the COVID-19 pandemic in April 2020, attributing a broad range of interpretations, evaluations, and impact to this perception. Even though privacy was a common concern among participants, many also framed surveillance in a positive way and saw contact tracing apps as tools that could benefit society in containing the viral spread. Others saw the potential for personal and societal benefit, affording users better control over their exposure risk. Voluntariness and trustworthiness were most frequently discussed by Austrian participants, in line with Austrian newspaper coverage and political discussions at that time. The early launch of the Austrian Stopp Corona app has, on the one hand, made the topic more immediately relevant for both study participants and mass media. On the other hand, ongoing debates about the voluntariness and the use of apps for checking individual compliance through the authorities might have caused more severe and lasting rejections in Austria than in Germany or Switzerland, where the relative uptake of the apps was slightly higher.

Although communication from authorities and app developers shapes peoples' early perceptions of contact tracing apps, their previous experiences and expectations with authorities and digital tools also play an important role. Thus, when authorities plan to implement new digital tools and practices in the future, they should be very clear in communicating the objectives, the contribution of this technology, and how it differs from other, possibly similar, tools that may be problematic or may have been previously used in a problematic way. Similarly, even in cases where there is a pressing need for the use of new tools, it is important to address publicly and solve ethical, legal, and social issues related to such technologies prior to their launch—existing concerns related to new technologies need to be addressed proactively. Finally, to overcome the privacy paradox, the effectiveness of contact tracing apps needs to be evaluated and communicated.

Acknowledgments

The interview study was conducted as part of the SolPan consortium, and we acknowledge all consortium members for their valuable discussions and contributions concerning study design and strategy. We particularly thank Dr. Katharina Kieslich for her insights into Austrian contact tracing app policies and student assistants Magnus Tibbe and Justus Bredthauer for extracting data from Austrian and Swiss newspaper articles. This work was supported by the German Federal Ministry for Education and Research (Bundesministerium für Bildung und Forschung; Grant number 01Kl20510), which had no role in the project design; in the collection, analysis, or interpretation of data; in the writing of the article; or in the decision to submit the manuscript for publication.

Conflicts of Interest

Abstract

Background: Contact tracing apps are an essential component of an effective COVID-19 testing strategy to counteract the spread of the pandemic and thereby avoid overburdening the health care system. As the adoption rates in several regions are undesirable, governments must increase the acceptance of COVID-19 tracing apps in these times of uncertainty.

Objective: Building on the Uncertainty Reduction Theory (URT), this study aims to investigate how uncertainty reduction measures foster the adoption of COVID-19 tracing apps and how their use affects the perception of different risks.

Methods: Representative survey data were gathered at two measurement points (before and after the app's release) and analyzed by performing covariance-based structural equation modeling (n=1003).

Results: We found that uncertainty reduction measures in the form of the transparency dimensions disclosure and accuracy, as well as social influence and trust in government, foster the adoption process. The use of the COVID-19 tracing app in turn reduced the perceived privacy and performance risks but did not reduce social risks and health-related COVID-19 concerns.

Conclusions: This study contributes to the mass adoption of health care technology and URT research by integrating interactive communication measures and transparency as a multidimensional concept to reduce different types of uncertainty over time. Furthermore, our results help to derive communication strategies to promote the mass adoption of COVID-19 tracing apps, thus detecting infection chains and allowing intelligent COVID-19 testing.

Introduction

Background

At the onset of the COVID-19 pandemic, people, organizations, and governments worldwide were plunged into uncertainty [1], leading to changes in everyday behavior [2,3]. To control the pandemic and protect lives, the authorities have implemented different policies, which range from recommendations (eg, enhanced hand and respiratory hygiene or ventilating rooms) over relatively mild measures (eg, maintaining social distance or mandatory face masks) to far-reaching interventions in civil rights (eg, restrictions in human mobility or lockdowns) [4-6].

Fighting the pandemic effectively is a complex challenge, since limited resources in the health care system and restrictions in everyday life need to be considered simultaneously [7,8]. Consequently, measures to control the pandemic have to be coordinated [9]. Especially when there is no widely available appropriate vaccine, testing, contact tracing, and isolation are considered to be the most essential measures against COVID-19 [9,10]. From a health care management perspective, testing is a key element and provides valuable information regarding the

spread of the virus over time [9]. However, limited testing budgets and test resources such as trained personnel, indicator reagents, polymerase chain reaction devices, or laboratories are the bottlenecks that limit test capacities [11]. Eames and Keeling [12] already showed during the first severe acute respiratory syndrome–related coronavirus pandemic in 2003 that contact tracing, followed by treatment or isolation, is an effective measure in the fight against infectious diseases when testing capacities are limited [13]. Nevertheless, the effectiveness of contact tracing depends primarily on timely and comprehensive collection and processing of data [14,15]. Manual contact tracing only meets these requirements to a limited extent, as it is time and resource intensive, and prone to errors [16]. The resulting urgent need for action toward digital solutions has become evident, as health authorities are collapsing under the burden of manual contact tracing [16].

Contact tracing apps have attracted discussions among politicians, epidemiologists, and the public. These apps aim to systematically identify COVID-19 infection chains and allow a timely and targeted implementation of further measures such as testing and quarantine [14]. Simulation models indicate that digital contact tracing is more efficient compared to manual solutions and has the potential to prevent up to 80% of all transmissions [14,17]. To realize this potential, a majority of the population has to use the same or compatible COVID-19 tracing apps [18]. Achieving mass but voluntary acceptance of the technology is a substantial challenge for several governments [19]. The first positive effects are already expected at a penetration rate of about 20% [15]. However, the penetration rate in several countries as of October 2020 was far below this value, which illustrates the imperative for action to realize the potential of contact tracing apps [20]. Although previous studies have focused on the effectiveness [14,17,19,21] or technical specifications of COVID-19 tracing apps [22], none have examined the factors that affect a rapid and widespread adoption of a COVID-19 tracing app after its release.

Thereby, the use of COVID-19 tracing apps may be related to various uncertainties. These uncertainties can be classified into general health-related COVID-19 concerns and app-specific risks in the form of performance risks and privacy risks that arise because the apps require the processing of sensitive user data [22-24]. In addition, social risks can occur as people might fear social pressure or social exclusion from using or not using the tracing app [25]. According to the Uncertainty Reduction Theory (URT), these uncertainties can be reduced by appropriate means such as transparent communication, social influence, and trust [26-29]. Thereby, the uncertainty reduction means can foster the adoption process of technologies in general [28] and COVID-19 tracing apps in particular. Since COVID-19 tracing apps are mainly released by governments or in cooperation with governmental institutions, trust in the government was examined in addition to the initial trust in a COVID-19 tracing app [24]. For a deeper understanding of the factors at play, the following research questions (RQs) were examined:

- RQ1: How do transparency, social influence, trust in the government, and initial trust in a COVID-19 tracing app affect the adoption process of the app?
- RQ2: What effect does the actual use of COVID-19 tracing apps have on uncertainties in the form of perceived privacy, performance, and social risks, as well as general COVID-19 concerns?

To address the two RQs, we developed a theoretical model based on URT. For testing the model, a representative sample of potential users of a COVID-19 tracing app were surveyed at two different times (1 week before and 4 weeks after the launch of the app) via structured online surveys. Based on this data, we performed covariance-based structural equation modeling (CB-SEM; n=1003). In the following sections, we provide information about COVID-19 tracing apps, explain the theoretical foundation, and derive the hypotheses.

Contact Tracing Apps as a Countermeasure Against COVID-19

This brief review aims to outline the characteristics of automated contact tracing apps for identifying contacts at risk and controlling disease transmission in humans. So far, several countries and some regions have developed and introduced independent COVID-19 tracing apps, which differ in administrative procedure and technical configuration [21]. Two major technical approaches exist: (1) GPS data is used to determine whether individuals, respective to their devices, were located within a geographical proximity for a defined period of time and (2) Bluetooth Low Energy is used to track the concrete proximity and exchange encrypted tokens with other devices in the defined proximity [30,31]. In both cases, data is used to notify people that have been in contact with a person who is infected. The recorded data is either stored on central servers (eg, the tracing app of France) or decentralized locations (eg, the tracing app of Germany) on the particular device [31]. Beside the technical configuration, tracing apps also differ in terms of administrative procedure. Although European tracing apps have been voluntarily used so far, some countries (eg, China) require citizens to install the app [24,32]. Moreover, the source code might be published or withheld by the developers (open source policy). Despite these options, regions need one specific COVID-19 tracing app or at least a suitable interface linking the different apps to achieve a sufficient adoption rate and alert people who are possibly infected [22,33]. A frequently updated overview of the COVID-19 tracing apps used in different regions and their characteristics is provided by MIT Technology Review [20]. Although Trang et al [22] showed that app design influences the likelihood of mass acceptance, there is a lack of evidence to what extent administrative aspects affect the (mass) adoption of COVID-19 tracing apps.

Uncertainty Reduction Theory

URT [26] originally addressed the initial interactions between strangers from a communication science perspective. The core assumption states that individuals face uncertainties in interactions with unknown partners, and individuals attempt to reduce these uncertainties. Berger and Calabrese [26] described uncertainty as a state in which a person is confronted with several alternatives concerning a stranger's behavior. More alternatives make the individuals feel more uncomfortable because the other person's behavior is harder to predict [34]. Although URT was initially developed to explain initial

interactions between individuals, the theory has been applied to other contexts such as recruiting processes [35], computer-mediated communication [36], online commerce [37], or organizational behavior [38]. Hence, URT is not only limited to the interaction of individuals but is also useful in other settings. For instance, Venkatesh et al [28] demonstrated that URT is suitable for explaining the technology-supported communication of individuals and institutions in an e-governance setting. Beyond, URT is also suitable in crisis situations in general and in the current COVID-19 pandemic in particular [29].

The application of URT is appropriate in times of COVID-19 since the situation is marked by various far-reaching uncertainties. Looking at COVID-19 tracing apps, different uncertainties are apparent. First, health care technologies in general often bear uncertainties concerning data privacy [39]. These uncertainties are also identified in cases of COVID-19 tracing apps, as they require the processing of sensitive personal data [22,30]. Individuals fear that their privacy will be violated and cause undesirable outcomes such as governmental surveillance [30,40]. Moreover, people are concerned that personal data is used to impose quarantine or restrict access to public places for people who do not use a COVID-19 tracing app [24]. Second, uncertainties about the true performance and functionality of tracing apps are apparent [23]. Using a mobile app to contain a pandemic is new to individuals in most countries. Hence, they cannot draw on past experiences and might question its utility (eg, false alerts or only few people using the app). Third, social risks are recognizable as people might fear social pressure or social exclusion from using or not using the tracing app [25]. Beside tracing app–related uncertainties, general health-related COVID-19 concerns arise from the pandemic itself. The main aspects of the four uncertainties considered are summarized in Table 1. In addition, the four described uncertainties are further reinforced by unverified information and fake news [41-43].

Table 1. Summary of relevant uncertainties in the context of COVID-19 tracing apps.

Relevant uncertainties	Related to tracing apps	Description
Privacy risks	Yes	Individuals are uncertain about data security (ie, possible data leaks or misuse by third parties). Hence, tracing apps are perceived as risky because they bear the potential loss of control over personal data [22,44].
Performance risks	Yes	Individuals are concerned that the product may not work and perform as it was designed and advertised. As a result, people are uncertain whether enough people will use apps for contact tracing and whether the technology will work as expected [23].
Social risks	Yes	Individuals might fear potential loss of status in one's social group for using or not using the app. In addition, forced quarantine might lead to social isolation [25].
COVID-19 concerns	No	Individuals worry about negative impacts arising from the COVID-19 pandemic. Fear and anxiety about a new disease, for their own health and their relatives, can be overwhelming [45].

Uncertainty Reduction Measures

According to URT, individuals reduce uncertainties by passive (observing), active (target-orientated search), and interactive (interaction with the stranger) information-seeking approaches [26,27]. We discuss transparency, social influence, and (initial) trust, as these factors facilitate individual's information-seeking strategies [28,46-48].

Notably for passive and active strategies, individuals rely on accessible and valuable information [46]. To enable people to reduce uncertainty through observation or targeted research, information must be available. If no information is obtainable, people cannot reduce uncertainties through observation or targeted research. Therefore, transparency is examined as an enabler for passive and active information-seeking strategies. We defined transparency as "the perceived quality of intentionally shared information from a sender" [49]. Drawing on recent transparency research, transparency is best understood as a multidimensional construct consisting of disclosure, clarity, and accuracy of information [49-51]. In the context of this study, disclosure is the perception that sufficient relevant information about a COVID-19 tracing app is timely and accessible. Similarly, clarity is the perception that the received information about a COVID-19 tracing app is comprehensible and lucid. For instance, the disclosure of a huge amount of information cannot be considered transparent if the information is not understandable for individuals (eg, because the information is cryptic and only consists of the technical code of the COVID-19 tracing app). This information would hinder an individual's ability to effectively perform active and passive information seeking. Lastly, accuracy is the perception that the information about a COVID-19 tracing app is correct [49]. The apparent incorrectness of information would not lower uncertainty but might lead to concerns about hidden governmental intentions. Notably in the context of a pandemic, each transparency dimension contributes to the reduction of uncertainty, as individuals rely on sufficient, relevant, timely, clear, and accurate information to observe the unknown technology and to actively search for information [29].

Furthermore, interactive information-seeking approaches have been shown to be more efficient than passive or active strategies in reducing uncertainty [46]. As it is not possible to interact with COVID-19 tracing apps before they are released or to directly communicate with the people responsible for the app, people seek alternatives for interactive information gathering. Therefore, individuals may communicate with their peers who

are also affected by the decision whether to use the app or not. This, in turn, has to be regarded as another active information-seeking approach rather than an interactional strategy. Although communication with the social environment is interactive, the social environment is not the publisher of the app, and therefore, referring to URT, social influence is an active information-seeking approach. Social influence is expected to reduce people's uncertainty about COVID-19 tracing apps, and it is defined "as the degree to which an individual perceives that important others believe he or she should use the new system" [52]. By knowing the preferences of their social environment, individuals' attitudes toward using the app might be affected.

Lastly, trust is shown to reduce uncertainties and risks in different settings [53,54], and it is defined as "a psychological state comprising the intention to accept vulnerability based upon positive expectations of the intentions or behaviors of another" [55]. We distinguish between initial trust in COVID-19 tracing apps and individuals' trust in their government. Several positive links to uncertainty reduction exist for initial trust in new technologies. For example, in e-commerce, trust lowers customers' uncertainties about vendor behavior [56,57]. Additionally, initial trust reduces citizens' uncertainties in the wake of e-governance [25]. However, initial trust might change in the actual use of the app and become strengthened or weakened according to the specific experiences encountered [58]. In addition to initial trust, individuals' trust in their government is another means to reduce uncertainties. As most COVID-19 tracing apps are published by governments, trust in the administration might reduce fears related to app use [59]. People's trust in the government is expected to be relatively stable and not fundamentally changeable in the short term [60,61].

Transparency and Initial Trust

Based on the transparency and trust literature, it is widely believed that transparency perceptions are positively related to trust [62]. This is shown by Schnackenberg et al [63] who explored the positive role of employees' transparency perceptions (disclosure, clarity, accuracy) in the context of employees' trust in their manager in organizational settings. Rawlins [51] also showed a positive link between transparency and employee trust, and highlighted the mutual relation between transparency and trust. Regarding the consequences of corporate scandals, transparency can be used as a strategic tool to restore stakeholder trust in firms [64]. In financial markets, transparency is shown to influence citizens' trust in central banks [65]. In the case of COVID-19 tracing apps, a certain degree of transparency must be achieved for people to trust the app and use the technology [24]. The formation of peoples' initial trust in COVID-19 tracing apps relies on the quality of available information as long as there are no prior interactions between citizens and the app [53,57]. Fulfilling certain information needs (eg, by providing sufficient clear and accurate information) enables people to initially trust a COVID-19 tracing app.

- Hypothesis (H)1: (a) Disclosure, (b) clarity, and (c) accuracy are positively related to individuals' initial trust in a COVID-19 tracing app.

Trust in the Government and Initial Trust

Trust transfer theory states that individuals' trust in a specific area can influence initial trust in other domains that are believed to have certain links to the known and trusted domain [66]. For instance, Lu et al [67] demonstrated that customers' trust in internet payment in general influences trust in mobile payment services. As the majority of COVID-19 tracing apps are published by government institutions, trust in the government might affect initial trust in a COVID-19 tracing app. Peoples' trust in the government is defined as the "perceptions regarding the integrity and ability of the agency providing [a] service" [53]. When people believe that the government is generally acting in citizens' best interest and when citizens perceive the government agencies as capable to appropriately offer services, the initial trust in a COVID-19 tracing app is strengthened [53]. Recent studies on COVID-19 tracing apps noted that trust in the government influences peoples' attitude toward the specific app [59,68]. In addition, a main reason for general negative attitudes against COVID-19 tracing apps is a lack of trust in the government [68]. Therefore, based on trust transfer theory, trust in the government fosters peoples' initial trust in a COVID-19 tracing app [28].

- H2: Trust in the government is positively related to peoples' initial trust in a COVID-19 tracing app.

Social Influence, Initial Trust, and Intention to Use

As previously stated, social influence can also aid the understanding of uncertainty reduction, as it might function as a substitute for interaction with the unknown and not yet available technology. Therefore, social interaction serves as an active means to gather information. The presumed reactions of the social environment will influence an individual's attitude and behavior in a technology adoption context [52]. In terms of URT, people access their social environment as an active information-seeking means by interacting with their peers to exclude possible consequences of using or not using the specific technology. In this sense, social interaction, just like transparency, is a means of obtaining information and excluding alternatives and, hence, serves to reduce uncertainties. Li et al [69] showed that social influence is an important factor for the formation of initial trust and is therefore contributing to the exclusion of expectable negative outcomes such as perceived risks. Against this background, we argue that initial trust in a COVID-19 tracing app is not only influenced by transparency and trust in government, but is also affected by social influence.

- H3a: Social influence is positively related to individuals' initial trust in a COVID-19 tracing app.

In addition, it is well known that social influence is an important antecedent of intention to use new technologies [70-72]. Being part of social groups (eg, family or colleagues) creates pressure on individual behavior, as people try to behave in accordance to established standards [73]. In health care settings, it has been shown that social influence is, for example, leading to smoking cessation [74] or supporting to maintain a diet [73,75]. Besides positive effects, the peer group might also foster negative behaviors such as drug abuse [76]. Therefore, social influence is a major factor to consider in the adoption process of health

care technologies. This is particularly reinforced in the case of preventive behaviors like using tracing apps whose positive effect is not directly evident [73]. Therefore, we expect that social influence is not only influencing one's initial trust in COVID-19 tracing apps but also impacts one's intention to use the technology.

- H3b: Social influence is positively related to individuals' intention to use a COVID-19 tracing app.

Initial Trust and Intention to Use

In the technology acceptance literature, trust has been shown to be positively correlated with the intention to use technology [69]. For instance, Nicolaou and McKnight [77] demonstrated that individuals' trusting beliefs increase the intention to engage in interorganizational information exchange. Furthermore, (initial) trust is identified to be an antecedent of citizens' intention to use e-governance services [28,53]. Parker et al [24] argued that the successful launch of mobile apps to fight the COVID-19 pandemic in democratic countries relies on the ability to ensure peoples' trust in the technology. Based on URT, we argue that initial trust is a means to exclude potential negative behavior of the technology provider. Citizens who trust a COVID-19 tracing app estimate the probability of deceitful intentions as low.

- H4: Initial trust in a COVID-19 tracing app is positively related to individuals' intention to use it.

Intention to Use and Actual Use

According to the theory of planned behavior [78], established technology acceptance theories (eg, technology acceptance model [TAM] or unified theory of acceptance and use of technology [UTAUT]) [52,79], and the application of URT in the technology context [28], explains that individuals' actual use of new technology is influenced by individuals' intention to use the technology [80]. This relationship is also expected to be applicable in the context of COVID-19 tracing apps.

- H5: Intention to use is positively related to individuals' actual use of a COVID-19 tracing app.

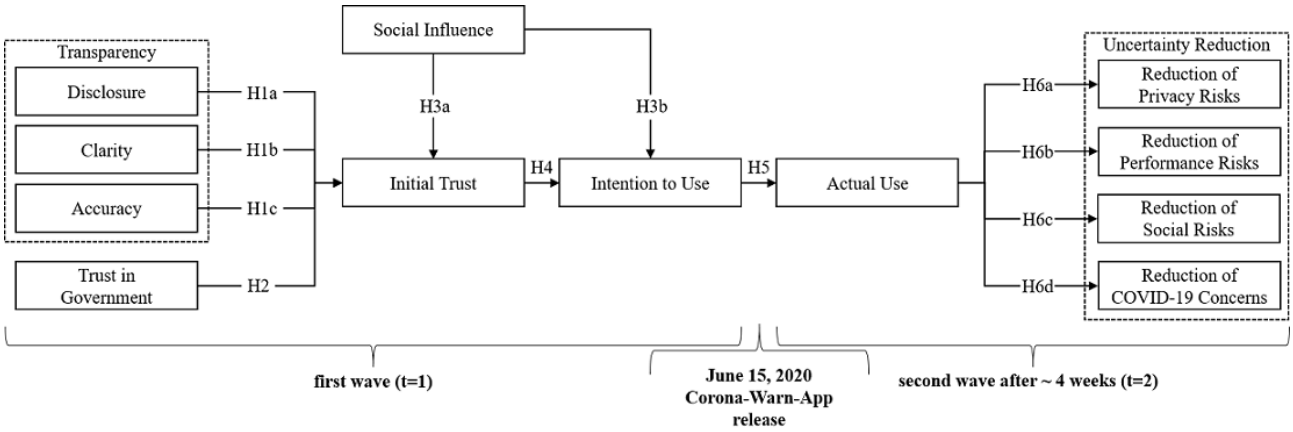
Actual Use and Uncertainty Reduction

Referring to URT, uncertainties concerning data privacy, app performance, social consequences, and general COVID-19 concerns are decreased by the aforementioned means during the adoption process. The actual use of a COVID-19 tracing app is the only available interactive information-seeking possibility for individuals. Therefore, it is effective as it involves a direct interaction with the unknown technology [27]. This interaction enables individuals to discard uncertainties such as performance uncertainties (eg, functionality and handling) of COVID-19 tracing apps [29]. However this mean can obviously only be used after the app has been released. The investigation of the relationship between actual use and the reduction of different forms of uncertainty further addresses the applicability of URT for technology acceptance in uncertain environments.

- H6: The actual use of a COVID-19 tracing app is positively related to the reduction of (a) privacy risks, (b) performance risks, (c) social risks, and (d) COVID-19 concerns.

The proposed research model is summarized in Figure 1.

Figure 1. Proposed research model. H: hypothesis.



Methods

Data and Procedure

To investigate the adoption process of COVID-19 tracing apps and test the theoretical model, data on the German "Corona-Warn-App" were collected via the panel platform respondi in two waves using structured online surveys. Members of this panel voluntarily agree to receive invitations to scientific surveys and may unsubscribe or delete their personal information at any time. Participants were assigned a randomly generated identifier, allowing us to match the results of both surveys. Nevertheless, since a third party (respondi) collected the data for both waves, we did not have direct contact with participants or access to identifying participant information. In addition, the survey did not collect any personal identifying information. Consequently, we were able to guarantee the anonymity and privacy of the participants at all times and acted in accordance with the ethical principles of the German Research Foundation.

The data collection of the first wave (t1) lasted 1 week and was completed 1 day before the app was released on June 15, 2020. Prior to the survey, the participants received the official information from the Federal German Government about the app [81]. For detailed information, see Multimedia Appendix

1 [81]. The app was developed on Android and iOS platforms by Robert Koch-Institut in conjunction with the private companies SAP, Deutsche Telekom, and other partners on behalf of the German government [81]. For the administrative conditions, the source code is publicly available on GitHub [82,83]. Furthermore, no registration is required to run the app, and the use is voluntary. The app uses Bluetooth Low Energy technology to record contact between people. Considering data privacy and security concerns, the devices exchange temporary encrypted random codes (Bluetooth ID) with each other [84]. The use of random codes prevents conclusions from being drawn about individual users or their specific locations. These codes are stored decentralized on the mobile devices, and the tracing data collected are automatically deleted after 14 days [85].

Subsequently, the participants received a quantitative questionnaire concerning their evaluations and perceptions of the app as well as demographical information. In the second survey wave (t2), the same participants were surveyed again 4 weeks after the app was released. The actual use of the app was queried in addition to their evaluations and perceptions.

To maintain data quality and ensure scale validity, we included three attention checks and screened out participants that failed these tests. Finally, 1373 individuals completed the first survey, and 1050 participated in the second wave, yielding a completion rate of 76.47% (1050/1373). Owing to four "knock-out" criteria regarding low response times, missing data, suspicious response patterns, and outliers, 47 participants were excluded from the analysis to ensure data quality [86]. A final sample size of 1003 was then obtained. This sample is representative of Germany in terms of gender, age, and education (see Table 2).

Table 2. Representativeness description.

Characteristic	Germany, %	Sample, n (%)
Gender		
Male	50	490 (48.85)
Female	50	512 (51.05)
Divers	0	1 (0.10)
Age (years)		
14-29	22	190 (18.94)
30-39	16	138 (13.76)
40-49	16	168 (16.75)
50-59	20	214 (21.34)
≥60	25	291 (29.01)
Education		
Low	36	368 (36.69)
Middle	31	315 (31.41)
High	33	320 (31.90)
Adoption rate of Corona-Warn-App (August 2020)[a]	27	379 (37.80)

[a]Calculation of adoption rate in Germany: 16.6 million downloads / approximately 62 million smartphone users (source: Statistisches Bundesamt [87,88], and Robert Koch-Institut [83]).

Measures

To test the proposed research model, we used established scales that have been validated in previous studies. Except for demographics, use behavior (binary), and control variables (gender, age, education), the participants rated all items on 5-point Likert scales. Intention to use was measured by a 3-item scale [52]. For initial trust in the Corona-Warn-App, we built on a 5-item scale developed by Koufaris and Hampton-Sosa [58]. Trust in government was examined through a 4-item scale adapted from Bélanger and Carter [53]. Transparency (reflecting individuals' perceptions of information quality) was adopted from Schnackenberg et al [63], and each dimension was based on 4 items. Privacy risks was measured on a 5-item scale developed by Rauschnabel et al [44], and a 5-item measure was adopted from Featherman and Pavlou [89] to assess performance and social risks. Finally, general COVID-19 concerns were measured through a 6-item scale by Conway et al [45].

We calculated differences for the four dimensions of risk perceptions between the two survey waves to measure the change in the perceived risk assessments. The differences were calculated using the following formula: difference variables = risk perception$_{(t1)}$ – risk perception$_{(t2)}$. The means, SDs, and correlations for all constructs are reported in Table 3. Age, gender, and education were used as controls.

Table 3. Mean, SD, and correlations.

[a]Not applicable.

Before conducting the structural equation modeling (SEM) analysis, we tested the reliability and validity of the measurement model. One item displayed poor factor loadings and was dropped (TR_5). All other factor loadings exceeded the threshold of 0.6. Internal consistency and composite reliability were assumed, as the Cronbach alpha met the quality criteria of >.7, and the average variance extracted exceeded 0.5 [90,91]. Composite reliability of all items exceeded the cut-off value of 0.6 [92]. The final questionnaire with all constructs, related survey items, their sources, and the aforementioned indexes is presented in Multimedia Appendix 2 [44,45,52,53,58,63,89,93].

Data Analysis

We used the R-based JASP software (University of Amsterdam) environment to evaluate our proposed research model [94] and the lavaan code to conduct CB-SEM [95] analysis. Before performing the SEM analyses, we tested the fit, reliability, and validity of the applied model. The comparative fit index (>0.95), Tucker-Lewis index (>0.95), root mean square error of approximation (<0.08), and standardized root mean square residuals (<0.08) complied with the conventional cut-off criteria [96,97]. Based on Kline [98], the χ^2 / df ratios indicated a sufficient model fit across models (<3). Common method bias was not a problem, as the Harman single factor test indicated that only a variance of 27.6% were explained by a single factor consisting of all model items [99]. In summary, all fit indexes revealed a very good overall model fit (see Table 4), with all indicators reaching their respective thresholds.

Table 4. Covariance-based structural equation modelling results.

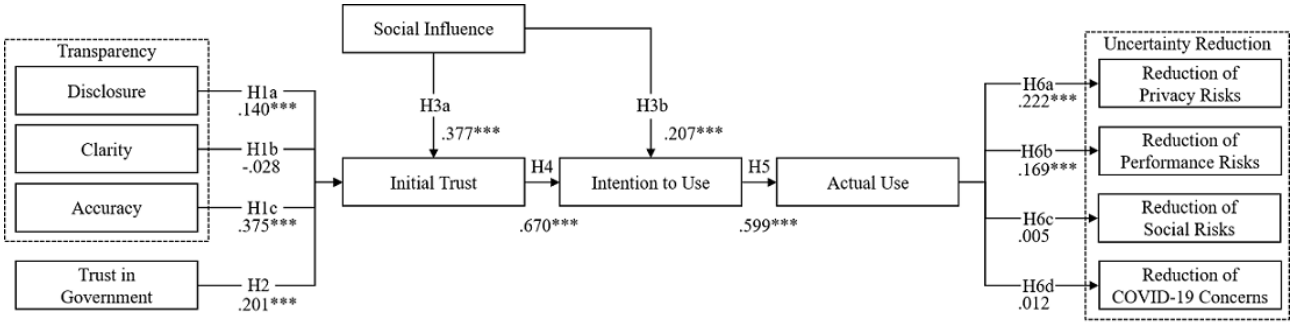
Results

The standardized path coefficients, significance levels, and fit indexes are summarized in Table 4. As illustrated in Figure 2, information disclosure and accuracy are positively related to initial trust, supporting H1a (β=.140; *P*<.001) and H1c (β=.375; *P*<.001). In contrast, H1b was rejected (β=–.028; *P*=.45), as information clarity shows no relation to initial trust. H2 was supported (β=.201; *P*<.001) as trust in governance and initial trust were positively related. Furthermore, there was support for H3a (β=.377; *P*<.001) and H3b (β=.207; *P*<.001), as the results showed a positive relation between social influence toward initial trust and intention to use. The observed relationship between initial trust and intention to use was positive, supporting H4 (β=.670; *P*<.001). We also found support for H5 (β=.599; *P*<.001), as intention to use was positively related to the actual use of a COVID-19 tracing app. Finally, we found a positive relationship between actual use and privacy and performance risks, thus supporting H6a (β=.222; *P*<.001) and H6b (β=.169; *P*<.001). In contrast, H6c (β=.005; *P*=.88) and H6d (β=.012; *P*=.72) were rejected as actual use was not related to social risks or COVID-19 concerns, respectively. The control variables gender and education were not related to the reduction of the four dimensions of uncertainty reduction, while age was negatively related to privacy risk reduction.

Figure 2. Results of structural equation model. H: hypothesis. ***P<.001.



In addition to the hypothesized direct relationships between social influence and the intention to use the COVID-19 tracing app, we conducted a post hoc analysis to investigate the potential indirect effects of social influence on the intention to use the COVID-19 tracing app mediated by initial trust. The mediation effects were examined with the help of the procedure according to Baron and Kenny [100] and are depicted in Table 5. We found evidence that the indirect effect was significant (β=.253; *P*<.001). As the direct effect of social influence toward the intention to use has been shown to be significant before (H5), we postulated that the relationship of social influence and intention to use is partially mediated by initial trust.

Table 5. Mediating effect.

Effect	β (SE)[a]	*P* value	Mediation
Indirect effect: social influence → initial trust → intention to use	.253 (.022)	<.001	partial mediation
Total effect: social influence → intention to use	.460 (.029)	<.001	–

[a]Standardized path coefficients; standard error of the estimators in parentheses.

Discussion

General Discussion

In this study, we investigated how uncertainty reduction measures can foster the adoption of COVID-19 tracing apps and, consequently, the reduction of uncertainty perception. In this section, we discuss the antecedents of initial trust, intention, and actual use of the app, as well as the reduction of specific uncertainties. Based on URT, transparency and social influence are antecedents of initial trust. In terms of transparency, we found that initial trust in COVID-19 tracing apps is positively influenced by the disclosure and accuracy of information. However, accuracy had a considerably higher effect on initial trust than the disclosure dimension. This shows that, although it is important to receive sufficient information, the perceived validity of the information is crucial. Unexpectedly, we found no effect between information clarity and initial trust in the Corona-Warn-App. This may be due to the peculiarities of the COVID-19 pandemic, as people likely became used to constantly encountering new complex information and thus accepted a lower level of information lucidity. Despite the missing effect between clarity and initial trust, our findings are consistent with the existing transparency-trust literature [51,62,63].

As proposed, social influence positively affects individuals' initial trust. The integration of social influence in the URT context reveals that social influence serves as an active information-seeking strategy, thus meeting the demand of Venkatesh et al [28] to integrate UTAUT variables into URT. Especially in situations where direct interaction with the unknown technology is not possible, the communication with peers becomes important. In addition, we identified a positive relation between social influence and intention to use. This is in line with technology acceptance and health care literature [52,70,73]. In addition, we were able to show that initial trust partially mediates the relationship between social influence and intention to use COVID-19 tracing apps. Furthermore, we examined the effect of trust in the government on initial trust

in COVID-19 tracing apps and found a positive relationship between these concepts. This is consistent with the trust transfer theory and current studies on COVID-19 tracing apps [59,68]. It is important to note that trust in government has a smaller effect on individuals' initial trust compared to transparency and social influence. Therefore, people who are critical of the government can still develop initial trust in the app through other short-term influenceable means such as transparent communication.

Additionally, we observed a positive relation between initial trust and intention to use. This result is consistent with URT [27,28] and confirms the common understanding of trust in the context of technology acceptance (for a meta-analysis, see Wu et al [101]). As expected, people who have a high intention to use a COVID-19 tracing app are more likely to use it. Nevertheless, our results also revealed, as most studies have, that an intention-behavior gap exists [102].

Considering uncertainty reduction specifically, we found that the actual app use increases COVID-19 tracing app–related uncertainty reduction. Individuals' uncertainty reduction of perceived privacy and performance risks was significantly increased by using the app. Thus, we found support for Trang et al [22], who stated that data privacy and app performance (benefits) need to be considered in the development of tracing apps. In addition, our results did not indicate a reduction of social risks nor a reduction of general COVID-19 concerns. As COVID-19 concerns span broader health-related fears, they cannot be solely linked to the functionality of the app or interaction with it. Tracing apps do not provide direct protection but are mainly intended to identify infection chains to implement further appropriate actions such as intelligent testing and quarantine [9]. This explains why the use of a COVID-19 tracing app has no impact on the reduction of these general health-related fears. Further, it indicates that people using tracing apps are not getting more reckless but still recognize the virus's threat. Regarding social risks, the use and nonuse of the app is less visible to nearby people than wearing a face mask or complying with social distance regulations. Therefore, individuals' actual use behaviors might be unrelated to social consequences as long as the use of such an app is not mandatory, for example, to use public transportation or enter restaurants or other places. For the controls, we found that age was negatively correlated to the reduction of privacy risks. This effect is rather small and in line with research emphasizing that privacy concerns are more pronounced and stable among older people than among younger individuals [103].

Theoretical Implications

Our study design and findings contribute to the literature in several ways. First, we demonstrated with our study design how mass adoption problems can be investigated over time in the health care management context using the example of a COVID-19 tracing app. By applying URT, we contributed to its empirical validation in general and introduced it to the field of health care management. The application is particularly valuable in the health care context, as this area is characterized by uncertainties that may lead to serious and far-reaching consequences, as is apparent in times of the COVID-19 pandemic [104]. Second, it was shown that interactive information-seeking strategies, such as app use, are appropriate for reducing related uncertainties (eg, privacy and performance risks). By collecting the data in two measurement periods (before and after the release of the app) and calculating difference variables to quantify the uncertainty reduction, we validated the impact of the use of a technology on uncertainty reduction. The use of specific uncertainty reductions as outcome variables is theoretically stronger for URT than the use of outcome variables such as satisfaction proposed by Venkatesh et al [28]. Third, further theoretical contributions were made by integrating recent transparency research [49] into URT. Thereby, our results highlighted the importance of considering transparency as a multidimensional construct [49]. Transparency perceptions are essential as they form the basis for active and passive information-seeking strategies. By using the recent DCA-transparency scale [63], we further elaborated on the role of transparency (ie, information quality) in URT as proposed by Venkatesh et al [28]. Finally, it was shown that trust transfer theory holds true in the investigated setting. Although trust in the government is not a major antecedent for initial trust in COVID-19 tracing apps, individuals' trust in the government should still be considered in governmental technology publishing.

Implications for Practice

The adoption rates of voluntary COVID-19 tracing apps differ largely among countries and are mostly below the critical thresholds, which hinders their effectiveness [14,20]. To improve acceptance, governments can adopt the following implications in their communication strategies. First, governments that introduce a voluntary COVID-19 tracing app (or other technologies) should engage in a transparent communication process. A supply of sufficient information, which must be perceived as accurate, is thus required. However, transparent communication only works if the service itself exceeds certain standards such as data privacy and security [22]. Second, interactive information-seeking strategies of individuals must be managed. These strategies (eg, app use) are shown to be efficient in terms of uncertainty reduction. Hence, governments should provide appropriate formats to enable interactive information seeking before release. Such formats can be demo versions, realistic previews, question and answer sessions, or even hackathons. Finally, our findings are extendable to other technologies and settings. For example, if there are other digital trends in the health care system (eg, digital health record or video doctor), our results can be applied to achieve (voluntary) technology (mass) acceptance. Whenever governments or organizations develop and publish new services (eg, disaster alarm app), other uncertainties such as financial risk, time risk, or psychological risk may arise and should be considered. The conscious management of the (transparent) publication process can promote a successful launch of a technology. By understanding the multidimensional nature of perceived information quality, both organizations and governments can reflect and develop their own technology implementation strategy. Hence, many of the implications outlined here may also be relevant to future pandemics and public health crises.

Limitations and Future Research

Although the results of this study provide important insights, the study has some limitations. As the results are based on data related to the German COVID-19 tracing app, the generalizability of our findings for other regions may be restrained due to cultural differences. Thus, future research should expand this study by including other countries. Further, actual app use was self-reported by the participants and might be untrue in some cases. However, the app adoption rate in our sample was comparable with the adoption rate in the German population during the second survey wave (see Table 2). To advance URT, researchers can examine the communication channels that are most suitable to ensure transparency and reduce different uncertainties. After some studies have dealt with the design [105], the technical configuration [22], and the ethical guidelines [106], we studied the requirements for adequate app implementation and communication. Therefore, future research should investigate means to ensure mid- and long-term app acceptance and use.

For most of the population, the Corona-Warn-App was a new concept at the time of its release. Since then, the app and its functionality have become relatively well known and widespread. For this reason, follow-up research should investigate the role of descriptive norms (ie, how others actually behave) besides subjective norms, which we have investigated in the form of social influence (ie, how important others think one should behave), for the adoption process [107].

Moreover, the data underlying this study originated a few days (t1) before and 4 weeks (t2) after the launch of the COVID-19 tracing app in Germany and, thus, between the first and second waves of infection. In the meantime, various measures against the pandemic have been implemented, and more information about the virus, its spread, and mortality are available. These insights should be considered in follow-up studies. For example, the distribution and adoption of new SARS-CoV-2 vaccines represent a milestone in the fight against the pandemic. Therefore, follow-up studies should examine whether these insights influence the use of the COVID-19 tracing app and uncertainty perceptions.

Conclusion

A key strategy in fighting the COVID-19 pandemic is the testing and subsequent isolation of individuals who are potentially infected. The automatic contact tracing via mobile apps offers an important contribution to the decision of which people need to be tested with regard to limited testing capacities. Our study offers original insights on the factors driving the mass acceptance of COVID-19 tracing apps to identify infection chains and control the pandemic. Building on URT and through a longitudinal empirical study on the adoption process, we investigated how uncertainty reduction measures affect the adoption of COVID-19 tracing apps and how their use affects the perception of different risks. We analyzed representative data through CB-SEM. The results revealed that the transparency dimensions of disclosure and accuracy, as well as social influence, trust in government, and initial trust positively affect the adaptation process, whereas no effect was observed for the transparency dimension clarity. Further, we showed that the actual use of COVID-19 tracing apps reduces the perceived uncertainty regarding performance and privacy risks, but no effect on the reduction of social risks and COVID-19 concerns was identified. Finally, we derived theoretical and practical implications concerning the communication strategy of contact tracing apps in particular and for health care technologies in general.

Abstract

Background: The COVID-19 pandemic imposed an acute, sharp rise in the use of video consultations (VCs) by general practitioners (GPs) in Norway.

Objective: This study aims to document GPs' experiences with the large-scale uptake of VCs in the natural experiment context of the pandemic.

Methods: A nationwide, cross-sectional online survey was conducted among Norwegian GPs during the pandemic lockdown (April 14-May 3, 2020). Each respondent was asked to evaluate up to 10 VCs. Basic demographic characteristics of the GPs and their practices were collected. The associations between GPs' perceived suitability of the VCs, the nature of the patients' main problems, prior knowledge of the patients (relational continuity), and follow-up of previously presented problems (episodic continuity) were explored using descriptive statistics, diagrams, and chi-square tests.

Results: In total, 1237 GPs (26% of the target group) responded to the survey. Among these, 1000 GPs offered VCs, and 855 GPs evaluated a total of 3484 VCs. Most GPs who offered VCs (1000/1237; 81%) had no experience with VCs before the pandemic. Overall, 51% (1766/3476) of the evaluated VCs were considered to have similar or even better suitability to assess the main reason for contact, compared to face-to-face consultations. In the presence of relational continuity, VCs were considered equal to or better than face-to-face consultations in 57% (1011/1785) of cases, as opposed to 32% (87/274) when the patient was unknown. The suitability rate for follow-up consultations (episodic continuity) was 61% (1165/1919), compared to 35% (544/1556) for new patient problems. Suitability varied considerably across clinical contact reasons. VCs were found most suitable for anxiety and life stress, depression, and administrative purposes, as well as for longstanding or complex problems that normally require multiple follow-up consultations. The GPs estimate that they will conduct about 20% of their consultations by video in a future, nonpandemic setting.

Conclusions: Our study of VCs performed in general practice during the pandemic lockdown indicates a clear future role for VCs in nonpandemic settings. The strong and consistent association between continuity of care and GPs' perceptions of the suitability of VCs is a new and important finding with considerable relevance for future primary health care planning.

Introduction

Background

The digitalization of medical consultations in general practice (family medicine) has in many countries received increasing interest in recent years, with a particular focus on video consultations (VCs) [1-3]. However, the implementation of VCs by general practitioners (GPs) has been relatively slow and supported by limited and inconclusive evidence [4]. The emergence of the COVID-19 pandemic introduced an abrupt and strong stimulus for rapid adoption of VCs in many contexts, producing an effect that was arguably most striking in settings where a digitalization process had already started [5,6].

Prepandemic research on VCs in general practice has mostly been characterized by small studies on selected patient groups [7,8]. Results indicate that VCs might be useful for selected patients or health problems and have the potential for increased patient empowerment, practical convenience, and efficiency gains [9,10]. However, concerns have been raised regarding the clinical quality and suitability of VCs, and both patients and clinicians still consider face-to-face consultations the gold standard [7,8,11,12]. More knowledge is needed about the optimal use of VCs in general practice, from both an organizational and a clinical perspective [13].

In the context of face-to-face consultations, continuity of care [14] has been associated with positive health outcomes for patients, including increased life expectancy [15,16]. There is little knowledge regarding the impact of VCs on the doctor-patient relationship and to what extent a pre-existing doctor-patient relationship might impact the quality and outcome of VCs. The introduction of VCs in situations where GPs deliver continuity of care to their patients (relational continuity) and are familiar with their ongoing health problems (episodic continuity) may have a positive impact compared to situations where continuity of care is not established [17].

Use of VCs in Norway Before and During the COVID-19 Pandemic

Before the COVID-19 pandemic, around 3% of all GP consultations in Norway were performed digitally [18]. The societal lockdown in Europe in spring 2020 had a strong impact on general practice in Norway. On March 16, 2020, the Norwegian Ministry of Health and Care Services encouraged all GPs to adopt a solution for VCs [19]. The reimbursement system for GPs was also temporarily modified to strengthen the use of medical consultations via text, video, or telephone (Textbox 1). Data from the main providers of VC solutions showed that, while almost all 4822 GPs in Norway installed a solution for VCs, less than 2000 GPs used VCs during the period April 15-May 3, 2020.

During the first phase of the lockdown in mid-March 2020, many GP offices restricted physical access and triaged all contacts via telephone or online communication. Almost 60% (171,169/299,148) of all GP consultations in Norway were performed digitally from March 16 to March 22 (Multimedia Appendix 1). In the last week of March, 25% (34,814/141,501) of all digital consultations were VCs (Multimedia Appendix 2). From May 11 to May 17, the proportion of digital consultations decreased to 30% (85,026/286,419), of which 19% (16,278/85,026) were VCs.

Most GP offices still offered face-to-face consultations for urgent issues. However, digital consultations were conducted even in situations where a physical examination would have been deemed necessary before the COVID-19 lockdown, such as acute abdominal pain or chest pain. At the time of data collection, the main technical solution for VCs in Norway was an external video application not integrated with the GP's electronic patient record systems. However, the patients' medical record was available to the GPs during the VCs.

Textbox 1. The Norwegian General Practitioner Scheme.

The Norwegian health care system is based on the principles of universal access, decentralization, and continuity of care [20]. Since 2001, all Norwegian citizens may sign up with (and change, if desired) a GP, and 99% have chosen to do so. The system is financed by taxation, together with income-related employee and employer contributions and out-of-pocket payments (copayments). Private medical insurance is limited. Although national health care policy is controlled centrally, responsibility for the provision of primary health care is decentralized. GPs act as coordinators of municipal services and gatekeepers to specialized care. On average, a GP has about 1100 patients and often provides other medical services in the municipality one day per week.

Evaluation of VCs During the COVID-19 Pandemic

In association with the COVID-19 pandemic, recommendations regarding the use of VCs by GPs and their patients have been issued based on clinical expertise and relevant evidence [13,21]. The lockdown led to a rapid uptake of VCs during a very short time period, creating a natural experiment where the effectiveness and suitability of VCs could be explored across a wide range of health problems [5].

Ideally, the large-scale implementation of VCs should have been rigorously monitored by detailed research on both GPs and patients. Due to the pressing circumstances of the lockdown, such systematic evaluation was not deemed feasible. However, conducting a large-scale survey of GPs' experiences with the use of VCs during the lockdown was achievable and can contribute to filling important knowledge gaps.

The overall aim of this survey was to explore how GPs in Norway perceived the suitability of VCs compared to ordinary face-to-face consultations during the COVID-19 lockdown. In addition to addressing the suitability of VCs across a wide range of health problems (reasons for contact), we were also interested in knowing whether continuity of care (ie, prior knowledge of the patient/problem) had an impact on GPs' perceptions of VC suitability.

Methods

Study Design and Setting

A prospective nationwide online cross-sectional survey was conducted among GPs in Norway during the COVID-19 pandemic lockdown (April 14-May 3, 2020). The survey was addressed to all GPs registered in Norway. Basic demographic characteristics of the GPs and their practices were collected. Each GP also indicated the number of consultations and other activities conducted during the day when the survey was taken.

A central part of the survey addressed GPs' experiences with VCs before and during the pandemic. Each GP was asked to evaluate up to 10 consecutive (or otherwise unselected) VCs during the COVID-19 lockdown, preferably conducted during the same day. The evaluation of each VC included 13 questions that covered the GPs' prior knowledge of the patient (relational continuity), whether the reason for contact was a new problem or a follow-up (episodic continuity), the total number of presented problems, the nature of the main problem (as perceived by the GP), the perceived suitability of VC compared to an envisaged face-to-face consultation for the main problem, and actions (one or more) taken by the GP during/after the VC. The GP's perception of the patient's satisfaction with the VC, the technical quality of each VC, and their willingness to use VC in a similar situation after the COVID-19 pandemic were also recorded. Finally, the GPs were asked to estimate the overall proportion of VCs they personally envisaged in their practice in a "normalized" future, in light of their accumulated experience with the medium.

Questions were multiple choice with 2-11 alternative answers, depending on the topic. Questions concerning users' experiences were scored on a 3-point or 4-point Likert scale. Regarding patients' reasons for contact, a total of 78 alternatives were offered. This list was informed by the International Classification of Primary Care, second edition (ICPC-2), but was less detailed. Regarding actions taken during or after each VC, 16 alternatives were offered. We consulted the Checklist for Reporting Results of Internet E-Surveys (CHERRIES) to develop the survey and report its results [22]. The survey was pilot tested by a panel of experienced GPs. The survey was conducted in Norwegian through the Netigate application. The results have been translated into English for the purpose of publication.

Data Collection

To obtain access to GPs' updated contact emails on very short notice, the research team collaborated with Norwegian Health Informatics, a web-based portal that hosts an online clinical decision support product (NEL), to which approximately 98% of all Norwegian GPs subscribe [23]. An invitation was sent to all subscribers by a unique link that ensured both the authenticity and anonymity of the respondents. GPs who did not receive a personal invitation by email or were nonsubscribers of NEL were encouraged by a well-established social media group for GPs to register their email addresses on the Norwegian Health Informatics website. It took approximately 30-60 minutes to complete the survey. Data collection was undertaken in the period April 14-May 3, 2020. Several reminders were sent by email and social media.

Data Analysis

Results were summarized by descriptive statistics, diagrams, and chi-square tests with 95% CIs. Background data from this survey were compared to available information on all GPs in Norway. The associations between suitability of VCs and relational continuity, episodic continuity, and the nature of the patients' main problems were explored by diagrams, tables, and chi-square tests. The defined significance level was .05.

Before further analysis was performed, the 78 alternative reasons for contact were merged into 27 more overarching categories (eg, knee, hip, shoulder, and back problems were merged into "musculoskeletal issues"). We also merged "better" and "same" into one category regarding suitability. Data were analyzed in IBM Statistical Package for the Social Sciences (SPSS; Version 26.0, IBM Corp).

Ethics

Ethical considerations were included in all phases of the survey. Participating GPs were informed that participation was voluntary and anonymous. We did not elicit sensitive information or demographic characteristics that could reveal the identity of the GPs. For the evaluated VCs, we did not elicit patients' age, sex, specific diagnoses, or other sensitive or person-related information. Distribution of the survey to GPs' email addresses was handled by an independent party (Norwegian Health Informatics). No linkage key was established, and participants' IP numbers were not accessible to any party. Further approvals were thereby not required, according to Norwegian health research legislation, verified by the Norwegian Centre for Research Data (NSD).

Results

Characteristics of the GPs

A total of 1237 GPs participated in the survey, representing 26% (1237/4822) of the total GP population in Norway [24]. Of these, 1000 (81%) answered that they were equipped to offer VCs at the time of the survey, and 855 contributed evaluations of at least one VC (Table 1).

On average, each GP conducted 20 consultations during the surveyed working day. Of these, 6.9 (34.5%) were face-to-face consultations, 5.3 (26.5%) were VCs, 3.3 (16.5%) were text-based e-consultations, and 4.5 (22.5%) were telephone consultations. Of the 855 participants, 74 (9%) had no face-to-face consultations on the study day. Most of the respondents (80%; 687/855) did not have any experience with the use of VCs before the COVID-19 pandemic.

Table 1. Characteristics of the 855 general practitioners who evaluated one or more video consultations.

Characteristics of the general practitioners (N=855)	Participants, n (%)
Gender	
Female	480 (56.2)
Male	368 (43.0)
No answer	7 (0.8)
Experience in years as a general practitioner	
0-5	174 (20.3)
6-10	189 (22.1)
11-20	287 (33.6)
>20	205 (24.0)
Inhabitants of the municipality of practice	
<10,000	130 (15.2)
10,000-50,000	295 (34.5)
50,000-100,000	143 (16.7)
100,000-500,000	217 (25.4)
>500,000	70 (8.2)
Experience with video consultations before the COVID-19 pandemic	
None	687 (80.3)
Limited (1-50 video consultations)	123 (14.4)
Relatively good (>50 video consultations)	45 (5.3)

Description of the VCs

On average, each GP provided an evaluation of 3.8 VCs. The final data set included 3484 unique VCs between GPs and patients (Table 2).

In most VCs (79%; 2760/3484), the GP knew the patient well beforehand, while the GPs described only 8% (276/3484) of the patients as previously unknown. More than half of the consultations (55%; 1921/3481) were a follow-up of a previous problem. On average, 1.9 (median 2.0) problems/issues were discussed during each consultation. Half of the VCs (51%; 1766/3476) were considered to have similar or even better suitability to assess the main reason for contact compared to face-to-face consultations. For 15% (514/3476) of the VCs, the GPs expressed concern that they might not have detected potential signs of serious illness. The lack of opportunity to physically examine the patient was reported as a “major loss” or “some loss” in 25% (884/3475) and 36% (1232/3475) of the VCs, respectively. In 85% (2967/3475) of cases, the GPs perceived that the patient was satisfied with the VC. The technical quality was considered good in 90% (3118/3475) of the VCs. Half of the GPs (1704/3475) considered it realistic to handle a similar issue by VC after the COVID-19 pandemic.

Table 2. Characteristics of the 3484 recorded video consultations. Missing answers (ranging from 0-9 general practitioners per question) are not displayed.

Characteristics of the video consultations (N=3484)	Values, n (%)
General practitioner's pre-existing knowledge of the patient	
Very good	1788 (51.3)
Good	972 (27.9)
Some	448 (12.9)
None	276 (7.9)
Main reason for contact	
New problem	1560 (44.8)
Follow-up	1921 (55.1)
Total number of contact reasons discussed	
1	1471 (42.2)
2-4	1930 (55.4)
>4	75 (2.2)
Suitability of video consultation compared to a face-to-face consultation for the same reason	
Better or same	1766 (50.7)
Worse	1709 (49.1)
Suitability of video consultation to assess the severity of the main reason for contact compared to a face-to-face consultation	
Better or same	1767 (50.7)
Worse	1709 (49.1)
Loss from not being able to examine the patient physically	
No loss	1359 (39.0)
Some loss	1232 (35.4)
Major loss	884 (25.4)
Concern about not picking up signs of serious illness	
Not worried	2009 (57.7)
Neutral	953 (27.3)
Worried	514 (15.0)
General practitioner's perception of patient satisfaction with video consultation	
Very satisfactory	988 (28.4)
Satisfactory	1979 (56.8)
Unsatisfactory	368 (10.6)
Do not know	140 (4.0)
General practitioner's satisfaction with technology (connection, sound, image)	
Very satisfactory	1433 (41.1)
Satisfactory	1685 (48.4)
Unsatisfactory	273 (7.8)
Video consultation terminated due to technical problems	84 (2.4)
Motivation to conduct a video consultation for a similar health problem (reason for contact) in a nonpandemic future	
Yes	1704 (48.9)
Do not know	768 (22.0)
No	1003 (28.8)

Suitability of VCs and Continuity of Care

The association between GPs' perceptions of the suitability of VCs and their previous knowledge of their patients (relational continuity) is presented in Figure 1. When the GPs knew their patients "very well" beforehand, VCs were considered as having "better" or "same" suitability, compared to face-to-face consultations in 57% (1011/1785) of cases. When the patient was "unknown," the corresponding suitability rate dropped to 32% (87/274). The difference in proportions of better/same and worse suitability of VCs between the groups of relational continuity was statistically significant (χ^2_3=105.3, *P*<.001).

In Figure 2, we present the association between the GPs' perceptions of suitability of VCs and their previous knowledge of a given patient's presented problem (episodic continuity). VCs were considered better/same compared to envisaged face-to-face consultations in 61% (1165/1919) of follow-up consultations, as opposed to 35% (544/1556) when the patient presented a new problem. The difference in proportions of better/same and worse suitability of VCs between the groups of episodic continuity was statistically significant (χ^2_1=227.9, *P*<.001).

In Table 3**,** we have combined relational and episodic continuity of care. We present the proportion of VCs where the suitability is considered better or the same, compared to envisaged face-to-face consultations for the same contact reason. When the GP's prior knowledge of a patient was "very good" or "good" and the problem was a "follow-up," 62% (1070/1719) of the VCs were considered equally or better suited than envisaged face-to-face consultations. The corresponding proportion drops to 30% (155/521) when the GP's prior knowledge of the patient was "some" or "none" and the problem was "new." The differences in proportion of the suitability of VCs in Table 3 are statistically significant (*P*<.001).

Figure 1. Association between relational continuity (previous knowledge of the patient) and general practitioners' perceived suitability of video consultations compared to an envisaged face-to-face consultation for the same issue (95% CIs are illustrated by lines). GP: general practitioner; VC: video consultation.

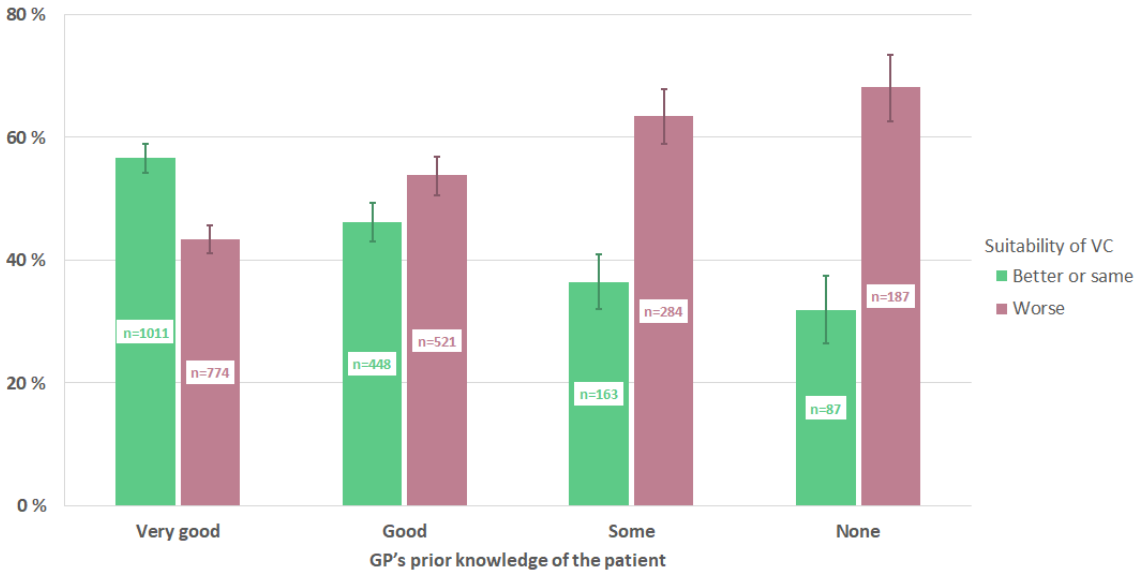

Figure 2. Association between episodic continuity (new problem or follow-up of previously defined problem) and general practitioners' perceived suitability of the video consultations, compared to envisaged face-to-face consultations for the same problem (95% CIs are illustrated by lines). VC: video consultation.

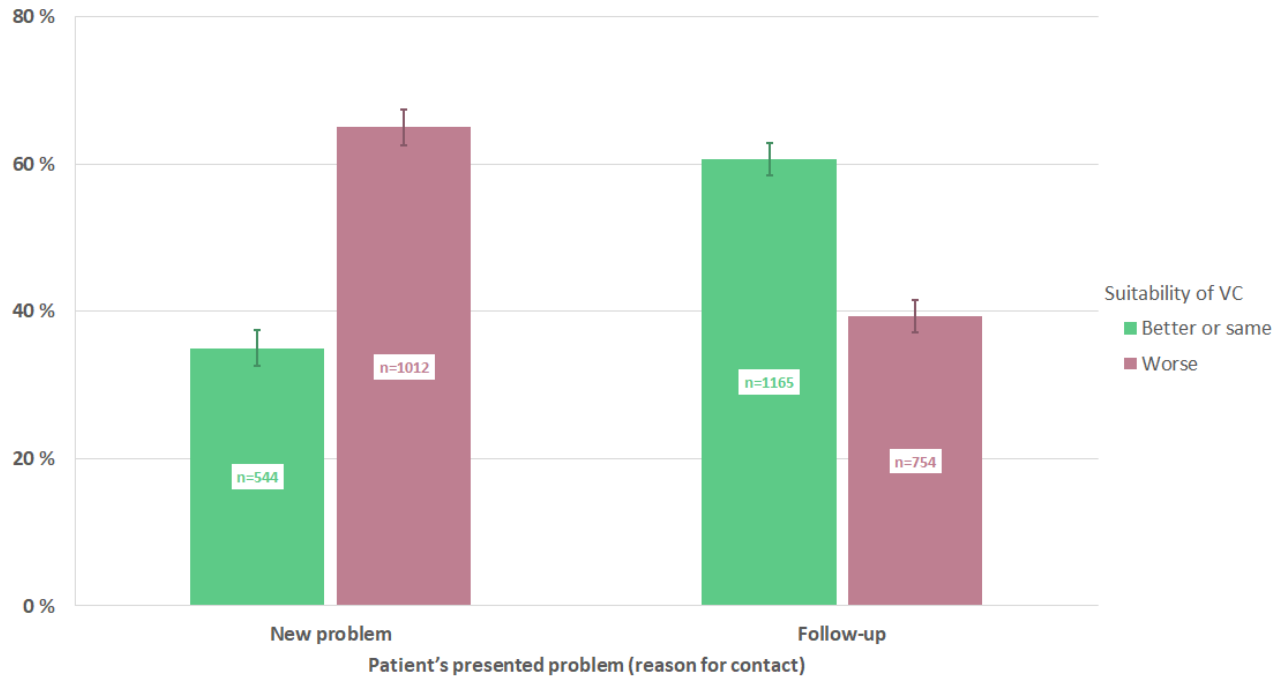

Table 3. Video consultations perceived by the GPs as equally or better suited compared to an envisaged face-to-face consultation, shown as combinations of pre-existing knowledge of the patient (relational continuity) and the main reason for contact (episodic continuity).

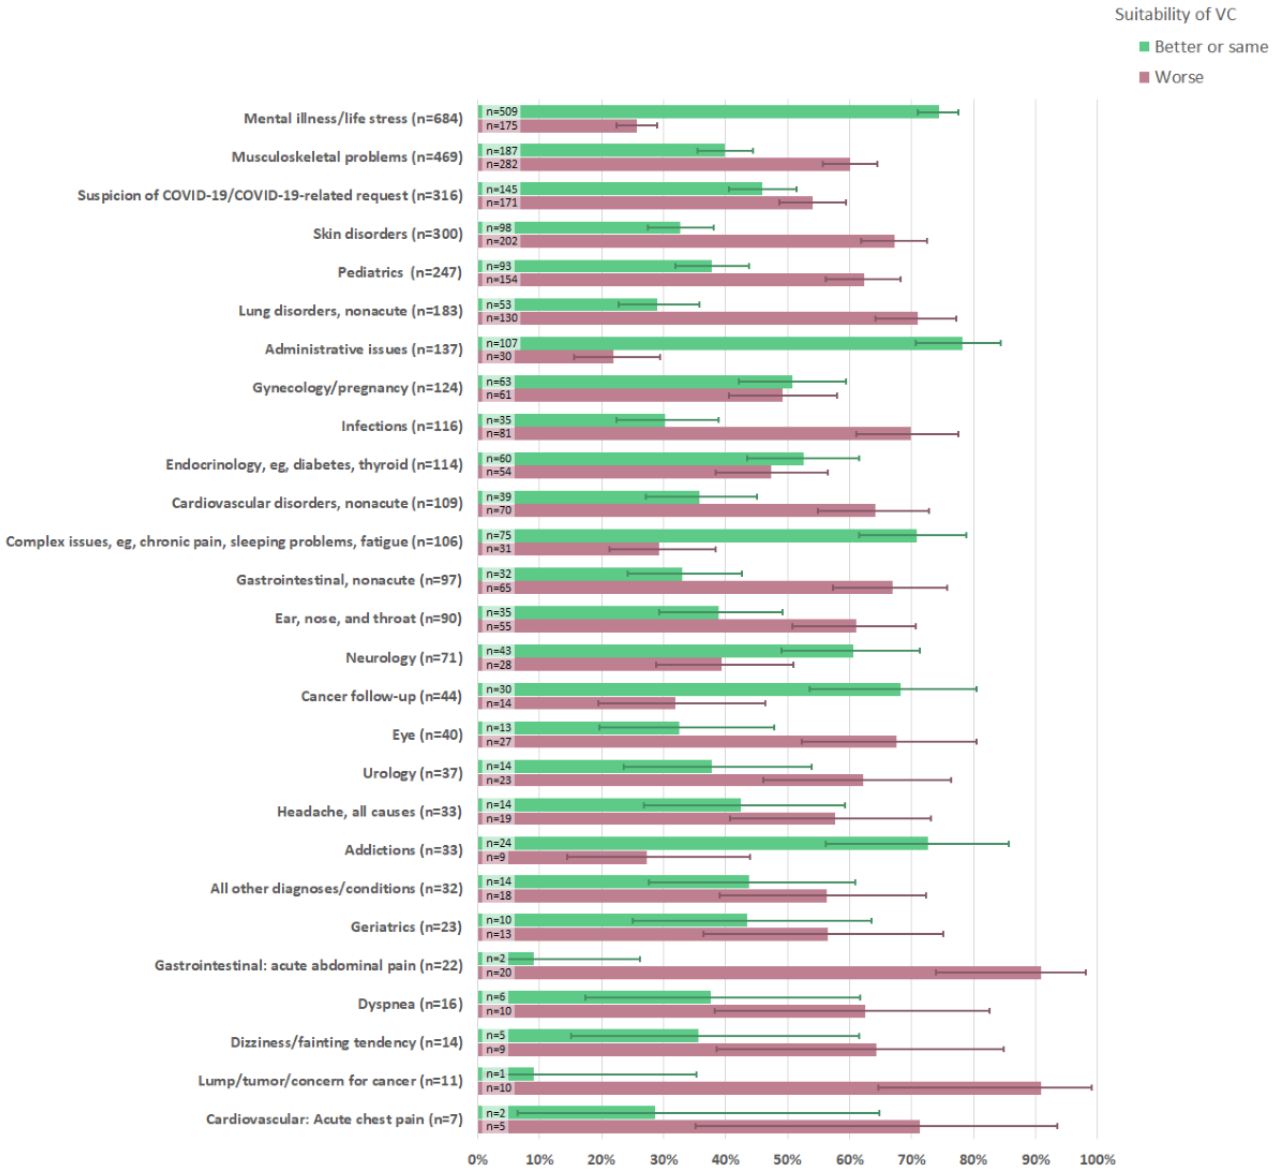
Main reason for contact	Pre-existing knowledge of patient			
	Very good/good (n=2754)		Some/none (n=721)	
	Number of video consultations, n/N	Proportion, % (95% CI)	Number of video consultations, n/N	Proportion, % (95% CI)
New problem (n=1556)	389/1035	38 (35-41)	155/521	30 (26-34)
Follow-up (n=1919)	1070/1719	62 (60-65)	95/200	48 (41-54)

Suitability of VCs and Reasons for Contact

GPs considered VCs to be equally or better suited for several reasons for contact, compared to envisaged face-to-face consultations (Figure 3); examples include mental illness/life stress (509/684; 74%, 95% CI 71%-78%) and various administrative purposes (107/137; 78%, 95% CI 70%-84%). On the other hand, other issues, including musculoskeletal problems (187/469; 40%, 95% CI 36%-44%) and skin disorders (98/300; 33%, 95% CI 28%-38%), were regarded as less suitable for VCs. VCs were also considered less suitable in situations involving acute chest pain, stomach pain, and fear/investigation of a potential new cancer.

Figure 3. General practitioners' perceived suitability of video consultations compared to an envisaged face-to-face consultation for the same issue, according to the nature of the main problem/reason for contact. The contact reasons are presented in decreasing frequency (n) from top to bottom, and 95% CIs are illustrated by lines. VC: video consultation.



Furthermore, for each main reason for contact, the perceived suitability of VCs differed according to episodic continuity of care (Table 4). For instance, the suitability of VCs for skin disorders was 30% (69/234) for a new problem and 44% (29/66) for a previously discussed problem. Corresponding numbers were 18% (33/183) and 54% (154/286) for musculoskeletal problems, and 20% (4/20) and 77% (39/51) for neurology disorders. The impact of relational continuity of care on the suitability of VCs for individual health problems is not reported due to low statistical power (few unknown patients).

Table 4. Suitability of video consultations compared to face-to-face consultations, association with main reason for contact (new problem/follow up), and the 20 most common issues/presented problems, N=3350.

Issue/presented problem	Main reason for contact							
	New problem (n=1484)				Follow-up (n=1866)			
	Better or same (n=529)		Worse (n=955)		Better or same (n=1140)		Worse (n=726)	
	Contacts, n/N	Proportion, % (95% CI)	Contacts, n/N	Proportion, % (95% CI)	Contacts, n/N	Proportion, % (95% CI)	Contacts, n/N	Proportion, % (95% CI)
Mental illness/life stress	67/105	64 (54-73)[a]	38/105	36 (28-46)[a]	442/579	76 (73-80)[a]	137/579	24 (20-27)[a]

[a]Nonoverlapping CIs.

Suitability of VCs and Actions Taken in the VCs

A total of 7647 actions were registered by the GP during/after the VCs (Table 5). The most common action (47%; 1646/3476) was "comprehensive advice and guidance," followed by planning a new VC or text-based e-consultation (34%; 1197/3476).

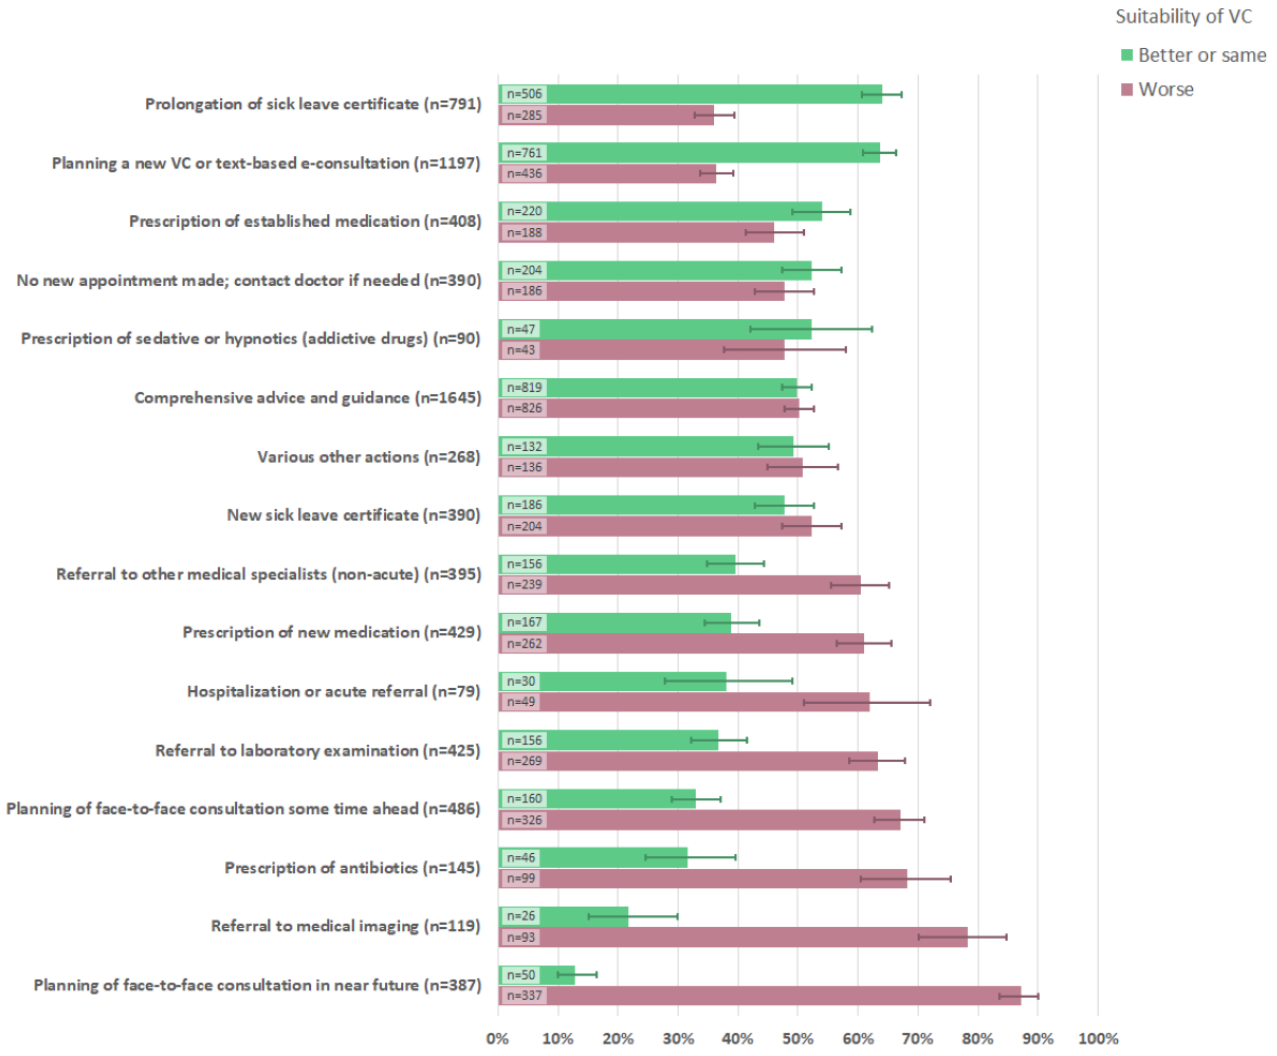
VCs were deemed to be less suitable in situations where a physical follow-up was subsequently planned (ie, a face-to-face consultation in the near future, referrals to medical imaging, laboratory examinations, and hospitalizations; Figure 4). Prescription of antibiotics or new medications were also situations where VCs were considered less suitable. Conversely, VCs were perceived as suitable for prolonging sick leaves.

Table 5. Action taken during/after the 3484 evaluated video consultations. Several actions could be registered for each video consultation.[a]

Type of actions taken during/after the video consultation (N=7647)	Count, n	%
Comprehensive advice and guidance	1646	47
Planning a new video consultation or text-based e-consultation	1197	34
Prolongation of sick leave certificate	791	23
Planning of face-to-face consultation some time ahead	486	14
Prescription of new medication	429	12
Referral to laboratory testing	425	12
Renewal of established medication	408	12
Referral to other medical specialists (nonacute)	395	11
New sick leave certificate	391	11
No new appointment made; contact doctor if needed	390	11
Planning of face-to-face consultation in near future	388	11
Various other actions	268	8
Prescription of antibiotics	145	4
Referral to medical imaging	119	3
Prescription of sedatives or hypnotics (addictive drugs)	90	3
Hospitalization or acute referral	79	2

[a]In total, 8 evaluated video consultations did not have a registered action.

Figure 4. Associations between general practitioners' perceived suitability of video consultations and actions taken during/after the consultation. The actions taken are sorted by general practitioners' perceived suitability (better or same) of the video consultation in question, displayed in decreasing order. 95% CIs are illustrated by lines. VC: video consultation.



Envisaging the Place for VCs in a Normalized Future

Based on their accumulated experience with VCs, participating GPs estimated that on average, 19% of all their consultations (median 20%) could be conducted via video in a normalized, nonpandemic future. Further analyses showed that this estimate was not associated with the GP's geographic context, previous experience with VCs, age, or gender.

Discussion

Principal Findings

This online, cross-sectional survey conducted among GPs in Norway during the COVID-19 pandemic lockdown provides new knowledge about GPs' experiences with large-scale uptake of VCs within the context of an established national primary health care system. Data collection took place in a phase of the lockdown when infection rates had peaked and most GPs had adapted their working practices, including implementation of VCs, to the pandemic circumstances.

Overall, VCs were perceived as equally or even more suitable than face-to-face consultations in about half of the 3484 evaluated cases. VCs appeared significantly more appropriate in the context of an established doctor-patient relationship and in relation to a previously defined reason for contact. GPs expressed concern about immediate patient safety (ie, the risk of missing signs of serious disease) in 15% (514/3476) of the evaluated cases.

Validating the Concept of Suitability

Most of the survey was developed around the perceived suitability of VCs in general practice, compared to ordinary face-to-face consultations. It was therefore essential to ensure that the participating GPs had a shared understanding of the concept of suitability. Face validity of the term was assessed when the survey was pilot tested and was found to be satisfactory. Moreover, GPs were instructed to evaluate the suitability of VCs without emphasis on the evident gain of reducing the risk of viral contamination. Furthermore, the analysis of the association between perceived suitability and actions taken in the VCs contributed to the validation of the

suitability concept. Consultations categorized with low suitability for VCs often had an "unfinished" character, thus requiring further clinical investigations and/or referrals that could have been more effectively managed in an ordinary face-to-face consultation (Figure 4).

Impact of Continuity of Care on the Perceived Suitability of VCs

A central finding in this survey was a strong and consistent association between both relational and episodic continuity of care and GPs' perceptions of the suitability of VCs (Figures 1 and 2, Tables 3 and 4). When GPs knew the patients very well beforehand, VCs were considered equally or better suited than face-to-face consultations in 57% (1011/1785) of cases, as opposed to 32% (87/274) when the patient was previously unknown. Moreover, the suitability rate for follow-up consultations was 61% (1165/1919), while for new problems it was 35% (544/1556). It is important to note that these findings arose within the Norwegian GP list system and that the patient was totally new to the GP in only 8% (276/3484) of the evaluated VCs. To our knowledge, our study presents the first large-scale analysis of the impact of continuity of care on GPs' perceptions regarding the clinical suitability of VCs. It remains to be seen whether the quantifiable, beneficial outcomes of continuity of care found in physical consultation settings can be replicated in relation to VCs. Beyond this question, our results are in good accordance with previous findings, deliberations, and recommendations regarding quality potentials and pitfalls related to VCs [10,21,25,26].

Suitability of VCs for Specific Contact Reasons

The predefined list of medical issues used to categorize the main contact reason (presented problem) for each evaluated VC was developed for the purpose of this survey to provide a clinically relevant overview while being general enough to safeguard patient anonymity. We acknowledge that the opportunity to categorize only one (perceived by the GP as the main) reason for contact underrates the clinical complexity of the evaluated VCs, as many of them dealt with two or more health problems (Table 2). In our VC material, mental problems and life stress, musculoskeletal disorders, and COVID-19–related contacts occurred most frequently. When most countries in Europe imposed a lockdown in March 2020, VCs were predicted to be potentially useful for consulting about COVID-19 for people with heightened anxiety, mild symptoms suggestive of COVID-19, or more severe symptoms [13]. The results from our survey confirm these predictions.

Moreover, under the given circumstances, we found that VCs were suitable for a variety of mental health problems, along with other chronic or complex issues such as chronic pain, tiredness, sleeping problems, follow-up of established cancer treatment, and administrative purposes (Figure 3). These results are also in line with previous expectations that VCs could replace in-person visits for contacts related to chronic disease reviews, counselling, or other talking therapies, or administrative appointments such as sick leave certificates [13,27]. Chronic and complex problems are prevalent in general practice and typically involve several consultations with the GP over time [28]. In the presence of continuity of care, such problems can typically be handled in a collaborative dialogical process between doctor and patient. Further research might elucidate to what extent effective clinical relationships can be established and maintained through VCs.

Contacts related to skin problems, pediatric issues, and acute and potentially severe health problems (such as abdominal pain, chest pain, and respiratory difficulties) were found to be the least suitable for VCs. Real-time video might be a feasible alternative to face-to-face and store-and-forward (asynchronous) consultations for selected skin issues [29,30]. However, the evidence regarding the diagnostic accuracy of VCs is still weak [30]. Particular caution must be shown in situations where patient safety might be at risk, including the evaluation of potential malignancy [29-31]. Figure 3 provides an informative overall overview of GPs' perceived suitability of VCs for various contact reasons, but there is a clear need for more research to refine the knowledge about suitability for VCs in a normalized setting.

Our material included only 23 cases where the main problem was categorized as "geriatric," and the majority of these cases were classified with low suitability for VC. This aligns well with previous concerns that VCs may not be suitable for use by frail, older patients [8]. Overall, we believe that our results regarding clinical suitability are in good accordance with previous research and recommendations for VCs [13,26], as well as with a recent paper on the interpretative and contextualized nature of diagnostic "knowing" in general practice [32].

Characteristics of the GPs

Our study participants constitute approximately 26% (1237/4822) of all registered GPs in Norway. Their demographic characteristics are well representative of the GP population in Norway, with the exception of a slightly higher representation of younger doctors [24]. Since the survey was distributed through a unique link to each respondent, multiple responses from the same source can be ruled out.

Before deciding to participate in the survey, invited GPs were informed that VCs would be a central topic, but not a prerequisite for participation. This may nonetheless have attracted GPs with a positive attitude toward digital solutions. As mentioned in the introduction, many GPs who acquired VC equipment in relation to the pandemic lockdown hardly used it in practice. As previously argued, the implementation of VCs is not mainly a simple question of equipment installation, but a complex process of integrating a new consultation modality into established working routines [33]. As explained in the introduction, our estimates suggest that almost 50% of Norwegian GPs who used VCs in April 2020 participated in this survey, which is a clear strength.

Selection Mechanisms Behind the Evaluated VCs

On average, each participating GP performed five VCs on the day of the survey, while typically evaluating three of these. The survey instructed the GPs not to purposefully select particular types of VCs for evaluation. Although we cannot rule out possible selection bias, it is unlikely that GPs would deliberately

restrict their contribution to specific cases. The risk of substantial confirmation bias is therefore considered low.

However, other important selection mechanisms may have influenced our VC material. The study was undertaken in a lockdown period when patients were typically recommended to consult their GPs digitally or by phone before a physical consultation could be considered. In some GP offices, patients could book a VC directly through an online booking system. Beyond this, there were no formal guidelines on how to select patients for VCs. Irrespective of variations in booking systems, many GP offices would arrange physical consultations for selected urgent health problems. Nevertheless, our material includes numerous cases that would normally be considered poorly suited for VC (eg, acute abdomen and chest pain). This aligns well with the fact that participating GPs relatively often reported that they missed the opportunity to perform a physical examination (61% of cases) or expressed concern that they might have misjudged the severity of the presented health problem (15% of cases). Our results cannot be generalized to the use of VCs under nonpandemic circumstances, but we believe they have substantial external validity.

Current Status and Future Perspectives

The COVID-19 pandemic has led to a crisis for many people and organizations worldwide. At the same time, it has offered opportunities to rethink what is important in general practice and really put new consultation modalities to the test [34]. Overall, our study indicates that VCs have a definite role in future general practice. A crucial question is how to apply VCs to appropriate purposes in an organizationally sustainable manner. On the positive side, VCs can facilitate access and provide rapid solutions in well-selected situations. They can also enhance access to care for disadvantaged or vulnerable patients who are digitally literate but reluctant to visit the GP office. On the flip side, too liberal a use of digital consultations may contribute to a more transactional and less relational way of dealing with deeply human issues, potentially undermining the health-promoting potential of person-centered, longitudinal care [17,25]. Furthermore, it is important to monitor the impact of the implementation of digital consultation modalities on the total clinical workload [35,36]. Patients' thresholds for contacting the GP for self-limiting conditions may decrease when digital options are easily accessible. Ineffective selection of cases for VCs might trigger physical follow-up consultations for the same problem, leading to increased workloads without associated clinical benefit.

In our study, GPs experienced technical difficulties in 10% of the consultations, somewhat less than a comparable study performed in New York City in March 2020, where technical problems were reported in 13% of consultations [37]. This indicates that more seamless integration of VCs with GPs' electronic record systems still remains a priority. Despite some technical challenges, the GPs reported that 85% of the patients seemed satisfied with the VCs, in accordance with existing knowledge on patient experience with VCs [9,37,38]. In about half the consultations, the GPs in our survey also deemed it realistic to handle a similar issue by VC in a future, normalized situation. At first glance, this might reflect a strong belief in digitalized health care. However, our findings emerged in an extraordinary setting, where many patients and GPs reportedly felt gratitude for being able to "see" each other at all, despite the ominous threat of contagion and dramatic lockdown measures.

Comparison of clinical practice during lockdown with practice-as-usual reveals numerous discrepancies, both obvious and subtle [39]. Experience-based insight into these differences and their impact on the effectiveness and quality of care is likely to explain why the typical GP in our survey envisaged conducting only about 20% of consultations by video in a normalized future. This prediction is substantially lower than the level of enthusiasm otherwise reflected in our material but would nevertheless represent an important organizational leap for Norwegian general practice as a whole.

Conclusion

Our study of VCs performed in Norwegian general practice during the pandemic lockdown indicates a future role for VCs in future, nonpandemic settings. The strong and consistent association between continuity of care and GPs' perceptions of the suitability of VCs is a new and important finding with considerable relevance for future primary health care planning. In accordance with existing literature and guidance, GPs' perceived suitability of VCs varied considerably across reasons for contact and presented health problems. The findings cannot be directly generalized beyond the specific context of the pandemic lockdown, but nevertheless provide interesting results regarding the performance of VCs for different reasons for contact and clinical conditions. The results indicate that GPs still consider the physical examination a crucial element of many consultations to enhance both diagnostic accuracy and quality of care in a wider sense. Reflecting on the accumulated experience with VCs, most participating GPs envisaged conducting 20% of their consultations by video in a future, nonpandemic setting.

Acknowledgments

After the survey was conducted, TMJ and BLN held part-time positions at the Norwegian Centre for E-health Research in Tromsø, Norway. FLO 2.0 (a GP-driven, nonprofit organization dedicated to the sustainable development of Norwegian general practice) covered the license to Netigate.

Norwegian Health Informatics made a crucial contribution with the dispatch of the survey through their subscriber email list and website. The Norwegian Directorate of eHealth and Confrere provided background data on video consultations.

Authors' Contributions

TMJ and NLB developed the survey together with LG, FHK, and BA. EK and PZ subsequently joined the team and contributed substantially to data analysis, interpretation of results, and writing, together with the rest of the authors.

Conflicts of Interest

The authors declare no conflicts of interests. The commercial actors who distributed the survey (Norwegian Health Informatics) and contributed information on the use of VCs in Norway in spring 2020 (Confrere) were at no point involved in the design of the survey or data analysis.

Abstract

Background: Many countries across the globe have released their own COVID-19 contact tracing apps. This has resulted in the proliferation of several apps that used a variety of technologies. With the absence of a standardized approach used by the authorities, policy makers, and developers, many of these apps were unique. Therefore, they varied by function and the underlying technology used for contact tracing and infection reporting.

Objective: The goal of this study was to analyze most of the COVID-19 contact tracing apps in use today. Beyond investigating the privacy features, design, and implications of these apps, this research examined the underlying technologies used in contact tracing apps. It also attempted to provide some insights into their level of penetration and to gauge their public reception. This research also investigated the data collection, reporting, retention, and destruction procedures used by each of the apps under review.

Methods: This research study evaluated 13 apps corresponding to 10 countries based on the underlying technology used. The inclusion criteria ensured that most COVID-19-declared epicenters (ie, countries) were included in the sample, such as Italy. The evaluated apps also included countries that did relatively well in controlling the outbreak of COVID-19, such as Singapore. Informational and unofficial contact tracing apps were excluded from this study. A total of 30,000 reviews corresponding to the 13 apps were scraped from app store webpages and analyzed.

Results: This study identified seven distinct technologies used by COVID-19 tracing apps and 13 distinct apps. The United States was reported to have released the most contact tracing apps, followed by Italy. Bluetooth was the most frequently used underlying technology, employed by seven apps, whereas three apps used GPS. The Norwegian, Singaporean, Georgian, and New Zealand apps were among those that collected the most personal information from users, whereas some apps, such as the Swiss app and the Italian (Immuni) app, did not collect any user information. The observed minimum amount of time implemented for most of the apps with regard to data destruction was 14 days, while the Georgian app retained records for 3 years. No significant battery drainage issue was reported for most of the apps. Interestingly, only about 2% of the reviewers expressed concerns about their privacy across all apps. The number and frequency of technical issues reported on the Apple App Store were significantly more than those reported on Google Play; the highest was with the New Zealand app, with 27% of the reviewers reporting technical difficulties (ie, 10% out of 27% scraped reviews reported that the app did not work). The Norwegian, Swiss, and US (PathCheck) apps had the least reported technical issues, sitting at just below 10%. In terms of usability, many apps, such as those from Singapore, Australia, and Switzerland, did not provide the users with an option to sign out from their apps.

Conclusions: This article highlighted the fact that COVID-19 contact tracing apps are still facing many obstacles toward their widespread and public acceptance. The main challenges are related to the technical, usability, and privacy issues or to the requirements reported by some users.

Introduction

Overview

The COVID-19 pandemic, the virus of which causes a highly contagious respiratory infection, has spread rapidly across the world and surpassed 20 million cases by early August 2020 [1]. The economic impact of the pandemic is felt globally with many countries slipping into recession. The COVID-19 pandemic is also turning into a job crisis, which is threatening to dismantle several industries, from aviation and manufacturing to services, tourism, and agriculture [2].

The global public health and government responses to the pandemic have been fragmented due to the urgency of actions required as a result of the stochastic spread of the virus. Some countries are implementing policies to eradicate the virus, such as Vietnam and New Zealand [3]; some countries are trying to suppress and contain the spread of the virus, such as Australia [4]; and some countries are relying on building herd immunity, such as Sweden [5]. Nonetheless, the virus continues to spread arbitrarily between regions and countries, and the epicenter of the pandemic has been moving between continents. It started with China and moved to Italy, Spain, the United States, and Brazil, with India as the next in line. Several other countries are now experiencing a second wave after initially suppressing it, with clusters of new cases popping up in many countries [6].

The speed of the authorities' response has also proven to be a major key in containing the spread of the virus. For instance, many experts weighed in on the relatively slow response of Italy to contain the virus [7] and the fast response of South Korea in suppressing it [8]. Despite the variations in the worldwide governmental crisis responses to the pandemic and the lack of clear and uniform advice on matters as simple as the role of a mask in containing the spread of the virus [9], the measures and policies used worldwide to contain the virus remained mostly precautionary in the absence of a vaccine or a treatment. Consequently, the direct safety advice as a result of the COVID-19 pandemic continues to be about maintaining good hand hygiene, practicing social distancing between people, testing as soon as virus symptoms appear, quarantining, and, importantly, contact tracing.

Contact tracing is the process of identifying, assessing, and managing people who have been exposed to a disease to prevent onward transmission [10]. Until a COVID-19 vaccine is commercially available to the public, contact tracing tools are vital in breaking the chains of transmission of the virus. This means identifying infected people and their close contacts, testing them, and isolating them for 14 days from day zero of the exposure. For countries that managed to control the exponential growth of the virus, known as flattening the curve, extensive contact tracing was essential in minimizing large-scale community transmissions. With countries recently coming out of lockdown and opening their economies and borders again, such as France and the United States, contact tracing is the key to rapidly identifying new cases; hence, maintaining low levels of community transmissions to remain successful in containing the outbreak of the virus. Thus, in addition to comprehensive testing capacity, contact tracing is increasingly becoming important in managing this pandemic until a vaccine or a reliable viral treatment is successful and made publicly available.

For contact tracing to be beneficial in preventing onward transmission, and thereby reducing the impact of a second wave of a contagious disease such as COVID-19, it should be implemented systematically. This means having a system to securely collect, compile, and analyze data about individuals in real time, while not impinging on their privacy. As with the lack of a uniform and standardized global response to the pandemic, contact tracing technologies and approaches adopted by several countries were also diverse. For instance, on the same day in which Canada announced that they were working on a new contact tracing app [11], the United Kingdom was abandoning their contact tracing app, stating that the technology does not work [12].

Background

Contact tracing using a mobile app relies on the concept of proximity tracking. The concept behind contact tracing is to identify and keep a record of people who may have been in close proximity (eg, typically less than 1.5 meters) to other people. Therefore, once an individual is identified to be infected with COVID-19, the app will be used to retrieve and trace the other close contacts. There have been various implementations for contact tracing apps, and a range of technologies, security, and privacy approaches have been adopted across the globe. Notably, the effectiveness of these contact tracing technologies remains to be seen. More evidence is required to demonstrate whether these tools were successful in contact tracing and to determine their usefulness.

Before the COVID-19 pandemic, a range of digital and mobile health tools had been utilized for the purposes of infectious disease control and public health interventions. Aba et al [13] illustrated the variety of functionalities provided by mobile apps to mitigate the spread of the Ebola virus in Africa, ranging from contract tracing to surveillance to case management. Mobile apps have also had a similar range of success in the use of public health interventions mitigating the spread of tuberculosis in Botswana [14].

The current contact tracing apps for COVID-19, which have been widely used by several countries, mostly use Bluetooth as the underlying technology for proximity sensing. In an effort to contribute toward having a unified solution for contact tracing and to counter the limitations of using Bluetooth on the iOS platform [15], Apple and Google have also recently released a new framework to support contact tracing [16]. However, apps that implement this framework have not matured enough yet. Nonetheless, surveying the current apps in use; analyzing their privacy features, penetration, and intake; and measuring their reception by the public, including the ensuing issues faced, have not been fully explored. This is demonstrated in a survey of the prior literature, which is presented in Table S1 from Multimedia Appendix 1. We briefly summarize a review of the main studies from the literature below.

The user acceptability of contact tracing apps in five countries hit by the pandemic using a survey were investigated in Altmann et al [17]; however, the study did not review specific contact tracing apps. Similarly, several studies [18-22] did not review current COVID-19 apps through direct access of app stores. For instance, the work reported in Anglemyer et al [18] did a meta-analysis on medical databases to review contact tracing apps. Others used various methodologies to conduct their reviews.

Other works, such as the one reported in Collado-Borrell at al [23], attempted to identify smartphone apps that aimed to address the COVID-19 pandemic and analyzed their characteristics. However, the study did not investigate any specific app. It only classified the apps under specific categories, such as health, fitness, or medicine. The main security and data protection aspects relating to digital contact tracing frameworks and apps were also investigated in Martin at al [24]; the paper analyzed some of the privacy aspects, such as personal information access, data retention, and location tracking. The paper also highlighted some of the app's public penetration; however, the study was only limited to apps from Google Play.

An overview of mobile apps being currently used for COVID-19 and their assessment using the Mobile Application Rating Scale was reported in Davalbhakta et al [25]. This study was limited only to India, the United States, and the United Kingdom. Other works, such as the one reported in Vaudena [26], studied Bluetooth-based contact tracing solutions, including Decentralized Privacy-Preserving Proximity Tracing (DP-3T) and Temporary Contact Numbers (TCN) protocols, from a centralized versus decentralized point of view. As such, the vulnerabilities and the advantages of both solutions were systematically reviewed. The work focused more on the underlying architecture used and the level of privacy protection each one presented; however, it did not review specific implementations of COVID-19 apps. Only a few apps were used to represent the centralized and decentralized approaches.

The work in Magklaras and Bojorquez [22] surveyed the data regulations and technology protocols relating to COVID-19 contact tracing apps. It also provided mapping for the global deployment of the COVID-19 contact tracing apps. The paper also discussed the challenges, including some privacy aspects, relating to Bluetooth-based contact tracking technologies. The work reported in Li and Guo [27] provided an in-depth review of COVID-19 tracing app technologies and processes, including app installation and registrations, encounter data processing and communication, and notifications. The paper also analyzed the security aspects of contact tracing app architectures (ie, centralized, decentralized, and hybrid) by assessing their risk against common security attacks, such as denial of service and carryover attacks. This paper as well as an additional review paper [28] discussed some users' common concerns, but it did not qualitatively analyze any users' reviews.

Study Aims

To this end, the work presented in this paper reviews and evaluates most categories of COVID-19 contact tracing mobile apps in use today. To our knowledge, this is the first research study that primarily investigated the public's and users' perceptions of COVID-19 contact tracing apps. This study also aimed at studying the privacy feature implementations and the level of penetration these apps achieved. In extension to the first aim, we aimed to determine the outreach of the collated apps in terms of number of downloads, as reported not only by the app stores but also by the authorities of each of the apps' corresponding countries. This is in addition to providing a quantitative overview of the common complaints suggested by app users in connection to privacy, battery drainage, technical difficulties, bugs, crashes, and more. Additionally, in relation to the second aim, the underlying apps' architecture and associated aspects, such as how the communication or handshake between two devices in proximity took place and then how close contacts were reported, were also analyzed. We also investigated the timeline of when these apps were introduced. Lastly, extending from the third aim, we attempted to understand the nature, type, and extent of data capture of the apps, such as granularity of data that was captured (ie, location, identification, and accomplices), duration of data retention, option to discard and delete records, and whether opt-out options were provided to the user without uninstalling the app.

Methods

Selection of Apps, User Intake, and Penetration

This study classified contact tracing apps based on the type of technology used for contact tracing of infected masses. This study identified six distinct technologies and an additional category commonly used or incorporated into COVID-19 tracing apps. These included Bluetooth, the DP-3T protocol, GPS, Pan-European Privacy-Preserving Proximity Tracing (PEPP-PT), the TCN protocol, Google and Apple, and other technologies, mainly the use of Quick Response (QR) codes paired with a digital diary. These technologies are outlined in Table S2 from Multimedia Appendix 1.

The classification criteria considered the underlying technology used by the apps rather than classifying the apps based on geographical or other architectural features. This is because most of the apps in use today use Bluetooth. Therefore, classifying the apps based on the underlying technology ensures that the research is capturing most contact tracing solutions in use. For instance, contact tracing solutions used by Singapore, Australia, and Malaysia use the same technology (ie, BlueTrace).

As such, there is little benefit to the research from surveying all three of these apps.

Therefore, the research evaluated 13 apps corresponding to 10 countries and covered all the contact tracing technologies identified above. All apps were free to download. The inclusion criteria also ensured that most of the COVID-19-declared epicenters (ie, countries) were included in the sample, such as Italy and the United States. The evaluated apps also included countries that did relatively well in controlling the outbreak of COVID-19, such as Singapore; countries that had a low daily number of new infections (ie, Australia); and countries that had a medium-level daily number of new infections (ie, Pakistan). The Swiss app was included in this study, as Switzerland was among the few countries that did not implement a lockdown. Similarly, the Swedish app was also included, given Sweden's unique approach to building herd immunity to combat COVID-19. Informational apps or unofficial contact tracing apps were excluded from this study, except for South Korea's Corona 100m app, which uses GPS technology for contact tracing. This app was included because Corona 100m was among the first major contact tracing apps that launched across the globe and because South Korea is one of the few countries that managed to quickly suppress the transmission of the virus. Figure 1 shows the apps that were included in this study.

Figure 1. The 13 apps corresponding to 10 countries included in this study. DP-3T: Decentralized Privacy-Preserving Proximity Tracing; PEPP-PT: Pan-European Privacy-Preserving Proximity Tracing; QR: Quick Response.

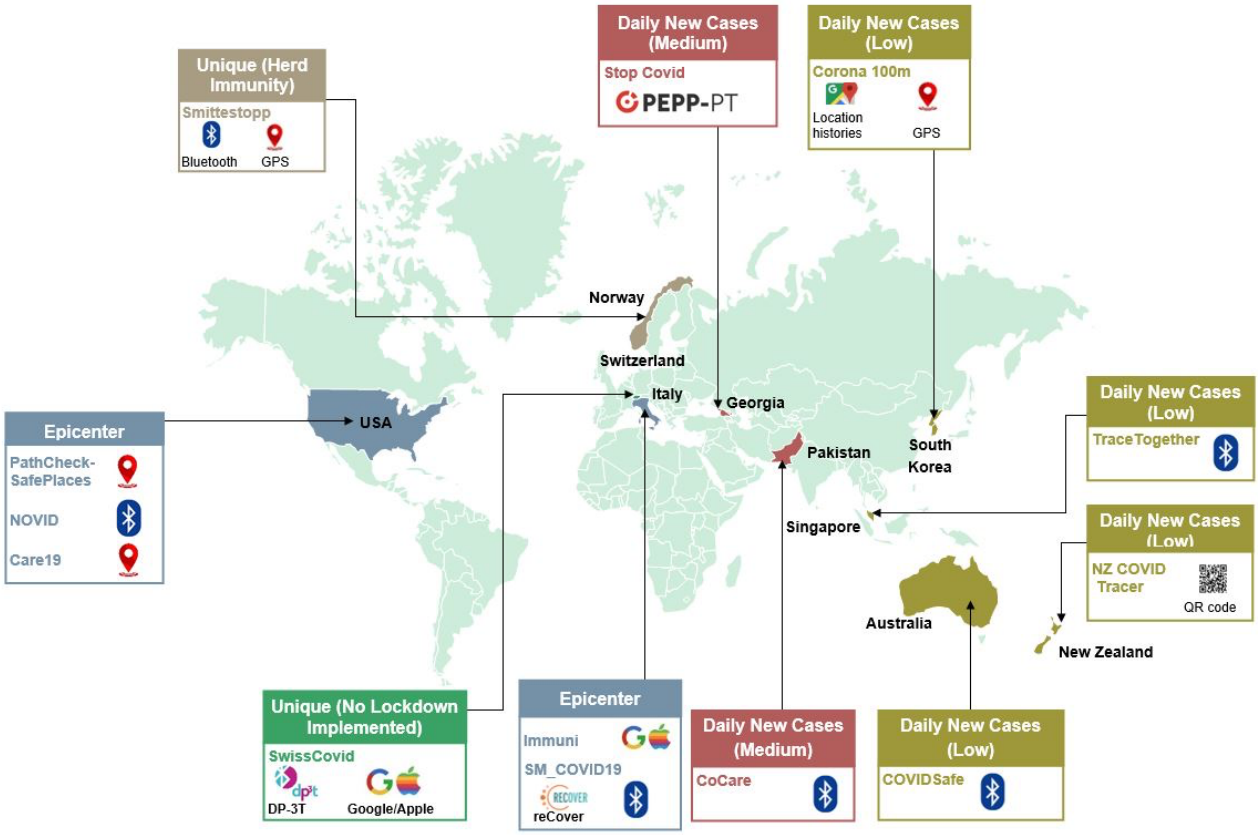

Table 1 details the architecture and approaches used by each of these technologies; these are as follows:

1. Country: For each type of technology used, a sample of countries that use this technology and their contact tracing apps are provided. Where there is more than one app used in a country, the name of the corresponding app is provided. It is worth noting that this is not a comprehensive list. The aim is to evaluate some of the countries for the purpose of adding context to the data presented in the table rather than creating an inventory of apps. The next section provides more details on the selection and inclusion criteria of the apps evaluated in this study.
2. Architecture: This criterion investigates whether or not the technology used by the contact tracing app incorporates the concept of uploading contact logs to a central reporting server. The criteria used are *centralized*, *semicentralized*, and *decentralized*. It has proven difficult to exclusively classify the architecture of each of these technologies, as implementations varied from one app to another. For instance, some apps uploaded contact logs to a central server, but the server did not have access to the uploaded contact logs, nor was it responsible for any further contact tracing processing, while others had access. As such, this criterion should be read in conjunction with the other criteria presented in Table 1, mainly the *encounter handshake* and *infection reporting* criteria.
3. Encounter handshake: This refers to how two devices coming into close contact perform a handshake (ie, exchange identification data). Most of the technologies surveyed exchanged some form of a temporary ID, while others exchanged some form of a unique identifier that was either encrypted or in plain text, which also depended on the specific implementation of each of the apps.

4. Infection reporting. This refers to how the contact log is reported to the central server and the role of this server in contact tracing. Most of the apps relied on the users to upload the contact logs. Implementations varied as well based on whether the health authorities had access to the contact logs or not.
5. Privacy by design. As the name suggests, this criterion explored whether the technology embedded any privacy considerations into its design specifications.

To analyze the users' intake of each of the 13 apps under review and the penetration by these apps, this study extracted the following data for each of the apps: the name and country where the app was launched, the number of installs as per Google Play and as reported by the local news in the home country of the app, the penetration percentage as per Google Play installs and as reported by local news sources, and the launch date of each of the apps.

The number of installs were not only sourced from Google Play but also from local news outlets from the home country of each of the corresponding apps. The penetration percentages sourced from Google Play and the ones extracted from local news sources were calculated by dividing the total number of installs by the total population of the home country.

Table 1. The technologies of the contact tracing apps and their salient features.

App information	App technology						
	Bluetooth	DP-3T[a]	GPS	PEPP-PT[b]	TCN[c]	Google and Apple	Others
Example countries[d]	Australia; Singapore; Malaysia (MyTrace)	Austria; Finland; The Netherlands	Iceland (Ranking C-19); Italy (Diary); Jordan (Aman)	France; Georgia; Italy (Immuni)	Germany (ITO); Italy; The United States	Canada; Switzerland (SwissCovid); Germany (Corona-Warn-App)	New Zealand (digital diary); Australia, Canada, and New Zealand (GetHomeSafe); Malaysia (SELangkah)
Architecture	Centralized	Decentralized	Centralized	Centralized	Semicentralized	Decentralized	Centralized
Encounter handshake	Users exchange temporary IDs issued by the server	Unique 128-bit pseudorandom identifier by the server	Varies by implementation; some identify users by phone numbers	Users exchange temporary IDs issued by the server	TCN	Unique identifiers that are encrypted with a secret daily key held by the sending device	Real ID
Infection reporting	User-triggered upload	User-triggered upload, but the health authority never has access to contact log	User-triggered upload	User-triggered upload, but received massive privacy backlashes	The app notifies the user to potential infection	Not provisioned; delegated to app implementation	Varies by implementation; mostly user triggered
Privacy by design	No	Yes	No	No	Yes	Yes	No

[a]DP-3T: Decentralized Privacy-Preserving Proximity Tracing.

[b]PEPP-PT: Pan-European Privacy-Preserving Proximity Tracing.

[c]TCN: Temporary Contact Numbers.

[d]Where there was more than one app used in a country, the name of the corresponding app is provided within parentheses.

Investigating the Privacy-by-Design Features and Privacy Implementations of COVID-19 Contact Tracing Apps

This study expands on previous work [29] that compared the privacy aspects of the COVIDSafe app (Australia, Bluetooth) and the COVID Tracer app (New Zealand, QR code). Each of the selected apps was downloaded and evaluated thoroughly. The study first identified the underlying technology used for contact tracing by an app and the amount of personal information each app collected (ie, personal information access). To do that, the following scale was used: if an app was only collecting the name, email, and phone number of the user, then the scale was designated as *low*; if, in addition to this personal information, the app collected the age of the user, then the scale was designated as *medium*; and if an app collected the name, email, phone number, age, and any additional information, such as the address, ethnicity, or location via GPS of the user, then this criterion was rated as *high*.

Additionally, the study analyzed the location features and tracking capabilities for each of the apps. It investigated whether an app was tracking the movement of individuals or not (ie, location tracking). It also investigated whether the app under review knew the identity of the people in close proximity to the user or just their locations or IDs (ie, true identity vs temporary ID, such as with the TCN protocol). The criterion *tracking and identifying proxies* combined the *encounter handshake* and *infection reporting* features.

Furthermore, this study investigated the record-keeping time frame of each app. This was achieved by researching the duration that the contact logs were kept on the device or the authority's remote servers for each of the apps under review.

In terms of user control, this study examined two criteria: the user's right to forget and the geo-restrictions imposed on an app. The first criterion considered whether or not users were informed about the procedures to delete the records collected by an app. The opting-out criterion explored whether the users were able to sing in and out of the app under review. Lastly, for each app under review, the study investigated whether an app could be downloaded from anywhere or whether it was a home or region geo-restricted app (ie, geo-restriction). We referred to governments' media releases, white papers, and developers' announcements for the apps that were in testing phases or were not available on the Apple App Store or Google Play.

Analyzing the Public Reception of COVID-19 Contact Tracing Apps

We aimed to identify the audience uptake and users' feedback of the COVID-19 contact tracing apps under review. Data were sourced by scraping the publicly available user reviews from the Apple App Store and Google Play webpages for each of the apps. Scraping is a process or tool used to extract data from a website; in this case, reviews from Google and Apple stores. Almost 30,000 reviews were scraped and analyzed in this study. The user reviews of each of the corresponding apps were then filtered and analyzed using a brute-force keyword search methodology; this means extracting the user reviews that contained a specific keyword used in the search. Table 2 lists the keywords used in scraping the reviews. The methodology used for analyzing these reviews also accounted for the variations of each of the keywords, referred to as subkeywords. For instance, the results of scraping and analyzing certain subkeywords—*doesn't work*, *didn't work*, *not working*, *Doesn't work*, *Didn't work*, and *Not working*—were all counted toward the results of the main keyword *Malfunctioning*. In other words, the results reported under the keyword *Malfunctioning* are a concatenation of each of the individual results returned by its list of subkeywords.

Table 2. The keywords used in this study.

Keywords	Subkeywords
Drainage	drain; battery; Drain; Battery
Spyware	spy; spied; spyware; Spy; Spied; Spyware
Malfunctioning	doesn't work; didn't work; not working; Doesn't work; Didn't work; Not working
Crashes	crash; freeze; Crash; Freeze
Privacy concerns	privacy issue; privacy concern; location concern; tracking me; track me; tracking us; Privacy issue; Privacy concern; Location concern; Tracking me; Track me; Tracking us
Ineffective	useless; rubbish; garbage; Useless; Rubbish; Garbage
Bugs	bug; buggy; Bug; Buggy
Installation issues	can't install; doesn't install; couldn't install; Can't install; Doesn't install; Couldn't install
Incompatible	can't download; couldn't download; incompatible; Can't download; Couldn't download; Incompatible

Results

Selection of Apps, User Intake, and Penetration

In this section, we initially describe results on app penetration. A challenging aspect of sourcing the data reported in Table 3 [30-40] was encountered when calculating the intake of the apps under study. For instance, the number of downloads for an app does not represent the true value of the actual intake. Downloading an app does not necessarily mean the app is being used. Users may simply download the app and never use it or uninstall it. In addition, there were little data available on the number of uninstalls for each of the surveyed apps. Regardless of this limitation, the number of installations for an app was not available on the Apple App Store. This has made the task of calculating the uptake of an app even more complex.

Consequently, the research required access to a more precise estimate of the installation values as compared to what Google Play was showing. Therefore, apart from consulting Google Play's number of installs, the study referred to reliable news sources to obtain the total number of registrations or downloads for each of the apps under review. The news sources were mainly from government or developer announcements, verifiable local news sources, and published research (ie, white papers). Some of the statistical information, such as the download intakes and any data sourced from local news, was available as of early July 2020. As such, there might be a slight variation in the values presented in Table 3 as compared those at the time of the archiving of this paper. Some apps were new, so this local value was not readily available for those either. Another challenge this research study ran into was the unavailability of some of the apps on the Google Play Store. This is because they were discontinued or because they were still in demo or beta stages.

Table 3. Penetration and intake of the 13 selected contact tracing apps.

Country	App	No. of installs, n		Penetration, %		No. of days of the app's launch since patient zero[a], n
		Local news	Google Play Store[b]	Local news	Google Play Store[b]	
United States	PathCheck SafePlaces	N/A[c]	10,000	N/A	0.001	93
United States	NOVID	N/A	10,000	N/A	0.001	110
United States	Care19	33,000 [31]	10,000	0.01	0.001	76
Italy	Immuni	2,700,000 [32]	1,000,000	4.47	1.65	122
Italy	SM-COVID-19	52,000 [33]	50,000	0.09	0.08	73
Norway	Smittestopp	1,427,000 [34]	100,000	26.32	1.84	50
Singapore	TraceTogether	2,100,000 [35]	1,000,000	35.89	17.09	57
South Korea	Corona 100m	1,000,000 [36]	N/A	1.95	N/A	20
Pakistan	CoCare	N/A	500	N/A	0.001	108
Australia	COVIDSafe	6,130,000 [37]	1,000,000	24.03	3.92	91
New Zealand	NZ COVID Tracer	573,000 [38]	100,000	11.88	2.07	82
Switzerland	SwissCovid	1,600,000 [39]	500,000	18.48	5.78	90
Georgia	Stop Covid	100,000 [40]	100,000	2.51	N/A	50

[a]The first case in the country was reported on the Johns Hopkins Coronavirus Resource Center portal [30].

[b]All download values have been extracted from the app's webpage on Google Play.

[c]N/A: not applicable; data for apps were unavailable because the app was new, in the case of local news, or because it was discontinued or was still in demo or beta stages, in the case of the Google Play Store.

The results of this study show that South Korea was the first country to use a mobile app for contact tracing during the COVID-19 pandemic. The South Korean app, Corona 100m, was only introduced after 20 days from the first detected case of COVID-19 in South Korea. This was followed by Singapore, Norway, and Georgia, which introduced their apps around 50 days since patient zero. The United States, Italy, and Pakistan were slower, as they introduced their contact tracing app around the 100-day mark. As reported by local news, the Singaporean (36%) and Norwegian (26%) apps had the highest penetration intake, followed by the Australian and Swiss apps, which had around 20% penetration, and the New Zealand app, which achieved around 11% penetration. Interestingly, the Italian and US apps had the lowest penetration values. The penetration intake of the apps on the Android platform, which was calculated based on the Google Play–reported number of installs for each of the apps, showed that all apps under review, except for the Singaporean app, had very poor intake (<5%).

Furthermore, this research initially intended to calculate the success rate of each of the apps in contact tracing reporting. It also aimed to survey and compare the efficacy of the apps under review. However, this was challenged by the lack of any reliable relevant data available in relation to those aspects; thus, this part of the review had to be excluded. Therefore, it is unclear whether the early introduction of contact tracing apps has contributed toward their rapid public adoption or whether these apps have played a major role in the contact tracing efforts of COVID-19. Perhaps these apps have played some part in raising awareness among the public, as in the case of the Singaporean and Australian apps, which had higher penetration intake values and lower infection numbers comparatively. However, due to insufficient data, no conclusive results can be made on the correlation between the early introduction of a contact tracing app, its higher penetration intake, and the case where low number of COVID-19 transmissions were reported.

Investigating the Privacy-by-Design Features and Privacy Implementations of COVID-19 Contact Tracing Apps

In the subsequent sections in this paper, when referring to an app, the following notation shall be used: app name (country of origin, technology used for contact tracing).

Table S3 from Multimedia Appendix 1 reviews the privacy features of the 13 apps evaluated in this study. Each of these apps was downloaded and evaluated thoroughly as per the criteria shown in Table S3 from Multimedia Appendix 1. The research also referred to white papers and developers' announcements for the apps that were in their testing phases or were not available or accessible on the Apple App Store and/or Google Play. The same methodology was followed for the apps that were not available in English, such as Immuni (Italy, Google and Apple application programming interface [API]) [41], SM-COVID-19 (Italy, ReCoVer) [42], and Smittestopp (Norway, Bluetooth and GPS) [43].

Nine of the apps were available for free on both the Apple App Store and Google Play. Two apps—SM-COVID-19 (Italy, Google and Apple) and CoCare (Pakistan, Bluetooth) [44]—were only available on Google Play, while Stop Covid (Georgia, PEPP-PT) [45] was only available on the Apple App

Store. The Corona 100m app (South Korea, location) [46] was not available on both stores. Smittestopp (Norway, Bluetooth and GPS) was not available to download due to geo-restrictions. The Australian COVIDSafe app required an Australian phone number and a postcode to run.

Bluetooth was the most frequently used underlying technology, employed by seven apps for digital contact tracing, whereas three apps performed contact tracing through location (eg, GPS). The apps using location as the underlying technology, namely Corona 100m (South Korea, location) and PathCheck SafePlaces (United States, location), tracked and recorded the locations visited by the users. Although Corona 100m (South Korea, location) was removed from Google Play, the app integrated GPS history, data from nationwide surveillance cameras, and credit card transactions. This has sparked privacy concerns, as users of the Corona 100m app could see the date when a COVID-19 patient was infected, along with his or her nationality, gender, age, and the locations they visited.

The Norwegian, Singaporean, Georgian [45], and New Zealand [47] apps were among the apps that collected the most personal information from the users, while some other apps, such as the Swiss app [48] and the Italian Immuni app, did not collect any user information. Other apps ranged from simply collecting users' phone numbers to additionally collecting their names or email addresses.

Data destruction was incorporated into most of the apps, which automatically deleted the users' records after 14 days, the observed minimum amount of time implemented in most of the apps. Some kept these records for 21 days (ie, Australia) and others for 30 days (ie, Switzerland and India); the New Zealand app kept them for 31 days, while the Georgian apps kept them for 3 years, the longest of any app.

Three of the US apps—PathCheck (United States, location) [49], NOVID (United States, Bluetooth radio waves and ultrasound) [50], and Care19 (United States, GPS) [51]—did not require users to sign up before using their app. On the other hand, many apps, such as the Singaporean TraceTogether app [52], the Australian COVIDSafe app [53], and the Swiss and Indian apps, did not provide the users with an option to sign out from their app. It is noteworthy to mention that the data presented in Table S3 of Multimedia Appendix 1 are accurate as of June 30, 2020.

Analyzing the Public Reception of COVID-19 Contact Tracing Apps

Figure 2 shows the percent occurrence for each of the keywords for each app. Figure 3 shows the average ratings of the reviews for each keyword. For example, consider if a user left a review for one of the apps saying, "the app keeps on crashing," and then gave it a rating of 2 stars. This review will then be counted toward the average mentions of the keyword *crashes* shown in Figure 2. The 2-star rating will also be counted toward the corresponding keyword average rating shown in Figure 3. All small values were rounded up to 0.001.

Figure 2. Percent occurrence of each keyword for each app. NA: not applicable; user reviews were unavailable, as the corresponding apps were not available on the corresponding platforms.

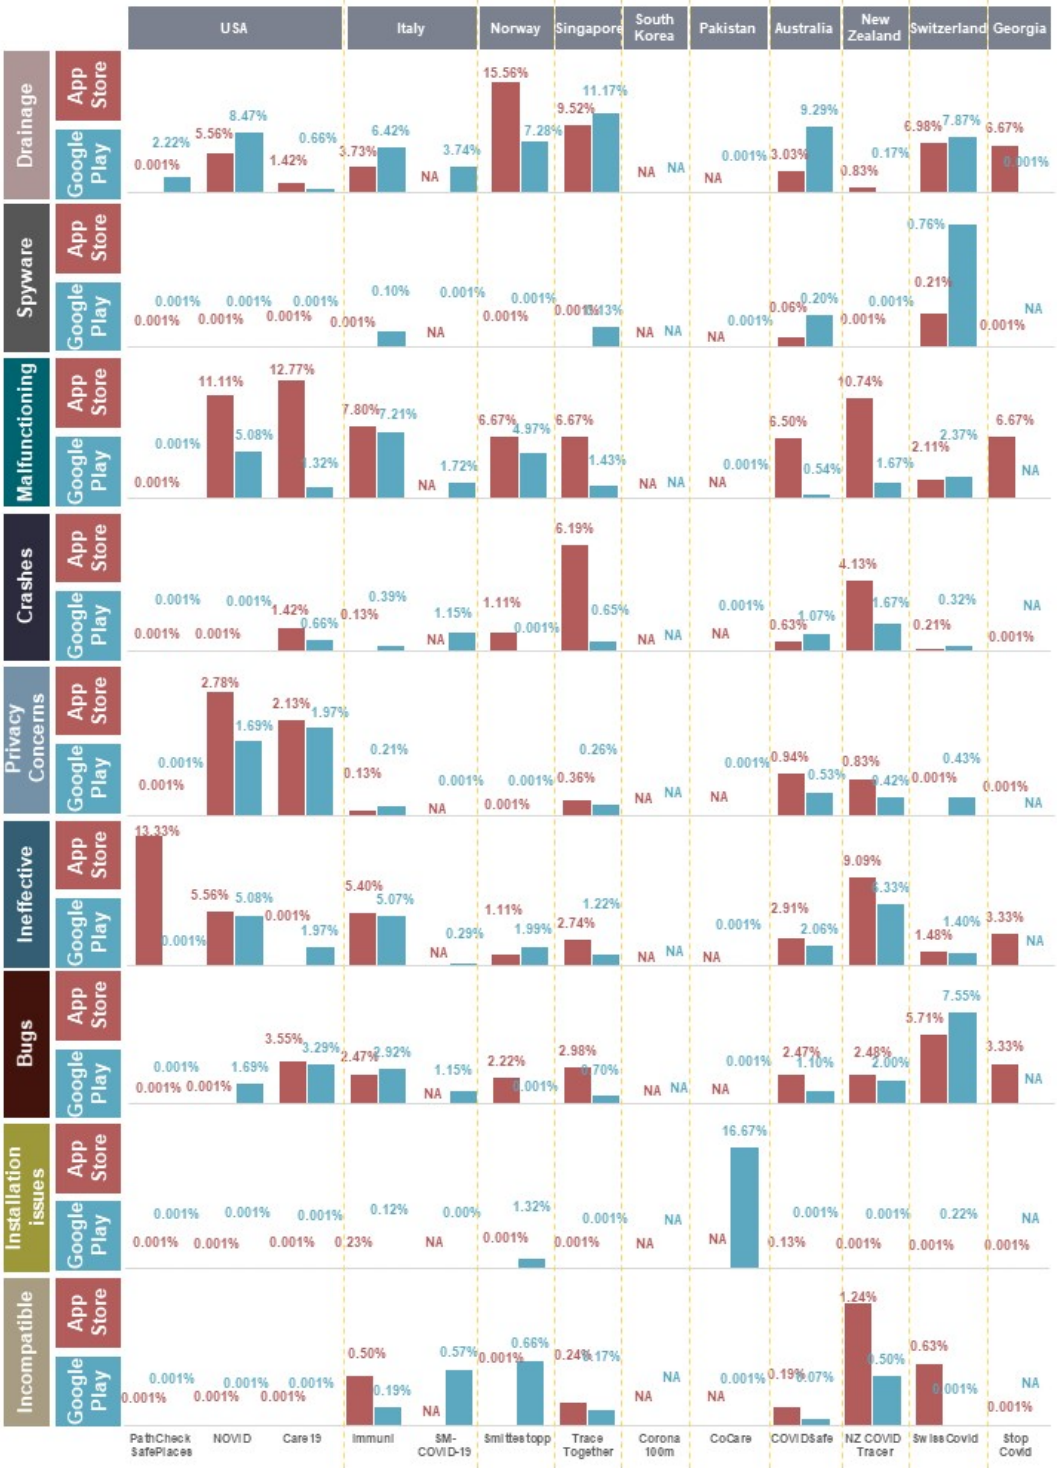

Figure 3. Average ratings out of 5 stars from user reviews in each category of each app on Google Play.

	Drainage	Spyware	Malfunctioning	Crashes	Privacy Concerns	Effective	Bugs	Installation	Incompatible
PathCheck SafePlaces	5	0.001	0.001	0.001	0.001	0.001	0.001	0.001	0.001
NOVID	3.2	0.001	2.333	0.001	5	2.667	5	0.001	0.001
Care19	2	0.001	1.5	1	1.667	1.333	1.8	0.001	0.001
Immuni	3.127	2.727	1.61	1.81	4.682	1.845	2.231	1.154	2.6
SM-COVID-19	2.846	0.001	2.333	2.5	0.001	5	3	0.001	3
Smittestopp	2.409	0.001	1.467	0.001	0.001	1.333	0.001	1	2
Trace Together	2.311	1	1.242	2.267	1.833	1.464	2	0.001	2.25
CoCare	0.001	0.001	0.001	0.001	0.001	0.001	0.001	1	0.001
COVIDSafe	2.751	1.571	2.289	1.8	4.108	1.257	2.338	0.001	2.6
NZ COVID Tracer	1.5	0.001	1.6	1.5	2.4	1.079	2.25	0.001	1

Three of the applications—CoCare (Pakistan, Bluetooth), SM-COVID-19 (Italy, ReCoVer), and Corona 100m (South Korea, location)—were not available on the Apple App Store, whereas two apps—the Corona 100m (South Korea, location) and Stop Covid (Georgia, PEPP-PT)—were not available on Google Play. Based on the frequency of keyword occurrences, *Drain*, *Malfunctioning*, and *Ineffective* were the most frequent issues reported by the users in their reviews.

On the Apple App Store, the keyword *rubbish* had a 13.33% occurrence for PathCheck SafePlaces (United States, location), 5.56% for NOVID (United States, Bluetooth), 5.40% for Immuni (Italy, Google and Apple API), and 9.09% for NZ COVID Tracer (New Zealand, digital diary). Similarly, many users did not find contact tracing apps functional. On the Apple App Store, many app users complained that their app did not work. This was represented by the keyword *Malfunctioning*, which had a 10.74% occurrence for NZ COVID Tracer (New Zealand, digital diary), 6.50% for COVIDSafe (Australia, Bluetooth), 6.67% for TraceTogether (Singapore, Bluetooth), 7.80% for Immuni (Italy, Google and Apple API), 11.11% for NOVID (United States, Bluetooth), and a sharp 12.77% occurrence for Care19 (United States, Apple and Google). Many users also had problems with the apps' compatibility with their operating system and frequent crashes. For instance, CoCare (Pakistan, Bluetooth) had a 16.67% occurrence for the incompatibility issue.

Interestingly, and as shown in Figure 4, no significant battery drainage issue had been reported for most of the reviewed apps. The privacy concerns reported by the users were also very minimal across all apps, as shown in Figure 5.

Figure 4. Percent occurrence of the keyword "drainage," pertaining to battery drainage.

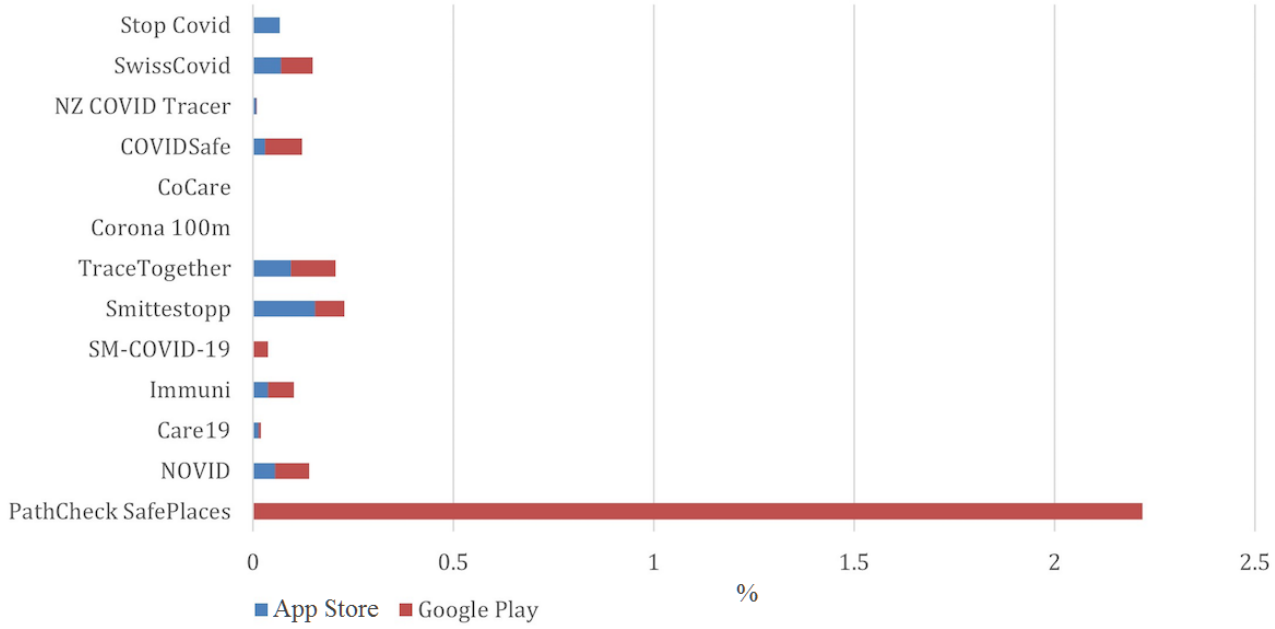

Figure 5. Percent occurrence of the keywords "privacy concerns" and "spyware".

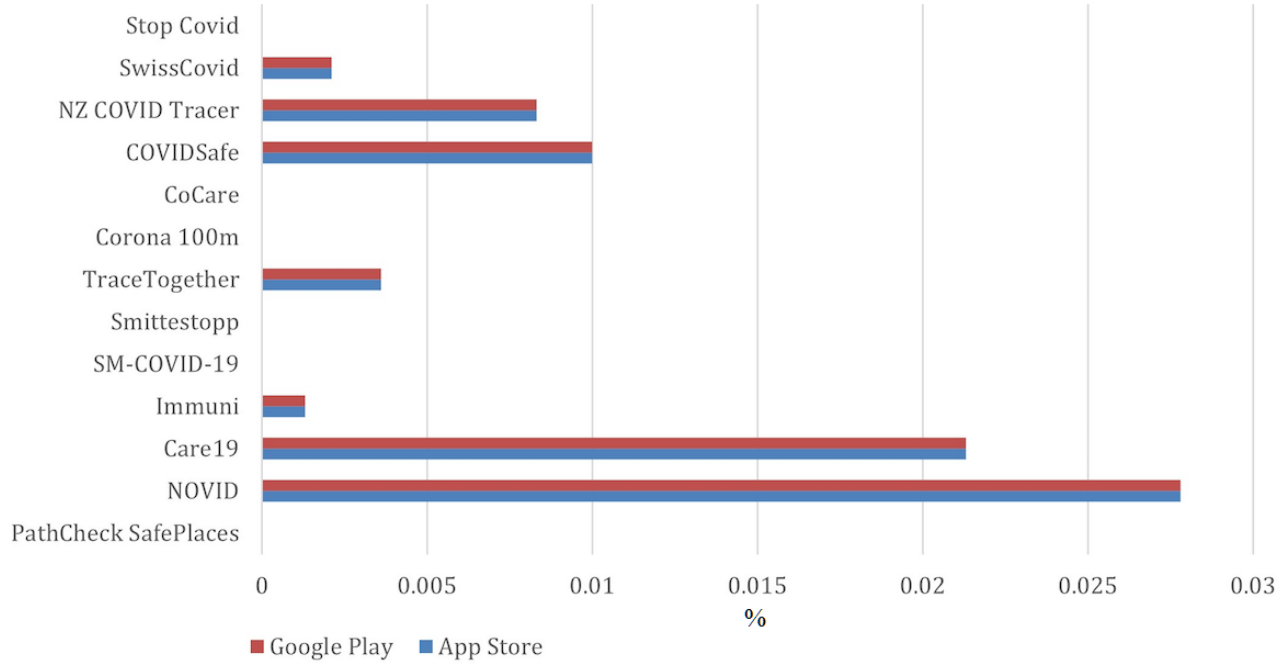

Figures 6 and 7 provide overall insights into the technical issues reported by the users for each of the apps. These figures combine the results of the following keywords, along with their respective subkeywords: *Malfunctioning, Crashes, Ineffective, Bugs, Installation issues, and Incompatible*. It is obvious that most apps on the Apple App Store had the most reported technical issues when compared to their Google Play counterparts, except for the Swiss contact tracing app. The US PathCheck app had the least reported technical issues on Google Play, while the New Zealand app version on the Apple App Store had the most technical issues that were complained about across all apps and platforms.

Figure 6. Summary of technical issues reported for each of the apps. The plot shows results from the combination of the following keywords, along with their respective subkeywords: "Malfunctioning," "Crashes," "Ineffective," "Bugs," "Installation issues," and "Incompatible".

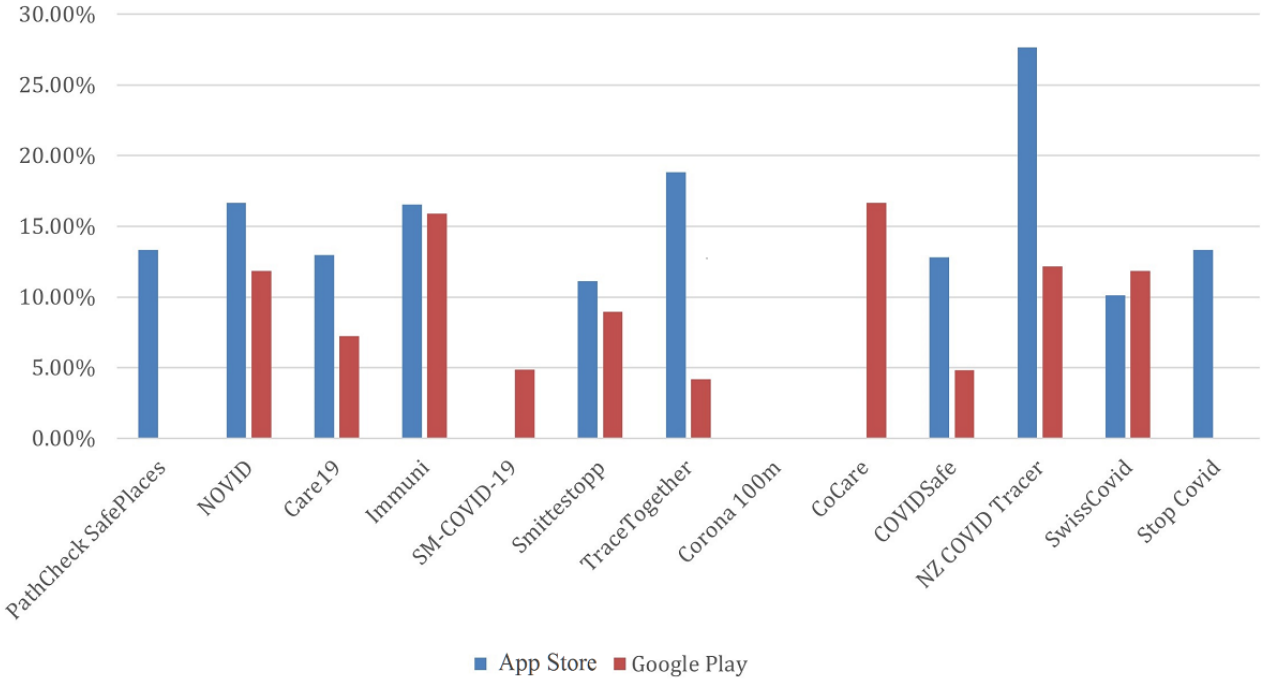

Figure 7. Comparison of user app reviews and their inclusion of various keywords.

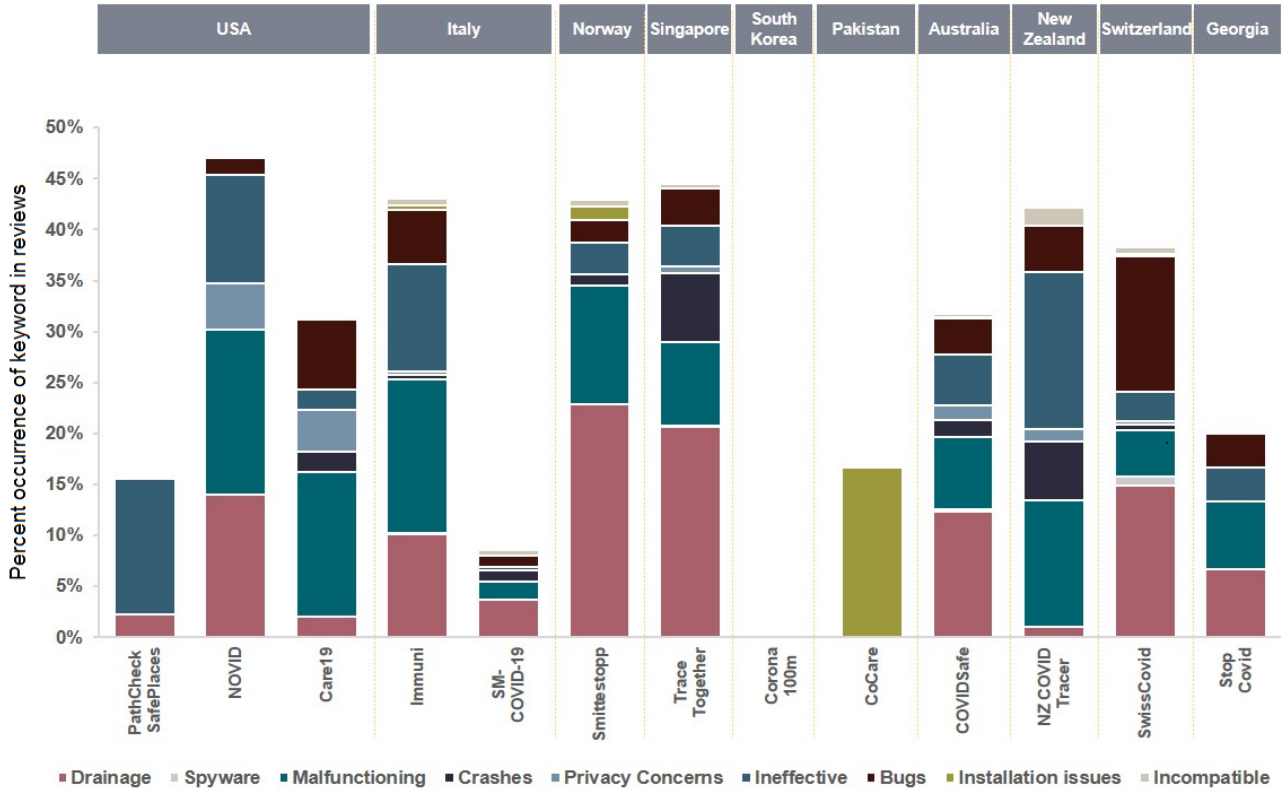

Discussion

Principal Findings

Our research study has highlighted the hindrances in the successful deployment of COVID-19 contact tracing apps. The use of mobile technologies for contact tracing has been met with a number of challenges [54], many of which also emerged in the contextual evaluation of user reviews on COVID-19 contact tracing apps as described in our study. Among these, the most popular were technical malfunctions and drainage of battery.

Other challenges included privacy. Of course, this is anticipated, as you cannot expect to trace and track peoples' movements by a government authority without addressing privacy issues [55].

Nonetheless, in addition to privacy, there were many other challenges and limitations hindering the anticipated efficacy from contact tracing apps.

For instance, a mobile contact tracing app needs to be widely adopted by a population for it to be of benefit; this is challenging to achieve. Penetration of COVID-19 contact tracing apps remains low despite governments pushing for mass use [56]. The widespread adoption of contact tracing apps requires that people would have access to a smartphone and, in most cases, access to a reliable internet connection. Hence, in countries with large populations, such as Pakistan [57], the smartphone penetration percentage sits at only 15%, and in Indonesia this value sits at only 31%. Users may also feel uncomfortable if there is no clear opt-out strategy [58]. Nearly half of the apps reviewed in our study did not provide a transparent withdrawal avenue.

Furthermore, the approaches used by contact tracing apps rely mostly on one single parameter (ie, proximity, such as via Bluetooth) [59]. However, proximity by itself is not enough to determine the risk of someone being exposed to the virus. There are a number of other parameters involved, such as being indoors or outdoors, being in a room with good air circulation or not, and the issue of surface infection exposure, irrespective of the proximity of an individual to an infected person. Furthermore, although as shown in our review that Bluetooth was one of the more popular technologies to implement contact tracing apps, every country's regulations may differ [60]; hence, a one-size-fits-all approach may be problematic.

Other challenges pertain to the limitations associated with the technology used for contact tracing. For instance, the use of GPS as a proximity technology is not reliable in indoor environments [61]. Determining the distance between two persons using Bluetooth technology also has its own set of challenges, such as signal strength attenuation caused by some environmental factors (eg, if the phone is placed inside a thick pocket or if the phone is at an angle facing a wall).

Nevertheless, contact tracing technologies surveyed in this work have been found to use a locationless tracking approach; that is, the app does not trace or record people's movements, obviously for privacy purposes. Therefore, most of these apps can only determine if two people were in proximity at a given time, but they do not keep a log of the users' movements. Consider, for example, if an infected person, labelled as Pi, is in a supermarket and Pi touches an item at time t–1 at a location designated as Li. Another person who is not infected, designated as Pn, is at a location designated as Ln. There is no proximity between Pi and Pn. Now assume Pi leaves the store at time t, when at the same time (ie, at t) person Pn moves from Ln to Li. There is a high chance that Pn is going to be infected if they touch the same item Pi touched at t–1 (ie, surface infection exposure). To be able to capture this exposure, contact tracing apps require the use of a location-oriented tracking approach in which the locations and movements of people are compared against each other to determine the overlapped and colluded locations. Future work will explore the use of our already well-established location obfuscation technique [62] in a contact tracing solution. The work will aim at providing a location-oriented contact tracing app without impinging on users' privacy.

Limitations

One of the challenges encountered in scraping the reviews was analyzing the apps that were not available in English. For example, most of the reviews for the Immuni app (Italy, Google and Apple), SM-COVID-19 (Italy, ReCoVer), and Smittestopp (Norway, Bluetooth and GPS) were available in the Italian and Norwegian languages, respectively. For these reviews, along with the rest of the app reviews that were in different languages, the keywords along with their subkeywords were translated into the language of their home app country. The results were incorporated when calculating the overall average values for all the apps. The translated keywords along with the subkeywords used can be found in Table S4 from Multimedia Appendix 1. Another limitation in our methodology for review scraping lies in the presence of false negatives in some of the reviews. This is one of the limitations of brute-force keyword search methodology. Take, for instance, one of the reviews for COVIDSafe (Australia, Bluetooth) on Google Play:

> *Installed from its release. Worked. No problems at all. It doesn't drain the battery. It doesn't crash. It's totally fine. I haven't been dragged into the back of a van, taken to an underground bunker and questioned by spies.*

The review is classified as a false negative for the words *drain* and *crash*. It can be debated that the number of false negatives could have been reduced by simply taking the *battery* subkeyword out from the keyword search (ie, battery; drain). However, in doing so, the number of 1-star reviews were significantly reduced by more than 50%. For instance, with NZ COVID Tracer (New Zealand, digital diary), the 1-star reviews dropped from 23 to 10 after taking the word *battery* out of the search filter. The reason behind this is that the users' reviews were not systematic. Most users represented their opinions in natural language. Some samples of 1-star reviews for COVIDSafe (Australia, Bluetooth) commenting on the app's drainage issue are as follows:

> *It is of no use whatsoever. A waste of money & a waste of my battery life.*
>
> *Battery went from 100% to zero in 5 hours with not much use. I usually get a full day out of it.*
>
> *Hard on the battery.*

Therefore, for the sake of including these comments, the subkeyword *battery* was not removed from the keyword search results.

This study has a number of additional limitations. This paper is based solely on 13 evaluated apps. While the selection criteria ensured that apps were selected to represent each of the categories of technology used for contact tracing, it did not review all COVID-19 contact tracing apps. Also, the study relied on data that were extracted and accurate as of July 2020. Another major limitation of this work relates to the penetration intake calculations done for each of the apps. The study derived the percent penetration for each app by dividing the number of installs of an app by the population of the home country. This

method suffers from several shortcomings. The number of downloads or installs cannot be precise; it ignores the fact that some users may install, uninstall, and reinstall the app several times or on more than one device owned by the user. A user may also download the app and never use it. Many users may not download an app yet may still post a review about it. For these reasons, the study attempted to gauge the penetration intake for each of the apps by analyzing the local government announcements and reports published by local news agencies. However, since the reported download values cannot be verified nor the methods used to derive them, the trustworthiness of these values also remains invalidated. Lastly, although the study evaluated about 30,000 user reviews, the reviews cannot not be verified.

Conclusions

While public health agencies attempt to understand the efficacy of nonpharmaceutical interventions [63], contact tracing has been a key part of the worldwide measure in response to the COVID-19 pandemic. For contact tracing to work effectively, solutions such as tracing apps should be implemented systematically. This requires the secure collection, processing, storage, and discarding of contact tracing information of people in real time, without impinging on their privacy and rights. The success of contact tracing apps greatly depends on their large uptake within a population, in addition to strong public health enforcement. This article highlighted the fact that COVID-19 contact tracing apps are still facing many obstacles toward their widespread and public acceptance.

The main challenges are related to the technical, usability, and privacy issues or requirements reported by some users. This meant that most tracing apps were not publicly well-received and had low penetration levels, which hinders their effectiveness. For instance, only the Singaporean app had a penetration of slightly over 30%, the Australian and Swiss apps achieved penetration just below 20%, and the penetration values reported for most of the other apps were very poor, sitting at below 5%. The amount of personal data collected by the apps varied widely, with some apps not collecting data at all and others collecting a significant amount of sensitive data about the user, such as their ethnicity. The majority of the surveyed apps did not provide the user with options to opt out from the apps, such as logging out, without uninstalling them.

The lack of a standardized contact tracing approach also meant that contact tracing apps used across the globe were fragmented and noninteroperable. As most countries are now coming out of lockdown and reopening their borders, there is an increased need for a cohesive, cross-border, and interoperable contact tracing app that can be used universally without impinging on users' privacy. Additionally, there is a lack of available data on the effectiveness of COVID-19 contact tracing apps. As we progressively recuperate from this pandemic, there is a need to re-evaluate and re-examine the values and roles of contact tracing apps in controlling infectious diseases such as COVID-19.

Conflicts of Interest

None declared.

Abstract

Background: As the number of COVID-19 cases increased precipitously in the United States, policy makers and health officials marshalled their pandemic responses. As the economic impacts multiplied, anecdotal reports noted the increased use of web-based crowdfunding to defray these costs.

Objective: We examined the web-based crowdfunding response in the early stage of the COVID-19 pandemic in the United States to understand the incidence of initiation of COVID-19–related campaigns and compare them to non–COVID-19–related campaigns.

Methods: On May 16, 2020, we extracted all available data available on US campaigns that contained narratives and were created between January 1 and May 10, 2020, on GoFundMe. We identified the subset of COVID-19–related campaigns using keywords relevant to the COVID-19 pandemic. We explored the incidence of COVID-19–related campaigns by geography, by category, and over time, and we compared the characteristics of the campaigns to those of non–COVID-19–related campaigns after March 11, when the pandemic was declared. We then used a natural language processing algorithm to cluster campaigns by narrative content using overlapping keywords.

Results: We found that there was a substantial increase in overall GoFundMe web-based crowdfunding campaigns in March, largely attributable to COVID-19–related campaigns. However, as the COVID-19 pandemic persisted and progressed, the number of campaigns per COVID-19 case declined more than tenfold across all states. The states with the earliest disease burden had the fewest campaigns per case, indicating a lack of a case-dependent response. COVID-19–related campaigns raised more money, had a longer narrative description, and were more likely to be shared on Facebook than other campaigns in the study period.

Conclusions: Web-based crowdfunding appears to be a stopgap for only a minority of campaigners. The novelty of an emergency likely impacts both campaign initiation and crowdfunding success, as it reflects the affective response of a community. Crowdfunding activity likely serves as an early signal for emerging needs and societal sentiment for communities in acute distress that could be used by governments and aid organizations to guide disaster relief and policy.

Introduction

As the number of COVID-19 cases precipitously accelerated in March throughout the United States, government and public health departments marshalled their pandemic responses. Support efforts quickly became necessary as shortages of medical supplies and testing worsened by the continued spread of the virus affected health care organizations, medical offices, and nursing homes [1]. The first effects of the pandemic were related to health; however, economic ramifications, including rapidly increasing unemployment and loss of revenue, quickly followed the spread of the disease and public health efforts to contain it [2,3]. Temporary and permanent closure of small businesses, furloughing of whole sectors of the economy (eg, airline and restaurant industries), and food price inflation created social, financial, and medical strain on the population [4,5]. Subsequent effects of the pandemic, such as the increased number of deaths and associated funeral costs, added more financial stress to the lives of Americans.

Donation-based web-based crowdfunding has become an increasingly popular tool to finance medical treatment, respond to financial hardships and natural disasters, and defray the downstream economic impacts of personal health care costs [6,7]. Previous research has shown that crowdfunding has been used to address the needs of individuals and communities after natural disasters [8]. However, the crowdfunding success of these donation-based platforms relies more heavily on emotional delivery to engage backers [9] as well as on social media for quick diffusion [10].

Despite anecdotal reports of the increased use of web-based crowdfunding to mitigate the economic impacts of COVID-19 [11], details on how crowdfunding has been used for COVID-19 relief efforts in the United States remain scarce. We evaluated web-based crowdfunding campaigns in the United States in the early stages of the COVID-19 pandemic on the GoFundMe platform, which represents 90% of the social crowdfunding market in the United States as of 2018 [12]. We hypothesized that (1) COVID-19–related campaigns raised more money and were more widely distributed on social media than non–COVID-19–related campaigns during the same timeframe and (2) COVID-19–related campaigns were initiated disproportionately in the early days and weeks of the pandemic, unrelated to the rate of incident COVID-19 cases.

Methods

Data Collection and Analysis

On May 16, 2020, we extracted all active US campaigns created between January 1 and May 10, 2020, on GoFundMe, the largest web-based crowdfunding platform in the United States. The time frame reflects approximately two months before and after the World Health Organization declared COVID-19 a pandemic on March 11, 2020. We used the *Beautiful Soup* library [13] to web scrape all data available for the GoFundMe campaigns and excluded all campaigns that originated outside the United States. We list all extracted data fields in Table S1 in Multimedia Appendix 1. We used keywords relevant to the COVID-19 pandemic to identify and label the subset of COVID-19–related campaigns (Table S2 in Multimedia Appendix 1). The University of Texas Southwestern Human Research Protection Program Policies, Procedures, and Guidance did not require institutional review board approval, as all data were publicly available.

We examined weekly new COVID-19–related campaigns juxtaposed with the weekly numbers of new COVID-19 cases both nationally and by state or territory. We evaluated the incidence of campaigns by state adjusted for new COVID-19 cases by week to determine the temporal association between disease spread and campaign initiation. To enable comparison among states, we defined week 0 as the first week in which each state had at least 100 new weekly cases. We displayed all states; however, we only highlighted the top six states by overall campaign per million. Given the presence of zip code–level data, we also explored more granular community trends. We also evaluated changes in COVID-19–related campaigns per million for each state and campaign categories over time. To better understand campaign narratives and motivation, we conducted a natural language processing (NLP) analysis of the campaign text to identify clusters of keywords that represent campaigns [14]. We used the term frequency–inverse document frequency (TF-IDF) technique to create a matrix of all of the words in the campaign narratives weighted by the frequency of the word in that document relative to the frequency of the same word in all documents [15]. We then used k-means clustering on the resulting matrix to identify clusters of campaigns and represent these clusters by the 20 most central words to that cluster [16]. Because there were 19 GoFundMe categories in the COVID-19–related campaign subset (out of 20 possible GoFundMe categories), we chose 19 topic clusters a priori.

We compared campaign characteristics, including fundraising, campaign information, and campaign category, for COVID-19–related and non–COVID-19–related campaigns over the same time period from March 11 to May 10, 2020. We used Mann-Whitney U, chi-square, and Fisher exact tests where appropriate to determine significance. The α level of significance was set a priori at .05, and all significance testing was two-sided. We did not adjust for multiple comparisons, as this was an exploratory study and should be interpreted as hypothesis-generating. Analyses were performed using Python, version 3.7.2 (Python Software Foundation).

Availability of Data and Materials

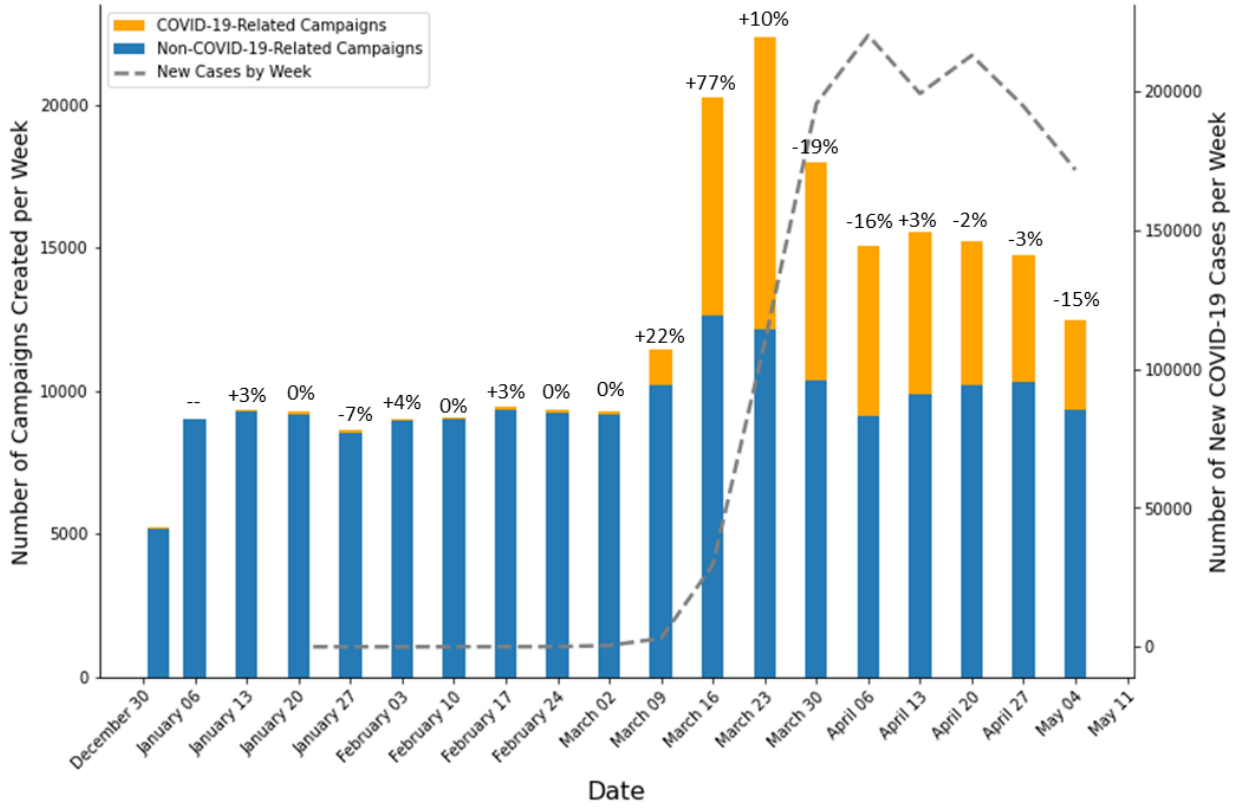
The data that support the findings of this study are available upon request.

Results

Of 310,695 total new campaigns created between January 1 and May 10, 2020, we analyzed 232,827 campaigns from the United States across all categories. Of these campaigns, 51,763/232,827 (22.2%) were identified as COVID-19–related, and these campaigns collectively raised US $237,418,235 by May 10, 2020. The vast majority of COVID-19–related campaigns were established after March 11 (50,828/51,763, 98.2%). New GoFundMe campaigns peaked in mid-March, mainly due to new campaigns related to or referencing COVID-19, and

declined in April (Figure 1). Total campaigns increased by 77% and 10% in the weeks of March 16 and 23 and then dipped by 19% and 16% in the following two weeks. In parallel, COVID-19–related campaigns increased by 736% and 512% in the weeks of March 9 and 16 and then eventually decreased by 25% and 23% in the weeks of March 30 and April 6. The COVID-19–related increase in campaigns was observed before the national peak of new COVID-19 cases in April. Subsequently, the incidence of new campaigns declined, while the incidence of new COVID-19 cases remained steady or declined slightly.

Figure 1. New GoFundMe campaigns by week versus incident COVID-19 cases by week. Percent changes of campaigns created from the previous week are shown above each bar.



Adjusting for the weekly incidence of COVID-19 cases, new COVID-19–related campaigns in all US states peaked within two weeks of the first week when 100 new cases were diagnosed in that state. For many states, the rate of COVID-19–related campaigns per case dropped by at least tenfold after the first two to three weeks (Figure 2). Population-rich states that also experienced early spread of COVID-19, such as New York, New Jersey, Massachusetts, Washington, and Illinois, had the most COVID-19–related campaigns per million inhabitants (Figure 3); however, they were ultimately among the states with the lowest number of COVID-19–related campaigns per 1000 cases during the study period.

Figure 2. COVID-19–related GoFundMe campaigns per 1000 COVID-19 incident cases for each state. Week 0 is defined as the first week in which a state had more than 100 cases to enable direct comparison among states. All states are shown, but only the top 6 states for total COVID-19 cases per million are highlighted in color (ordered from most to fewest in the legend).

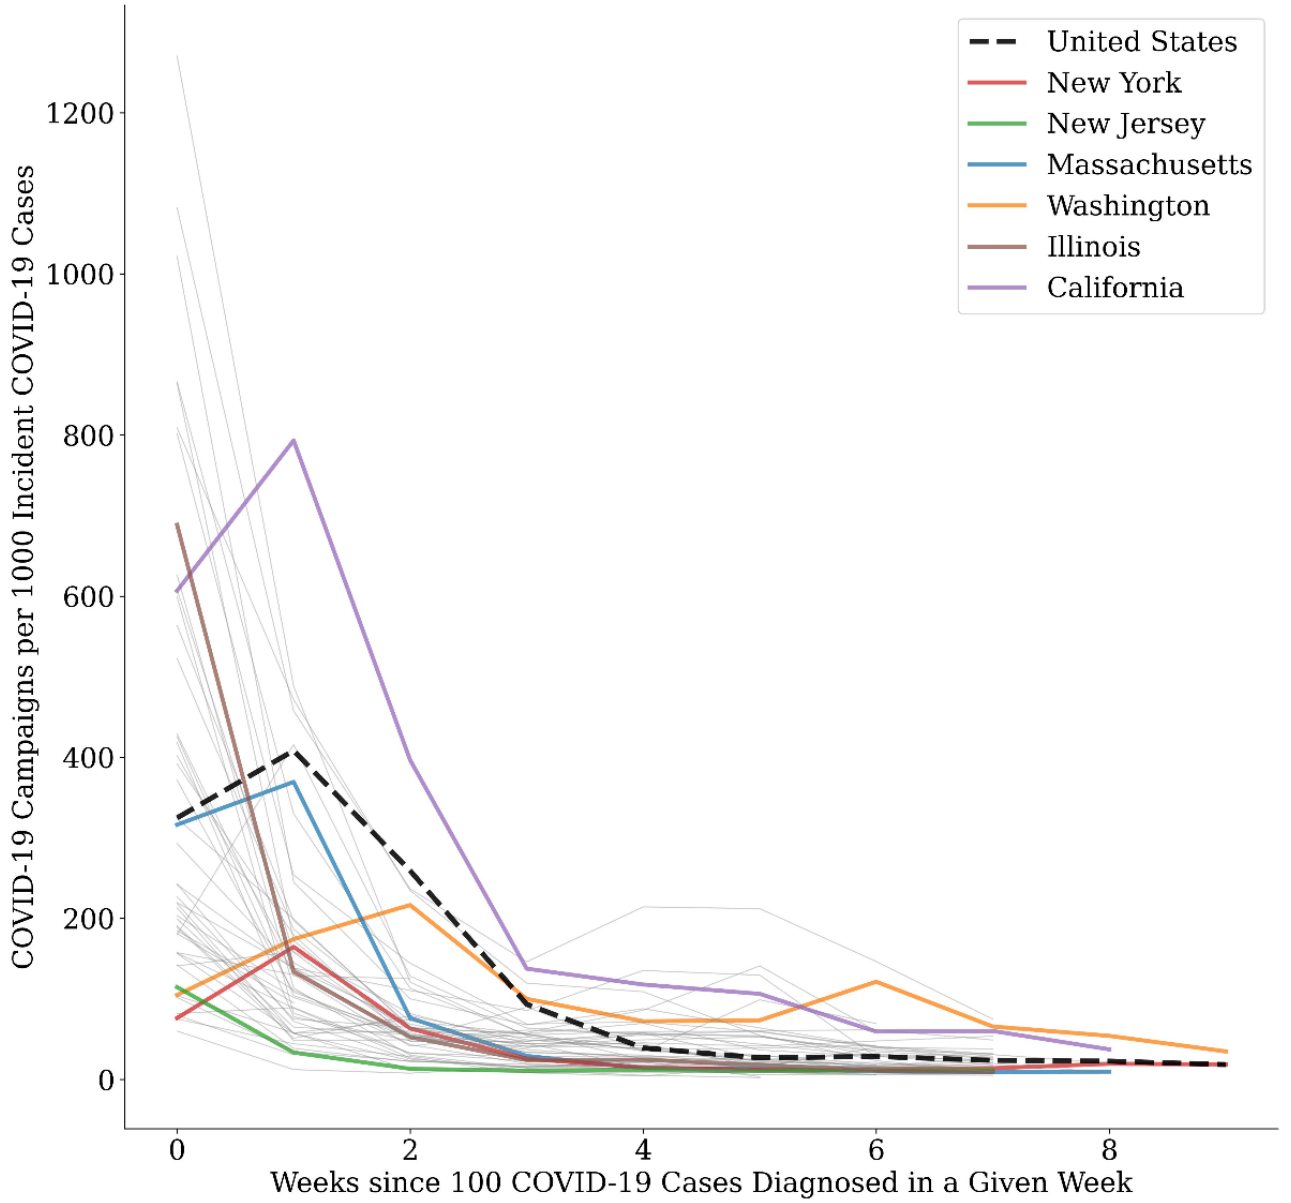


Figure 3. COVID-19–related GoFundMe campaigns per million by week by state. All states are shown, but only the top 6 states for total COVID-19 cases per million are highlighted in color (ordered from most to fewest in the legend). Dates on the x-axis start from February 25, as few COVID-19–related campaigns were present before this date.

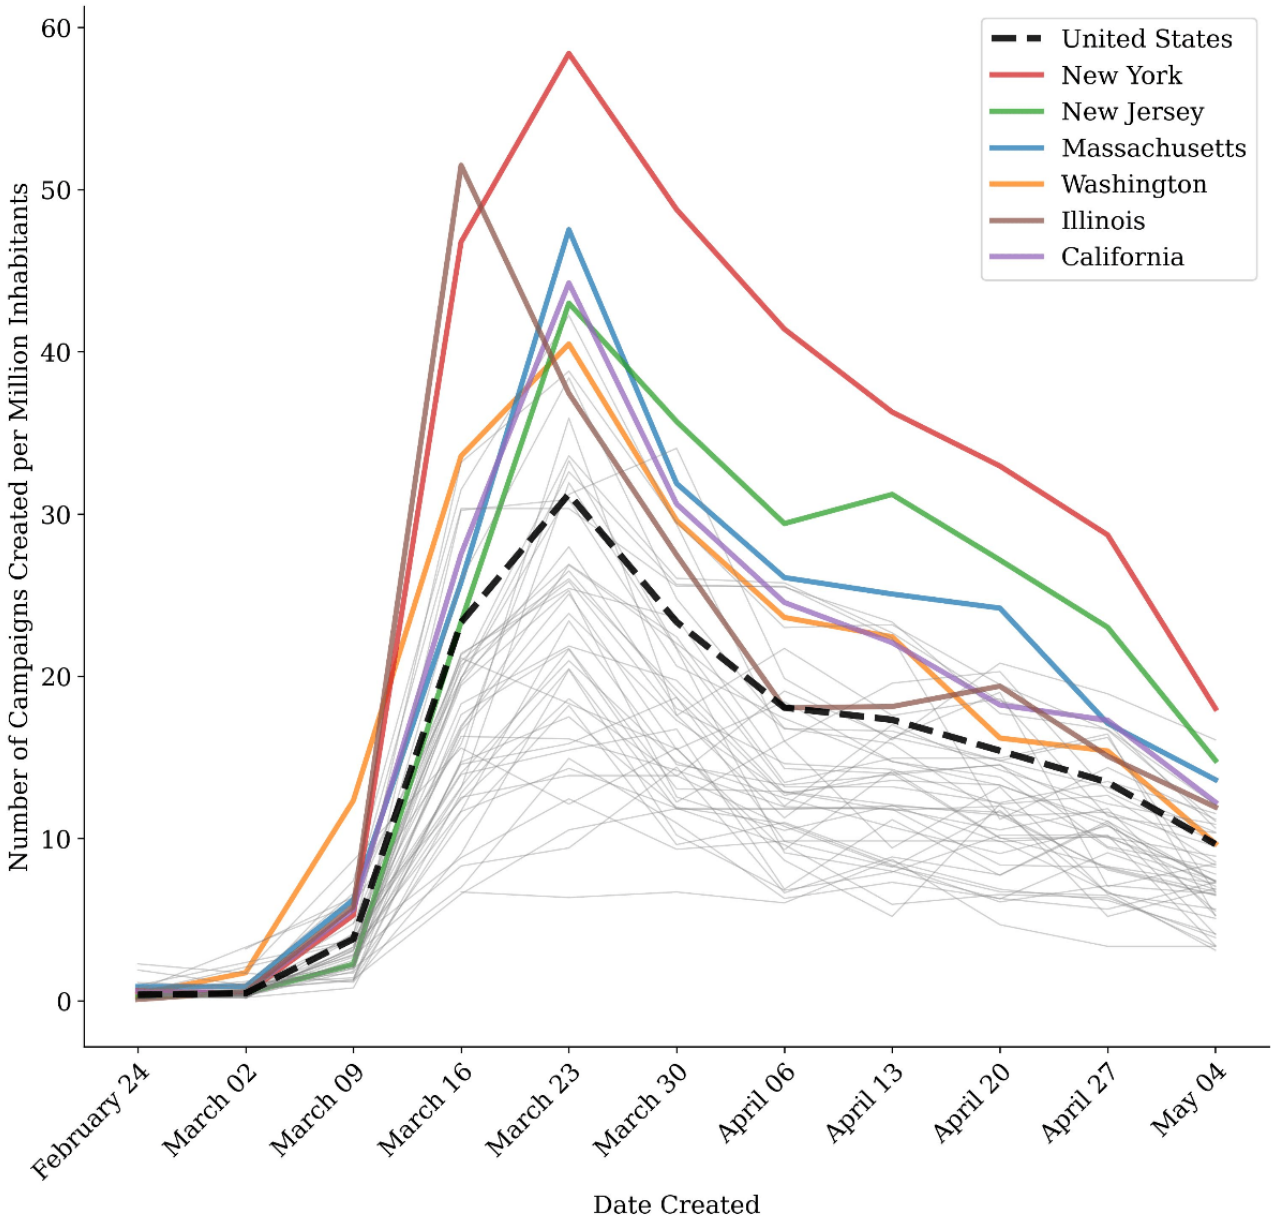

From March 11 to May 10, 2020, non-COVID-19–related campaigns (91,631/142,459, 64.3%) raised a median of US $625 (IQR $135-$2300), while COVID-19–related campaigns (50,828/142,459, 35.7%) raised a median of $930 (IQR $220-$3075), nearly 50% more per campaign (*P*<.001). Fundraising goals were higher in COVID-19–related campaigns (median $5000, IQR $2000-$10,000) than non–COVID-19–related campaigns (median $4000, IQR $1250-$10,000; *P*<.001). Even with the higher fundraising goals, COVID-19–related campaigns (median 25.0%, IQR 5.5%-69.5%) raised a higher percentage of their fundraising goals than non–COVID-19–related campaigns (median 22.2%, IQR 5.0%-65.5%) by date of data extraction (*P*<.001). COVID-19–related campaigns (median 23, IQR 0-163) had significantly more Facebook shares than non–COVID-19–related campaigns (median 0, IQR 0-145; *P*<.001). COVID-19–related campaigns also had longer narratives in their campaign description, were more likely to be listed as a charity, and were more likely to have the campaigner be the same as the beneficiary (Table 1).

Table 1. Baseline GoFundMe campaign characteristics stratified by COVID-19–related status. Only campaigns created after March 11, 2020, are included.

Characteristic	Total campaigns (N=142,459)	COVID-19–related campaigns (n=50,828)	Non–COVID-19–related campaigns (n=91,631)	*P* value[a]
Fundraising				
Goal (US $), median (IQR)	5000 (1500-10,000)	5000 (2000-10,000)	4000 (1250-10,000)	<.001
Raised (US $), median (IQR)	722 (160-2,565)	930 (220-3075)	625 (135-2300)	<.001
Percent of goal funded (US $), median (IQR)	23.3 (5.2-66.9)	25.0 (5.5-69.5)	22.2 (5.0-65.5)	<.001
Donors, median (IQR)	12 (3-35)	14 (4-40)	11 (3-32)	<.001
Amount per donation (US $), median (IQR)	56.3 (35.4-86.8)	59.9 (39.0-92.7)	54.5 (33.8-83.5)	<.001
Met funding goal, n (%)	20,593 (14.5)	7302 (14.4)	13,291 (14.5)	.48

Animals & Pets, n (%)	11,158 (7.8)	2131 (4.2)	9027 (9.9)	<.001
Babies, Kids, & Family, n (%)	6265 (4.4)	1990 (3.9)	4275 (4.7)	<.001
Volunteer & Service, n (%)	5176 (3.6)	2643 (5.2)	2533 (2.8)	<.001

[a]Given the non-Gaussian populations, we used Mann-Whitney U, chi-square, and Fisher exact tests to detect statistical differences among the three groups.

Creators of COVID-19–related campaigns most commonly selected the following categories (in descending order by number of campaigns): (1) Accidents & Emergencies, (2) Medical, Illness & Healing, (3) Community & Neighbors, (4) Business & Entrepreneurs, (5) Funerals & Memorials. In total, 19 of the 20 possible GoFundMe categories were represented in the COVID-19–related campaigns. Accidents & Emergencies as well as Community & Neighbors and Medical, Illness & Healing had the earliest peaks (Figure 4A). A week later, the category Business & Entrepreneurs peaked; however, this appeared to be driven by an isolated spike on March 24 (Figure 4B). Medical, Illness & Healing peaked next within the following 2 weeks. As these initial spikes decreased significantly, Funerals & Memorials campaigns lagged behind the first peak by 4 weeks. Compared to non-COVID-19–related campaigns after March 11, COVID-19–related campaigns had more campaigns in Accidents & Emergencies, Community & Neighbors, and Business and Entrepreneurs and fewer campaigns in Funerals & Memorials and Animals & Pets. Our NLP analysis provides granular insight into motivators for campaigns (Table 2). The largest cluster (Cluster 0) was about community support and fundraising for schools and children in a time of need. There are also multiple clusters about health care workers and personal protective equipment (Clusters 7, 11, and 18), small businesses and jobs (Clusters 3, 5, 6, and 9), as well as funerals and medical costs (Clusters 8, 15, and 17). We also observed the clustering of likely Spanish-only campaigns in Cluster 12. Cluster 19, with only 3 campaigns, likely accounts for outliers among the other campaigns and is included for completeness.

Figure 4. COVID-19–related GoFundMe campaigns per category (A) by week and (B) by day. Only the top 8 of the 20 possible categories are shown. The legend is ordered from most to least common category. Dates on the x-axis start from February 25, as few COVID-19–related campaigns were present before this date.

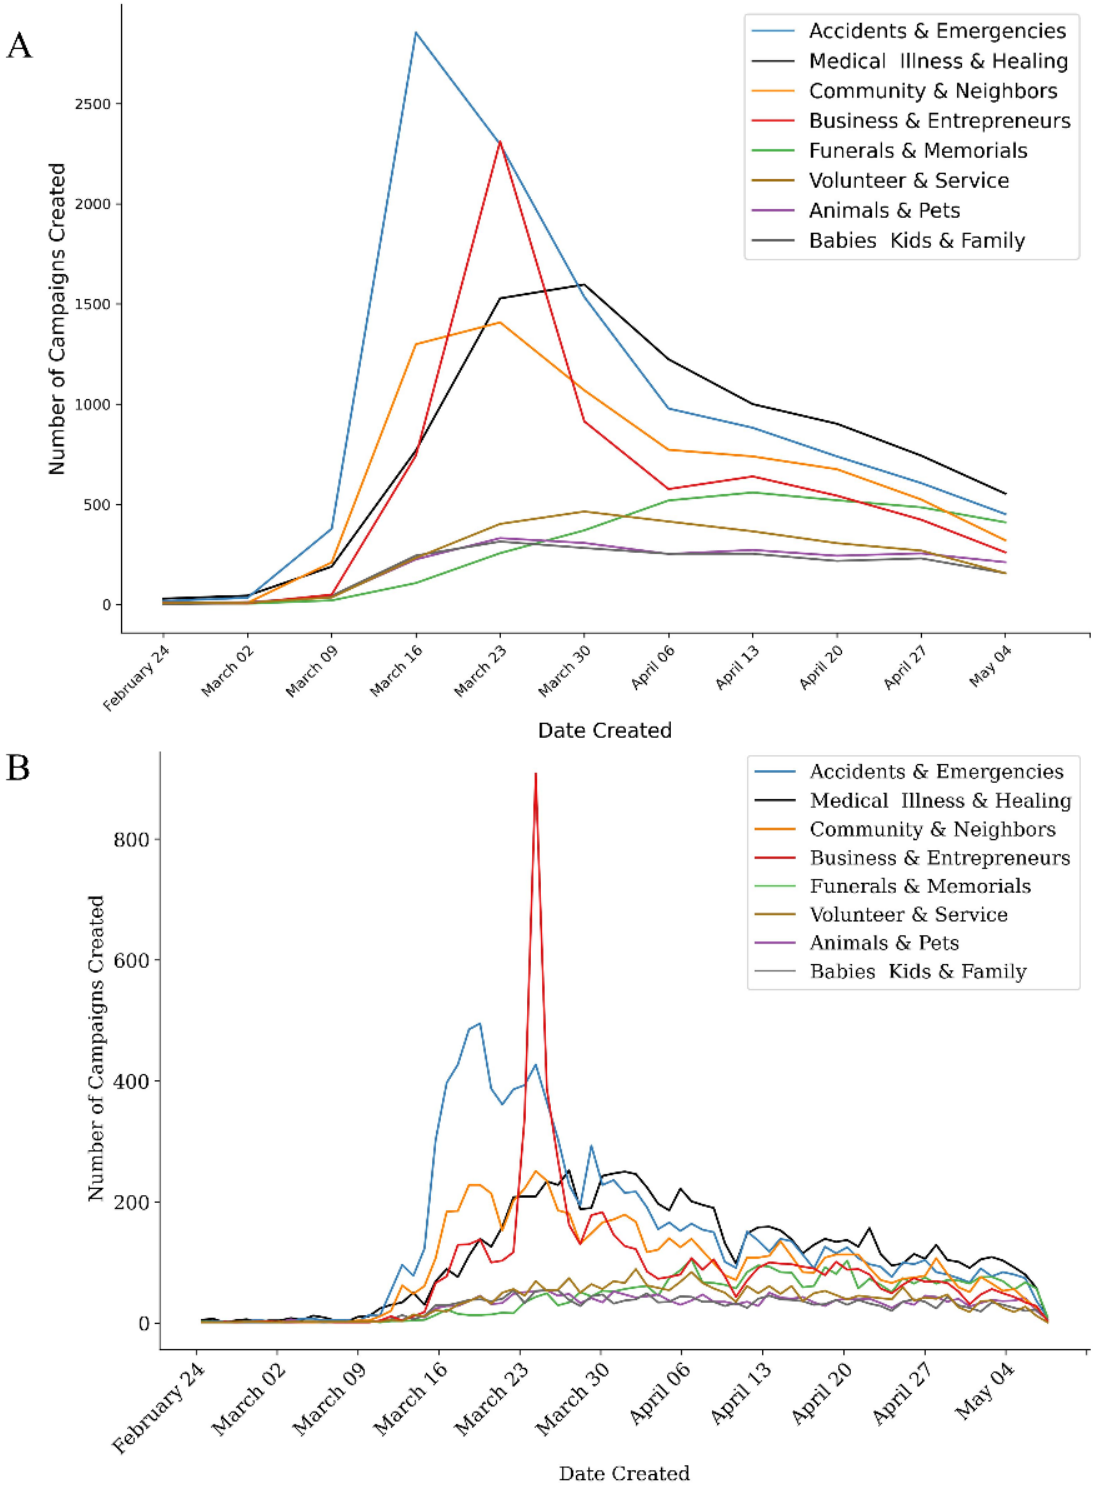

Table 2. Keywords at the center of the 19 clusters of campaigns obtained through the term frequency–inverse document frequency natural language processing technique and k-means clustering. The top 20 words for each cluster and the number of campaigns per cluster are displayed.

Cluster	Number of campaigns	Top 20 words in the cluster
1	10,421	community, school, support, students, time, need, pandemic, children, money, funds, thank, donation, make, continue, people, like, year, new, donations, teachers
2	6493	know, time, family, home, work, just, thank, life, need, able, baby, love, cancer, going, like, money, years, little, pandemic, people

Discussion

Principal Findings

Early in the COVID-19 pandemic, COVID-19–related campaigns were created more frequently. There was a substantial increase in overall GoFundMe web-based crowdfunding campaigns in March, mostly attributable to COVID-19–related campaigns. COVID-19–related campaigns raised more money than other campaigns, had longer narrative descriptions, and were more likely to be shared on Facebook. However, as the COVID-19 pandemic progressed, we suspect that the novelty of these campaigns wore off. As COVID-19 became a familiar and ubiquitous problem, the number of campaigns per COVID-19 case declined across all states. As proposed by Elmer et al [17], we agree that crowdfunding serves as a lens for the affective responses to the pandemic, showing both the economic uncertainties and the anxieties within a community.

We speculate that as in commercial advertising, the creativity and novelty of a campaign as well as its quick diffusion play major roles in the campaign's success, enabling it to progress from "friend and family funding" to crowdfunding. The subsequently declining number of COVID-19–related campaigns may be explained by potential campaign developers weighing the effort required to create a campaign with a shrinking potential for reward. Initially, the novelty and early shock of COVID-19 cases provided the chance for a campaign to "go

viral"; reach many people, especially through social media; and generate large donations. Social media and mobilizing users outside the immediate family and friend network are key to attract the attention of a larger group of funders [18] and achieve crowdfunding success [19]. In fact, the use of social media has been shown to predict the volume of emergency relief donations in cases of natural disasters more accurately than conventional techniques, highlighting the importance of quick diffusion [10]. As the issue became widespread and the ability to set a campaign apart as a worthy cause became more difficult, the effort (cost) of creating a campaign may have been outweighed by the perceived likelihood of funding. As others have found, the concept of worthiness and augmenting one's "illness narrative" become important factors in generating campaign appeal, influence, and ultimately fundraising success [6,20-22]. The states with the earliest disease burden had the fewest campaigns per case, indicating a lack of case-dependent response; this supports the premise that potential campaign designers perceive common illnesses as less likely to receive the attention of donors over time.

We recognize that the impetus for crowdfunding is a complex interplay of many factors. Campaigns may be generated for an individual, multiple individuals, an institution such as a business, or a larger community. External factors such as government readiness, supply shortages, and lockdowns may play roles in campaign incidence. However, the rapid rise and fall in campaigns over a timeline of two or three weeks in nearly all states points to a reactionary, affective community response; it also indicates that the external factors were not meaningfully reversed or corrected during this time. The gravity and magnitude of the event likely sparked reactions of desperation, fear, and anticipation that motivated campaigners to turn reaction to action, especially with the possibility of the absence of other immediate alternatives early on.

Although web-based crowdfunding raises millions of dollars, our study suggests that it may function as a financial safety net for a limited subset of beneficiaries. First, there is ample evidence that crowdfunding success disproportionately benefits those in areas with high socioeconomic status and those with the internet and media literacy necessary to portray beneficiaries as worthy [6,21-23]. Second, medical expenses alone due to COVID-19 in the United States are estimated to be in excess of $163 billion if 20% of the population is infected (on August 26, 2020, approximately 1.8% of the population had a confirmed infection) [24]. Rather, crowdfunding more likely functions as a weathervane indicating a community in distress. As Elmer et al [17] noted, "while clearly producing an economic crisis for governments, communities, families, companies and individuals, the [COVID-19] crisis is rooted in issues of community health." Further, crowdfunding is heavily swayed by marketing and storytelling, as it points a majority of funds toward a few cases (when these elements converge to virality) rather than aiding the many [11,25].

The large number of categories for COVID-19–related GoFundMe campaigns tells a poignant story of the broad, destructive effect that COVID-19 has had on society. Beyond creating the need to cover unexpected and costly medical expenses, the COVID-19 pandemic devastated small businesses, greatly increased unemployment, created food and housing insecurities, generated unexpected expenses such as funeral costs, and increased debt [5]. The campaign categories reflected the progression of the COVID-19 funding response, with the earliest peaks for accidents and emergencies and late growth and plateaus for funerals and memorials. Our NLP analysis provides further evidence of the content of the campaigns, as the clusters identified align with the specified categories listed.

The spike in small business campaigns was likely heavily based around the launch of the Small Business Relief Initiative on March 24, 2020 [26], and specifically, its GoFundMe.org (the charitable arm of GoFundMe) Small Business Relief Fund. The relief fund provided "one-time $500 matching grants to qualifying small businesses that created a fundraiser through the Small Business Relief Initiative or already had an existing GoFundMe until the relief fund [was] depleted." For "fundraisers started prior to this announcement or outside of this partnership, the organizer [could] update their fundraiser description with the hashtag #SmallBusinessRelief to receive funds," which likely accounted for the presence of this phrase in Cluster 3 in our NLP analysis. Importantly, another part of the initiative involved automatically creating fundraisers for small businesses with Yelp pages, where customers could donate directly on Yelp or on GoFundMe; however, because we only scraped GoFundMe-based campaigns that included a user-generated narrative, these fundraisers were not part of our dataset.

As newly generated GoFundMe campaigns showed a temporal association with the effect of the COVID-19 pandemic on society, we contemplated that GoFundMe campaigns may serve as an early indicator of a community in distress. To explore this, we isolated campaigns from communities that were affected by a natural disaster, including Puerto Rico (earthquake from January 6-7, 2020), Nashville (tornado from March 2-3, 2020), and Mississippi (tornado from April 12-13, 2020). We were able to discern an immediate peak for GoFundMe campaigns following each event (Figure S1, Multimedia Appendix 1).

Although GoFundMe campaigns failed to meet the needs of those seeking support, as demonstrated by the small fraction of funding goals met by the data extraction date, the signal of new campaigns at and after times of distress can provide unique insight into the community affected. The organic, user-generated content of these campaigns can inform both direct emerging needs (whether resource-related or financial) as well as the societal perception and sentiment in a time of crisis [17]. This signal does not appear to be limited to medical emergencies but also extends to natural disasters. Future research will show which types of negative events that affect communities are reflected by a spike in GoFundMe campaigns and how the content of the campaigns can be leveraged systematically.

Limitations

Although we were able to analyze the full available set of GoFundMe campaigns, which strengthened our study, it had several limitations. Web-based crowdfunding only provides a lens to view those who have access to the technical and social resources to be a part of a crowdfunding campaign (either to

create and coordinate a campaign directly or to be connected to another person who can fulfill that role). Therefore, only a subset of the population experiencing unmet financial strain or needs is represented. Moreover, we used data from one crowdfunding platform only. Although GoFundMe is the largest platform in the United States by number of campaigns, our study may have suffered from selection bias. Because of the large number of campaigns, we are unable to validate that campaigns using COVID-19–related keywords were indeed designed to mitigate the effect of COVID-19. Although we note significant differences in campaign and funding characteristics between COVID-19–related and non–COVID-19–related campaigns, future work will be important to further understand reasons for these differences and their implications in long-term crowdfunding. Finally, we only analyzed the first few months of COVID-19–related campaigns; therefore, more longitudinal analysis will be important to understand more completely how peaks and troughs in COVID-19 incidence nationally and in more granular communities affect campaign frequency.

Conclusions

Web-based crowdfunding activity leverages galvanized public reaction early in a public health emergency such as the COVID-19 pandemic. However, as disease spread persisted and economic burden continued to grow nationally, the creation of new campaigns faded. Web-based crowdfunding appears to be a stopgap for only a minority of campaigners. The novelty of an emergency likely impacts both campaign initiation and crowdfunding success, as it reflects the affective response of a community.

More importantly than its rather weak effect of mitigating the effect of the crisis, crowdfunding activity likely provides an early signal of the emerging needs and societal sentiment of communities in acute distress. This activity could be monitored by local, state, and federal government agencies, such as the Federal Emergency Management Association (FEMA), to provided targeted support and policy. Future research will determine what emergencies generate the strongest signals in crowdfunding activities and how content can be leveraged systematically.

Authors' Contributions

SS and RJM conceived and designed the study and acquired the data. SNS analyzed and interpretated the data. SNS and CUL prepared the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

CUL reports stock ownership in Celanese Corporation and Colfax Corporation. RJM has received research funding from Verily Life Sciences and research grants from the Centers for Disease Control and Prevention. The remaining author has no conflicts to declare.

Abstract

Background: The COVID-19 pandemic has had profound and differential impacts on metropolitan areas across the United States and around the world. Within the United States, metropolitan areas that were hit earliest with the pandemic and reacted with scientifically based health policy were able to contain the virus by late spring. For other areas that kept businesses open, the first wave in the United States hit in mid-summer. As the weather turns colder, universities resume classes, and people tire of lockdowns, a second wave is ascending in both metropolitan and rural areas. It becomes more obvious that additional SARS-CoV-2 surveillance is needed at the local level to track recent shifts in the pandemic, rates of increase, and persistence.

Objective: The goal of this study is to provide advanced surveillance metrics for COVID-19 transmission that account for speed, acceleration, jerk and persistence, and weekly shifts, to better understand and manage risk in metropolitan areas. Existing surveillance measures coupled with our dynamic metrics of transmission will inform health policy to control the COVID-19 pandemic until, and after, an effective vaccine is developed. Here, we provide values for novel indicators to measure COVID-19 transmission at the metropolitan area level.

Methods: Using a longitudinal trend analysis study design, we extracted 260 days of COVID-19 data from public health registries. We used an empirical difference equation to measure the daily number of cases in the 25 largest US metropolitan areas as a function of the prior number of cases and weekly shift variables based on a dynamic panel data model that was estimated using the generalized method of moments approach by implementing the Arellano-Bond estimator in R.

Results: Minneapolis and Chicago have the greatest average number of daily new positive results per standardized 100,000 population (which we refer to as speed). Extreme behavior in Minneapolis showed an increase in speed from 17 to 30 (67%) in 1 week. The jerk and acceleration calculated for these areas also showed extreme behavior. The dynamic panel data model shows that Minneapolis, Chicago, and Detroit have the largest persistence effects, meaning that new cases pertaining to a specific week are statistically attributable to new cases from the prior week.

Conclusions: Three of the metropolitan areas with historically early and harsh winters have the highest persistence effects out of the top 25 most populous metropolitan areas in the United States at the beginning of their cold weather season. With these persistence effects, and with indoor activities becoming more popular as the weather gets colder, stringent COVID-19 regulations will be more important than ever to flatten the second wave of the pandemic. As colder weather grips more of the nation, southern metropolitan areas may also see large spikes in the number of cases.

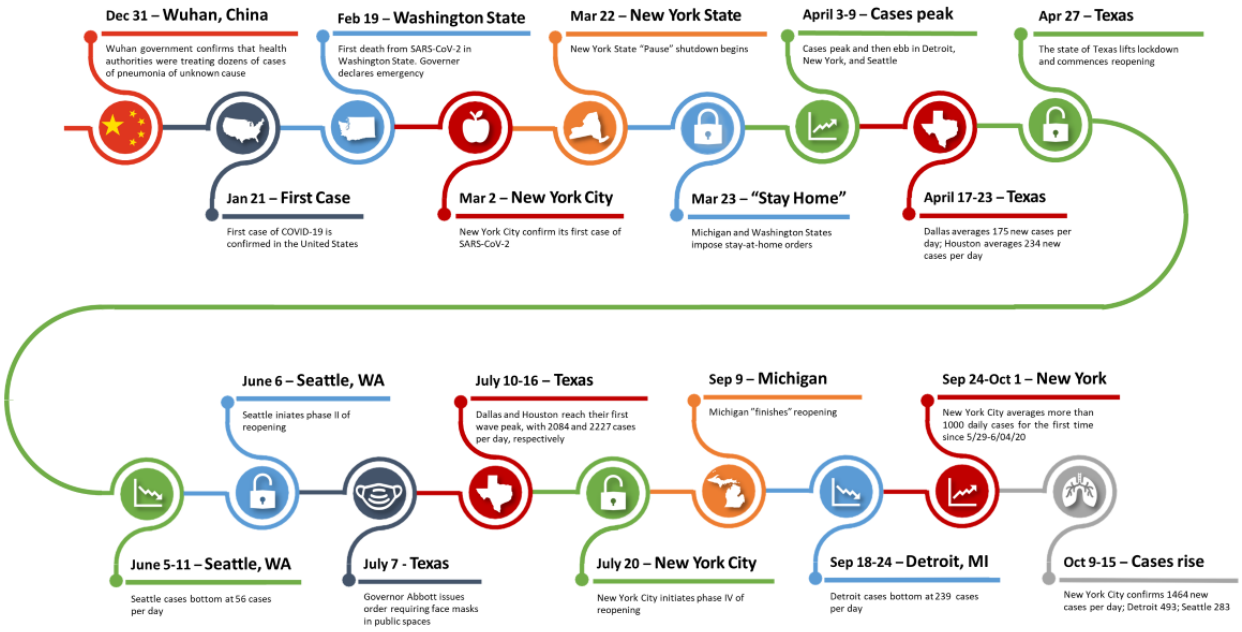
Introduction

In December 2019, a novel coronavirus, SARS-CoV-2, leading to severe pneumonia and acute respiratory disease, was observed in Wuhan, China (Figure 1) [1-4]. On January 21, 2020, the first confirmed case of COVID-19 was recorded in the United States [5]. As cases began to spread globally at an alarming rate, the World Health Organization officially recognized COVID-19 as a pandemic on March 11, 2020 [6]. Around the world, countries quickly implemented public health policies to mitigate the health and economic impacts caused by the virus [7]. The US federal government did not create a national unified pandemic control strategy [8-10], leading local state and city officials to implement their own public health and safety measures to "flatten the curve" [11]. However, by late May, many state and city leaders lifted their public health measures, leading to another alarming rise in COVID-19 case numbers [12,13]. As of October 29, 2020, there are 8,937,926 confirmed COVID-19 cases and 228,439 COVID-19–related deaths across the United States [14].

Figure 1. Timeline illustrating important events of the COVID-19 pandemic as related to US metropolitan areas.



Metropolitan areas largely drove the first wave of COVID-19 in the country [15], with northern travel hubs such as New York City, Chicago, Boston, Detroit, and Seattle seeing early spikes in the number of cases and deaths [14] (we refer to the area by the first city in its Census Bureau designation; eg, New York City for the New York-Newark-Jersey City, NY-NJ-PA core-based statistical area). Initial outbreaks around major east and west travel hubs are particularly important because they are gateways of international travel and have high population densities [16,17]. Genomic evidence from early SARS-CoV-2 strains suggests that initial infections in the United States were introduced to Washington State, a hub for travel to East Asia, by travelers from China [18-20]. There is also evidence that suggests New York City likely served as a primary entry point to the United States for the SARS-CoV-2 contagion from European hotspots in Spain and Italy early in the pandemic [19,21,22]. Chicago, Boston, and Detroit were likely additional entry points because of the large number of international travelers—Detroit's metro airport had over 1100 flights per day to 4 continents including direct flights to China and Europe [23], and was the least busy of the airports.

COVID-19 became endemic in the United States at the end of March [9], when many of these northern metro areas and travel hubs saw significant uptrends in their COVID-19 caseloads. In many of these areas, the first wave peaked in late March or early April after lockdowns and other preventive measures were imposed. For example, Washington State recorded its first death on February 19, 2020, and Governor Jay Inslee declared a state of emergency later that same day [24]. This led to increasingly stringent lockdown measures from Inslee, Seattle Mayor Jenny Durkan, and country executives, culminating in the governor issuing a "Stay Home Stay Safe" lockdown on March 23 [25,26]. Michigan's first case was recorded on March 10, and Michigan Governor Gretchen Whitmer imposed a "stay at

home" lockdown on March 23 [27,28]. In the Seattle metropolitan area, the first wave peaked the week of March 20-26, as it did in Detroit (authors' calculations using data from USAFacts.org [29]). New York peaked the week of March 27 to April 2, Boston the week of April 10-16, and Chicago the week of April 17-24. The ebb from the first peak is associated with the imposition of varying degrees of lockdown measures, social distancing, and mask wearing, among other COVID-19 responses and policies [11,30-33].

The first wave of the pandemic crested in southern cities about 3 months later, corresponding to a US-wide peak on July 16 with 77,352 new cases that day [19]. Phoenix peaked the week of July 3-9, with an average of 1404 new cases per day. Los Angeles peaked the week of July 10-16 with an average of 2080 new cases per day during that week; Miami also peaked that same week with an average of 1666 new cases per day.

The impact of the first wave on southern cities is associated with a lack of COVID-19 prevention measures in these areas [9,16,17,34,35]. For example, in Texas, on April 27, 2020, Governor Greg Abbott issued an executive order reopening the state including in-person retail and dining and prohibiting municipalities from imposing sanctions on individuals who chose not to wear a face mask [36], despite opposition from local government leaders [37,38]. On June 17, the governor allowed local jurisdictions to require face masks and, on July 2, mandated face masks across the state [37,38]. In Dallas and Houston, the pandemic initially peaked the week of July 10-16 and then ebbed (authors' calculations based on data from USAFacts.org [29]).

The United States is now entering the second wave of the COVID-19 pandemic [39,40]. As of November 2020, only 3 US counties have not reported a case of COVID-19, each of which has a population of less than 1000 people [41]. Many cities and states have reopened, citing the need to keep their economies functioning [42]. There has been considerable pushback against COVID-19 precautions, such as social distancing and face mask wearing. The pushbacks have reached the extremes of violent protests in Texas [43], and an alleged plot to kidnap the Governor of Michigan [44]. With the second—historically more deadly [45,46]—year of the pandemic coming up in a few months, surveillance of the disease will be even more relevant for determining appropriate COVID-19 precautions. The onset of the second wave requires taking initiative rather than relying on reactive public health measures, and in order to be proactive, an improved surveillance system is needed.

A robust surveillance system should answer relevant questions about the second wave: how many new cases appear in the metropolitan area per day per 100,000 population? Is the number of new cases an acceleration from the previous week, and is the acceleration indicative of explosive growth? Is there evidence of sustained transmission from new cases last week to new cases this week to new cases next week (eg, from Halloween, sports events, political rallies, etc)?

The objective of this paper is to provide novel, policy-relevant surveillance information about the second wave of COVID-19 cases in the 25 largest metropolitan areas in the United States. This information is of critical importance to controlling the second wave because in the absence of a national coronavirus policy, a COVID-19 policy is made and implemented at the state and local levels, including the metropolitan area [9,47]. Guidelines on reopening such as a 14-day downward trend in the number of new cases per day are difficult to implement at the local level without accurate quantitative data on the number of new cases and a local, area-specific trend. For example, in Los Angeles and New York City, day-to-day fluctuations in new case numbers were directly correlated to testing numbers rather than biological factors [48]. Additionally, there can be differences between state and local policies, leading to friction between governors and mayors with perhaps negative impacts on public adherence to social distancing, face mask wearing, and other public health guidelines and behaviors [49]. Consequently, surveillance information is needed at the metropolitan level to help inform policy needs and policy effectiveness.

Methods

Overview

This paper uses the dynamic panel data (DPD) modeling application and surveillance approach [50,51], which has been applied to sub-Saharan Africa, South Asia, and at the state level in the United States [52-54]. We apply these methods to the 25 most populous US metropolitan areas, as defined by the US Census Bureau [55]. For each metropolitan area, a panel data set is constructed using counties as the cross-sectional variable and days as the time variable.

The DPD modeling method is a novel approach to medical surveillance applications. Traditional contagion modeling techniques, including agent-based modeling and system dynamics, are complex, require sophisticated software (system dynamics), and are labor intensive, which makes them impractical for rapid surveillance across dozens of cities and counties in the United States, especially given the data that are readily available and easily accessible. Surveillance methods should rapidly generate understandable indicators to inform current decision making [56]. Our surveillance method can quickly be applied to existing data to generate indicators of pandemic outbreak locations and where explosive growth is likely to occur. The DPD-based modeling and surveillance method was validated previously [50,51]; these papers contain more detailed explanations and additional references to other methods.

Data

Data on the cumulative number of positive COVID-19 cases based on testing for each county and each day were downloaded from USAFacts.org [29] on October 17, 2020, as an excel file and are complete from January 22 through October 15, 2020. Data from March 20 to October 15 were used for statistical analysis and tables presented in this paper, which provides 30 weeks of data from the approximate start of the pandemic in the United States. On March 20, the country had 6367 new cases, the first day in which the number of new cases exceeded 5000 [57]. The only cleaning or processing of the data was to

create the novel surveillance metrics described below based on Oehmke et al [50].

Surveillance Methods

Following the procedures described by Oehmke et al [50], we calculated the novel surveillance metrics of speed, acceleration, and jerk for the COVID-19 caseloads for each of the 25 most populous metropolitan areas. Speed is defined as the number of new cases per day per 100,000 population; since reporting coverage depends on the day of the week, we report a weekly average value. Acceleration is the change in speed from one week to the next. It provides the primary indication of whether the pandemic is getting worse (positive acceleration) or better (negative acceleration or deceleration). Jerk is calculated as the change in acceleration from the prior week to the current week. Jerk is the second indictor of whether the pandemic is getting worse, with a positive jerk signaling growing acceleration that is possibly associated with a super-spreading event, ineffective reopening policy, colder weather, or other behavior or environmental change. A negative jerk indicates a slowing acceleration, possibly leading to a plateau or even a peak followed by deceleration in the pandemic.

Dynamic Panel Data Regression Methods

The DPD model generates the 7-day persistence surveillance indicator. This model relies in part on discerning common trends across counties within a metropolitan area, if present, to inform the modeling of overall metropolitan area trends in general and the 7-day persistence effect in particular.

We cannot replicate the full model described elsewhere [50,51] since testing data are available only on the number of positive tests administered by each county. Instead, we use the abbreviated model:

where the subscripts i and t denote the county within the metro area and the day of the measurement, respectively. $Speed_{it}$ is the number of new cases in county i on day t, ε_{it} is an error term, and the β_j parameters are those to be estimated. β_1 and β_2 quantify the 1-day and 2-day lag effects, and β_3 determines the base coefficient value for calculating the 7-day persistence effect. β_3 measures the number of new cases today that are statistically attributable to new cases 7 days ago, that is, it measures the propensity of the pandemic to travel in week-long "echoes" in which people newly diagnosed a week ago also infected others a week ago, and these others are diagnosed as new cases today. These week-long echoes could be caused by idiosyncratic factors such as super-spreading events and/or by systemic factors such as a systemic disregard for social distancing and mask wearing. The indicator variables $I_{10.9\text{-}10.15}$ and $I_{10.2\text{-}10.8}$ define the weeks October 9-15 and October 2-8, respectively, so that the coefficients β_4 and β_5 quantify weekly shifts in the 7-day persistence effect. A positive weekly shift could be caused by a super-spreading event that occurred during the week in question, by reopening, by the removal of mask-wearing requirements, or similar events.

We applied the DPD model to the 25 most populous metropolitan areas in the United States. The model was estimated using the generalized method of moments (GMM) approach [58] as implemented by Arellano and Bond [59] for DPD models and applied to the COVID-19 pandemic by Oehmke et al [50,51]. The Wald chi-square test was administered to test model fit based on the null hypothesis that the regression contains no explanatory power. The Sargan chi-square test was applied to determine model validity by testing the null hypothesis that the model is valid [58]. Statistical significance was determined at the 5% level. All estimations were conducted in STATA/MP 16.1 (StataCorp LLC) using the xtabond command.

Because of the use of lagged values in these formulae, we reported results for each of the 55 "weeks" (7-day periods) from Monday, March 2, 2020, through Sunday, January 3, 2021, in the Multimedia Appendices 1 and 2. This paper contains the results for the week of October 9-15, 2020.

Results

Persistence Rates

Complete data for persistence rates by International Standards Organization (ISO) week and metropolitan area are provided in an excel sheet (Multimedia Appendix 1). The full set of persistence results cover the week beginning on April 6, 2020, through the week ending on January 3, 2021. To optimize computer resources, weekly persistence rates were estimated using data for the annual quarter containing the week; for example, persistence rates for ISO week 53 (December 28, 2020, to January 3, 2021) are estimated from data for the fourth quarter of 2020.

We were unable to estimate a persistence rate for Phoenix for the week ending January 3, 2021, due to insufficient data at the time of estimation. The metropolitan areas of Los Angeles and Riverside comprise only 2 counties, and San Diego comprises 1 county, so at times there was insufficient cross-county variation for the application of DPD techniques. In this case, we estimated values for the combined Southern California region (combined Los Angeles, Riverside, and San Diego metro areas). In particular, persistence rates reported for Riverside and San Diego for the fourth quarter (ISO weeks 41 through 53) are estimates for the Southern California region.

A positive persistence rate most likely indicates continuing unsafe COVID-19 behaviors that recur over time, whereby infected individuals in a given week transmit the infection to other individuals who appear as COVID-19 cases the next week, leading to a "persistence" in the number of COVID-19 cases reported each week. Large positive persistence rates are associated with increasing case rates, and rates greater than 1 are indicators of potentially explosive growth. A negative persistence rate could indicate a choppy, up-and-down movement in the number of COVID-19 cases from week to week, or a period of downturn and decline in the number of cases.

Entering 2021, the metropolitan areas with the largest persistence were New York City (1.83), Miami (1.00),

Philadelphia (1.61), Tampa (1.08), Charlotte (1.29), and Orlando (1.04). These areas are at high risk for increased COVID-19 caseloads during the first full week of January, with a potential for explosive growth.

Surveillance Results

We report novel surveillance results of speed, acceleration, and jerk for each of the 44 "weeks" (7-day periods) from the week beginning on March 2, 2020, through the week ending on January 3, 2021, in Multimedia Appendix 2. Table 1 contains the results for the week of October 9-15, 2020. In relation to the timeline presented in Figure 1, notable findings are that for New York City and Seattle jerk turned negative the week of March 27 to April 2, 2020, 1 week after shutdowns. In Detroit, jerk turned negative the week of April 3-9, 2020, 2 weeks after the shutdown in Michigan. The negative jerks indicate a slowing of the pandemic acceleration; the chronological propinquity to the shutdown orders was consistent with a strong and rapid impact of these orders on the pandemic. The average number of daily new positive results for the week of October 9-15 ranged from 19 for San Antonio to 627 for Los Angeles (Table 2). The metropolitan areas with the greatest speed were Minneapolis (30) and Chicago (21). The metropolitan areas with the slowest speed were Portland (3) and San Francisco (5).

In the New York metropolitan area, the first wave peaked during the week of March 20-26, 2020, with an average of 12,855 new cases per day or a speed of over 68 new cases per day per 100,000 population. During the week of April 10-16, 2020, this area started to gain control of the pandemic, characterized by a negative acceleration (–10) and the area's largest negative jerk (–33). The next 8 weeks were characterized by negative acceleration, with speed declining to an average of 3 new cases per day per 100,000 population during the week of May 29 to June 4, 2020, and remaining at values of 3 or 4 before starting a second wave ascent the week of September 18-24, 2020. This general pattern was replicated to a large degree in other northern cities hit early by the first wave.

Although Dallas recorded its first 3 cases on March 9, case counts increased relatively slowly during an early Dallas shutdown to an average of 175 new cases daily and a speed of 2.3 new cases per 100,000 during the week of April 17-23. After the governor ordered Texas to reopen on April 17, case counts increased noticeably but not explosively, reaching a speed of 4.9 new daily cases per 100,000 the week of May 29 to June 4. During that week, acceleration and jerk turned positive and stayed positive through the week of July 10-16, possibly associated with the hot weather that encouraged people to visit crowded beaches or otherwise break social distancing and other COVID-19 protocols [60-62], which is considered risky behavior [63]. The first wave peaked in Dallas during the week of July 10-16 with an average of 2084 new cases per day that week and a speed of over 27.5 new cases per 100,000. Following the reimposition of COVID-19 prevention measures on July 2, acceleration turned negative and the number of cases declined during the weeks spanning July 17 to September 10, with the exception being the week of August 14-20 when a spike was associated with clearing a backlog of unreported prior test results [64]. However, even the trough during the week of September 4-10 had an average of 640 new cases per day and a speed of 8.4 new daily cases per 100,000, which is higher than during the early shutdown. In Dallas, the pandemic has now re-emerged with an average of 1116 new cases per day and a speed of 14.7 new daily cases per 100,000. Other southern metropolitan areas including Houston, Miami, Phoenix, and Tampa experienced similar first wave patterns, although evidence of a second wave has not hit all southern cities.

Table 1. Novel surveillance metrics for the week of October 9-15, 2020.

Metropolitan area	Number of daily new positive results, weekly average	Speed[a]	Acceleration[b]	Jerk[c]	7-day persistence effect[d]
1. New York	67	8	–1	–3	0.68
2. Los Angeles	627	8	0	0	2.90

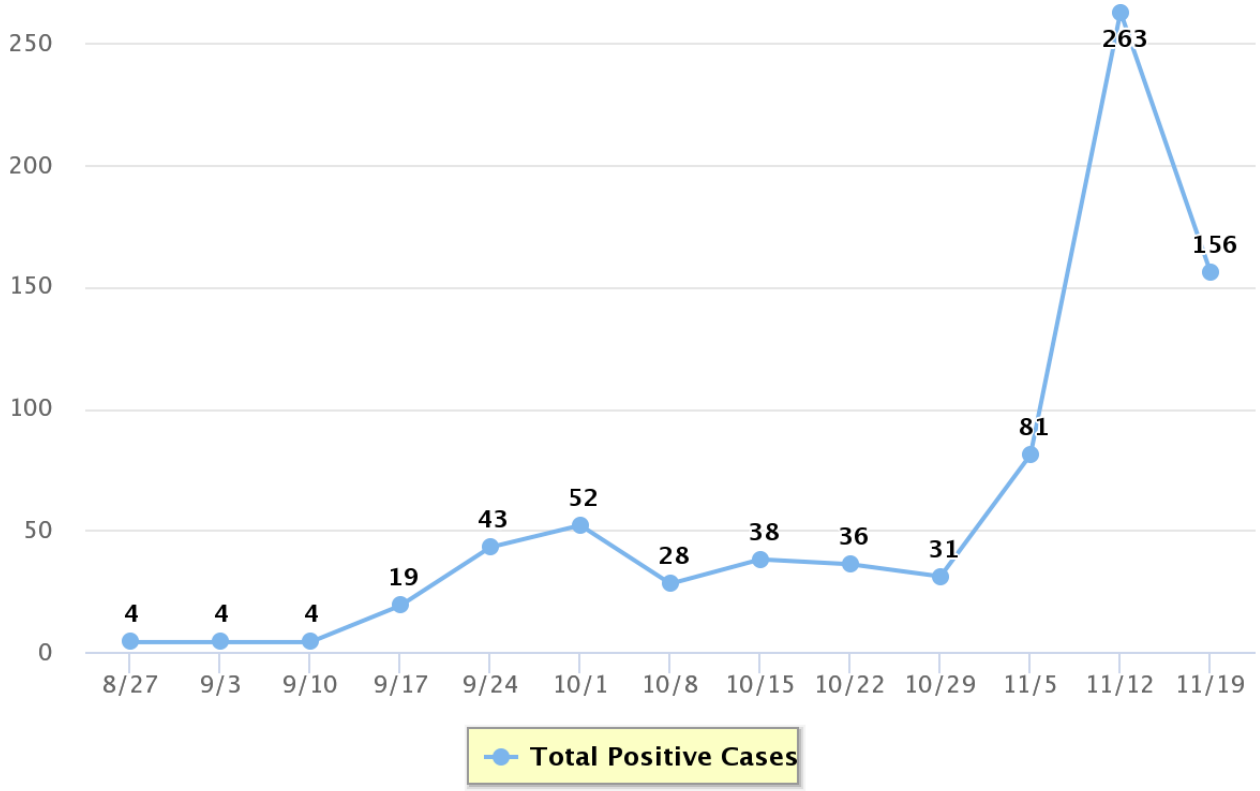
Dynamic Panel Data Model Results

Table 1 contains the regression diagnostics for the models. The Sargan tests of model validity failed to reject the null hypothesis of validity for all metro areas except for Minneapolis (χ^2_5=531.86, *P*<.001), showing model validity for all areas but Minneapolis. Rejection of the null hypothesis for the Sargan test for Minneapolis means that the model is not valid for this metro area and is insufficient to capture the rapid acceleration and jerk exhibited by Minneapolis. Minneapolis exhibited extreme behavior, with its speed jumping from an average number of 17 daily new positive results standardized per 100,000 population for the week of October 2-8 to 30 (67% increase) for the week of October 9-15. No other metropolitan area has exhibited that high a speed for the week of October 9-15.

Potential risk factors for the Minneapolis increase include the advent of colder fall weather, although the week of October 9-15 was warmer than average [65], and the phase II reopening of the University of Minnesota. During the prior weeks, the number of new cases reported at the University of Minnesota increased from 4 in the beginning of September to 52 the first week in October (Figure 2), which numerically contributes to Minneapolis' rapid acceleration and large jerk. The influence of universities reopening is consistent with state-level findings reported by Oehmke et al [50].

Figure 2. Number of positive COVID-19 cases recorded by the University of Minnesota, Twin Cities.



The Wald test of model significance shows that the model explains a statistically significant proportion of the variation in the caseload for 16 of the 25 most populous metropolitan areas. The lack of statistical significance in the other 9 most populous metropolitan areas is indicative of the absence of both 1-day and 7-day persistence effects, since the regression equation is designed specifically to measure these persistence effects. The lack of a persistence effect is most likely to occur when the number of new cases per day is relatively flat (constant speed). For example, the Wald test for the Tampa metropolitan area is 7.18 (*P*=.21), and for the weeks included in the regression analysis the speed was 9, 10, 8, 9, and 10, respectively. In other words, the lack of a significant persistence effect is consistent with and corroborates the finding of a low-level and flat profile for the pandemic in the Tampa metropolitan area during those weeks. Of the 9 areas where the model was not statistically significant, 8 had fewer than 10 counties. In the ninth area, St Louis, the speed ranged from 17 to 24 for the past 3 months with no discernable upward or downward trend—in this case, a simple constant provides a reasonably good model and the DPD model contributes only minimally.

Detroit's speed increased from 59 for the week October 2-8 to 82 in the week October 9-15. Its persistence factor increased by 0.6095 for the week of October 9-15 from 0.5095 to 1.290, which is indicative of explosive growth, although neither the base persistence effect nor the weekly shift effect was individually statistically significant. Chicago had one of the largest percentage increases in speed, from 87 the week of September 25 to October 1 to 100 for the week of October 2-8 to 142 for the week of October 9-15, an 80% increase in just 2 weeks, and Chicago's persistence for the weeks of October 2-8 and October 9-15 increased by 0.2238 and 0.5085, respectively. Minneapolis had the second highest increase in speed over the 2 weeks, from 38 at the beginning of the 2-week period to 42 at the end of the second week to 63 at the end of the third week. This represents a 67% increase in just 14 days. For the week of October 9-15, Minneapolis experienced a persistence shift of 0.8143, the largest persistence shift recorded during the 2-week period. An increasing persistence (positive and statistically significant shift) would be expected to lead to greater speed in the next week.

Discussion

Principal Findings

The DPD model successfully represented COVID-19 case dynamics for all metropolitan areas, except for the Minneapolis-St. Paul-Bloomington area that experienced extreme events. Calculating speed, acceleration, and jerk also helped with understanding case dynamics in metro areas, especially as they refer to characterizing a peak or wave progression.

The first wave of COVID-19 hit northern metropolitan areas first. These areas were able to flatten the curve by imposing shutdowns, social distancing, mask wearing, and other COVID-19 protocols. The first wave did not hit southern metropolitan areas as early or as hard as northern areas; southern metropolises reopened and only after reopening did the first wave truly hit. The current situation in the New York metropolitan area exemplifies the usefulness of the novel

metrics. The second wave hit New York during the week of August 28 to September 3, based on changes in acceleration and jerk from negative to positive values. The onset was confirmed the week of September 11-17, when acceleration nearly tripled from the prior week, and jerk more than quadrupled to a value of 0.98. However, the governors of New York and New Jersey did not impose additional restrictions until November 11, and then the restrictions were primarily curfews on bars and late-night entertainment, based on information available at the time [66]. Use of novel metrics could have influenced earlier, more forceful, and more proactive COVID-19 policy.

Limitations

A limitation of this data set is that it does not have data on the total number of tests reported per day at the county level. A limitation of the estimation technique is that the metropolitan areas of San Diego and Riverside, comprising one and two counties, respectively, had insufficient cross-sectional information and the estimation had to be conducted for a combined southern California region.

Conclusion

Our analysis including the use of novel surveillance metrics shows that the second wave of the pandemic has arrived in the United States and is accelerating, especially in northern metropolitan areas. For metropolitan areas in the Midwest, specifically Chicago, Detroit, and Minneapolis, there has been rapid and potentially explosive growth in cases during the first half of October 2020. This type of growth can be seen from the cities' speed, acceleration, and jerk, as well as the increasing 7-day persistence effects. It is critical for those cities already feeling the second wave to react swiftly and strongly. For those cities who have so far escaped the second wave, it is critically important to studiously monitor surveillance data to ascertain if and when the second wave is beginning to hit, and then to be proactive in reimposing COVID-19 protocols. The overall conclusion is that improved COVID-19 surveillance metrics can help cities be proactive in managing the pandemic, leading to fewer cases and saving lives.

Abstract

Background: The Centers for Disease Control and Prevention (CDC) is a national public health protection agency in the United States. With the escalating impact of the COVID-19 pandemic on society in the United States and around the world, the CDC has become one of the focal points of public discussion.

Objective: This study aims to identify the topics and their overarching themes emerging from the public COVID-19-related discussion about the CDC on Twitter and to further provide insight into public's concerns, focus of attention, perception of the CDC's current performance, and expectations from the CDC.

Methods: Tweets were downloaded from a large-scale COVID-19 Twitter chatter data set from March 11, 2020, when the World Health Organization declared COVID-19 a pandemic, to August 14, 2020. We used R (The R Foundation) to clean the tweets and retain tweets that contained any of five specific keywords—cdc, CDC, centers for disease control and prevention, CDCgov, and cdcgov—while eliminating all 91 tweets posted by the CDC itself. The final data set included in the analysis consisted of 290,764 unique tweets from 152,314 different users. We used R to perform the latent Dirichlet allocation algorithm for topic modeling.

Results: The Twitter data generated 16 topics that the public linked to the CDC when they talked about COVID-19. Among the topics, the most discussed was COVID-19 death counts, accounting for 12.16% (n=35,347) of the total 290,764 tweets in the analysis, followed by general opinions about the credibility of the CDC and other authorities and the CDC's COVID-19 guidelines, with over 20,000 tweets for each. The 16 topics fell into four overarching themes: knowing the virus and the situation, policy and government actions, response guidelines, and general opinion about credibility.

Conclusions: Social media platforms, such as Twitter, provide valuable databases for public opinion. In a protracted pandemic, such as COVID-19, quickly and efficiently identifying the topics within the public discussion on Twitter would help public health agencies improve the next-round communication with the public.

KEYWORDS

COVID-19; CDC; Twitter; public discussion; public opinion; social media; data mining

Introduction

Since first identified in Wuhan, China, in December 2019, COVID-19 has spread rapidly around the world. On March 11, 2020, the World Health Organization (WHO) declared the coronavirus outbreak a pandemic and was unable to determine the duration of the pandemic [1]. As of August 5, 2020, 213 countries and territories around the world have reported a total of 18,939,540 confirmed cases and a death toll of 709,700 [2].

The United States reported its first case on January 20, 2020 [3]; the country had 4,802,491 total COVID-19 cases and 157,631 total deaths as of August 5, 2020 [4].

The Centers for Disease Control and Prevention (CDC) is the "nation's health protection agency, working 24/7 to protect America from health and safety threats" [5]. Since January 21, 2020, the CDC has launched an agencywide response to this pandemic, including preparing health care providers and health systems, supporting governments at various levels on the front lines, and learning and sharing COVID-19 knowledge via a variety of communication channels. Amid the unprecedented public health crisis caused by the pandemic, the bewildered public in dire need of guidance depends on the quick response of public health authorities and is in greater demand for information and advice from them [6]. Previous studies found that the public willingness to take the advice (eg, handwashing) proposed by public health agencies, which will further impact the success of disease control strategies and policies, is related to the trust that the public has in the agencies [7-12]. During the Zika outbreak, studies found a substantial topic discrepancy between public concern and the CDC's response to Zika [13-16], undermining the efficacy of the CDC's Zika control efforts. Considering that the COVID-19 pandemic will last for a protracted time, timely information about public opinion regarding the CDC's COVID-19 response efforts and their concerns about COVID-19 can provide insight to improve the next round of communication with the public.

Social media platforms such as Twitter have not only become increasingly important for the public to seek, share, and discuss information, but have also provided valuable platforms for the surveillance of public opinion, allowing for the monitoring of the public's questions, concerns, and responses to health threats [17-19]. In previous public crises, such as the Ebola virus [20], Zika virus [13,17,21], and H1N1 virus outbreaks [22], Twitter was used as an up-to-date information source to gauge the public's knowledge and reactions to the epidemics. During the Zika outbreak, it was found that inaccurate information proliferated on social media, and conspiracy theories regarding the Zika virus were more popular than public health education materials from health agencies [23]. Therefore, using social media to monitor public knowledge, to evaluate the information spread online, and to address the identified problems in a timely manner is crucial in battling public health crises. In addition, when an epidemic situation is not clear, the discussion on social media can provide timely information for improving epidemic surveillance and forecasting [24-27]. Therefore, the value of online discussion on social media platforms, especially during infectious disease epidemics, has gained ever more attention by public health agencies and officials [24-26]. The CDC has been actively using Twitter to reach out with timely health and safety information [28] and even hosted live Twitter chats to directly communicate with the general public in the periods of the Ebola outbreak [20] and the Zika outbreak [13].

The ongoing COVID-19 pandemic demands continuous and evolving efforts of using social media data to understand the public's thoughts and concerns. While a series of studies made significant contributions along these lines, the majority of existing studies analyzed data collected before the middle of April 2020 [29-39]. In addition, there have been scarce social media studies with a focus on the CDC during the COVID-19 pandemic [6], the main source for evidence-based information about the pandemic [40]. To fill the gaps in knowledge after the WHO's declaration of a pandemic, we used text mining methods to analyze COVID-19-related tweets about the CDC from March 11 to August 14, 2020. By doing so, this study identified the topics emerging from the tweets and the overarching themes of these topics, shedding light on a series of questions: What are the public concerns over COVID-19? What does the public expect from the CDC? and How does the public comment on the current performance of the CDC in response to COVID-19?

Methods

Data Extraction and Preprocessing

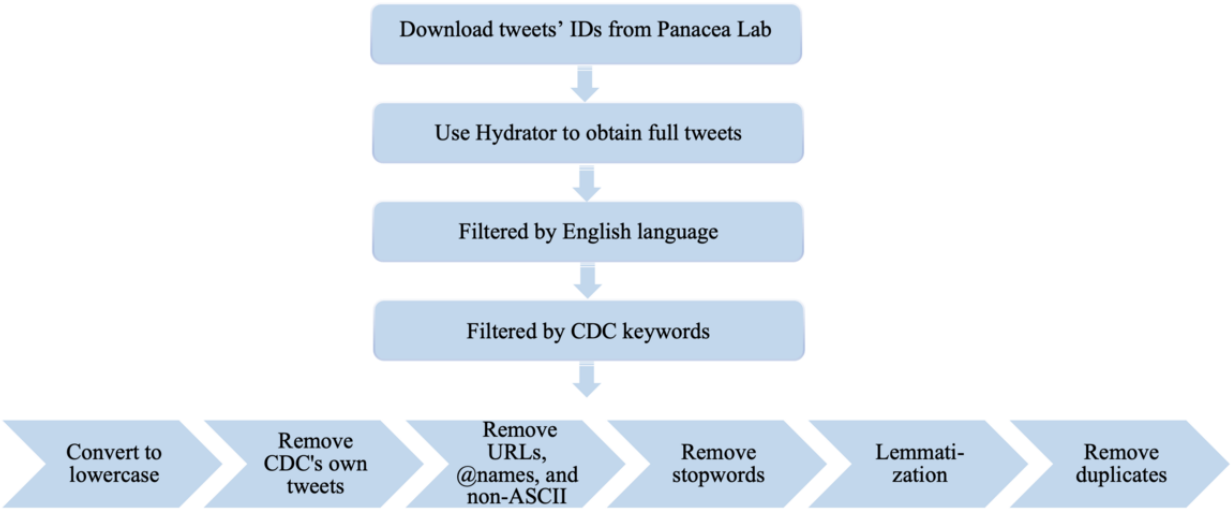
The IDs from a total of 128,432,021 tweets, without retweets, from March 11 through August 14, 2020, were obtained using the data set maintained by Georgia State University's Panacea Lab [41]. These tweets were collected by the Panacea Lab using the following 13 keywords: COVD19, CoronavirusPandemic, COVID-19, 2019nCoV, CoronaOutbreak, coronavirus , WuhanVirus, covid19, coronaviruspandemic, covid-19, 2019ncov, coronaoutbreak, and wuhanvirus. Since Twitter's Terms of Service do not allow the full JavaScript Object Notation (JSON) for data sets of tweets to be distributed to third parties, Georgia State University's Panacea Lab can only provide tweet IDs [42], which can be hydrated to obtain the JSON objects from these tweets.

During the tokenizing stage, we used the *gsub* function in R (The R Foundation) to extract the tweets whose language field in the tweets' metadata was specified as English. All text mining was done using R 4.0.2 GUI (graphical user interface) 1.72 Catalina build (7847) on a Mac running 10.15 Catalina.

We converted all the tweets to lowercase and created a script to remove the URLs, mentioned names, non-ASCII (American Standard Code for Information Interchange) characters such as emojis, and anything other than English letters or spaces (eg, "1," "?," etc). Using the R package *dplyr*, version 1.0.2, we cleaned the tweets by removing duplicates, retained only tweets that contained any of five specific keywords—cdc, CDC, centers for disease control and prevention, CDCgov, and cdcgov—and eliminated all 91 tweets posted by the CDC itself. The final cleaned data set consisted of 290,764 unique tweets from 152,314 different users. We further cleaned the tweets by removing words and characters that were of little or no analytical value (eg, "the," "very," "&," etc). We performed this task by creating our own list of stop words by appending the 13 keywords related to "COVID19" and the five keywords related to "CDC" to the English stop words list from the R package *tidytext*, version 0.2.6; this was done because we already knew that every tweet would contain one or more of those keywords, and having them in the tweets does not contribute to further our understanding of the main content of the tweets. Lastly, we stemmed and lemmatized the words to their root forms using the R package *textstem*, version 0.1.4 (eg, *studying*, *studies*, and

studied were converted to *study*). See Figure 1 for a summary of our data extraction and preprocessing procedure.

Figure 1. Flowchart for data extraction and preprocessing. CDC: Centers for Disease Control and Prevention.

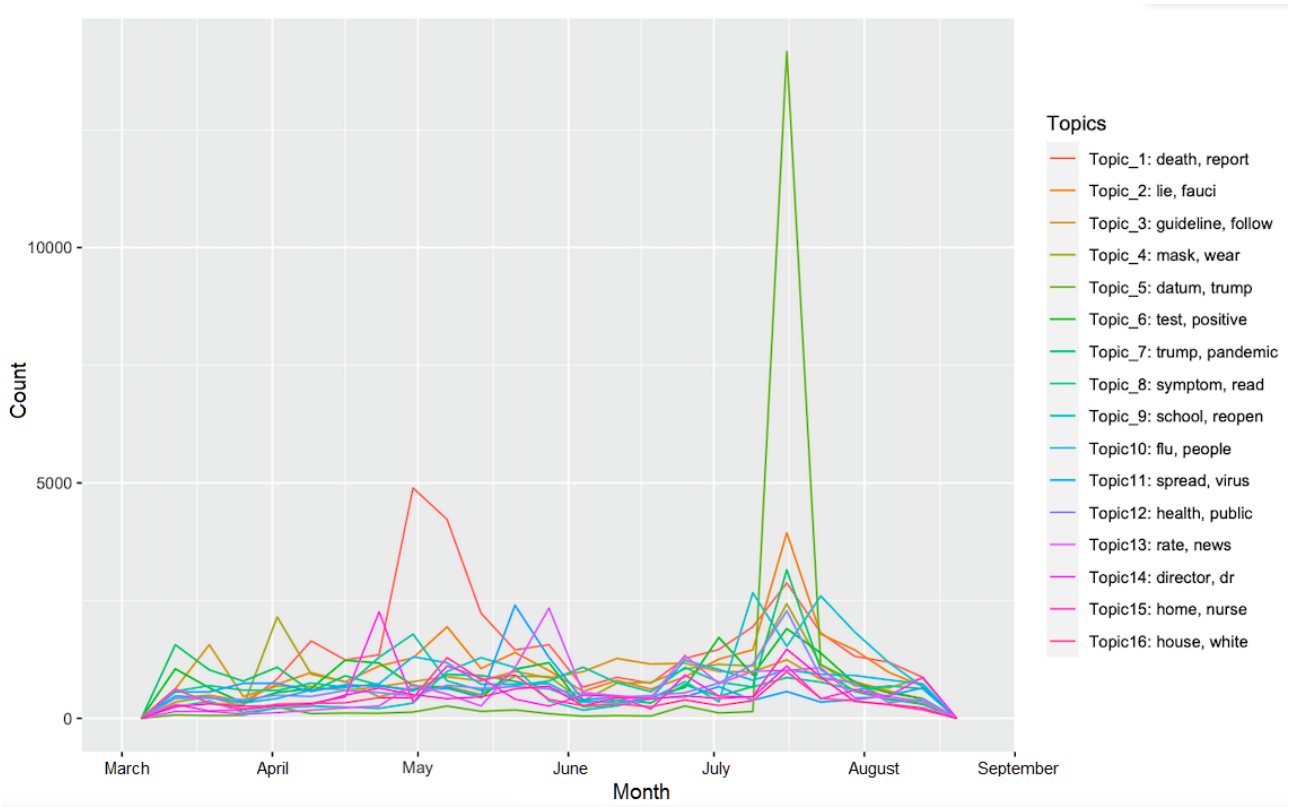


Topic Modeling

Topic modeling provides an automatic, or unsupervised, way of summarizing a large collection of documents. It can help discover hidden themes in the collection, group documents into the discovered themes, and summarize the documents by topic. Topic modeling is often referred to as *soft* clustering, but it is more robust and provides better and more realistic results than typical clustering (eg, k-means clustering) or *hard* clustering [43]. A typical clustering algorithm assumes a distance measure between topics and assigns one topic to each document, whereas topic modeling assigns a document to a collection of topics with different weights or probabilities without any assumption on the distance measure between topics. There are many topic models available. "The most widely used model for topic modeling is the latent Dirichlet allocation (LDA) model" [43], developed by David Blei, Andrew Ng, and Michael I Jordan in 2002 [44].

To extract common topics from this sheer number of tweets, we used the LDA algorithm for topic modeling. We performed the LDA algorithm on the data using the R *textmineR* package, version 3.0.4. The LDA algorithm requires manually inputting the number of expected topics. We ran the LDA algorithm on the data by varying the topic number from 2 through 40. For each topic number, we calculated the coherence score using the *textmineR* package; we ended up choosing 16 topics for the final model, as the topic number that was equal to 16 yielded the highest coherence score. The top eight terms from each of the 16 topics were generated. We also used the *geo_freqpoly* function in the R package *ggplot2*, version 3.3.2, to generate the frequency polygons (see Figure 2) in order to visualize the weekly frequency of the 16 topics from March 11 to August 14, 2020. For each tweet, the LDA assigned a probability to each of the 16 topics. We assigned the topic with the highest probability to a tweet and we grouped the tweets according to the most prevalent topics. To obtain representative tweets for each topic, we randomly sampled 100 tweets from each topic; the two authors then independently examined the sampled tweets, followed by a group discussion to select the most representative ones. If one of the authors thought that there were no conspicuous topics that emerged from the first 100 sampled tweets, another 100 tweets would be sampled and further reviewed; the authors continued this process until the two judged that there was a clear common topic and they reached a consensus. We used the *textmineR* package's topic label function to generate an initial labeling for the topics. After carefully reading through the sampled tweets from each topic, the two authors refined the machine-generated labeling to give each topic the most accurate, concise, and coherent description (see Table 1). Through discussions, the authors further grouped the topics into overarching themes.

Figure 2. Weekly frequency of each topic on Twitter, from March 11 to August 14, 2020.



Results

Overview

The Twitter data generated 16 topics that the public linked to the CDC when they talked about COVID-19. Table 1 shows the topics generated, the number and percentage of each topic, description of topics, and the representative tweets. The topics are sorted according to the number of the tweets in decreasing order. Among the topics, the most discussed was COVID-19 death counts, accounting for 12.16% of the total tweets included in the analysis, followed by general opinions about the credibility of the CDC and other authorities and the CDC's COVID-19 guidelines, with over 20,000 tweets for each topic. The topics in Table 1 can be categorized into four overarching themes, as discussed in the four sections following the table.

Table 1. COVID-19-related tweets about the Centers for Disease Control and Prevention (CDC) by topic.

Topic No.	Terms contributing to topic model	Total tweets (N=290,764), n (%)	Description	Examples of representative tweets (date posted)
1	Death, report, count, week, numb, total, datum, and pneumonia	35,347 (12.16)	Discussion of COVID-19 death counting, focusing on whether the accounting of COVID-19 cases is accurate	"Actually, they aren't even lying about it. The CDC was frank about changing their accounting of COVID-19 cases to encompass contacts with presumptive cases, statistically causing this sudden huge case explosion. [link]" (July 13, 2020) "COVID death counts are inflated. According to CDC: 'ideally testing for COVID-19 should be conducted but it is acceptable to report COVID-19 on a death certificate without this confirmation if the circumstances are compelling within a reasonable degree of certainty.' Read and rt! [link]" (August 7, 2020)
2	Lie, Fauci, people, Trump, trust, doctor, listen, and vaccine	26,026 (8.95)	General opinions about credibility of the CDC and other authorities	"Coronavirus is not political. the curve has not flattened and people are still dying. Trump and our leaders need to listen to scientists and the CDC. You are, most definitely, a cultist." (July 10, 2020)(July 28, 2020) "People: I don't believe anything about the coronavirus I hear from the government, Dr. Fauci, CDC, FDA, WHO, JLA, OPP, or anyone else I've ever heard of. Nope." (July 28, 2020)"
3	Guideline, follow, follow_guideline, people, stay, recommendation, social, and distance	20,032 (6.89)	CDC's COVID-19 guidelines, with a considerable number of tweets about the social distancing and stay-at-home orders	"Bottom line: the more adherent we are to the CDC guidelines, the faster the economy will recover. Stop gathering, put masks on and we will get out of this. Labor secretary: discipline now in following COVID-19 guidelines will end economic slump 'quickly'. [link]" (April 4, 2020) "Coming back to work after 3 months stay-home order (COVID-19) following all safety measures CDC guidelines. Theme 1: Knowing the Virus and the Situation

Based on the number of tweets, the most tweeted theme was knowing the virus and situation (132,139/290,764, 45.45%). This theme consisted of seven topics: discussion of COVID-19 death counting (35,347/290,764, 12.16%), accuracy of antibody test (18,937/290,764, 6.51%), new symptoms added to the list of COVID-19 (18,326/290,764, 6.30%), number of COVID-19 deaths (16,950/290,764, 5.83%), spread of COVID-19 (15,223/290,764, 5.24%), death rate of COVID-19 (13,963/290,764, 4.80%), and the CDC director Dr Robert Redfield's warning of a deadlier second wave (13,393/290,764, 4.61%). This theme reflected the public's desire to know the virus, such as how it spreads, symptoms of infection, the risk of death, and the situation, such as whether the current response is accurate and effective and how the situation will change. COVID-19 death–related discussion, including death counting, death number, and death rate, dominated this theme.

Theme 2: Policy and Government Actions

The second most tweeted theme was policy and government actions (92,633/290,764, 31.86%). This theme consisted of six topics: commenting on COVID-19 data reporting being routed away from the CDC (19,098/290,764, 6.57%), the Trump administration's health care policies (18,888/290,764, 6.50%), the policy of reopening schools (18,201/290,764, 6.26%), the CDC not leading the control over COVID-19 (15,010/290,764, 5.16%), the practice of sending COVID-19 patients to nursing homes (10,906/290,764, 3.75%), and the tension between the White House and the CDC (10,530/290,764, 3.62%). Tweets under this theme featured comments that challenged the government's actions and policies. Many tweets mentioned that the dismissal of the pandemic response team in 2018 and cutting the CDC's funding weakened the CDC during the COVID-19 pandemic. When the government announced on July 15, 2020, that COVID-19 hospital data would not be reported to the CDC, the number of tweets related to the topic of the CDC not leading the control over COVID-19 for a single day and a single week both set the record (5954 tweets on July 15, 2020, and 13,392 tweets in the week starting on July 15, 2020; see Figure 2 for reference). The dominant voices were complaints against this policy change.

Theme 3: Response Guidelines

The third most tweeted theme was response guidelines (39,966/290,764, 13.75%), which was about how to respond to COVID-19. This theme covered two topics: the CDC's COVID-19 guidelines with a focus on social distancing and stay-at-home orders (20,032/290,764, 6.89%) and the CDC's recommendation of wearing face masks (19,934/290,764, 6.86%). Both of these topics were highly discussed on Twitter, ranking third and fourth, respectively, according to the number of tweets for a single topic. Most of the tweets under this theme suggested that the CDC's guidelines for individuals, businesses, and other organizations should be followed. Many tweets provided the CDC links to the public for further details; one of the most common CDC links mentioned by Twitter users was the video tutorial released by the CDC about making cloth masks.

Theme 4: General Opinion About Credibility

The topic of general opinion about credibility of the CDC and other authorities in charge, such as Dr Fauci, Dr Birx, President Donald Trump, the Food and Drug Administration, and the WHO, stands alone as a category of themes, being the fourth most tweeted theme (26,026/290,764, 8.95%) and the second most tweeted topic, trailing only behind the topic of COVID-19 death counting. Different from the other topics, the tweets under this topic did not point to one or a few specific things; instead they usually expressed general opinions and sometimes together with emotions. Words reflecting "credibility," such as "lie," "trust," "listen," "hoax," "conspiracy," "stupidity," and "fail," were frequently used by Twitter users. However, it was noted that the negative words did not always point to the CDC; instead, there were a substantial number of tweets grouped under this same theme asking people to stand with the CDC and listen to the scientists (see the representative tweets of this topic in Table 1).

Discussion

Principal Findings

Revealed by the quantity of tweets, the public's most prominent concern was death, with over 22.79% of tweets relating to death-related discussion. Previous infoveillance studies of Twitter data in the early period of COVID-19 found that 4.34% of tweets were about death reporting [45] and 10.54% of tweets pertained to deaths caused by COVID-19 [29]. The substantial increase in the death-related discussion with the progression of the pandemic highlighted the urgency of communicating adjusting information to the public, which refers to the information helping them to cope psychologically in threatening situations [46]. Fear and stress were common emotions during the COVID-19 pandemic [29]. Much fear derives from uncertainty and the unknown. Furthermore, the perceived threat in challenging situations motivated people to actively seek information to ease the uncertainty caused by the crisis [47,48]. This explained why a considerable amount of discussion focused

on understanding the COVID-19 virus and how the virus has been coped with. In order to put the impact of COVID-19 into perspective, many tweets compared the death rate of COVID-19 with influenza, H1N1 swine flu, Ebola, and pneumonia, which are more familiar to the public. Discussion about the accuracy of COVID-19 death counting and antibody tests also shows the public's concerns about the current actions of the agencies in charge in response to COVID-19. These findings indicate that in large-scale public health crises such as the COVID-19 pandemic, an imperative component of communication to the public should be informing them of the knowledge of the virus and the factual information about the situations to alleviate fears and confusion. More direct interaction with the public on social media, such as holding an online chat as the CDC had done in the Ebola [20] and Zika outbreaks [13], may also help provide the public with reassurance. In addition, comprehensibility is an important consideration for COVID-19 communication to the public: using language that fits the level of public knowledge helps address the possible misunderstanding of information and avoid the dissemination of misinformation and even rumors.

The majority of the public discussion involved how to act during the COVID-19 pandemic. This echoed past crisis research: in risky environments, the first information that should be conveyed to the public is the information that instructs the public on how to protect themselves in the threatened environments [46]. It also showed that taking actions to prevent the virus from spreading, such as wearing masks and observance of social distancing orders, is a constant topic of the public from the prepandemic period to the peripandemic period [29,45]. The CDC's instructions on how to act in the context of the COVID-19 pandemic, such as guidelines for reopening, recommendations on wearing masks, and how to make masks, have successfully attracted the public attention as soon as they were released. The public not only spread the guidelines widely on Twitter, but they also tweeted explicitly to urge people to follow the CDC's guidelines by providing official CDC links in their tweets. This reflected the public's urgent need for such information to guide their actions, and they took the instructing information from the CDC very seriously. During the unprecedented crisis of COVID-19, scientific understanding of the virus takes time and keeps evolving. Our study suggested that in the next round of COVID-19 communication, the CDC should continue to strive to translate scientific findings into practical instructions, to provide guidance on how to act for both individuals and organizations, and, finally, to protect the public during the pandemic.

As to the CDC's performance in the COVID-19 response, the public expressed mixed comments. One factor contributing to this may be that the CDC has not played a central role in controlling the pandemic; this deviated from what the CDC had done historically during epidemics [49,50]. Even so, it is noted that the discussions on Twitter showed that most of the Twitter users still looked up to the CDC as the authority in disease control and had great expectations for the CDC to lead the fight against COVID-19. While there were negative wordings (eg, "liars," "hoax," "stupidity," and "failed") in the public's general opinions about agencies in charge during the pandemic, including the CDC, it was noticeable that many tweets attributed the current performance of the CDC to the government's policy, criticizing the Trump administration's policies and actions for undermining the functioning of the CDC in response to COVID-19. An early study on the outreach efforts of public health authorities on Facebook found that the spike in public response happens in conjunction with specific events [6]. In our study, the trigger event for a record number of tweets was the announcement that the reporting of COVID-19 hospital data would be sent to the Trump administration rather than the CDC, and the dissenting voice dominated the discussion on this topic. To a large extent, this finding is consistent with the findings of a survey study that showed that Americans' average trust rating for the CDC was significantly higher than that for President Trump [40]. The significance of positive public perception of public health agencies has been receiving increasing recognition [9,10,51,52]. It has been found that greater trust in the CDC was associated with increased knowledge and a lower acceptance of misinformation [40]. The widespread dissemination of the CDC guidelines, as well as the fast speed at which they were circulated, on the one hand reflected the public's urgent need for information as discussed above and, on the other hand, it reflected their trust in the CDC. Even though the CDC's coping so far has not been satisfactory as shown in the tweets, the public's general trust in the CDC is an intangible asset that the CDC can tap into in the next round of the fight against COVID-19.

Limitations

There are a few limitations to this study. First of all, tweets from accounts marked as private might be missed in the data collection, and tweets generated by bots or fake accounts might not have been filtered. Second, this study identified topics from the public discussion about the CDC but did not examine the temporal variance of topics. Although this is not in our research scope, it may deepen our understanding of how the public changed their focus as time and specific situations during that time changed. Therefore, we highly suggest that future studies put emphasis on the temporal dimension of online public discussion about COVID-19 to get more insight into the formation and variation of the discussion topics. Third, this study did not investigate the public's emotions shown in the tweets, which is an important dimension of the public discussion. Future research in this line of study may shed light on the public's affective response to the CDC's actions and may inform the CDC about the public's emotions to be addressed during the pandemic. Lastly, Twitter users do not represent the US population [20]. Therefore, as with all social media analyses, findings of this study cannot be generalized to the whole American public.

Conclusions

In public health crises, social media platforms, such as Twitter, can provide valuable databases for public health agencies to understand the public's concerns, focus of attention, and expectations. The ability of text mining to derive high-quality information from massive data sets is ideal for performing surveillance work. Especially in a protracted pandemic such as COVID-19, quickly and efficiently identifying the topics within the public discussion on Twitter would provide insight for the

next round of public health communication in order to mitigate public concerns and avoid the spread of misinformation.

Abstract

Background: The World Health Organization has recognized the importance of assessing population-level mental health during the COVID-19 pandemic. During a global crisis such as the COVID-19 pandemic, a timely surveillance method is urgently needed to track the impact on public mental health.

Objective: This brief systematic review focused on the efficiency and quality of data collection of studies conducted during the COVID-19 pandemic.

Methods: We searched the PubMed database using the following search strings: ((COVID-19) OR (SARS-CoV-2)) AND ((Mental health) OR (psychological) OR (psychiatry)). We screened the titles, abstracts, and texts of the published papers to exclude irrelevant studies. We used the Newcastle-Ottawa Scale to evaluate the quality of each research paper.

Results: Our search yielded 37 relevant mental health surveys of the general public that were conducted during the COVID-19 pandemic, as of July 10, 2020. All these public mental health surveys were cross-sectional in design, and the journals efficiently made these articles available online in an average of 18.7 (range 1-64) days from the date they were received. The average duration of recruitment periods was 9.2 (range 2-35) days, and the average sample size was 5137 (range 100-56,679). However, 73% (27/37) of the selected studies had Newcastle-Ottawa Scale scores of <3 points, which suggests that these studies are of very low quality for inclusion in a meta-analysis.

Conclusions: The studies examined in this systematic review used an efficient data collection method, but there was a high risk of bias, in general, among the existing public mental health surveys. Therefore, following recommendations to avoid selection bias, or employing novel methodologies considering both a longitudinal design and high temporal resolution, would help provide a strong basis for the formation of national mental health policies.

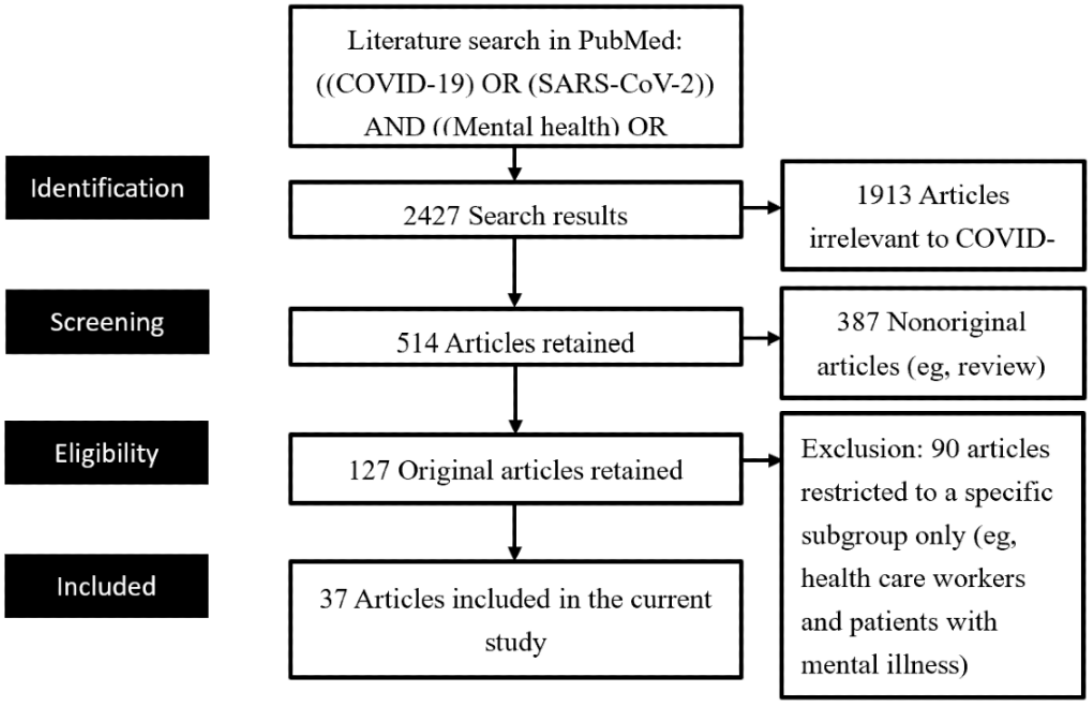
Introduction

The World Health Organization has recognized the importance of assessing population-level mental health during the COVID-19 pandemic. More than 463 articles on the mental health impact of COVID-19 have been published in 2020, and several more mental health surveys are underway [1]. Most of these studies evaluated the psychiatric symptoms among the general public and health care workers, and some others evaluated patients with COVID-19 or those with psychiatric disorders [2]. In a global crisis such as the COVID-19 pandemic, time-sensitive policy decision-making underscores the importance of fostering an agile empirical approach that can monitor population-level mental health in a timely manner. Any change in the mental health impact of COVID-19 is likely to be dynamic. For example, the 20% decrease in suicide rate in Japan observed during the early stage of the pandemic seemed to have reversed in August 2020, when a 7.7% rise was reported [3]. Therefore, a timely surveillance method is urgently needed to track the impact of COVID-19 on public mental health. This brief systematic review focused on studies on the general public conducted during the COVID-19 pandemic and analyzed the efficiency and quality of data collection in the existing literature.

Methods

We used the following search strings to select relevant articles in the PubMed database: ((COVID-19) OR (SARS-CoV-2)) AND ((Mental health) OR (psychological) OR (psychiatry)). We screened the titles, abstracts, and texts of the published articles to exclude irrelevant studies. We also excluded articles published on preprint platforms such as bioRxiv, because we were unable to analyze the time between the receipt of the articles and their availability online. A PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram detailing the study retrieval process is shown in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of article selection for the systematic review.



We used the Newcastle-Ottawa Scale to evaluate the quality of each research article. The Newcastle-Ottawa Scale includes four criteria for selection bias, with scores ranging between 0 and 5; scores <3 points are regarded as high risk for selection bias in a cross-sectional study [1,4]. The four quality assessment criteria were as follows: sample representativeness (1 point), predetermined and satisfactory sample size (1 point), comparability between respondents and nonrespondents (1 point), and ascertainment of the measurement tool (2 points for the validated measurement tool; 1 point for the nonvalidated measurement tool, but the tool is available or described).

Results

In all, we found 37 relevant mental health surveys of the general public during the COVID-19 pandemic by searching the PubMed database, as of July 10, 2020. All these public mental health survey studies examined had a cross-sectional study design. The journals efficiently made these articles available online in an average of 18.7 (range 1-64) days from the date they were received. The average duration of recruitment period of these studies was 9.2 (range 2-35) days, and the average sample size was 5137 (range 100-56,679). The correlation coefficient (r=0.164, P=.40) between these durations and the corresponding sample sizes suggested that the samples in the studies selected from the existing literature were collected in an efficient manner; even larger sample sizes did not require proportionately longer to collect the data. Although there was a potential publication bias in the recruitment or data collection period, it is noteworthy that approximately 92% (34/37) of the studies reported the use of a web-based or an app-based survey,

thereby promoting the efficiency of large-scale data collection, especially during the COVID-19 pandemic.

Unlike most studies on health care workers, which have a low risk of selection bias [1], our review showed that 73% (27/37) of the selected studies evaluating the mental health impact of COVID-19 on the general public had Newcastle-Ottawa Scale scores of <3 points, which suggests that these studies were of very low quality to be considered for inclusion in a meta-analysis. All of the selected studies met the criterion of validated measurement tools, but only 8 studies met the criterion of sample representativeness, 5 met the criterion of justified sample size, and 1 met the criterion of comparability between respondents and nonrespondents (Table 1).

Discussion

The general public surveys examined in this review most commonly used the web-based format to promote efficiency of large-scale data collection, especially in the countries with significant COVID-19 outbreaks that had introduced social distancing or lockdown measures. However, the web-based survey approach has an inherent methodological limitation to show the comparability between respondents and nonrespondents. The sample representativeness of the target population is critical for selection bias. Web-based survey platforms using sampling methods could avoid such selection bias. Two published surveys [6,11] used Qualtrics Panels, a web-based survey platform that uses quota sampling methods to identify participants who meet a given study's eligibility criteria, with a target to recruit a sample that is demographically similar to the 2010 United States census distributions for age, sex, and race or ethnicity (with a ±10% variation). Qualtrics Panels maintains a database of several million US residents who have volunteered to participate in periodic survey-based research. Another study [20] used AmeriSpeak, a probability-based research panel designed to be representative of the adult US population. AmeriSpeak data is sourced from National Opinion Research Center's area probability sample and a US postal service address–based sample covering approximately 97% of all US households. In this national survey study [20], a higher proportion (13.6%) of the US adult sample reported symptoms of serious psychological distress in 2020 than in 2018 (3.9%).

The limitations of cross-sectional studies should also be noted when interpreting the role of the COVID-19 outbreak on the mental health of the general public. These epidemiological studies identified general risk factors during the COVID-19 outbreak, rather than the specific impacts of COVID-19 on the mental health of the public. For example, a cross-sectional study of 4827 participants [12] showed that lower education levels and higher social media exposure result in a high risk of individuals developing depressive symptoms, but these findings did not suggest that COVID-19 had an impact on the public's mental health. There was only one longitudinal study [35], which conducted two-wave surveys during the initial COVID-19 outbreak (ie, January 31 to February 2, 2020) and during the peak 4 weeks later (ie, February 28 to March 1). Although this study recruited 1210 and 861 participants within 3 days by using a web-based survey approach, no significant longitudinal changes in stress, anxiety, or depression levels were observed. These findings might result from a lack of baseline data, few follow-ups with the same respondents (333/1210, 27.52%), or insufficient temporal resolution to detect mental health changes. Only one study compared the prevalence of symptoms of serious psychological distress before and during the COVID-19 pandemic by using an identical measure. This survey, which used AmeriSpeak for sample recruitment, showed that the prevalence of serious psychological distress symptoms among US adults was higher during the COVID-19 pandemic in 2020 than that reported in the 2018 National Health Interview Survey [20]. However, this study did not monitor the changes in population-level mental health through the unfolding pandemic. Timely mental health survey studies with a high temporal

resolution, such as internet search data (eg, Google Trends) [42] and sentiment analysis on social media (eg, Weibo posts) [43], are warranted in the future to monitor the long-term impacts of the fast-moving COVID-19 outbreak.

In conclusion, this systematic review found that the data collection methods used in the public mental health surveys in the existing literature were efficient but generally had a high risk of bias. Therefore, following recommendations to avoid selection bias, or to apply novel methodologies considering both longitudinal design and high temporal resolution, would help provide a strong basis for the formation of national mental health policies.

Acknowledgments

The authors thank Hsiao-Han Lin and Ting-Chen Hsu for their excellent technical assistance during this study. This study was supported by grants from National Health Research Institute in Taiwan (10A1-PHPP22-014; 10A1-PHPP16-014).

Authors' Contributions

YHL, CYC, and SIW conceptualized the study, and analyzed and interpreted the data. YHL and CYC drafted the manuscript. All authors have read and approved the final version of the manuscript.

Abstract

Background: COVID-19 has spread very rapidly, and it is important to build a system that can detect it in order to help an overwhelmed health care system. Many research studies on chest diseases rely on the strengths of deep learning techniques. Although some of these studies used state-of-the-art techniques and were able to deliver promising results, these techniques are not very useful if they can detect only one type of disease without detecting the others.

Objective: The main objective of this study was to achieve a fast and more accurate diagnosis of COVID-19. This study proposes a diagnostic technique that classifies COVID-19 x-ray images from normal x-ray images and those specific to 14 other chest diseases.

Methods: In this paper, we propose a novel, multilevel pipeline, based on deep learning models, to detect COVID-19 along with other chest diseases based on x-ray images. This pipeline reduces the burden of a single network to classify a large number of classes. The deep learning models used in this study were pretrained on the ImageNet dataset, and transfer learning was used for fast training. The lungs and heart were segmented from the whole x-ray images and passed onto the first classifier that checks whether the x-ray is normal, COVID-19 affected, or characteristic of another chest disease. If it is neither a COVID-19 x-ray image nor a normal one, then the second classifier comes into action and classifies the image as one of the other 14 diseases.

Results: We show how our model uses state-of-the-art deep neural networks to achieve classification accuracy for COVID-19 along with 14 other chest diseases and normal cases based on x-ray images, which is competitive with currently used state-of-the-art models. Due to the lack of data in some classes such as COVID-19, we applied 10-fold cross-validation through the ResNet50 model. Our classification technique thus achieved an average training accuracy of 96.04% and test accuracy of 92.52% for the first level of classification (ie, 3 classes). For the second level of classification (ie, 14 classes), our technique achieved a maximum training accuracy of 88.52% and test accuracy of 66.634% by using ResNet50. We also found that when all the 16 classes were classified at once, the overall accuracy for COVID-19 detection decreased, which in the case of ResNet50 was 88.92% for training data and 71.905% for test data.

Conclusions: Our proposed pipeline can detect COVID-19 with a higher accuracy along with detecting 14 other chest diseases based on x-ray images. This is achieved by dividing the classification task into multiple steps rather than classifying them collectively.

Introduction

Background

The COVID-19 pandemic has been causing significant health concerns since 2019. Symptoms of the disease include fever, cough, headache, and severe respiratory complications, which can subsequently lead to death. When this disease first started to spread in December 2019, numerous unknown facts were reported in Wuhan, China, where the first outbreak occurred [1]. By early January 2020, the government of China and the World Health Organization recognized SARS-CoV-2, the novel coronavirus known to cause COVID-19, as a pathogenic virus that belongs to the same family (Coronaviridae) as the virus known to cause severe acute respiratory syndrome (SARS). A SARS outbreak was previously reported in China in 2002-2003 [2].

Medical x-rays (short for x-radiation) are a form of visible light rays but with higher energy that penetrate the body to generate images of tissues and structures within the body, including bones, chest, and teeth. X-ray imaging is a very effective diagnostic tool and has been used for several decades by specialists to detect fractures, certain tumors, pneumonia, and dental problems [3]. In advanced cases, computed tomography (CT) can be used to produce a series of body images, which is later assembled into a 3D x-ray image that is processed by a computer. However, the traditional x-ray is a lot faster, easier, cheaper, and less harmful than a CT scan [4].

Research has shown that deep learning can be used to make predictions based on medical images by extracting characteristic features, including the shape and spatial rotation, from the images. Convolutional neural networks (CNNs) have played a very vital role in feature extraction and learning patterns that enable prediction. For example, a CNN is used to improve extraction high-speed video-endoscopy when the training data is very limited [5]. Advancements in image processing tools have brought about a radical change in the current techniques for the detection of pulmonary diseases. Researchers are employing traditional computer vision as well as deep learning algorithms to achieve satisfactory performance [3]. Several primary benefits are strongly correlated with the advancement of radiographic image classification tools. For example, in rural areas, owing to a shortage of doctors and places where doctors cannot be reached, such tools can prove useful. Once these tools become pervasive in the health care industry, radiologists, clinic practitioners, and even patients may utilize radiographic image classification tools to monitor and treat several diseases. As a result, this can reduce the burden on radiologists all over the world, by abolishing the requirement to examine every x-ray image for anomalies. Instead, the doctors will only need to focus on the patients whose x-ray images are flagged by this tool. The use of such tools can also eliminate the subjective opinion of doctors, increase the speed of early diagnosis of disease, and identify the minor details that may be overlooked by the human eye in some cases.

For this study, owing to computational restraints, we did not build a model from scratch, as such models require extremely high-end computers. Rather, we used CNN as a class of deep neural networks to propose a model to classify COVID-19 x-ray images from x-ray images of a wide range of chest diseases. Although the x-ray images of the other diseases are inadequate for proper training and to achieve state-of-the-art results, we generalized the data by considering data augmentation. This mainly rescales the x-ray images and flips them horizontally, in addition to a few other functionalities such as shift range, zooming, and rotation.

The strength of this study is that it classifies x-ray images at two different stages. The first stage involves enhancing the model to detect COVID-19–specific x-ray images at a faster speed than x-ray images of other chest diseases. This will result in a significant increase in the classification speed. Thus, considering a part of a dataset of chest x-ray (CXR) images for the analysis will result in low-quality output and unsatisfactory diagnoses. Accordingly, if the case is not classified as “normal” or “COVID-19” at this stage, then the classification is continued to the second stage, which involves classification for 14 other chest and related conditions (ie, atelectasis, cardiomegaly, effusion, infiltration, mass, nodule, pneumonia, pneumothorax, consolidation, edema, emphysema, fibrosis, pleural, and hernia). This also saves processing power if the x-ray image has been classified as “normal” or “COVID-19” in the first stage itself. To further enhance the accuracy of detection, we used UNet to complete lung and heart segmentation. Because we used a pretrained model, we were able to independently train 5 different models for each stage. Models with the best training and test accuracy were then selected for further analyses.

Based on our findings, we found that ResNet50 is the best model for classification in both scenarios: classifying 3 classes and 14 classes. Moreover, image segmentation helps in increasing the classification accuracy by up to 5%. We also trained a model for all 16 classes and found that classifying for a large number of classes significantly reduces the overall accuracy of the model.

The main contributions of this study are as follows:

1. Introduction of new classification pipeline for more accurate, automated classification in case of a large number of classes, primarily to increase the accuracy of a specific class.
2. Use of augmentation and semantic segmentation to increase accuracy of the model.
3. Comparison between different deep learning models on the basis of classification in cases of small and large number of classes.

In this paper, we first review previous studies that used deep neural networks for the detection of COVID-19 and other chest diseases. Then, we discuss the datasets used for our experiments as well as the study methodology, including data preprocessing, data segmentation, and the setup for classification of the models.

Finally, we present the results and analyses on the basis of the models and dataset available.

Previous Work

Recently, with the rapid development of artificial intelligence, an increasing number of researchers have begun to pay attention to intelligent, deep learning−based diagnostic techniques. Some of them have achieved significantly prominent results. In this section, we first review the current, state-of-the-art techniques concerning the application of artificial intelligence to chest diseases in general, and then, we discuss the literature related to COVID-19 detection using deep neural networks.

Detection of Chest Diseases Based on CXR Images by Using Deep Neural Networks

Sivasamy and Subashini [6] used a Keras framework to classify CXR images to predict lung diseases and reported an accuracy of 86.14%. The accuracy of the model improved as the number of epochs for training was increased. Wang et al [7] used pixel-wise annotated digital reconstructed radiograph data to train an unsupervised multiorgan segmentation model based on x-ray images. In this case, the gaps in nodules annotated directly on 2D x-ray images are quite challenging and time-consuming due to the projective nature of x-ray imaging. Rajpurkar et al [8] proposed a binary classifier for the detection of pneumonia from frontal-view CXR images that achieved an f1 score of 0.435. Salehinejad et al [9] used a Deep Convolutional Generative Adversarial Network (DCGAN) tailored model designed for training with x-ray images wherein a generator is trained to generate artificial CXR images. Their model obtained its best accuracy when trained on an augmented dataset with DCGAN-synthesized CXRs to balance the imbalanced real dataset (D3). Chandra and Verma [10] used 5 different models to identify pneumonia and reported 95.631% as the best accuracy. The model is limited to analyzing only nonrigid, deformable, registration-driven automatically lung regions and segmented region of interest–confined feature extraction. Previous studies using state-of-the-art techniques have achieved effective results with one or two cardiothoracic diseases, but these techniques could lead to misclassification.

A few techniques have targeted all 14 classes of chest diseases. Wang et al [11] presented the largest publicly available dataset of CXR images, which has provided a new dimension to the research community. They achieved promising results using a deep CNN and suggest that this dataset could be further extended by using more disease labels. Smit et al [12] proposed a deep learning−based technique to identify the 14 underlying chest diseases. They trained the model to input a single-view chest radiograph and output the probability of each of the 14 observations. Several models were trained to identify the one with the best accuracy. They used DenseNet121 for their research and found that it yielded the best accuracy, but it was limited to the CheXpert dataset and liable to overfitting. A pretrained DenseNet121 model and feature extraction techniques were used for accurate identification of 14 thoracic diseases in the study by Ho and Gwak [13].

Detection of COVID-19 Cases Based on CXR Images by Using Deep Neural Networks

There are several state-of-the-art studies on deep learning and machine learning models for COVID-19 diagnosis. A study by Apostolopoulos and Mpesiana [14] took advantage of CNNs for the automatic detection of COVID-19 by using CXR images. They adopted transfer learning to solve for the small image dataset challenge. Their COVID-19 dataset consisted of 224 sample medical images. Despite the size limitation, their results showed effective automatic detection of COVID-19−related diseases. Abbas et al [15] used the CNN-based DeTraC framework. They also used transfer learning to achieve the best performance. This model achieved 95.12% accuracy and 97.91% sensitivity. Chen et al [16] provided a prediction of patients with or without COVID-19 by using the UNet++ based segmentation model. Narin et al [17] classified CXR images using the ResNet50 model and obtained the highest classification performance with 98% accuracy, using a dataset comprising only 50 COVID-19 and 50 normal samples. Li et al [18] also used a ResNet50 model with a dataset comprising 468 COVID-19 samples, 1551 community-acquired pneumonia samples, and 1445 non-pneumonia samples; this model achieved 90% sensitivity. Using deep learning approaches to extract and transform features, Li et al proved their model's efficacy in COVID-19 diagnosis [18]. Furthermore, Sethy and Behera [19] used deep learning to extract deep features from x-ray images and then used state vector machine to classify them into COVID-19–positive and COVID-19–negative classes; they achieved an accuracy of 95%. Hemdan et al [20] used transfer learning and fine-tuning on state-of-the-art networks like VGG and ResNetV2 to classify COVID-19–positive and COVID-19–negative x-ray images; they achieved an accuracy of 90%. Wang et al [21] proposed the M-inception model, a variant of the inception model. They detected only COVID-19 CT images from all available images and achieved an accuracy of 82%. Table 1 presents a comparison of previously studies models using radiographic imaging classification for COVID-19 cases, normal cases, and other chest diseases.

Table 1. Comparison of models detecting COVID-19 cases, normal cases, and other chest diseases based on medical images (data derived from [22]).

Reference	Medical image	Disease detected, n			Accuracy (%)	Methodology	Gaps in classification
		COVID-19	Normal	Other chest diseases			
Apostolopoulos and Mpesiana [14]	X-ray	224	504	700	93	Used transfer learning on VGG19. MobileNetV2, Inception, Xception, and InceptionResNetV2	Used only 3 classes: COVID-19, pneumonia, and other
Wang et al [23]	X-ray	53	8066	5526	92	Introduced COVID-Net—the first open-source COVID-19 detection system	Used only 3 classes: COVID-19, pneumonia, and normal
Narin et al [17]	X-ray	50	50	N/A[a]	98	Used 5 pretrained networks and applied 3 binary classifications for 4 classes of chest x-rays	Used only 3 classes: normal, COVID-19, viral and bacterial pneumonia
Brunese et al [22]	X-ray	250	3520	2753	97	Defined 2 models based on VGG16: one to classify affected x-ray images from healthy ones and the other to classify COVID-19 from affected x-ray images. Then, they localized the affected areas.	Although they used x-ray images of most diseases, they used only 3 classes: COVID-19, healthy, and disease
Song et al [24]	CT[b]	777	708	N/A	86	Proposed DRE-Net and compared its performance with VGG-16, DenseNet, and ResNet	Used only 3 classes: COVID-19, bacterial pneumonia, and healthy
Zheng et al [25]	CT	313	229	N/A	90	Proposed DeCoVNet for classification	Used only 2 classes: COVID-19–positive and COVID-19–negative
Xu et al [26]	X-ray	219	175	224	86	Proposed ResNet-18 based CNN[c] network	Used only 3 classes: COVID-19, Influenza-A viral pneumonia, and normal
Ozturk et al [27]	X-ray	250	1000	500	92	Proposed DarkCovidNet	Used only 3 classes: COVID-19, pneumonia, and no findings

[c]CNN: convolutional neural network.

Methods

Dataset

The first step involved preprocessing of the data, which includes segmentation of the lungs and the heart from the whole image, as an x-ray image contains many unnecessary details. To perform this segmentation task, we trained the UNet model on segmented CXR data obtained by the Japanese Society of Radiological Technology, which were downloaded from their official website [29], and their corresponding masks, which were downloaded from the SCR database [30]. This dataset contains 247 images. For classification purposes, data for COVID-19 was collected from Cohen et al's COVID Chest X-ray dataset [31]. This dataset contains x-ray images of many other diseases. Furthermore, x-ray images from the datasets were separated using the available metadata file. Data for the other 14 chest diseases were provided by the National Institute of Health (NIH) and can be downloaded from the NIH Chest X-ray Dataset of 14 Common Thorax Disease Categories [32]. Data available on the NIH Clinical Center website contains 112,120 images, belonging to 15 classes, which include 14 disease classes and 1 normal class—all of which were extracted through the available metadata file. The number of images per class is presented in Table 2.

Table 2. Number of images per class in the National Institute of Health Chest X-ray Dataset of 14 Common Thorax Disease Categories [32].

Model and class	Training set, n	Testing set, n
Model 1		
COVID-19	455	22
Normal	1995	405
Other	4600	730
Model 2		
Atelectasis	200	100
Cardiomegaly	200	100
Consolidation	200	100
Edema	200	100
Effusion	200	100
Emphysema	200	100
Fibrosis	200	100
Hernia	150	100
Infiltration	200	100
Mass	200	100
Nodule	200	100
Pleural thickening	200	100
Pneumonia	200	100
Pneumothorax	200	100

The data were randomly split into training and testing sets, as there were very few data related to COVID-19. The idea was to keep the training set as large as possible given the small number of images present. Image augmentation compensated for the lack of data. This was not an issue for model 2 images. For model 1, however, the lack of data can cause a change in testing accuracy. To compensate for this issue, we also applied data augmentation while testing.

Data Preprocessing

Every x-ray image has a different contrast and illumination as they are taken under different lighting conditions. Therefore, in the first step of preprocessing, histogram equalization was applied. CXR images also contain unnecessary details, such as the collarbone, shoulders, neck, and torso region. To remove these unnecessary details, lungs and heart segmentation were applied. For this purpose, the UNet segmentation model was trained on images from the Japanese Society of Radiological Technology with their corresponding masks. The architecture of the UNet model is shown in Table 3. The input image size fed to the network was 256×256×3. The contraction part acts as an encoder that extracts the context from the image using downsampling through the max-pooling layer. The expansive path acts as a decoder that precisely localizes the segmentation part using transpose convolution layers. It is an end-to-end, fully connected network and does not contain any dense layers. It also restores the image through upsampling.

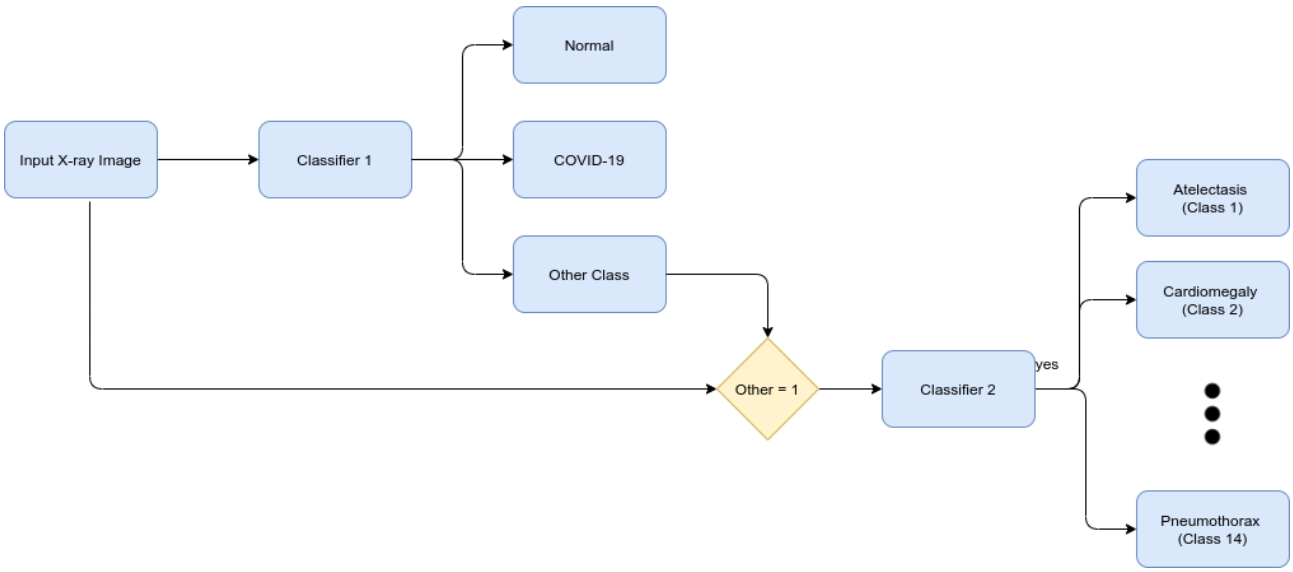
Data Augmentation

Before feeding the data to the network, image augmentation was applied to tackle the problem of fewer data, that is, in the case of COVID-19. For applying augmentation, the rotation range was set to 90°, the horizontal flip was set to true, and the vertical flip was also set to true. For each iteration, the image data generator used a different transformation of the original images. In the case of COVID-19, we had 445 input images and 20 iterations; therefore, the data generator used 8900 images for training in this case.

Classification Models

The main objective of this study was to classify COVID-19 x-ray images from normal x-ray images and those of 14 other chest diseases. When a single model is trained for classifying 16 different classes, its accuracy tends to decrease, and in the case of COVID-19 detection, that is not acceptable. To solve this problem, a new pipeline was formed, which is illustrated in Figure 1. Two models were trained. The first model was trained to classify 3 classes: COVID-19, normal, and some other disease. The second model was trained to classify the 14 other chest and related diseases. Both models were trained separately. To automate the process, if the first model classified the x-ray as "some other disease," then the second model was called to further classify the disease as one of 14 other chest diseases, using a simple "IF" condition. This architecture makes the classification process easy, as there are fewer features that need to be classified at the first stage.

Figure 1. Proposed pipeline of classification.



Classifier 1 only needs to learn how to distinguish COVID-19 and normal x-ray images from those of all the other 14 chest diseases. The rule is simple: the fewer the classes, the fewer features there are to learn and distinguish, and the greater the accuracy. This is critical because the classification of COVID-19 is much more important than that of other diseases during the ongoing pandemic. Finally, the burden of classifying the other 14 x-ray diseases falls on classifier 2, which now has 14 classes to classify instead of 16. Furthermore, the 2 most important classes have already been classified by classifier 1. Moreover, to support the statement that accuracy indeed decreases when classifying into 16 classes, a third model was trained for classification into all 16 classes.

For classification purposes, the following 5 models were trained for both classifications:

NasNetLarge, Xception, InceptionV3, InceptionResNetV2, and ResNet50.

NasNetLarge was proposed by "Google Brain" in 2018 [33]. It has two types of architectures—CIFAR10 and ImageNet. CIFAR10 architecture has N number of normal cells and one reduction cell repeating after each other; in the end, it has the SoftMax function. ImageNet has two strides of convolutional layers with a 3×3 kernel size at the start, followed by two reduction cells; thereafter, it has the same architecture as CIFAR10.

Xception was proposed by Google in 2017 [34]. It consists of one entry flow, eight middle flow, and one exit flow. Entry flow consists of convolutional and max-pooling layers with ReLU as the activation function. The middle flow consists of only convolutional layers with the ReLU activation function. Exit flow consists of convolutional, max pooling, and global average pooling layers with the ReLU activation function; in the end, it has fully connected layers for classification.

InceptionV3 was proposed by Google in 2015 [35]. The basic architecture of the model is the same, as it consists of convolutional and pooling layers; in addition, it has three

inception architectures as proposed previously [35]. Finally, at the end, it has the logistic and SoftMax function for classification into 1000 classes.

InceptionResNetV2 was proposed by Google in 2016 [36]. It has the proposed inception and reduction blocks at the start, and in the end, it has a pooling layer and dropout layer to prevent overfitting. It classifies using the SoftMax function.

ResNet50 was proposed by Microsoft in 2015 [37]. It takes residual learning as a building block and consists of convolutional layers with an average pooling layer at the end.

Models were taken from Keras library in Python, which were initialized with ImageNet weights. These models can classify 1000 classes, but we only needed to classify 3, 14, and 16 classes for classifier 1, classifier 2, and classifier 3, respectively. Therefore, these models were fine-tuned, and additional layers were added. Table 4 shows the fine-tuning layers added at the end of each pretrained model. The input image size given to the models was 331×331×3.

Table 4. Fine-tuning layers for classifier 1, classifier 2, and classifier 3.

Type	Classifier 1		Classifier 2		Classifier 3	
	Output	Kernel	Output	Kernel	Output	Kernel
Average pooling	2048	2×2	2048	2×2	2048	2×2
Flatten	8192	N/A[a]	8192	N/A	8192	N/A
Dense	1024	N/A	1024	N/A	1024	N/A

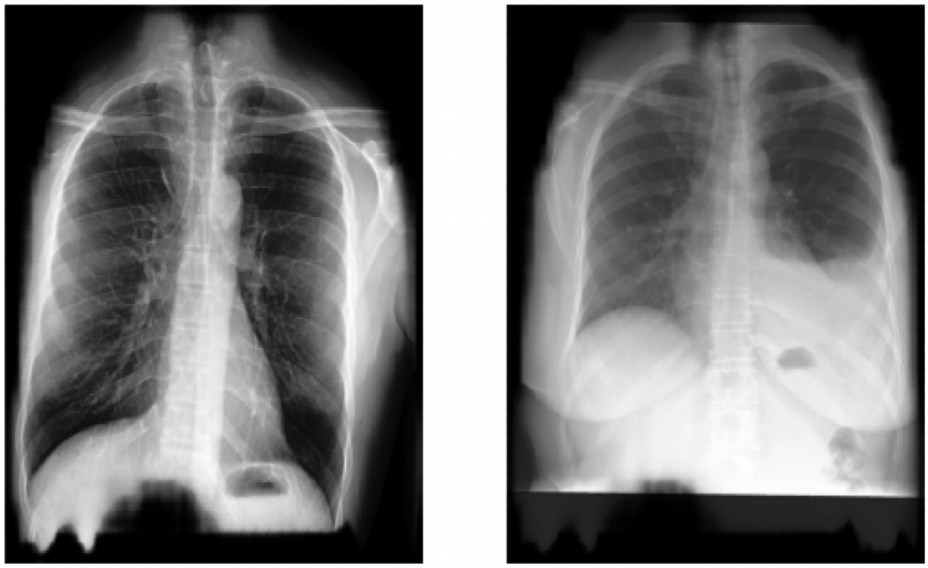
All the models explained in the Methods section were trained and tested on Google Colab with 12 GB of RAM and GPU (graphics processing unit) assigned by Google Colab.

Results

Initially, the UNet model was trained for segmentation of lungs and heart. After Training UNet, the model had a training loss of 16.75%, training accuracy of 87.13%, validation loss of 12.27%, and validation accuracy of 89.64%.

Figure 2 shows some sample segmented CXR images. With image segmentation, we achieved up to 5% increase in the accuracy of our models.

Figure 2. Sample segmented chest x-ray images.



After image segmentation was completed and new training data were obtained, each training model was trained for 20 epochs with a batch size of 8. The accuracy obtained from training is shown in Table 5. The table shows that the maximum accuracy for classifying the 3 classes, including COVID-19 was achieved by using ResNet50 followed by NasNetLarge. These two models yielded accuracy that competes with that of the available state-of-the-art models for COVID-19 prediction.

Classifier 2 did not show promising results in classifying the 14 other diseases. The main reasons for this were the large number of classes and the continued overfitting of the model. The maximum test accuracy achieved was 65.63% with ResNet50 followed by 61.47% with NasNetLarge.

As described, our proposed model pipeline helps to increase the accuracy of COVID-19 diagnosis when classifying 16 classes. Table 5 shows that when the 16 classes were combined and classified, the detection accuracy decreases. In all the cases except in the case of NASNetLarge and ResNet50 models, the test accuracy decreased when classifying 16 classes. Moreover, in the case of the NASNetLarge model, the increase in accuracy is not very notable. The maximum test accuracy was achieved with ResNet50, with an average of 71.905% over 10-fold cross-validation.

Table 5. Average training, validation, and test accuracy achieved by different models through a 10-fold cross-validation.

Model and classifier	Training accuracy (%)	Training loss (%)	Validation accuracy (%)	Validation loss (%)	Test accuracy (%)	Test loss (%)
NasNetLarge						
1st	91.80	33.78	91.25	31.32	89.66	32.028

InceptionResNetV2						
1st	65.10	80.32	62.46	76.35	63.19	75.79
2nd	83.37	81.30	54.08	197.66	53.75	197.07
Combined	54.45	134.20	33.84	200.61	33.97	200.26
ResNet50						
1st	96.32	9.84	94.16	23.09	92.52	20.32
2nd	87.83	35.85	67.55	105.63	65.63	108.24
Combined	88.92	26.16	73.14	87.05	71.91	88.95

The results obtained by our proposed approaches compete with that of state-of-the-art methods (shown in Table 1). Graphs illustrating the training and validation accuracy and loss for classifiers 1, 2, and 3 are shown in Figures 3, 4, and 5, respectively. To further evaluate the results, the AUC (area under the curve), sensitivity, and specificity results for all the networks were studied (Table 6). We found that ResNet50 achieved the maximum AUC, sensitivity, and specificity scores compared to any other model.

Discussion

Principal Findings

In this study, we classified normal cases, COVID-19 cases, and 14 other chest diseases based on CXR images. We proposed a novel, multiclass method for this purpose and used models that were pretrained on ImageNet dataset to save training time and resources. Our multilevel approach resulted in an increase in the classification accuracy. We found that ResNet50 was the best model for classification, yielding the highest accuracy.

Future Suggestions

This study tried to cover most aspects of detection of chest diseases, but there is still work to be done. Most importantly, there is a need for more data for patients with COVID-19, which could help improve the accuracy of the model. At present, there is a significant difference in the number of images per class for the first level of classification.

This model can help in the first level of classification to determine whether the person has COVID-19 or some other chest disease, as x-rays are easier and less expensive than other forms of radiographic imaging and can help determine the severity of the disease. Although disease severity was not within the scope of this study, future work in detecting the severity of the disease can also be an important improvement in the already-existing model. In addition, techniques such as the Grad-Cam algorithm can be used to visualize the features in radiographic images affecting the algorithm and to determine disease severity. This algorithm will highlight which features help the algorithm with the classification and which features likely mislead the algorithm. This algorithm might also be the key to investigating the low accuracy of the level-2 classifier and can help improve its accuracy.

Conclusions

Deep learning has played a major role in medical image analysis and feature extraction, which are applied to the detection of a wide range of chest diseases. CNN architectures are popular for their ability to learn mid- and high-level image representations and to make predictions. Detecting the presence, or absence, of COVID-19 in a patient is insufficient without addressing other chest diseases. However, a deep learning system that is trained to classify a large number of classes—16 in our case—has less accuracy. This work aimed to deal effectively with this new pipeline to help with a first-level differential diagnosis of COVID-19 from other chest diseases. Subsequently, we applied further enhancement to detect other chest diseases in order to tackle multi-class chest classification in the detection of anomalies on x-ray images. This approach yielded satisfactory results.

Thus, we showed how our proposed models use state-of-the-art deep neural networks to classify 16 cardiothoracic diseases by training the models based on x-ray images in the database. Image

segmentation was applied to remove unnecessary details, and both classifiers were independently trained on segmented data. However, our model can classify not only COVID-19 but also 14 other chest diseases, as well as normal x-ray images, with satisfactory accuracy as compared with previous studies.

Abstract

Background: Predicting early respiratory failure due to COVID-19 can help triage patients to higher levels of care, allocate scarce resources, and reduce morbidity and mortality by appropriately monitoring and treating the patients at greatest risk for deterioration. Given the complexity of COVID-19, machine learning approaches may support clinical decision making for patients with this disease.

Objective: Our objective is to derive a machine learning model that predicts respiratory failure within 48 hours of admission based on data from the emergency department.

Methods: Data were collected from patients with COVID-19 who were admitted to Northwell Health acute care hospitals and were discharged, died, or spent a minimum of 48 hours in the hospital between March 1 and May 11, 2020. Of 11,525 patients, 933 (8.1%) were placed on invasive mechanical ventilation within 48 hours of admission. Variables used by the models included clinical and laboratory data commonly collected in the emergency department. We trained and validated three predictive models (two based on XGBoost and one that used logistic regression) using cross-hospital validation. We compared model performance among all three models as well as an established early warning score (Modified Early Warning Score) using receiver operating characteristic curves, precision-recall curves, and other metrics.

Results: The XGBoost model had the highest mean accuracy (0.919; area under the curve=0.77), outperforming the other two models as well as the Modified Early Warning Score. Important predictor variables included the type of oxygen delivery used in the emergency department, patient age, Emergency Severity Index level, respiratory rate, serum lactate, and demographic characteristics.

Conclusions: The XGBoost model had high predictive accuracy, outperforming other early warning scores. The clinical plausibility and predictive ability of XGBoost suggest that the model could be used to predict 48-hour respiratory failure in admitted patients with COVID-19.

Introduction

On March 11, 2020, COVID-19, the disease caused by SARS-CoV-2 infection, was declared a pandemic by the World Health Organization [1]. As of December 16, 2020, there were more than 17 million confirmed COVID-19 cases and over 300,000 deaths in the United States. During the first wave, New York was the epicenter of the pandemic in the United States, with over 390,000 cases and 30,000 deaths before the summer [2].

Respiratory failure is the leading cause of death among patients with COVID-19, with up to one-third of patients admitted with COVID-19 requiring invasive mechanical ventilation (IMV) [3-8]. The decision to initiate IMV in these patients is not straightforward. Many patients with severe disease appear comfortable despite profound hypoxemia, and they are commonly managed with supplemental oxygen, self-proning, and close monitoring [9,10]. However, some of these patients subsequently deteriorate and require IMV following transfer from the emergency department (ED). This subgroup has worse outcomes than those placed on IMV initially [11]. Before the surge of COVID-19, patients initially admitted to a non–critical care setting who needed an unplanned transfer to an intensive care unit (ICU) had greater morbidity and mortality than those admitted directly to a critical care unit [12-14]. Thus, accurately identifying patients at high risk for deterioration could improve clinical outcomes as a result of closer monitoring, direct admission to a critical care unit, or earlier discussions regarding patient preferences and goals of care.

Methods of identifying patients at high risk for or in the early stages of clinical deterioration have been actively researched for decades. The field has generated many severity-of-illness calculators, early warning scores, and, more recently, predictive analytic tools that use advanced machine learning and artificial intelligence [15-23]. Our goal was to derive a prediction model that estimates the risk of short-term (<48 hours) respiratory failure for patients with COVID-19 who were not initially placed on IMV. Such a tool could improve outcomes by avoiding delayed admission to a critical care unit, resulting in the provision of additional respiratory support and closer monitoring, or the initiation of earlier discussions around the goals of care.

Methods

Overview

This retrospective observational cohort drew data from 13 acute care hospitals of Northwell Health, the largest health care system in New York State. Data were extracted from the electronic health record (EHR) Sunrise Clinical Manager (Allscripts). EHRs were screened for adult patients (aged ≥21 years) who received a positive test result for SARS-CoV-2 based on a nasopharyngeal sample tested using polymerase chain reaction assays. Included patients were hospitalized and were discharged, died, or spent a minimum of 48 hours in the hospital between March 1, 2020, and May 11, 2020. For patients who had multiple qualifying hospital admissions, only the first hospitalization was included. Patients who were transferred between hospitals within the health system were treated as one hospital encounter. A total of 11,919 patients were identified. Patients were excluded if they were placed on mechanical ventilation prior to inpatient admission. A total of 11,525 patients remained for analysis. The Institutional Review Board of Northwell Health approved the study protocol and waived the requirement for informed consent.

Data Acquisition

Data collected from EHRs included patient demographics, comorbidities, home medications, initial vitals and laboratory values, treatments (eg, oxygen therapy, mechanical ventilation), and clinical outcomes (eg, length of stay, discharge, mortality). Vitals and laboratory testing were restricted to those obtained while the patient was in the ED.

Outcomes

The target outcome variable was defined as intubation and mechanical ventilation within 48 hours of admission. In the EHR, the admission time was recorded, and the intubation event was defined as the first time mechanical ventilation was recorded.

Predictive Machine Learning Model

We evaluated three predictive models: XGBoost, XGBoost + SMOTEENN (combined oversampling using SMOTE and undersampling using edited nearest neighbors) [24], and logistic regression [25]. XGBoost combines a recursive gradient–boosting method, called Newton boosting, with a decision-tree model. Given that each tree is boosted in parallel, the model efficiently provides accurate predictions [26]. Furthermore, because each tree is boosted recursively and in parallel, the model benefits from the high interpretability of the variable importance features.

The XGBoost + SMOTEENN method involves combined oversampling using SMOTE and undersampling using edited nearest neighbors on the training set before training an XGBoost model [27]. This method has been shown to have the best performance in the resampling data sets [28]. Furthermore, in our experience, when using any of the oversampling or undersampling methods alone, calibration of the model is severely affected. However, when we combine oversampling the minority class with undersampling of the majority class, we found that we get a more accurate model both in terms of discriminability and minimizing the effect on the calibration of the model.

For every learning framework, we validated the model with external validation using each hospital (ie, for each fold, one hospital was picked as a testing set and the others as a training set). Only hospitals with >1000 patients with COVID-19 in the data set were picked for the testing sets, and a random sample of 1000 patients was picked to be our testing set for each fold. Grid search was used to hypertune the parameters of the respective models. The XGBoost model was tuned based on min_child_weight, gamma, subsample, colsample_bytree, and max_depth parameters, and the ranges of the values were 1-20, 0.5-20, 0.2-1.0, 0.2-1.0, and 2-40, respectively.

When data were missing, we imputed weighted k-nearest neighbors [29] for numerical values and added a category "missing" for categorical values. We used one-hot [30] to encode categorical variables as a one-hot numeric array. The most important variables were calculated based on a decrease in the mean Gini coefficient (ie, the variables most useful in splitting the data to help make a prediction) for XGBoost and XGBoost + SMOTEENN; and by the absolute value of the regression coefficient for logistic regression, and were calculated based on the largest hospital testing set. The resulting receiver operating characteristic (ROC) curves and corresponding accuracy, recall (sensitivity), specificity, geometric mean, and F_β-score were averaged. For the F_β-score, the β parameter value was designated as $\beta=4$ to capture a higher detriment of false negatives than false positives (ie, if we value recall, β times as much as the precision). For definitions of these measures and how they were calculated, see Multimedia Appendix 1.

Calibration curves (reliability curves) were plotted by dividing the testing sets (for each hospital fold) into 10 bins randomly with an increasing fraction of patients that had respiratory failure in the sample. The fraction positives (patients who had respiratory failure) and their mean corresponding predicted value from the corresponding model were depicted and averaged into 10 bins. The Brier score was calculated for each external hospital fold and the mean Brier score and standard deviation were calculated and depicted in the legend of the calibration curve. For further explanation of these measures and how they were calculated, see Multimedia Appendix 1.

Python 2.6 (Python Software Foundation) was used to implement our machine learning framework. The respective prediction models of XGBoost and logistic regression from the scikit-learn application programming interface (API) in Python were used [31]. GridSearchCV from the scikit-learn API was used to perform the grid search and hypertune the parameters. We used the default imblearn API version of the SMOTEENN [27]. SimpleImputer [32] was used for imputations, which were replaced with a new category, "missing." KNNImputer [33] was used to impute the missing numerical data [29]. The default value for k=5 was not changed. OneHotEncoder from the sklearn API was used to transform categorical variables to one-hot numeric arrays.

Modified Early Warning Score

The Modified Early Warning Score (MEWS) was computed from patient vital signs (Multimedia Appendix 2) and is a variant of other known and used risk scores [34,35]. The MEWS ranges from 0 to 15 and incorporates heart rate (beats per minute), respiratory rate (breaths per minute), systolic blood pressure (mm Hg), and body temperature (degrees Celsius). In our data set, one MEWS subcomponent, the AVPU (alert, verbal, pain, unresponsive) neurologic assessment, had a significant amount of missing data (>80%; data not shown) and was not included in the MEWS calculation for this project. An elevated MEWS indicates a risk for clinical instability, including death or the need for ICU admission [36]. In 2012, our health system created a custom modification that was incorporated into the EHR. It includes automatic calculation and display of MEWS and other modules via Arden Syntax Medical Logic Modules [37]. Based on local health system guidelines, any score ≥7 requires an escalation in intensity of care. For example, MEWS >7 requires increased frequency of vital sign measurement (every 2 hours), MEWS >8 requires evaluation by a licensed independent provider, MEWS >9 requires consideration of evaluation by a rapid response team, and MEWS >10 requires a change in the level of service per a defined protocol. For the MEWS, we chose the highest value the patient had while in the ED.

Results

Patient Characteristics

During the study period, we identified 11,525 patients admitted from the ED with a diagnosis of COVID-19. Of these, 933 (8.0%) were placed on IMV within 48 hours of admission. Baseline characteristics (demographics, baseline vital signs, and laboratory measurements) for all patients are shown in Table 1, stratified by study outcome. Comorbidities were captured from ICD-10 codes listed in the EHR.

Prediction Models for Respiratory Failure

Based on XGBoost, the mean area under the curve (AUC) of the ROC (AUCROC) curve was 0.77 (SD 0.05) and the mean AUC of the PR curve (AUCPR) was 0.26 (SD 0.04; Figure 1). The 10 most important variables, in order of decreasing importance, were as follows: most invasive mode of oxygen delivery being a nonrebreather mask, Emergency Severity Index (ESI) values of 1 and 3, maximum respiratory rate, maximum oxygen saturation, Black race, age on admission, eosinophil percentage, serum sodium level, and serum lactate level (Figure 1). The confusion matrix for the model's largest hospital testing set showed that most false predictions were false negatives (those who were predicted to not require intubation but were intubated within 48 hours). False positives (those who were predicted to require intubation but were not intubated within 48 hours) were the minority of predictions (Figure 1). The model had a mean accuracy of 0.919 (SD 0.028). The corresponding mean precision, recall, specificity, geometric mean, and F_β-score were 0.521 (SD 0.329), 0.051 (SD 0.030), 0.994 (SD 0.005), 0.337 (SD 0.042), and 0.054 (SD 0.029), respectively (Table 2).

Based on the XGBoost + SMOTEENN model, the mean AUCs of the ROC and PR curves were 0.76 (SD 0.03) and 0.24 (SD 0.06), respectively (Figure 2). The 10 most important variables, in order of decreasing importance, were as follows: most invasive mode of oxygen delivery being a nonrebreather mask, ESI value of 3, male gender, White race, minimum respiratory rate, Black race, ESI value of 2, most invasive mode of oxygen delivery being nasal cannula, ESI value of 1, and Hispanic ethnicity (Figure 2). The mean confusion matrix showed that most false predictions were false positives (those who were predicted to require intubation but were not intubated within 48 hours). False negatives (those who were predicted to not require intubation but were intubated within 48 hours) were the minority of predictions (Figure 2). Although this model did not have the highest accuracy, it achieved the highest mean recall, geometric mean, and F_β-score of 0.228 (SD 0.095), 0.508 (SD 0.063), and 0.226 (SD 0.010), respectively. The corresponding mean accuracy, precision, and specificity were 0.893 (SD 0.016), 0.303 (SD 0.089), and 0.955 (SD 0.005), respectively (Table 2).

Figure 1. The XGBoost model for predicting respiratory failure within 48 hours. (A) ROC curve and (B) PR curve based on a cross-hospital validation performed by leaving a hospital out as a testing set and using the rest in the training set. Only hospitals with >1000 patients with COVID-19 were selected for testing sets. The mean ROC and PR curves are shown in dark blue and their corresponding standard deviations are shown in gray. The MEWS metrics are shown in light yellow. (C) Measurement of the 10 variables with the highest relative importance based on the amount they reduced the Gini coefficient for the largest hospital testing set. (D) Confusion matrix visually represents the predicted values versus actual prediction for the largest hospital testing set. AUC: area under the curve of ROC; AUCPR: area under the curve of the precision-recall curve; ED: emergency department; LIJ: Long Island Jewish; MEWS: Modified Early Warning Score; PR: precision-recall; ROC: receiver operating characteristic.

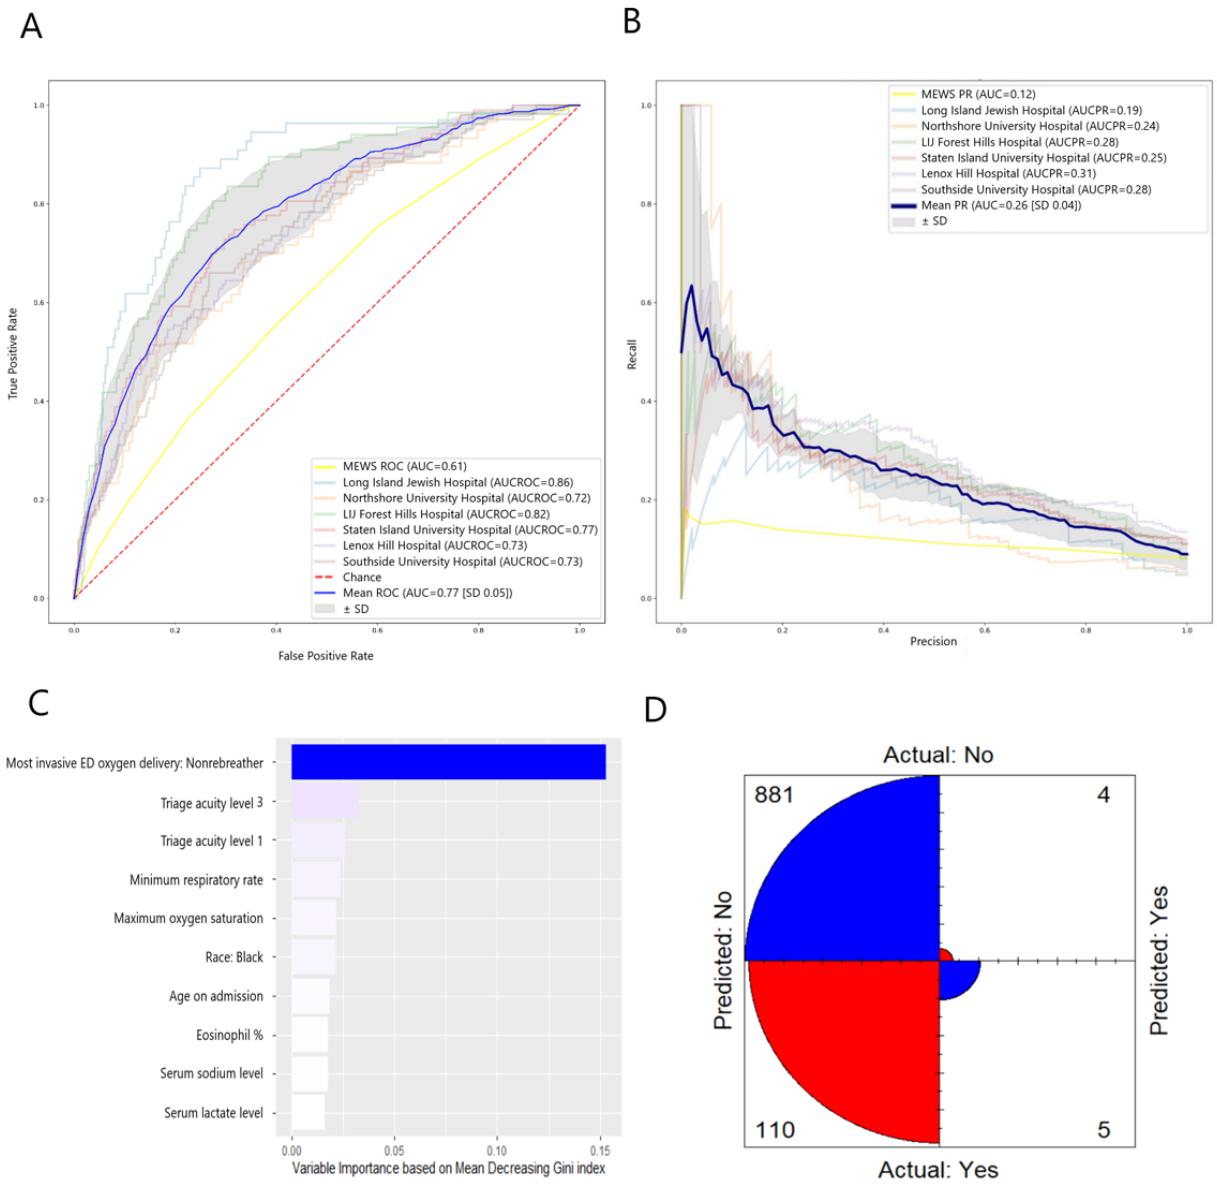

Table 2. Mean area under the curve of the receiver operating characteristic curve, area under the curve of the precision-recall curve, accuracies, precisions, recalls, specificities, geometric means, and Fβ-score (β=4) for models investigated.

Measure	XGBoost, mean (SD)	XGBoost + SMOTEENN, mean (SD)	Logistic regression, mean (SD)	Modified Early Warning Score
Area under the curve of the receiver operating characteristic curve	0.77 (0.05)	0.76 (0.03)	0.70 (0.05)	0.61
Area under the curve of the precision-recall curve	0.26 (0.04)	0.24 (0.06)	0.18 (0.06)	0.12
Accuracy	0.919 (0.028)	0.893 (0.016)	0.915 (0.027)	0.913
Precision	0.521 (0.329)	0.303 (0.089)	0.322 (0.375)	0.165
Recall	0.051 (0.030)	0.228 (0.095)	0.009 (0.013)	0.017
Specificity	0.994 (0.005)	0.955 (0.005)	0.998 (0.002)	0.992
Geometric mean	0.337 (0.042)	0.506 (0.063)	0.285 (0.051)	0.296

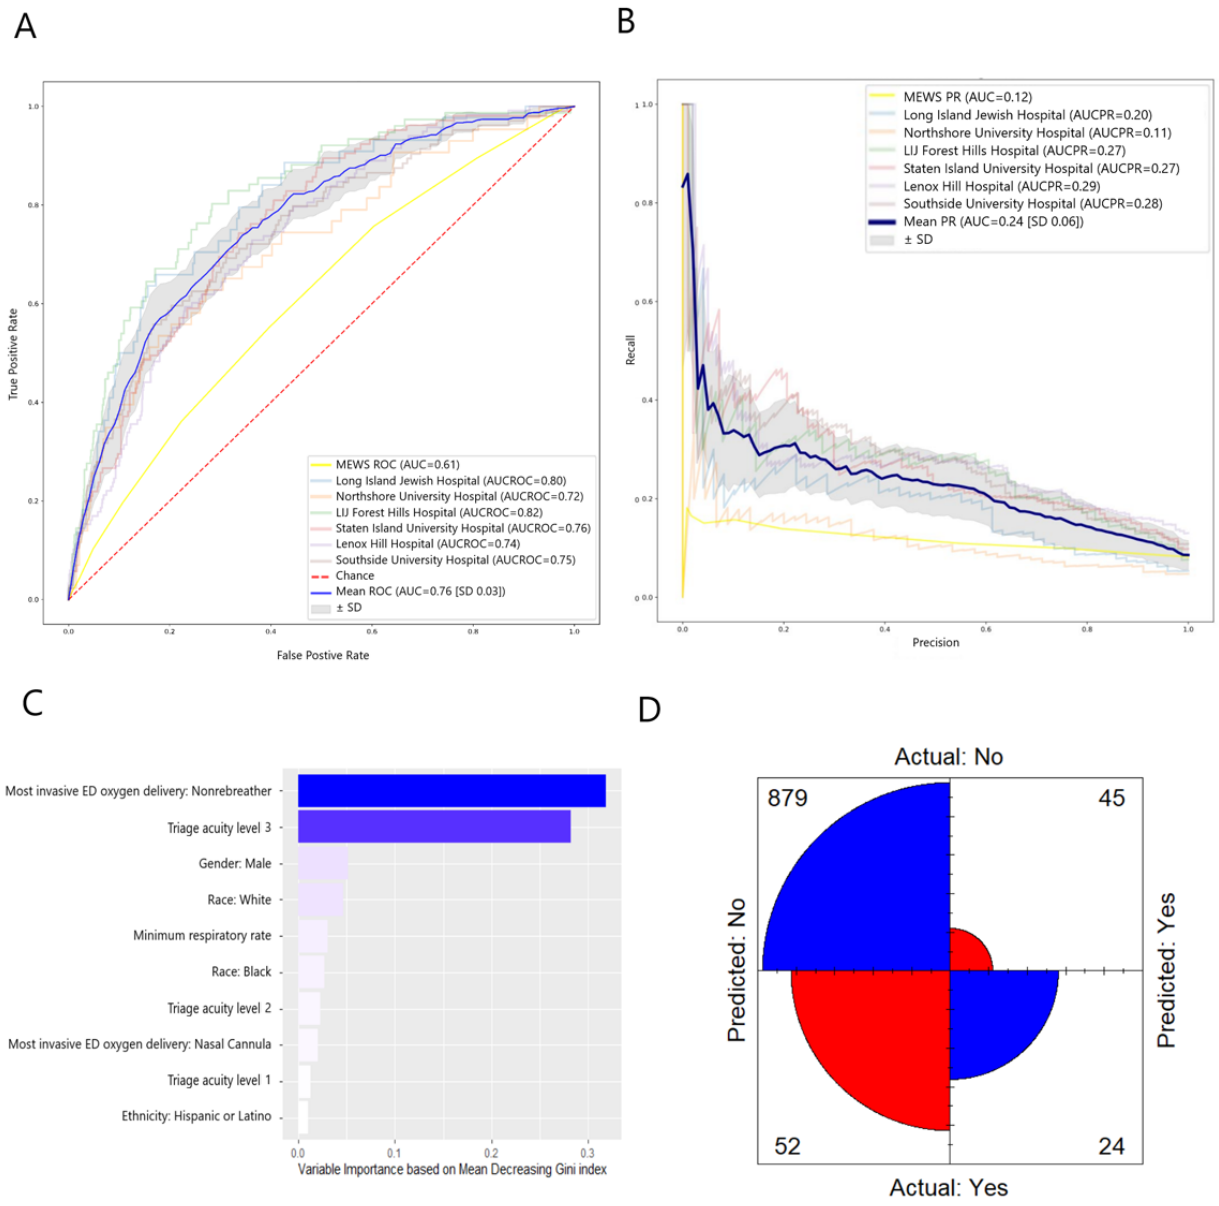
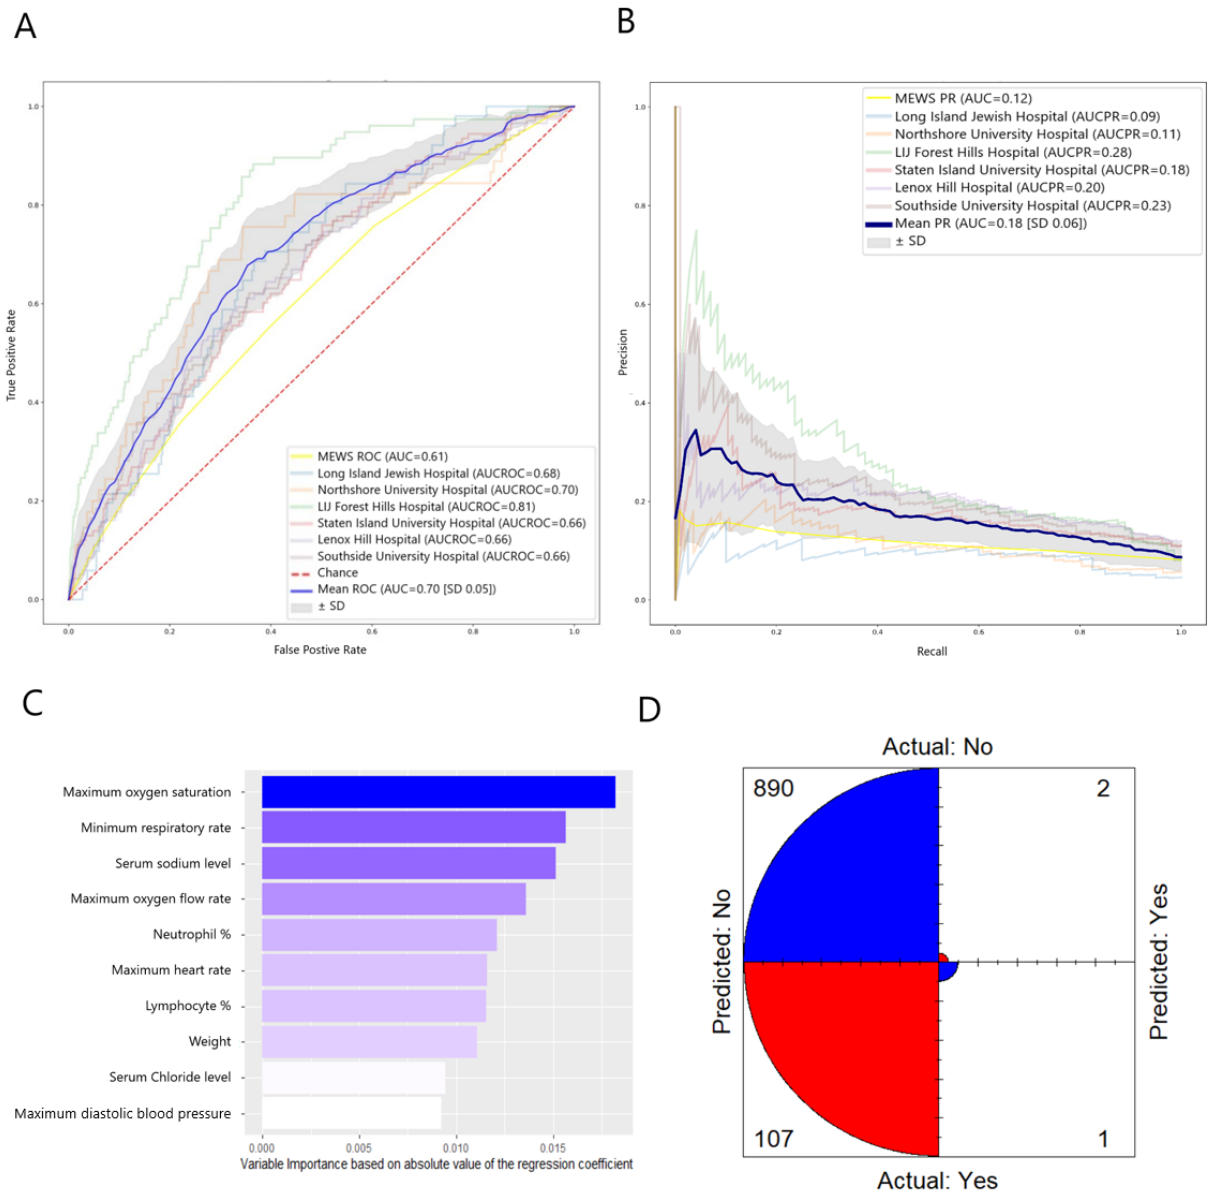
Figure 2. The XGBoost + SMOTEENN model for predicting respiratory failure within 48 hours. (A) ROC curve and (B) PR curve based on a cross-hospital validation performed by leaving one hospital out as a testing set and using the remaining hospitals for the training set. Only hospitals with >1000 patients with COVID-19 were selected for testing sets. The mean ROC and PR curves are shown in dark blue and their corresponding standard deviations are shown in gray. The MEWS metrics are shown in light yellow. (C) The 10 variables with the highest relative importance measured by the amount the variable reduced the Gini coefficient. (D) Mean confusion matrix visually represents the predicted values versus actual prediction. AUC: area under the curve of ROC; AUCPR: area under the curve of the precision-recall curve; ED: emergency department; LIJ: Long Island Jewish; MEWS: Modified Early Warning Score; PR: precision-recall; ROC: receiver operating characteristic.



We also examined the performance of a logistic regression model. The mean AUCs of the ROC and PR curves were 0.70 (SD 0.05) and 0.18 (SD 0.06), respectively. Mean accuracy, precision, recall, specificity, geometric mean, and F_β-score were 0.915 (SD 0.027), 0.322 (SD 0.375), 0.009 (SD 0.013), 0.994 (SD 0.005), 0.285 (SD 0.051), and 0.010 (SD 0.014), respectively (Figure 3 and Table 2). MEWS was used to compare ROC and PR curves. MEWS resulted in AUCs of the ROC and PR curves of 0.61 and 0.12, respectively (Figures 1-3). For MEWS, accuracy, precision, recall, specificity, geometric mean, and F_β-score were 0.913, 0.165, 0.017, 0.992, 0.296, and 0.018, respectively.

The calibration curves showed that all three models were well calibrated among all hospital folds, although all three deviated from perfect calibration as the fraction of positives increased (Figure 3). The corresponding mean Brier score for XGBoost, XGBoost + SMOTEENN, and logistic regression was 0.071 (SD 0.019), 0.079 (SD 0.016), and 0.077 (SD 0.018), respectively (Figure 3).

Figure 3. The logistic regression model for predicting respiratory failure within 48 hours. (A) ROC curve and (B) PR curve based on a cross-hospital validation performed by leaving a hospital out as a testing set and using the rest for the training set. Only hospitals with >1000 patients with COVID-19 were selected for testing sets. The mean ROC and PR curves are shown in dark blue and their corresponding standard deviations are shown in gray. The MEWS metrics are shown in light yellow. (C) The 10 variables with the highest relative importance measured by the absolute value of the regression coefficient. (D) Mean confusion matrix visually represents the predicted values versus actual prediction. AUC: area under the curve of ROC; AUCPR: area under the curve of the precision-recall curve; LIJ: Long Island Jewish; MEWS: Modified Early Warning Score; PR: precision-recall; ROC: receiver operating characteristic.



Discussion

We presented three models (two of which were based on XGBoost) for predicting early respiratory failure in patients given a diagnosis of COVID-19 and admitted to the hospital from the ED. One model was tilted toward precision and specificity (XGBoost) and the other was tilted toward recall (XGBoost + SMOTEENN). These models are based on baseline characteristics, ED vital signs, and laboratory measurements. Using an automated tool to estimate the probability of respiratory failure could identify at-risk patients for earlier interventions (eg, closer monitoring, critical care consultation, earlier discussions about goals of care) and improve patient outcomes.

We evaluated three machine learning models: XGBoost, XGBoost + SMOTEENN, and logistic regression [38-40]. XGBoost is widely used due to its high efficiency and predictability, and it has been used to predict health care outcomes in patients with [41,42] and without [43-45] COVID-19. In our study, XGBoost was the most accurate prediction model, with an accuracy of 0.919 (SD 0.028) and precision of 0.521 (SD 0.329; Figure 1), similar to the findings of another study that examined combined outcomes [46]. However, what is different in our model is that it achieves

cross-hospital validation. Such accuracy showcases the ability of the model to separate intubations from nonintubations within the 48-hour window of interest. Such a model would be useful for physicians as it more accurately and consistently identifies patients at high risk for intubation.

We also constructed an XGBoost + SMOTEENN model. SMOTEENN was used to improve the sensitivity of our prediction, as our data set was imbalanced (ie, only ~8% of our COVID-19 cohort were intubated), while keeping deviation from accuracy and calibration of the model to a minimum. Compared to XGBoost, the XGBoost + SMOTEENN model had lower accuracy and precision, but greater recall (or sensitivity; 0.228 [SD 0.095]; Figure 2). This higher sensitivity can identify more patients who require IMV, suggesting that this model may be more suitable for broad or automated screening of patients.

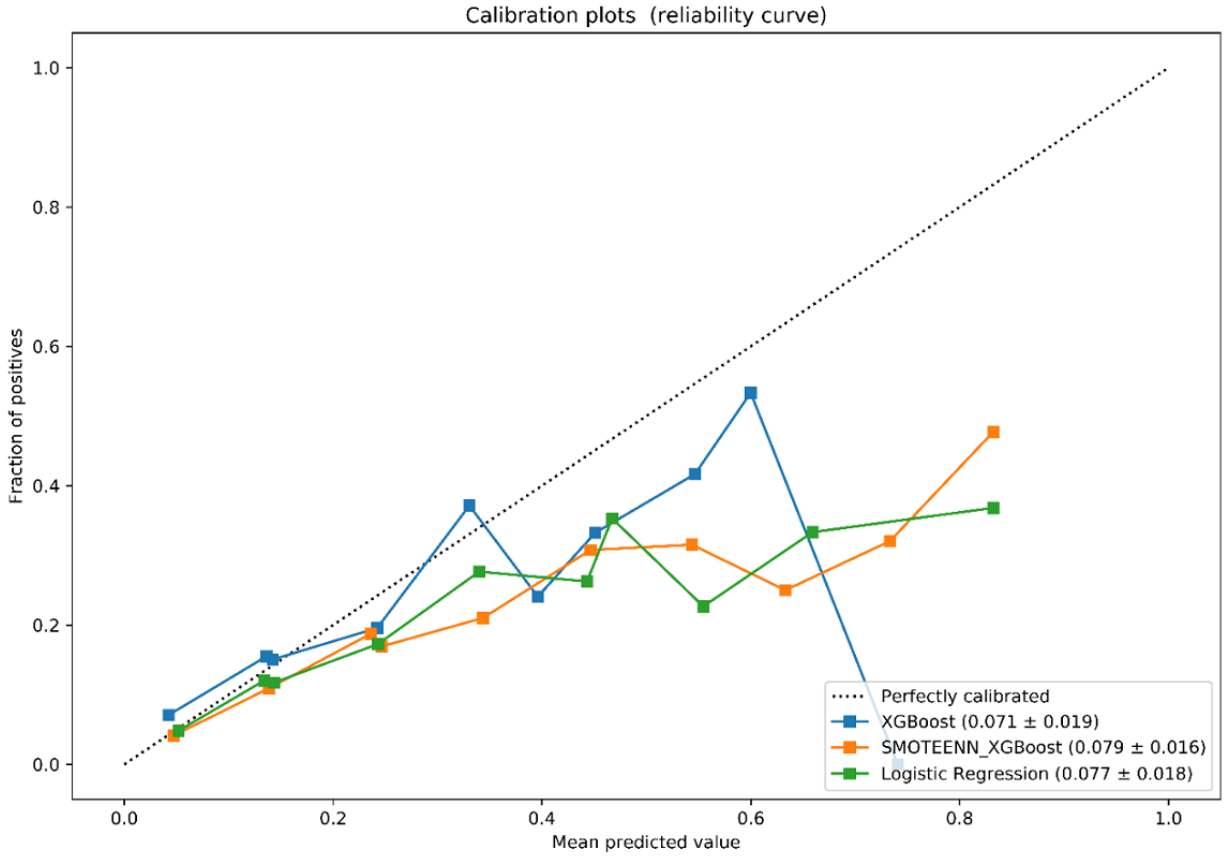
We also examined the performance of a logistic regression model to determine whether a compact, linear model could accurately predict patient risk (Figure 3 and Table 2). Model performance was inferior to the XGBoost model. This supports earlier reports that machine learning techniques outperform classic models of logistic regression in their ability to predict many prognostic and health outcomes [47-49]. Finally, we compared the performance of our predictive machine learning models to the widely used MEWS [36]. MEWS was inferior to all three models described above in most of the measures examined.

Using the most important variables for our models, we identified clinically relevant measures that can best inform clinical decision making (Figures 1, 2). The XGBoost model was accurate and precise, as reflected by the low number of false positives of the model predictions (Figure 1). A more sensitive alternative to this model would be the XGBoost + SMOTEENN model, which had fewer false negatives than XGBoost (Figure 2). Both models share important predictors, such as information about the mode of oxygen delivery, triage acuity, demographic information, and respiratory rate. However, XGBoost (the more accurate model with higher precision) adds serum lactate, sodium, and eosinophil percentage to the top 10 most important variables. This indicates that when precision is important, measures such as lactate can rule out the most severe cases by becoming strong predictors. Among hospitals in Northwell Health, certain hospitals such as Long Island Jewish (which is one of the largest in terms of number of patients with COVID-19) had a high drop in their predictive ability when logistic regression was used. When Long Island Jewish was being validated, the 0.86 AUCROC of the XGBoost model dropped to 0.68 for logistic regression. This could partially be due to the nature of the outcome predicted (choice of ventilation from hospital staff), where one would expect different hospitals to possibly exhibit higher variability, not only for patient demographics, but also for hospital staff therapy choices.

Variable importance metrics revealed that the linear logistic regression models use laboratory variables primarily, whereas nonlinear XGBoost-based models prioritize clinical and demographic variables that better capture hospital-specific behavior (eg, oxygen delivery types prior to intubation) and increase the robustness of the model. However, we need to validate whether providing these variables along with the probability of respiratory failure would decrease the rate of identifying at-risk patients. Further prospective studies and randomized clinical trials are needed for this validation.

When examining the calibration of the models (Figure 4), we found that all models were well calibrated, yet as the fraction of positive cases increased, calibration suffered. This suggests that if a specific population of patients has a greater likelihood of intubation (eg, those aged >70 years, or with specific comorbid conditions), the model would need to be retrained to increase its accuracy and calibration.

Figure 4. Calibration plots (reliability curve) of the XGBoost, XGBoost + SMOTEENN, and logistic regression models for respiratory failure within 48 hours. Calibration is based on the precision probability (using predict_proba in Python). For creating the plots, sklearn.calibration.CalibratedClassifierCV (in Python) was used by inserting a fraction of positives and mean predicted values into 10 bins with an increasing fraction of positives (respiratory failures) for each hospital fold. The mean Brier score (SD) across all hospitals tested corresponding to the model is shown in the figure legend in parentheses.



Our study has several limitations. We extracted data on intubation timing from our EHR, which may have minor inaccuracies. Although a consistent temporal inaccuracy could create bias in underestimating/overestimating the intubation rate, we believe that these small inaccuracies are overcome by the average calculated from our large number of cases. Another limitation is that we relied on data from a multicenter, single health system for both implementation and validation. Thus, we were unable to externally validate the models in other health systems and hospitals with different protocols, which might affect the model's performance. In addition, because the study is retrospective, we can only suggest associations and correlations rather than identify the main contributors that lead to intubation and mechanical ventilation. Furthermore, the numerical missing variables were imputed with weighted k-nearest neighbors. Thus, the conclusions made from these variables assume uniformity in patient data based on those missing values. In the case of nonuniformity, the order of variable importance might change. Additionally, some clinical variables included in the model may appear to be obvious correlates of the clinical decision for intubation within 48 hours (eg, having nonrebreather oxygen flow as the most invasive form of ventilation). However, the association of all included variables is not deterministic: only 453 of 2633 patients on nonrebreather oxygen flow in the ED were intubated within 48 hours. In addition, given that these variables are available to clinicians and part of their decision making, we included them in our model. Finally, we used supervised learning on a homogenous database. Although we used cross-hospital validation and retrospectively validated our learning method, external generalizability of these learning methods to other health systems requires validation in prospective studies and randomized trials. Such high-quality evidence could provide more clues on clinical and economic impacts, as well as measures to improve them.

COVID-19 has evolved into an extremely challenging clinical and public emergency worldwide, especially in the New York City metropolitan area. As public health measures attempt to mitigate this disaster by slowing the spread and alleviating the heavy burden placed on health care systems, clinicians must make important decisions quickly and hospital administrators must manage resources and personnel. Furthermore, as predicted by many models [50-52], we are in the midst of a second wave of infection. Our models could inform clinical care by offering complementary performance characteristics (one model with superior recall, the other with greater precision) and supporting clinical decision making as we tackle this unprecedented public health crisis.

Members of the Northwell COVID-19 Research Consortium include: Matthew Barish, Stuart L Cohen, Kevin Coppa, Karina W Davidson, Shubham Debnath, Lawrence Lau, Todd J Levy, Alexander Makhnevich, Marc D Paradis, and Viktor Tóth.

We acknowledge and honor all of our Northwell team members who consistently put themselves in harm's way during the COVID-19 pandemic. We dedicate this article to them, as well as all patients, as their vital contributions to knowledge about COVID-19 made it possible.

Authors' Contributions

SB, DPB, and TPZ conceptualized and designed the study. SB, JSH, and TPZ had full access to all data in the study and are responsible for the integrity of the data. SB and JSH performed data extraction and cleaning. MB, PW, TM, and JSH contributed to many discussions during manuscript development. SB, DPB, and TPZ contributed to drafts of the manuscript. SB trained and validated the models. SB and TPZ designed and created the figures. DBP and TPZ critically reviewed the paper, and PW and TPZ obtained funding. The Northwell COVID-19 Research Consortium prioritized this manuscript, organized meetings between contributing authors, and provided support in finalizing the manuscript for submission. All named authors read and approved the final submitted manuscript.

Abstract

Background: COVID-19-related information on social media is overabundant and sometimes questionable, resulting in an "infodemic" during the pandemic. While previous studies suggest social media usage increases the risk of developing anxiety symptoms, how induced anxiety affects attitudes and behaviors is less discussed, let alone during a global pandemic. Little is known about the relationship between older adults using social media during a pandemic and their anxiety, their attitudes toward social trust in information, and behaviors to avoid contracting COVID-19.

Objective: The goal of this study was to investigate the associations between using social media for COVID-19-related information and anxiety symptoms as well as the mediation effect of anxiety symptoms on social trust in information and COVID-safe behaviors among older adults.

Methods: A cross-sectional telephone survey was conducted in Hong Kong between May and August 2020. A rapid warm-call protocol was developed to train social workers and volunteers from participant nongovernmental organizations to conduct the telephone surveys. Questions related to COVID-safe behaviors, social trust in information, social media use, anxiety and depressive symptoms, and sociodemographic information were asked. The number of confirmed COVID-19 cases at the community level was used to account for the risk of contracting COVID-19. Ordinary least squares regressions examined the associations between social media use and anxiety symptoms, and how they were associated with social trust in information and COVID-safe behaviors. Structural equation modeling further mapped out these relationships to identify the mediation effects of anxiety symptoms.

Results: This study collected information regarding 3421 adults aged 60 years and older. Use of social media for COVID-19-related information was associated with more anxiety symptoms and lower social trust in information but had no significant relationship with COVID-safe behaviors. Anxiety symptoms predicted lower social trust in information and higher COVID-safe behaviors. Lower social trust in information was predicted by using social media for COVID-19 information, mediated by anxiety symptoms, while no mediation effect was found for COVID-safe behaviors.

Conclusions: Older adults who rely on social media for COVID-19-related information exhibited more anxiety symptoms, while showing mixed effects on attitudes and behaviors. Social trust in information may be challenged by unverified and contradictory information online. The negligible impact on COVID-safe behaviors suggested that social media may have caused more confusion than consolidating a consistent effort against the pandemic. Media literacy education is recommended to promote critical evaluation of COVID-19-related information and responsible sharing among older adults.

KEYWORDS

COVID-19; anxiety; social media; infodemic; Hong Kong

Introduction

The COVID-19 pandemic is the first in history in which technology and social media have been used on a massive scale to keep people safe, informed, productive, and connected [1]. Although older adults are arguably less tech-savvy and do not use social media as often as younger adults, previous studies suggest that using social media for communication may help maintain relationships and prevent loneliness among older adults while having the potential to enhance health-related knowledge through information seeking [2,3]. However, the overabundance of information, especially misinformation about the COVID-19 pandemic because of its novelty and associated uncertainty, is fueling an infodemic [4]. Since the pandemic is likely to be enduring, its prolonged impact on mental health is anticipated, rendering it an important research and practice priority [5]. Therefore, effort should be made to understand the role of social media use in mental health among older adults during the COVID-19 pandemic.

Exposure to mass media in crises has been associated with anxiety symptoms and distress [6,7]. Meanwhile, the use of social media presents a higher risk of having anxiety disorder [8], where passive information consumption such as reading the news is associated with stronger anxiety symptoms [9,10]. The characteristics of social media and the way older adults consume it may further facilitate the spread of anxiety during a public health crisis such as the COVID-19 pandemic. Most recent evidence suggests an association between social media use and increased anxiety symptoms during the pandemic [11-13]. Researchers suggest that in the epicenter, Wuhan, China, this association could be a result of the fear inflicted by misinformation circulating online, while social media amplified widespread nervousness and worry [14]. Previous experiences during the Korean Middle East Respiratory Syndrome (MERS) outbreak also demonstrated the positive relationship between social media exposure and higher perceived public health risks [15]. Therefore, reliance on social media for acquiring information related to the COVID-19 pandemic introduces a higher chance of being overwhelmed by unverified and contradictory messages that promote the vicious cycle of anxiety.

During the COVID-19 pandemic, adults aged 60 years or older in Hong Kong had a significantly higher risk of exhibiting anxiety symptoms compared to the general population [16]. Challenges are presented to older adults, who may respond to the pandemic and social media differently. Contrary to the primarily unidirectional communication process in traditional media, interactive social media platforms allow users to engage in different modes of health communication [17]. A systematic review showed that previous research seldom distinguished different purposes of social media use among older adults [18]. Active usage, such as sharing or posting personal content, is different in nature from passive usage, such as browsing or seeking information that requires less effort and no need to communicate a self-concept with others in the virtual world [9]. While digital technologies designed for older adults typically stimulate passive usage [2], digital-savvy older adults are developing distinct ways of adopting internet usage, substituting online sources for traditional media for news and information consumption [19]. Passive usage is common among older adults in Hong Kong, of whom 68% use the internet for reading news and 71% listen to or watch multimedia content [20]. While their one-way consumption of information and the social media environment suggest a higher risk of having anxiety symptoms [9,10], more evidence is needed to understand whether using social media for COVID-19 information has a negative impact on older adults during the pandemic.

Worries over physical health are a major source of anxiety-related concern among older adults, where the cognitive phenomenon of worrying is central to their experience [21]. The higher the health risk, the more likely older adults feel anxious. These health-related concerns could be intensified by COVID-19-related media consumption portraying the virus as particularly harmful to the older population [22]. Inconsistent and overwhelming information available on social media exacerbates worries about the pandemic [23]. Therefore, exposure to COVID-19-related information on social media during the pandemic may induce anxiety symptoms [23-25]. It is hypothesized that older adults who use social media for COVID-19-related information will exhibit more anxiety symptoms.

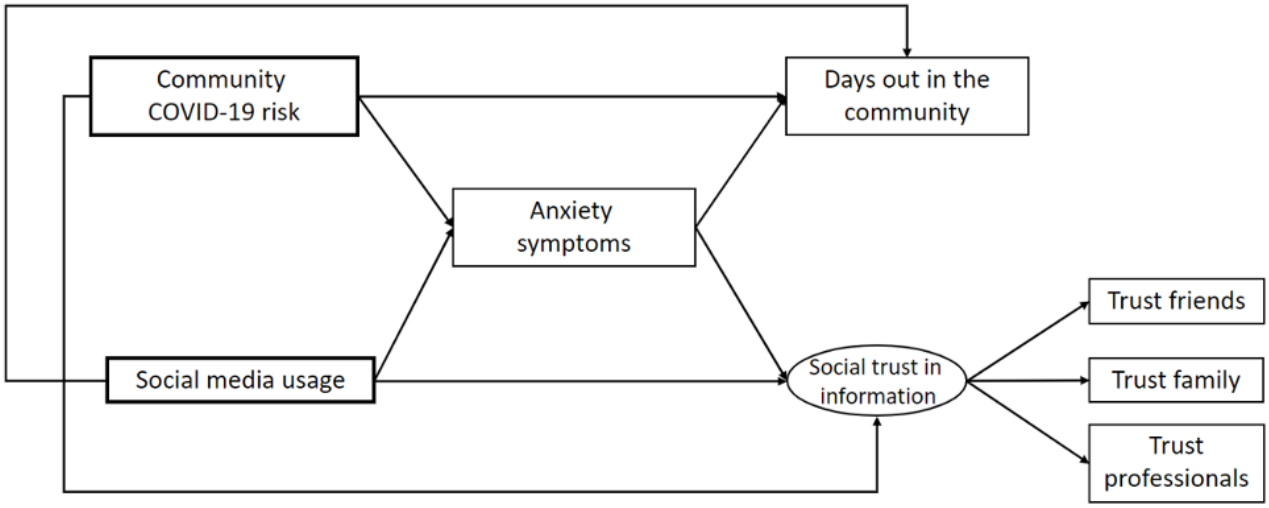
Anxiety may contribute to pandemic-related attitudes. One of the impacts of anxiety on attitudes is its association with social distrust [26]. Recent research in the context of COVID-19 demonstrates that using social media as an information source is associated with conspiracy beliefs [27]. Anxious about contradictory information online, older adults using social media may show more disbelief toward what is told. As a result, the attitudes in trusting the information about COVID-19 from the social circles around these older adults may be affected. While trust in information may also affect how much older adults use a particular media platform, this study is particularly interested in how the infodemic may affect older adults. Especially when the literature suggested that information on social media may prompt anxiety, the implication of investigating the mediation effect from using social media for COVID-19 information on social trust in information is to unveil the effects of media usage and the ways older adults are getting to know the world. It is hypothesized that older adults for whom social media is their main source of COVID-19-related information have lower social trust in information, mediated by anxiety symptoms.

While the information on social media mediates personal mitigation strategies, anxiety may prompt COVID-safe behaviors, including handwashing and social distancing [28]. Meanwhile, excessive anxiety may lead to maladaptive COVID-safe behaviors, such as panic purchasing, or

nonadherence to public health recommendations [29]. Given the immense public health risk, anxious older adults should be encouraged to adopt more COVID-safe behaviors. Wearing face masks, frequent hand hygiene, and social distancing by staying home were three COVID-safe behaviors suggested by infectious disease experts in Hong Kong [30]. Both recommendations of wearing face masks and frequent hand hygiene were widely followed by residents. For example, 98.8% of all residents wore face masks in early 2020 before it was mandated by the government [31]. However, the social distancing recommendation was observed by fewer people for various reasons (eg, work, shopping, exercise, and meals with friends). Therefore, we chose social distancing, measured by the number of days each week older adults ventured into the community, as a proxy for COVID-safe behavior in this study. It is hypothesized that older adults who use social media as their source of COVID-19-related information will reduce social contact by reducing time spent in the community, mediated by anxiety symptoms.

Anxiety symptoms, social trust in information, and time spent in the community may be influenced by the objective risk of contracting COVID-19. In order to distinguish the effects of the actual risk from the effects of the perceptions acquired via social media, the hypothesized theoretical framework put the risk of contracting COVID-19 as another independent factor (see Figure 1).

Figure 1. Theoretical framework.



The specific focus of this study was to investigate the effects of consuming public health–related information via social media on anxiety among the older population during a public health crisis. Some of the most recent studies investigating the impact of information sources on confidence in coping with COVID-19 [32], behaviors [33], and beliefs about health-related information [34] have primarily used internet-based questionnaires to survey their participants. Since, in this study, we were interested in evaluating older people, some of whom may be less engaged in digital communication, an online survey would present difficulties in reaching them and could create sampling bias. Therefore, a telephone survey was chosen to capture a more diverse sample. To address the gap in the current literature, this study investigated how using social media for COVID-19 information among older adults during the pandemic was associated with anxiety symptoms and how the two contribute to social trust in information and COVID-safe behaviors.

Methods

Study Design and Sampling

A cross-sectional telephone survey was conducted during the COVID-19 outbreak in Hong Kong between May and August 2020; participants included adults aged 60 years and older using services provided by community elderly centers and community mental wellness centers. The former centers provide active aging programs and social support for community-dwelling older adults. The latter centers run programs to promote mental wellness in the community and provide psychosocial support for community-dwelling residents of all ages with mental health challenges. The research team developed a short survey instrument and trained center-based social workers and volunteers to conduct the survey. We called a total of 3550 members and completed 3421 interviews, giving a success rate of 96.4%. All respondents had no prior history of COVID-19.

Data Collection

Data were collected through telephone interviews. Each interview lasted for about 10 to 15 minutes. The questionnaire was tested and revised before full-scale implementation. Qualified clinical psychologists and the researchers of this study designed the drafted questionnaire, which was reviewed and pretested by frontline social workers. Questions that were identified as challenging for older people with limited education to understand were revised and simplified. The process was repeated for two rounds before large-scale implementation. Interviewers were trained to make phone calls to respondents using a standardized, rapid, warm-call protocol. The protocol started with a warm call; that is, getting in touch with service recipients with known personal information. After greeting them and asking for their needs amid the pandemic, the questionnaire was fielded. Frontline social workers followed up with participants who demonstrated mental health challenges. This

study was approved by the Human Research Ethics Committee of the University of Hong Kong (reference No. EA2003001[A]).

Measurements

The major dependent variables of the study were anxiety, social trust in information, and COVID-safe behaviors. Anxiety was measured using the validated Chinese version of the 2-item Generalized Anxiety Disorder (GAD-2) scale, which ranged from 0 to 6, where a GAD-2 score of 3 or more indicated a high possibility of anxiety [35,36]. For social trust in information, respondents were asked to rate the extent to which they believed the COVID-19-related information that was shared from people in their social circles, including family, friends, and professionals (eg, social workers and general practitioners), on a scale from 1 (total distrust) to 5 (complete trust). The scale included a *not applicable* option that resulted in only 1480 respondents completing all three questions. Social trust in information was computed as the average of the three items for ordinary least squares (OLS) regressions (Cronbach α=.69) and as a latent variable of the three items in structural equation modeling (SEM). Only responses with complete answers in all three items were compiled. By treating social trust in information as missing when the respondents selected *not applicable* in any of the three components, the valid number of responses of social trust in information in OLS regressions was reduced to 1480. In the SEM, missing data were treated with full information maximum likelihood (FIML) estimation. The sample size for the SEM was 3415. COVID-safe behaviors were proxied by social distancing, measured by the older adults' responses to how many days each week they ventured into the community.

The major independent variable was social media usage for COVID-19-related information, which was measured with three categories: (1) no usage, (2) social media used for COVID-19-related information, and (3) social media used as the main source of COVID-19-related information. Usage of social media for COVID-19-related information was recoded from a survey item on the trust level of media sources. The trust levels of social media and traditional media were captured in a 5-point scale, ranging from 1 (total distrust) to 5 (complete trust). The scale included a *not applicable* option. Only respondents using social media for COVID-19-related information were prompted to answer the question about trust level of social media, while nonusers picked the *not applicable* option. To measure any use of social media for COVID-19-related information, valid responses on social media trust were, therefore, recoded as *used social media for COVID-19-related information*. The nonusers who picked *not applicable* were considered to have no usage. The main information source was captured by a dichotomous variable of *traditional media* or *social media*, where the *social media* responses were recoded into *social media used as the main source of COVID-19-related information*.

The control variables include the risk of contracting COVID-19, depressive symptoms, and demographics. The risk of contracting COVID-19 was measured by the number of all confirmed cases in the week of data collection in the district in which the respondent lived. This information was obtained from the government daily report of newly confirmed cases. This measurement is geographically sensitive and reflected the risk of anyone contracting COVID-19, older adults included, who ventured into their neighborhood. Depression was measured using the validated Chinese version of the 2-item Patient Health Questionnaire (PHQ-2), with scores ranging from 0 and 6, where a PHQ-2 score of 3 or more indicates a high possibility of depression [37,38]. Demographics collected included respondents' age in years, gender (ie, male or female), district of residency, and membership of service unit (ie, elderly center or mental wellness center). Respondents from mental wellness centers, who had a history of mental challenges, were included in the sample. A dummy variable was added to statistical models to control for its effects on mental health status and to investigate any difference in using social media for COVID-19 information.

Statistical Analysis

Descriptive statistics of all variables were computed and reported as appropriate. Social media usage categories were entered into the statistical models as dummy variables of *used social media for COVID-19 information* and *used social media as the main COVID-19 information source*, with *no usage* as the reference group. Multivariate OLS regressions were applied to investigate the effect of using social media for COVID-19 information on anxiety symptoms as well as the effects of using social media for COVID-19 information and anxiety symptoms on time spent in the community and social trust in information. The theoretical model was then examined by SEM to test the mediation effect of anxiety symptoms. Social trust in information was treated as a latent construct with the three trust items. The first level of the SEM predicted anxiety symptoms with depressive symptoms, using social media for COVID-19 information, and demographics. The second level predicted time in the community and social trust in information with using social media for COVID-19 information, anxiety symptoms, and demographics. The FIML approach, which estimates parameters and standard errors directly with all data but does not impute missing data, was employed to account for the missing data in SEM. FIML generates relatively unbiased estimates and the least convergence failures compared to other methods, such as listwise or pairwise deletion and multiple imputations in SEM [39]. It is also less affected by nonnormal missing data and data distribution shape [40].

All data were consolidated and analyzed with SPSS software, version 26 (IBM Corp), after the removal of personal identifying information. SEM was conducted using the R package *lavaan* (The R Foundation) [41].

Results

Table 1 shows the respondents' characteristics. Their average age was 76 years (SD 8.9), 25.4% (869/3418) were male, and 77.9% (2666/3421) were recruited from elderly centers. The average number of COVID-19 cases in a community was 25.7 (SD 27.5), ranging from 0 to 135. Depression and anxiety were not prevalent: the average PHQ-2 score was 0.83 (SD 1.3) and the average GAD-2 score was 0.74 (SD 1.2). While 8.7% (298/3421) of the respondents exhibited a risk of having depression (ie, PHQ-2 score ≥3), 7.0% (241/3421) of the

respondents exhibited a risk of having anxiety disorder (ie, GAD-2 score ≥3). Out of 3421 respondents, 1399 (40.9%) used social media to obtain COVID-19-related information and 203 (5.9%) used social media as their main source of COVID-19 information. The respondents had spent some time outside the home in the community on an average of 4 days (SD 2.4) in a week. In terms of their attitudes, the respondents had moderate to high levels of social trust in information (family: mean 4.4, SD 0.83; friends: mean 3.6, SD 0.96; professionals: mean 4.5, SD 0.74).

Compared to respondents recruited from mental wellness centers, respondents from elderly centers showed a different profile in their demographics and mental health status, but not in their usage of social media. Respondents from elderly centers were, on average, 4.4 years older (t_{3419}=12.0, *P*<.001), and more of them were male (elderly centers: 703/2663, 26.4%; mental wellness centers: 166/755, 22.0%; χ^2_1=6.0, *P*=.01). They also showed fewer depressive symptoms as measured by the PHQ-2 (elderly centers: mean 0.69, SD 1.18; mental wellness centers: mean 1.33, SD 1.53; t_{3416}=12.3, *P*<.001) and fewer anxiety symptoms as measured by the GAD-2 (elderly centers: mean 0.61, SD 1.13; mental wellness centers: mean 1.22, SD 1.43; t_{3386}=12.1, *P*<.001). Nevertheless, there was no significant difference in their usage of social media (t_{3419}=1.35, *P*=.18), which was the main independent variable. To account for the potential bias from a different mental health profile, the nature of the service was treated as a control variable in the subsequent analysis.

Table 1. Respondent characteristics.

Variable	Value (N=3421)
Demographics	
Age (years), mean (SD)	76.0 (8.9)
Gender (male) (n=3418), n (%)	869 (25.4)
Service nature (aged care), n (%)	2666 (77.9)
Community COVID-19 risk, mean (SD)	
Weekly number of COVID-19 cases in district	25.7 (27.5)
Psychological well-being (range 0-6), mean (SD)	
2-item Patient Health Questionnaire (n=3418)	0.83 (1.3)
2-item Generalized Anxiety Disorder scale (n=3388)	0.74 (1.2)
Trust in media (range 1-5), mean (SD)	
Traditional media (n=3335)	4.27 (0.88)
Social media (n=1399)	3.18 (1.1)
Using social media for COVID-19 information	
Used social media for COVID-19 information, n (%)	1399 (40.9)
Social media as the main source of COVID-19 information, n (%)	203 (5.9)
Days out in the community per week (n=3161), mean (SD)	4.1 (2.4)
Social trust in COVID-19 information (range 1-5), mean (SD)	
Family (n=2620)	4.4 (0.83)
Friends (n=2023)	3.6 (0.96)
Professionals (n=2150)	4.5 (0.74)

Table 2 shows the results of the OLS regressions. After controlling for demographics and depressive symptoms, the category *used social media for COVID-19-related information* was not associated with anxiety symptoms but *used social media as the main source of COVID-19 information* did (B=0.18, *P*=.003). Using social media as the main source for COVID-19-related information was associated with more anxiety symptoms. Although social media use did not predict time spent in the community, it was associated with lower social trust in information. Both levels of usage—*used social media for COVID-19-related information* (B=–0.11, *P*=.005) and *used social media as the main source of COVID-19 information* (B=–0.30, *P*<.001)—showed a negative association. Anxiety symptoms were also negatively associated with time spent in the community and social trust in information (days out: B=–0.08, *P*=.02; social trust: B=–0.04, *P*=.02). Community COVID-19 risk was not significantly associated with anxiety symptoms (B=0.001, *P*=.69) but predicted less time spent in the community (B=–0.01, *P*<.001) and higher social trust in information (B=0.003, *P*<.001). Aged care respondents showed fewer anxiety symptoms (B=–0.17, *P*<.001) and higher social trust in information (B=0.23, *P*<.001), while older respondents spent the least amount of time in the community (B=0.03, *P*<.001). Male respondents were less anxious (B=–0.09, *P*=.004), spent more days out in the community (B=0.24,

P=.02), and had lower social trust in information (B=–0.10, *P*=.02).

Table 2. Results from ordinary least squares regressions predicting anxiety symptoms, days out in the community, and social trust in information.

Variable	GAD-2[a] scale (n=3384)		Days out in the community (n=3126)		Social trust in information (n=1480)	
	B[b] (95% CI)	*P* value	B (95% CI)	*P* value	B (95% CI)	*P* value
Gender (male)	–0.09 (–0.15 to –0.03)	.004	0.24 (0.04 to 0.43)	.02	–0.10 (–0.18 to –0.02)	.02
Age (years)	–0.002 (0)	.19	–0.03 (–0.04 to –0.02)	<.001	–0.001 (–0.01 to 0)	.80
Community COVID-19 risk	0.001 (0)	.07	–0.01 (–0.01 to 0)	<.001	0.003 (0)	<.001
Service nature (aged care)	–0.17 (–0.24 to –0.10)	<.001	0.04 (–0.17 to 0.26)	.68	0.23 (0.14 to 0.32)	<.001
Depressive symptoms	0.71 (0.69 to 0.73)	<.001	N/A[c]	N/A	N/A	N/A
Used social media for COVID-19 information	0.002 (0 to 0.10)	.95	0.02 (–0.17 to 0.22)	.81	–0.11 (–0.19 to –0.03)	.005
Used social media as the main COVID-19 information source	0.18 (0.06 to 0.30)	.003	0 (–0.36 to 0.36)	.99	–0.30 (–0.43 to –0.16)	<.001

[a]GAD-2: 2-item Generalized Anxiety Disorder.

[b]Unstandardized coefficient.

[c]N/A: not applicable. The 2-item Patient Health Questionnaire (PHQ-2) was used for controlling the comorbidity with anxiety in the equation regressing GAD-2; there are no PHQ-2 values because the PHQ-2 was not included in the equations.

The results of SEM analysis (see Table 3 and Figure 2), modeling the mediation effect of anxiety symptoms, showed a good fit (χ^2_{19}=48.0, *P*<.001; Comparative Fit Index [CFI]=0.993; Tucker-Lewis Index [TLI]=0.985; root mean square error of approximation [RMSEA]=0.021; standardized root mean residual=0.014) and coincided with most findings in the OLS regressions. Since a lower level of social media use for COVID-19-related information was not associated with anxiety symptoms in the OLS regressions, the category was collapsed with *no social media usage* in the SEM. Using social media as the main source of COVID-19-related information predicted more anxiety symptoms (SEM coefficient=0.036, *P*=.002). Anxiety, meanwhile, was associated with lower social trust in information (SEM coefficient=–0.093, *P*<.001) and less time spent in the community (SEM coefficient=–0.043, *P*=.02). Using social media as the main source of COVID-19 information had a direct association with lower social trust in information (SEM coefficient=–0.071, *P*=.001), which means relying on social media for COVID-19 information was a significant predictor of social trust in information. Moreover, an indirect effect of using social media for COVID-19 information was mediated by anxiety (total effect=–0.074, *P*=.001). However, using social media as the main source of COVID-19 information was not associated with time spent in the community (SEM coefficient=–0.001, *P*=.97). No mediation effect was detected either (total effect=–0.002, *P*=.90). Sensitivity checking using social trust in information and time spent in the community to predict anxiety symptoms in SEM showed no significant associations (CFI=0.988; TLI=0.976; RMSEA=0.027), suggesting that anxiety was a valid independent factor in the second level of the original SEM model.

Discussion

Principal Findings

Our findings are not only consistent with previous studies on the association between social media use and anxiety [8,9], especially during the COVID-19 pandemic [11-13], but they also identified the major type of social media use among older adults (ie, consuming information) as predicting more anxiety symptoms. Both the OLS regression and SEM results demonstrated the association between using social media for COVID-19-related information and more anxiety symptoms among older adults. On the one hand, the ecology of social media, characterized by information overload and sensationalizing of information [42,43], could have amplified older users' nervousness and perceptions of the risks of contracting COVID-19. The inconsistency in unverified information on social media exacerbates this anxiety. On the other hand, older people's passive usage of social media suggests an intensified anxiety [9,10]. Since mental well-being decreases when social media users fail to acquire direct social interaction to satisfy their relatedness needs [44,45], passive usage may intensify unmet needs resulting from social isolation during the pandemic, thus prompting anxiety symptoms.

The SEM results suggested that anxiety symptoms mediated the effect of using social media for COVID-19 information on social trust in information. It demonstrated the two pathways of the associations between using social media and attitudes in trusting information. The proliferation of unverified and emotional information may drive anxiety and lower social trust in information among social media users. Algorithms in social media platforms prioritize sensational information [43]. User attention is drawn to the emotions induced while diminishing the ability to critically evaluate the accuracy of information, promoting the impulsive spread of unverified misinformation [46]. As a result, social media users may face contradictory information on social media, which may also be inconsistent with the information acquired from family, friends, or even health professionals. Not only would they become anxious about what to believe, but social trust in information was also undermined by reading conflicting claims. Another problem brought by social media use is the overwhelming amount of information overloading users as a result of uncontrolled news consumption [42]. On popular social media platforms, such as Facebook and Twitter, an infinite scroll feeds content to users without a "stopping cue" [47], while algorithms tailor content that suits user preference [43]. The environment in social media suggests that users are encouraged to stay on their sites as long as possible, consuming more information than intended. Overload is further magnified by the challenge to process the unverified, anonymous, and overwhelmingly subjective news on social media [48]. Consequently, it is difficult to digest all the information flooding into the social media feed because of both its enormous quantity and questionable quality.

Differences were observed from various demographic profiles as well. Older age was associated with spending fewer days venturing into the community, which was likely related to the lowered mobility in aged respondents. Male respondents were less anxious and more critical of COVID-19 information from people around them, and they went into the community more often. The results may have demonstrated a more authoritative gender role in older East Asian men. Respondents from mental wellness centers showed more anxiety symptoms and lower social trust in information. This suggested that a history of mental health challenges may exacerbate the effects of the infodemic.

Our results demonstrated that the infodemic may have caused more confusion than promoting COVID-safe behaviors. While older adults' usage of social media for COVID-19 information showed no association, the number of COVID-19 cases in the community and anxiety symptoms predicted less time spent in the community, suggesting that older adults adopted COVID-safe behaviors when the risk was high and when they became anxious. COVID-safe behaviors may have been further encouraged by the surge of social distancing and stay-home advice when the number of confirmed cases grew. However, these messages might not be transmitted equally to all social media users. Health-related misinformation proliferated well before the pandemic, facilitated by "information silos" and

"echo chambers" in social media [49]. The clustering of users in social media means that both useful information and harmful misinformation may not reach a mass audience but is amplified within social bubbles. Different stories could be proliferating among different user subgroups, resulting in the uneven effects of consuming information on social media regarding COVID-safe behaviors.

A greater understanding of how anxiety affects behaviors could inform ways to communicate COVID-19-related information to older adults to promote appropriate COVID-safe behaviors and social trust in information and contribute to the wider public health effort. On the one hand, our results suggested that anxiety encouraged older adults to avoid social contact. Nevertheless, more research is warranted to understand if this is rational risk aversion or panic-induced maladaptive behavior. On the other hand, while it is normal to be anxious in the face of a global pandemic, future research should also focus on the management and mitigation of anxiety during a prolonged pandemic so that older adults' trust in the people around them, who may provide the most adequate and timely support, is less likely to be undermined.

Although this study suggests some adverse effects of using social media, it does not mean that older adults should avoid using it. On the contrary, it is necessary to address these problems and identify the potential benefit of using social media to promote adequate COVID-safe behavior and reduce loneliness amid social distancing. Digital skills alone may no longer be sufficient to enable older adults to navigate the complex contemporary media environment. Media literacy among older adults should be advocated to enable them to critically analyze and interpret information. Guidance should be provided to promote healthy coping behaviors, such as verifying suspicious information and searching for credible information sources in response to the infodemic in social media. Advice on responsible social media use is essential for building a constructive social media environment for older adults. Media literate older adults should understand the consequences of spreading misinformation and refrain from sharing unverified information. By empowering older adults to distinguish and reject misinformation, the infodemic may be alleviated if the transmission of misinformation is curbed in its early stages. Anxiety may be reduced when older adults acquire agency while mutually building a healthy social media environment.

Limitations

Since the rapid warm-call protocol was designed to conduct interviews quickly with an extensive reach, our questions were designed to be simple and concise. While the data collection period spanned across 4 months, the study was cross-sectional in nature, which could not allow it to demonstrate causal relationships between use of social media for COVID-19, social trust, and anxiety. The self-reported survey design may also suffer from data inaccuracy as a result of issues including social desirability bias or loss of memory. Although a measurement for social media usage for COVID-19 information was constructed for this study, the sensitivity of the measurement may have been compromised for the conciseness of the survey. The range in measuring *used social media for COVID-19 information* may be too wide to fully capture its pro rata effects. On top of that, the frequency of media use is yet to be addressed. The frequency or time spent on social media may provide greater information about the influence of media usage patterns on anxiety, attitudes, and behaviors. Our scale did not capture the variance in the amount of time exposed to social media, only its ratio. Therefore, the study may underestimate the effect of using social media for COVID-19 information. Meanwhile, only one COVID-safe behavior—staying home to avoid social contact—was measured. Potential bias may occur when other factors contribute to older adults staying at home, such as the closure of businesses and social services, that were unrelated to using social media for COVID-19 information and anxiety.

Our sample, recruited from both elderly and mental wellness centers, was not a representative sample of the city. The findings may not be generalized to the whole population. Without support from social service units, the unsampled cluster of older adults could have experienced a greater challenge in navigating the pandemic. They might exhibit greater anxiety from not receiving adequate social support, and social media might be a more significant source of information about the COVID-19 pandemic.

Conclusions

This study suggests that using social media for COVID-19 information by older adults in Hong Kong during the COVID-19 pandemic was associated with anxiety symptoms. Meanwhile, anxiety symptoms mediated the effect from using social media for COVID-19 information on social trust in information but not COVID-safe behaviors. This suggests that the infodemic may have caused confusion when older adults digested health information, prompting anxiety among them about what and who to believe and, thus, reducing social trust in information. The fragmentized social media landscape further promoted an uneven impact of the infodemic between different groups of users. It could explain why objective risk and anxiety predicted older adults' avoidance of leaving home but using social media for COVID-19 information did not. To encourage the healthy use of social media, media literacy education should be promoted among older adults.

Acknowledgments

The authors would like to thank the social workers and volunteers for their help in recruiting study participants and collecting data, the research assistants for checking and managing data, and all participants for their contribution to this research. The Jockey Club Holistic Support Project for Elderly Mental Wellness (JC JoyAge) is funded by The Hong Kong Jockey Club Charities Trust.

Abstract

Background: The COVID-19 pandemic has had a negative impact on both the physical and mental health of individuals worldwide. Evidence regarding the association between mental health problems and information exposure among Thai citizens during the COVID-19 outbreak is limited.

Objective: This study aimed to explore the relationship between information exposure and mental health problems during the COVID-19 pandemic in Thailand.

Methods: Between April 21 and May 4, 2020, we conducted a cross-sectional, nationwide online survey of the general population in Thailand. We categorized the duration of exposure to COVID-19-related information as follows: <1 h/day (reference group), 1-2 h/day, and ≥3 h/day. Mental health outcomes were assessed using the Patient Health Questionnaire-9, the Generalized Anxiety Disorder-7 scale, the Perceived Stress Scale-10, and the Insomnia Severity Index for symptoms of depression, anxiety, perceived stress, and insomnia, respectively. Multivariable logistic regression models were used to evaluate the relationship between information exposure and the risk of developing the aforementioned symptoms. An ancillary analysis using multivariable multinomial logistic regression models was also conducted to assess the possible dose-response relationship across the severity strata of mental health problems.

Results: Of the 4322 eligible participants, 4004 (92.6%) completed the online survey. Of them, 1481 (37.0%), 1644 (41.1%), and 879 (22.0%) participants were exposed to COVID-19-related information for less than 1 hour per day, 1 to 2 hours per day, or 3 or more hours per day, respectively. The major source of information related to the COVID-19 pandemic was social media (95.3%), followed by traditional media (68.7%) and family members (34.9%). Those exposed to information for 3 or more hours per day had a higher risk of developing symptoms of depression (adjusted odds ratio [OR] 1.35, 95% CI 1.03-1.76; *P*=.03), anxiety (adjusted OR 1.88, 95% CI 1.43-2.46; *P*<.001), and insomnia (adjusted OR 1.52, 95% CI 1.17-1.97; *P*=.001) than people exposed to information for less than 1 hour per day. Meanwhile, people exposed to information for 1 to 2 hours per day were only at risk of developing symptoms of anxiety (adjusted OR 1.35, 95% CI 1.08-1.69; *P*=.008). However, no association was

found between information exposure and the risk of perceived stress. In the ancillary analysis, a dose-response relationship was observed between information exposure of 3 or more hours per day and the severity of mental health problems.

Conclusions: These findings suggest that social media is the main source of COVID-19-related information. Moreover, people who are exposed to information for 3 or more hours per day are more likely to develop psychological problems, including depression, anxiety, and insomnia. Longitudinal studies investigating the long-term effects of COVID-19-related information exposure on mental health are warranted.

coronavirus; COVID-19; insomnia; mental health; social media; depression; anxiety; stress; psychosocial problem

Introduction

On December 31, 2019, the world witnessed the occurrence of a new public health emergency, the COVID-19 outbreak, in Wuhan, China [1]. On March 11, 2020, the World Health Organization (WHO) declared COVID-19 a pandemic due to the rapid global spread of the causative virus [2]. As of January 6, 2021, approximately 86 million confirmed cases and over 1.8 million deaths due to COVID-19 were reported worldwide. In addition to the physical effects of COVID-19, the COVID-19 pandemic has negatively affected the mental health of the public globally [3-5].

During the outbreak, people may need some information from the media to better understand the situation and determine strategies to protect their health. Information-seeking behavior may reduce anxiety caused by uncertainty during a disease outbreak or disaster [6]. In contrast, excessive consumption of information provided by the media may create new problems. Large volumes of information may amplify the perception of risk, and consumption of fear-related information may have a negative impact on consumers who cannot discern real news from fake news or cannot obtain a more balanced view of the media coverage of said event [7]. This infodemic has the potential to affect the population's mental health and well-being. Many previous studies have illustrated that media exposure is associated with adverse psychological outcomes in different contexts, including bioterrorism [8], war [9], natural disasters [10], and mental health of the general population [11].

Since the start of the COVID-19 pandemic, people have been highly dependent on information from the media, especially those who are not directly affected by the disease. People who are quarantined or isolated may also experience psychological problems due to the widespread media coverage related to the COVID-19 outbreak as well as financial difficulties. In addition, patients with confirmed or suspected COVID-19 may experience disease progression and transmit the virus to their families and friends. Numerous studies have investigated the association between COVID-19-related information exposure and mental health [12-17]. A previous study conducted in Wuhan demonstrated that social media exposure was positively associated with anxiety and depression during the COVID-19 outbreak, after controlling for covariates [4]. These results were supported by those of studies conducted in Germany [18], Saudi Arabia [19], and China [20] indicating that the frequency and duration of media or information exposure may predispose individuals to mental distress. These findings highlight the need to address mental health problems as part of public health policy.

In Thailand, the government announced a lockdown on March 26, 2020, in an effort to stop the spread of COVID-19. This measure seemed to have greatly prevented or slowed down the nationwide spread of the disease. However, during this lockdown, people who were quarantined or isolated might have developed psychological distress and other mental health problems due to media information overload and fear of the effects of COVID-19. To our knowledge, no study has reported the relationship between information exposure and mental health in the general population in Thailand during the COVID-19 outbreak. Therefore, we conducted a cross-sectional nationwide online survey to investigate the relationship between information exposure and symptoms of depression, anxiety, stress, and insomnia during the COVID-19 pandemic in Thailand.

Methods

Study Design and Study Population

The *Health Outcomes and Mental Health Care Evaluation Survey: Under the Pandemic Situation of COVID-19 (HOME-COVID-19)* was a cross-sectional online survey administered via the SurveyMonkey platform. The HOME-COVID-19 study was specifically developed by our research group and comprised baseline sociodemographic characteristics and a set of measurement tools for evaluating mental health and psychosocial problems; we used the Thai versions of the validated measurement tools or tools developed by our team. The questionnaire was initially revised by a panel of health care professionals, including three epidemiologists, two psychiatrists, one social scientist, and two hospital directors. This was further validated by a pilot survey of 30 health care professionals and 30 individuals from the general population. Further details about the HOME-COVID-19 study have been provided in a previous study [21]. This was a nationwide survey conducted between April 21 and May 4, 2020. This survey was performed by first selecting a sample of individuals from the general population in Thailand. Convenience sampling and a snowball strategy were used for participant recruitment through various social media networks (ie, public websites, Facebook, LINE, Twitter, and Instagram). The characteristics of the target population and the questionnaire used were subsequently presented [21]. We included Thai citizens, permanent residents, and nonresidents with employment or work permits who could read and communicate in the Thai language and were at least

18 years of age during the survey period. We excluded individuals who lacked internet access, were unable to complete the online survey, and spent less than 2 minutes, or more than 60 minutes, completing the survey, which likely made their data invalid. Based on the HOME-COVID-19 survey protocol [21], the participants spent approximately 20 to 30 minutes completing the survey.

Written consent was obtained from the participants in the first section of the online survey before completing the questionnaire. This study was approved by the Research Ethics Committees of the Faculties of Public Health (ET010/2020) and Pharmacy (23/2563), Chiang Mai University, Thailand. The study was reported in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology statement [22] and the Checklist for Reporting Results of Internet E-Surveys guidelines [23].

Measurements

COVID-19-Related Information Exposure

Information on the duration of information exposure was obtained by asking the participants how often they were exposed to news and information about the COVID-19 pandemic. The duration of information exposure was categorized as follows: <1 h/day, 1-2 h/day, or ≥3 h/day. Sources of information were classified as traditional media (eg, newspaper, television, radio, etc), social media (eg, Facebook, Twitter, blogs, etc), colleagues and neighbors, family members, government organizations (eg, Ministry of Health), and others.

Mental Health Outcomes

The mental health outcomes of interest included symptoms of depression, anxiety, perceived stress, and insomnia during the COVID-19 pandemic. The aforementioned symptoms were assessed using the Thai versions of the validated measurement tools. The measurement tools used in this study were as follows:

1. The Patient Health Questionnaire-9 (PHQ-9) consists of nine items that reflect the severity of depression symptoms. The score ranges from 0 to 27, and an overall PHQ-9 score of 9 or higher indicates depression (see Multimedia Appendix 1) [24].
2. The Generalized Anxiety Disorder-7 (GAD-7) scale comprises seven items that reflect the severity of anxiety symptoms. The total score ranges from 0 to 21, and a GAD-7 score of 5 or higher indicates anxiety (see Multimedia Appendix 2) [25].
3. The Perceived Stress Scale-10 (PSS-10) is a 5-point Likert scale consisting of 10 items. The scores range from 0 to 40, and a score of 14 or higher indicates perceived stress (see Multimedia Appendix 3) [26].
4. The Insomnia Severity Index (ISI) is an 8-item scale used to assess the nature, severity, and impact of insomnia. The scores range from 0 to 28 points and vary based on the severity of insomnia. In our study, an ISI score of 7 or higher indicated insomnia symptoms (see Multimedia Appendix 4) [27].

Power

Using the HOME-COVID-19 survey protocol, the target sample size for this study was estimated based on the findings of previous studies conducted during the COVID-19 outbreak, which reported a prevalence rate of mental health and psychosocial problems of 3.3% to 75.5% [21]. To compensate for a design effect of 2.0 and an estimated response rate of 60%, a minimum sample size of 2492 participants was obtained to achieve a power of 80% and a type I error α level of .05. However, there was no restriction on the maximum number of participants in the online survey.

Statistical Analysis

Descriptive analyses were performed to describe the characteristics of participants among the three information exposure groups. Categorical variables were expressed as the number (%), while continuous variables were expressed as the mean (SD) or median (IQR), as appropriate. Intergroup differences in the duration of COVID-19-related information exposure were tested using the χ^2 or Fisher exact tests; analysis of covariance and the Kruskal-Wallis test were used to evaluate categorical and continuous variables, respectively.

For the primary analysis, multivariable logistic regression models were used to explain the association between the duration of daily information exposure and the risk of depression (PHQ-9 score 9), anxiety (GAD-7 score 5), perceived stress (PSS-10 score 14), and insomnia (ISI score 8) during the COVID-19 outbreak, after controlling for the covariates of each outcome. The covariates included age, sex, marital status, education level, religion, occupation, region of residence, living status, reimbursement scheme, mental illness history, chronic noncommunicable disease history, income loss, financial problems, confirmed cases in the community, working from home, quarantine status, fear of COVID-19, and resilient coping. The degree of fear against COVID-19 was measured using a 10-point rating scale. The scores were then grouped as follows: no or minimal fear (0-3 points), moderate fear (4-6 points), and severe fear (7-10 points). Resilient coping was defined using the Brief Resilient Coping Scale: low-resilient copers (4-13 points), moderate-resilient copers (14-16 points), and high-resilient copers (17-20 points) [28].

An auxiliary analysis was conducted using multivariable multinomial logistic regression models to explain the association between the duration of information exposure and the severity of mental health problems. Sensitivity analysis was performed using a multivariable linear regression model to confirm the linear relationship between the duration of COVID-19-related information exposure and the risk of mental health problems. Meanwhile, a multivariable ordinal logistic regression model was used to examine the association between the duration of information exposure and severity strata of each mental health problem while controlling for the aforementioned covariates.

The effect estimates were presented as odds ratios (ORs), along with their corresponding 95% CIs, and weighted to match the estimates for the national population and internet users in all models based on data from the National Statistical Office under the Ministry of Information and Communication Technology.

All data were analyzed using Stata, version 14.0 (StataCorp LP). A 2-tailed test with $P<.05$ was considered statistically significant.

Results

Baseline Characteristics

A total of 4997 participants were invited to complete an online survey, but only 4381 participants responded to the survey. Among 4381 participants, 59 individuals who were under 18 years or age at the time of the survey and/or spent less than 2 minutes, or more than 60 minutes, completing the survey were excluded. Of the 4322 participants who met the eligibility criteria, 4004 completed the online survey (see Figure 1). Of the 4004 participants who completed the survey, 2619 (65.4%) were female, 1231 (30.7%) were male, and 154 (3.8%) selected *other* for the sex question. The mean age was 29.1 (SD 10.8) years; moreover, 3208 (80.1%) participants were single. As shown in Table 1, 127 (3.2%) participants had completed junior high school, while 1893 (47.3%) had completed high vocational education. Among the 4004 participants who completed the survey, 1589 (39.7%) were college students, 526 (13.1%) were government or state enterprise employees, and 500 (12.5%) were private enterprise employees. The participants were mainly from the noncapital city and its environs (2579/4004, 64.4%) in Thailand, whereas 1425 (35.6%) were from the capital city and its environs. Only 383 (9.6%) participants had no fear of COVID-19, whereas 1940 (48.4%) had a severe fear of COVID-19. The majority of the participants were low-resilient copers (1756 /4004, 43.9%), while 678 (16.9%) were highly resilient.

Figure 1. Flow diagram for study participants. HOME-COVID-19: Health Outcomes and Mental Health Care Evaluation Survey: Under the Pandemic Situation of COVID-19.

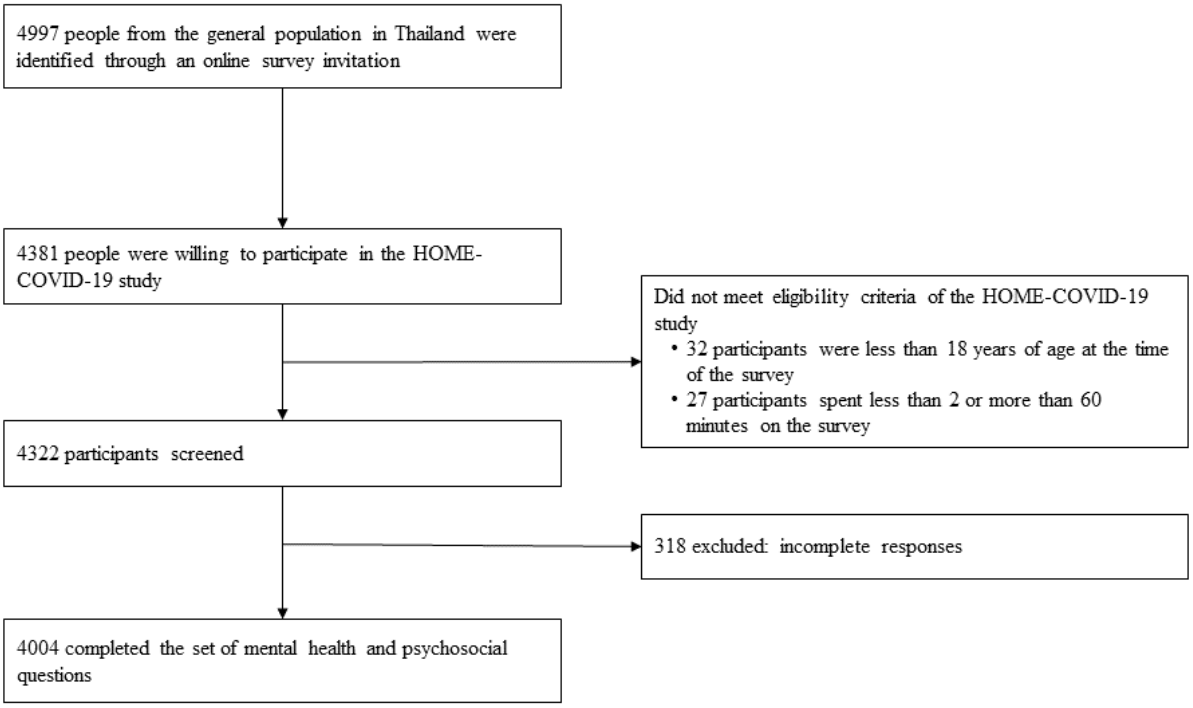

Table 1. Participant characteristics and the duration of exposure to COVID-19-related information in Thailand, from April 21 to May 4, 2020.

Participant characteristics	Overall (N=4004), n (%)	Duration of exposure to COVID-19-related information

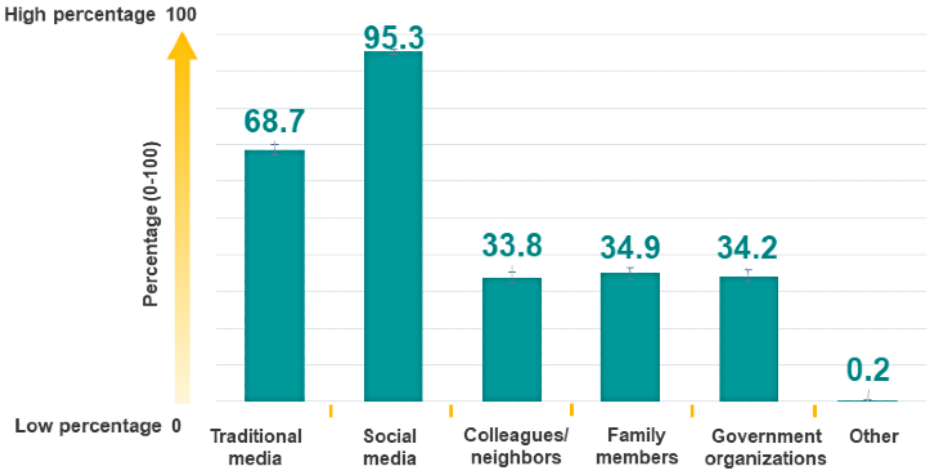
[a]Includes diabetes mellitus, hypertension, dyslipidemia, stroke and heart disease, chronic kidney disease, chronic lung disease, and cancer.

Information Exposure

Of the 4004 participants, 1644 (41.1%) were exposed to information 1 to 2 hours per day, followed by less than 1 hour per day (1481/4004, 37.0%) and 3 or more hours per day (879/4004, 22.0%). The sources of COVID-19-related information were social media (95.3%, 95% CI 94.6-95.9),

followed by traditional media (68.7%, 95% CI 67.2-70.1), and family members (34.9%, 95% CI 33.4-36.4) (see Figure 2).

Figure 2. Sources of COVID-19-related information in Thailand. One person can be exposed to more than one source.



Mental Health and Information Exposure

Table 2 presents the results of the multivariable logistic regression analysis that was performed to explain the association between the duration of information exposure and the risk of mental health problems during the COVID-19 pandemic, after controlling for covariates. In the primary analysis, participants who were exposed to COVID-19-related information for 3 or more hours per day had higher odds of developing symptoms of depression than those exposed to COVID-19-related information for less than 1 hour per day (adjusted OR 1.35, 95% CI 1.03-1.76; *P*=.03). Similarly, participants who were exposed to COVID-19-related information for 3 or more hours per day were more likely to develop anxiety and insomnia than those exposed to COVID-19-related information for less than 1 hour per day (adjusted OR 1.88, 95% CI 1.43-2.46; *P*<.001; and adjusted OR 1.52, 95% CI 1.17-1.97; *P*=.001, respectively). Meanwhile, participants who were exposed to COVID-19-related information for 1 to 2 hours per day only had a risk of developing anxiety symptoms (adjusted OR 1.35, 95% CI 1.08-1.69; *P*=.008). No association was observed between the duration of information exposure and the risk of perceived stress in the general population during the study period in Thailand.

Table 2. Mental health outcomes according to the duration of exposure to COVID-19-related information: multivariable logistic regression model.

Symptoms developed and duration of exposure to COVID-19-related information	Number of cases, n (%)	Adjusted OR[a] (95% CI)[b]	*P* value
Depression: Patient Health Questionnaire-9			
<1 h/day (n=1481)	567 (38.3)	Reference (1.00)	N/A[c]
1-2 h/day (n=1644)	696 (42.3)	1.08 (0.86-1.35)	.52
≥3 h/day (n=879)	391 (44.5)	1.35 (1.03-1.76)	.03
Anxiety: Generalized Anxiety Disorder-7			
<1 h/day (n=1481)	578 (39.0)	Reference (1.00)	N/A
1-2 h/day (n=1644)	701 (42.6)	1.35 (1.08-1.69)	.008
≥3 h/day (n=879)	446 (50.7)	1.88 (1.43-2.46)	<.001
Stress: Perceived Stress Scale-10			
<1 h/day (n=1481)	1076 (72.7)	Reference (1.00)	N/A
1-2 h/day (n=1644)	1200 (73.0)	0.96 (0.74-1.23)	.72
≥3 h/day (n=879)	640 (72.8)	1.01 (0.75-1.36)	.93
Insomnia: Insomnia Severity Index			
<1 h/day (n=1481)	760 (51.3)	Reference (1.00)	
1-2 h/day (n=1644)	877 (53.3)	1.04 (0.84-1.29)	.71
≥3 h/day (n=879)	520 (59.2)	1.52 (1.17-1.97)	.001

[a]OR: odds ratio.

[b]ORs and corresponding 95% CIs are presented as weighted according to the national population and internet users in Thailand. ORs were adjusted for age, sex, marital status, education level, religion, occupation, region of residence, living status, reimbursement scheme, history of mental illness, history of chronic noncommunicable disease, income loss, financial problems, confirmed cases in the community, working from home, quarantine status, fear of COVID-19, and resilient coping.

[c]N/A: not applicable.

In an ancillary analysis, using a multivariable multinomial logistic regression model (<1 h/day of information exposure [reference group]), a dose-response relationship was noted between exposure to COVID-19-related information for 3 or more hours per day and the severity of mental health problems, particularly anxiety symptoms (see Table 3). For instance, individuals exposed to COVID-19-related information for 3 or more hours per day demonstrated substantial effect modification in terms of the severity strata of anxiety symptoms: the adjusted ORs were 1.35 (95% CI 0.99-1.83; *P*=.06), 2.87 (95% CI 1.91-4.33; *P*<.001), and 4.45 (95% CI 2.45-8.08; *P*<.001) for mild, moderate, and severe anxiety symptoms, respectively.

Table 3. Multivariable multinomial logistic regression model results of the duration of exposure to COVID-19-related information and severity of mental health problems.

Severity of mental health problems	Number of cases (N=4004), n (%)	Duration of exposure to COVID-19-related information			
		1-2 h/day		≥3 h/day	
		Estimated adjusted OR[a] (95% CI)[b]	*P* value	Estimated adjusted OR (95% CI)[b]	*P* value

[a]OR: odds ratio.

[b]Multinomial logistic regression was performed using information exposure of <1 h/day as the reference group. ORs and corresponding 95% CIs are presented as weighted according to the national population and internet users in Thailand. ORs were adjusted for age, sex, marital status, education level, religion, occupation, region of residence, living status, reimbursement scheme, history of mental illness, history of chronic noncommunicable disease, income loss, financial problems, confirmed cases in the community, working from home, quarantine status, fear of COVID-19, and resilient coping.

[c]N/A: not applicable.

Sensitivity Analysis

Sensitivity analysis was performed by considering the mental health outcomes. A linear relationship was seen between adverse mental health outcomes and the duration of COVID-19-related information exposure, particularly for 3 or more hours per day (see Multimedia Appendix 5, Table S1). Moreover, after using a multivariable ordinal logistic regression model, our findings remained the same compared to those in the primary analysis (see Multimedia Appendix 5, Table S2).

Data Sharing

Data will be shared upon reasonable request and with permission according to the Health Outcomes and Mental Health Care Evaluation Survey Research Group data release policy.

Discussion

Principal Findings

This nationwide online survey was conducted in Thailand. The results indicated that many Thai people used social media as the main source of information during the COVID-19 pandemic. Most participants were exposed to COVID-19-related information for 1 to 2 hours per day. Participants who were exposed to information for 3 or more hours per day had a higher risk of developing depression, anxiety, and insomnia.

Our results were in line with those of a previous study conducted in Wuhan, China, demonstrating that social media exposure was associated with higher odds of developing anxiety and depression [17]. Moreover, previous studies [17,18,20,29] showed that not only the frequency but also the daily duration of exposure to COVID-19-related information was associated

with psychosocial problems [29], which corroborated with our study results. The results of a survey conducted in Germany indicated a positive correlation between COVID-19-related media exposure and the severity of nonspecific anxiety and depression [18]. Similar results were reported in a previous study conducted among the Saudi Arabian general population [19].

In essence, during a lockdown or social isolation, people are exposed to a lot of pandemic-related information, especially through social media, which predisposes them to mental health problems. During a severe social disruption, the mass media are expected to satisfy the needs of individuals for information about operationalized guidance to the public, the response of organizations, and an exchange of views with others [30-32]. However, the amount of information that circulated during the COVID-19 pandemic exceeded the information demand. A recent study indicated that repeated media exposure could lead to anxiety due to the effect of vicarious traumatization [31]. Furthermore, media exposure can cause an infodemic, which is defined as fake news, misinformation, and conspiracy theories, making it difficult for individuals to find trusted information [33]. This infodemic may negatively impact an individual's mental health.

In Thailand, the government issued a national emergency decree, which was put into effect beginning on March 26, 2020, and announced a nationwide curfew on April 3, 2020. People were requested to stay indoors and limit all social contacts. The government also requested that people should wear face masks, practice social distancing, and remain indoors from 10 PM to 4 AM [34]. Due to the implementation of curfews and isolation measures, the number of persons with suspected or confirmed COVID-19 decreased from mid-January to April 6, 2020, which indicated a positive impact of the lockdown on viral transmission reduction and epidemic control [35]. However, the quarantine and isolation measures, coupled with media coverage exposure, increased anxiety and fear in the people, thereby affecting their mental health. Moreover, during the national lockdown and home confinement, the community movement in Thailand had eventually decreased, which resulted in home-based exposure of people to huge amounts of COVID-19-related media information.

Therefore, during a public health crisis, several actions should be taken regarding crisis-related information. First, the media should convey information to the public without sensationalizing the situation and without providing disturbing images to help prevent mental distress. Second, the public should rely on trustworthy sources of information, such as the Centers for Disease Control and Prevention or the WHO, for accurate information. Third, health care providers should play an important role in informing people about practicing protective behaviors [36]. Fourth, public awareness campaigns should be conducted, focusing on the maintenance of mental health in the prevailing situation [37]. Finally, people should spend time with family members who engage in different healthy exercises and sports activities, follow a schedule and routine in daily life, and reduce their time spent on traditional and social media to remain healthy [37]. In terms of mental health policies during the COVID-19 pandemic, the United Nations suggested the application of a whole-of-society approach to promote, protect, and care for an individual's mental health [38]. Furthermore, public policy solutions would ensure the widespread availability of emergency mental health and psychosocial support. All affected communities require quality mental health services to help their society recover from the effects of the COVID-19 pandemic.

Strengths and Limitations

This study had several strengths. To our knowledge, this is the first nationwide survey on mental health based on information exposure during the COVID-19 outbreak in Thailand. From a methodological point of view, the analyses were also performed using rigorous statistical approaches to confirm the main findings.

However, our study has some limitations. First, this was a cross-sectional study; therefore, a causal relationship could not be accurately drawn. Second, the survey was conducted online, which is appropriate for short-term evaluation; therefore, the results reflect short-term relationships. Hence, additional longitudinal studies investigating the long-term relationship between mental health and COVID-19-related information exposure are warranted. Third, the survey was conducted over the internet, which is subject to bias due to nonresponse effects and selection bias. Moreover, as information exposure was self-reported, recall bias may be present, and the measures may be influenced by social desirability. Fourth, not everyone in Thailand can access the internet and there could be significant demographic differences between those who can access the internet and those who have limited access to the internet. Thus, selection bias or limited representativeness of the Thai population may be present. Fifth, the majority of the participants were young adults. Only a few older adults participated in the survey; thus, some respondent bias could not be excluded. In addition, the majority of participants (66.4%) were below 30 years of age, which might not reflect the Thai society in its entirety. However, internet usage data in Thailand have demonstrated that workers spend the highest average number of hours surfing the internet per day and account for the highest proportion of internet users [39]. The internet usage data of this group of people may potentially represent the internet consumption of the Thai population. Finally, we lacked information on risk perception and self-care behaviors. This information could help encourage self-improvement and self-management during the COVID-19 pandemic, which may improve an individual's overall mental health and wellness.

Conclusions

Our findings from the nationwide online survey indicated a positive association between information exposure during the COVID-19 pandemic and the occurrence of symptoms of depression, anxiety, and insomnia. The strength of the association increased with the duration of media exposure. However, prospective longitudinal studies are needed to investigate the long-term relationship between information exposure and mental health during and after the COVID-19 pandemic.

Acknowledgments

This work was partially supported by the Chiang Mai University, Thailand, with support provided to SN. Its contents are solely the responsibility of the authors and do not necessarily represent the official views of Chiang Mai University. No funding source had any role in the study concept and design; data collection, analysis, and interpretation; writing of the report; or in the decision to submit for publication. We would like to thank all staff and research personnel from the Pharmacoepidemiology and Statistics Research Center, Chiang Mai University, Thailand. Particular thanks are given to the study participants.

Authors' Contributions

PM and SN had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. PM and SN were responsible for the study concept and design. PM, CR, and SN were responsible for the acquisition, analysis, or interpretation of data. PM and SN were responsible for drafting of the manuscript. Critical revision of the manuscript for important intellectual content was performed by KT, BH, NW, and TW. Statistical analysis was performed by PM, CR, and SN. Administrative, technical, or material support was provided by RA. Study supervision was provided by SN.

Abstract

Background: In a fast-evolving public health crisis such as the COVID-19 pandemic, multiple pieces of relevant information can be posted sequentially on a social media platform. The interval between subsequent posting times may have a different impact on the transmission and cross-propagation of the old and new information that results in a different peak value and a final size of forwarding users of the new information, depending on the content correlation and whether the new information is posted during the outbreak or quasi–steady-state phase of the old information.

Objective: This study aims to help in designing effective communication strategies to ensure information is delivered to the maximal number of users.

Methods: We developed and analyzed two classes of susceptible-forwarding-immune information propagation models with delay in transmission to describe the cross-propagation process of relevant information. A total of 28,661 retweets of typical information were posted frequently by each opinion leader related to COVID-19 with high influence (data acquisition up to February 19, 2020). The information was processed into discrete points with a frequency of 10 minutes, and the real data were fitted by the model numerical simulation. Furthermore, the influence of parameters on information dissemination and the design of a publishing strategy were analyzed.

Results: The current epidemic outbreak situation, epidemic prevention, and other related authoritative information cannot be timely and effectively browsed by the public. The ingenious use of information release intervals can effectively enhance the interaction between information and realize the effective diffusion of information. We parameterized our models using real data from Sina Microblog and used the parameterized models to define and evaluate mutual attractiveness indexes, and we used these indexes and parameter sensitivity analyses to inform optimal strategies for new information to be effectively propagated in the microblog. The results of the parameter analysis showed that using different attractiveness indexes as the key parameters can control the information transmission with different release intervals, so it is considered as a key link in the design of an information communication strategy. At the same time, the dynamic process of information was analyzed through index evaluation.

Conclusions: Our model can carry out an accurate numerical simulation of information at different release intervals and achieve a dynamic evaluation of information transmission by constructing an indicator system so as to provide theoretical support and strategic suggestions for government decision making. This study optimizes information posting strategies to maximize communication efforts for delivering key public health messages to the public for better outcomes of public health emergency management.

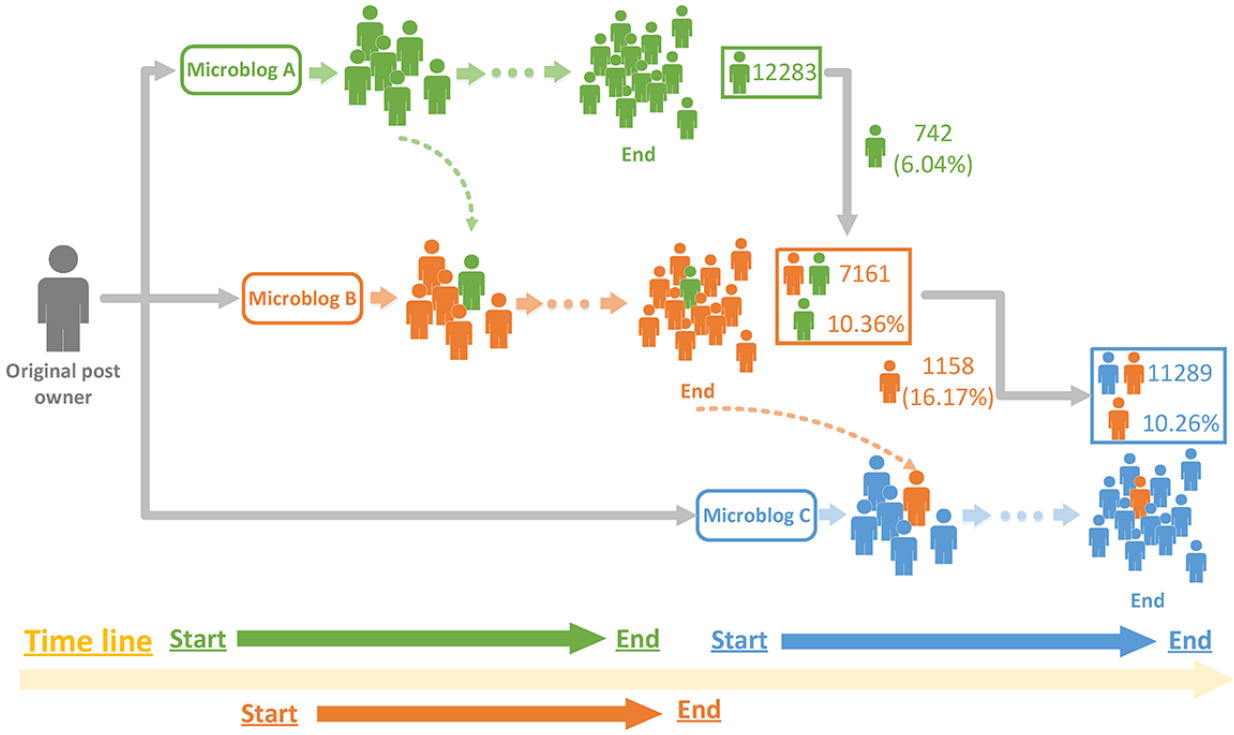
Introduction

In the absence of effective treatment or a vaccine, the success or failure of mitigating COVID-19 transmission in the population relies heavily on the effectiveness of social distancing, self-protection, case detection, quarantine, isolation, and testing. The effectiveness of these nonpharmaceutical interventions depends on the active participation and engagement of residents in the community, which is substantially influenced by the public opinion. Given the short disease transmission doubling time, the timing (and hence time lags) in the communication of critical public health information to the community has a profound impact on the outcome of public adherence to nonpharmaceutical measures and, ultimately, on the outcome of outbreak mitigation. Adding to the challenging of effective communications is the cross-propagation of relevant, and sometimes inconsistent, pieces of information that enter social media at different time points. This calls for a strategy of optimizing the timing of posting key information in social media during a fast-evolving pandemic.

Figure 1 shows the cross-propagation of three pieces of related information about COVID-19: titled as "Just want a regular 20200202," "Announcement of donation acceptance by Wuhan JinYinTan hospital," and "Three cases of community transmission were reported in Shenzhen for the first time." These pieces of information were posted in Sina Microblog, with different beginning and ending time points marked in the (horizontal) timeline. Almost immediately after reading information A, some users forwarded information B, so both pieces of information shared similar life cycle but with beginning and ending time points close to each other. There were 12,283 information A users, among which 742 (6.04%) forwarded information B. Eventually, 7161 of users forwarded information B, and those who simultaneously forwarded information A accounted for 10.36% (n=7161). Information C was then released, and users of information B started to forward information C. At the end, among 7161 users of information B, 1158 (16.17%) also forwarded information C, accounting for 10.26% (n=11,289) of the users for C.

Figure 1. Cross-propagation of three relevant pieces of information related to the COVID-19 pandemic, posted in sequence on Sina Microblog.



In general, relevant information, when posted with an appropriate time lag, can attract the interest of social media users in public hot events by increasing the efficiency of dissemination of a group of information cross-propagated. It is an important topic of research; the main objective of our study is to understand the information cross-propagation dynamics to inform optimal strategies of posting relevant information in an appropriate time sequence to ensure their maximum interaction for effective copromotion during a public health emergency situation.

To the best of our knowledge, no appropriate model framework has been developed and analyzed to examine the impact of information cross-propagation dynamics for a group of relevant information that is posted subsequently. Here, we try to fill this gap by proposing a susceptible-forwarding-immune model with

time-delayed posting and transmission. We developed and illustrated this framework, and parametrized our model by using the forwarding quantity that represents public attention to some popular opinions on the COVID-19 pandemic. Our focus is on the dynamic interactions among several pieces of information posted sequentially, and we aim to examine the impact of time lags between different posting time points on the evolution and steady states of cross-propagation.

In the field of information propagation dynamics, there is a strong similarity between the propagation of rumors and a pathogen's spread in the population [1]. Many studies have used epidemic models to examine rumor propagation in the hope that the negative influence of rumors can be eliminated or at least minimized. For example, the susceptible-infected-exposed-recovered (SIER) model [2-5], susceptible-infected model [6-9], susceptible-infected-susceptible [10,11] model, and susceptible-infected-recovered (SIR) model [12-14] have all been developed and recognized as classical propagation dynamics models.

The development of the internet and the enrichment of social media mandate further extensions of traditional models to reflect novel transmission mechanisms and to take advantage of data from multiple platforms. Gu and Cai [15] and Gu et al [16] proposed the forget-remember mechanism to study the spreading process in a 2-state model. Zhao et al [17] combined the forgetting mechanism and the SIR model to represent the rumor spreading process in an online social blogging platform LiveJournal. In 2014, Zhao et al [18] integrated the refutation mechanism in homogeneous social networks into the SIR model and analyzed the dynamic process of rumor propagation. Considering the three influencing factors of enterprises affected by rumors, pinion leaders, and a microblog platform, an SIR model based on browsing behavior was constructed to explain how rumors spread among followers under the influence of different rumor refuting measures [19]. Other features of the new media were further incorporated by Zhao et al [20]. Borge-Holthoefer et al [21] considered the case when spreaders were not always active and an ignorant was not interested in spreading the rumor, and then separately introduced these ideas into two different models. They concluded that these models provided higher adhesion to real data than classical rumor spreading models. In 2020, Yin et al [22] considered the user's behavior of re-entering new topics and proposed a multiple-information susceptible-discussing-immune model to investigate COVID-19–relevant information propagation in the Chinese Sina Microblog. Ding et al [23] proposed an improved SIR model, which used differential equations to study the rule of information transmission on media platforms and predicted microblog information accurately. Wang et al [24] proposed a modeling method that considers Weibo propagation behavior based on the susceptible-infected-susceptible model, so the forwarding trend in the future can be predicted. Zhang et al [25] focused on the impact of media transmission and interpersonal relationships on information propagation and then proposed the media and interpersonal relationship susceptible-infected-exposed-recovered model. Zhao et al [26] developed a new rumor spreading model called the susceptible-infected-hibernator-removed model, introducing a new kind of people-hibernators to reduce the maximum rumor influence. Woo et al [27] proposed an event-driven SIR model based on the impact of news releases on social media to reflect the impact of specific events on opinion diffusion. Yao et al [28] concentrated on examining the influence of different interactions among information on the spread of public opinion and modeling based on the SIR model, which verified the otherness of public opinion under a distinct information environment. For other studies relevant to our paper, see [29-32]. In particular, Tanaka et al [32] added a new module to the traditional model by using two data sets from the Japanese Mixi and Facebook rather than a single data set.

Many studies on cross-transmission in disease diffusion are highly significant to study the cross-propagation of information. Feng et al [33] established a mathematical model that incorporated the virus mutation dynamics in the transmission of the Chikungunya virus among mosquitoes and humans. However, the important phenomenon of time lag in posting and cross-propagation of relevant information for information dissemination in real social media networks has not been adequately addressed in these earlier studies. We noted that Zan [34] studied the double rumors spreading with different launch times, in which the new rumor was launched with a certain delay but also could interact with the old rumor. Zan [34] proposed two classes of double-rumors spreading models: a double-susceptible-infected-recovered model, where it was assumed that the rumor was disseminated by direct contacts of infective nodes with others, and a comprehensive double-susceptible-infected-recovered model, with which the authors studied the whole spread situation of all rumors with a focus on determining how many people did not spread all rumors in the entire period or how many were spreading or had spread at least one of the rumors.

In comparison with the aforementioned studies, here we consider the phenomenon where at different propagation stages of a piece of information posted in social media other pieces of information are posted, and their relevance in contexts and posting time sequence combined generate an outbreak for each piece of information and, more importantly, cross-propagation in which users of one piece of information forward other pieces of information they are exposed to later. We developed two classes of dynamic propagation models that focus on the single information transmission and multi-information cross-propagation patterns during explosive and quasi–steady-state periods of the information posted sequentially. We aim to examine emphatically the influence of different participating groups of posted information on the spread of the information from the participating groups. As populations who have forwarded, whether exposed or not exposed to relevant posted information, are attracted to a new piece of information differently, by introducing and analyzing the impact of *attractiveness indexes* on relevant information propagation and examining the significant factors of delaying in posting relevant information propagation, we inform strategies for sequentially posting relevant information to achieve effective communication of key public opinions. We will illustrate this

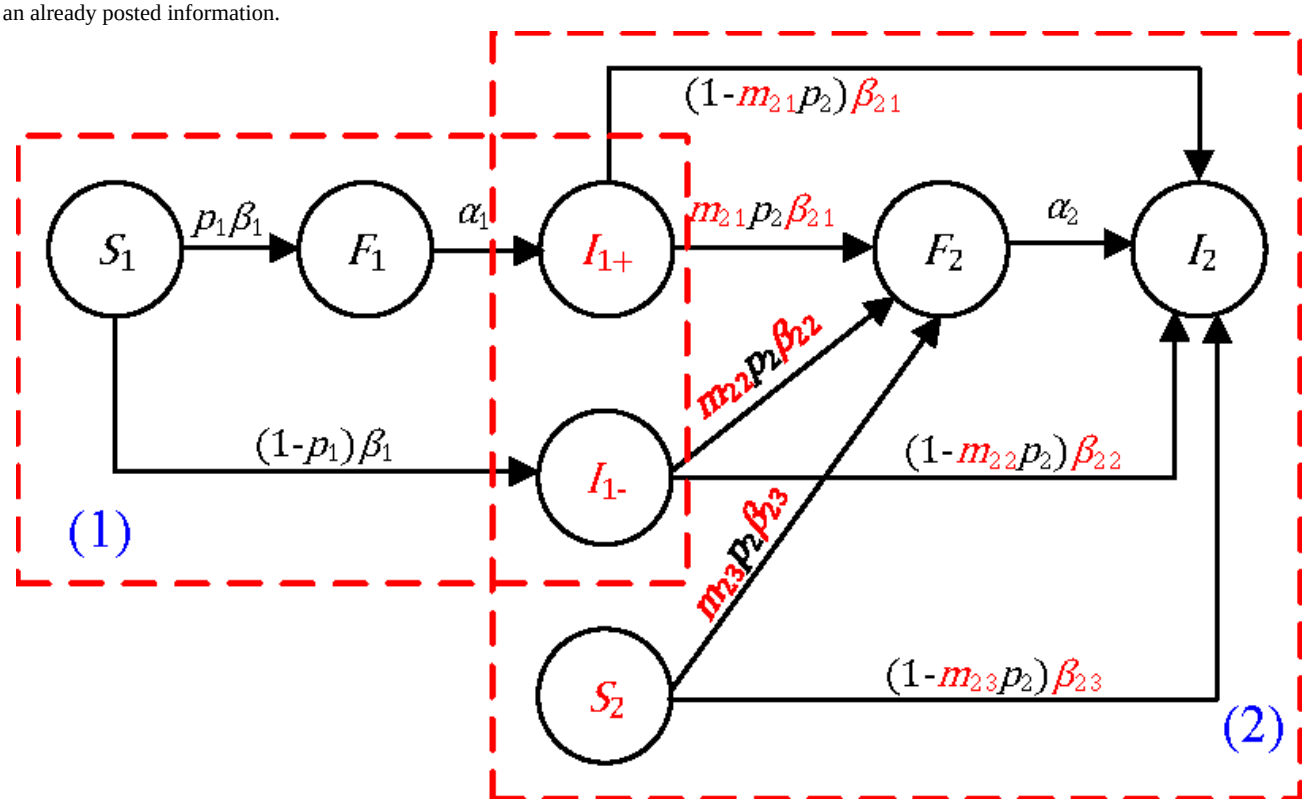
with data from public opinions about COVID-19 pandemic management.

Methods

Large Delay in Transmission Susceptible-Forwarding-Immune Dynamics Model

The structure of our proposed large interval delay in transmission susceptible-forwarding-immune (LTI DT-SFI) dynamics model is shown in Figure 2. There are two phases involved. In phase 1, a piece of stand-alone information (information 1) is spreading; and in phase 2, another piece of information (information 2) is posted during the quasi–steady-state period of the posted information.

Figure 2. A schematic illustration of the information cross-spreading, where a new piece of information is posted during the quasi steady-state period of an already posted information.



Phase 1: Post a Piece of Stand-alone Information

The propagation dynamics during phase 1 for one piece of posted information is modeled based on the traditional susceptible-forwarding-immune [35] model, with a novel stratification of the immune population. Namely, there will be two classes of immune populations (as far as information 1 is concerned): those who have forwarded the posted information but are no longer in the active period of forwarding this posted information (I_{1+}) and those who have been exposed to the information but are not interested in forwarding it (I_{1-}). This distinction of immunity is important, as individuals in these two distinct compartments will have different levels of interest in other relevant information that will be posted later. This will allow us to introduce different measures of attractiveness to new relevant information.

So, in our model, we stratify the population (N_1) into four states: the susceptible state of the posted information (S_1), the forwarding state of the posted information (F_1), the inactive immune state (I_{1+}), and the direct immune state (I_{1-}). A susceptible user can be exposed to the posted information with an average exposure rate β_1 and will forward the information with the forwarding probability p_1. The forwarding users can become inactive immune users with an average rate α_1. So a user may have a unique state, with $S_1(t)$, $F_1(t)$, $I_{1+}(t)$, and $I_{1-}(t)$ denoting the number of users in the susceptible, forwarding, inactive, and direct immune state, respectively. We obtain the following delay in transmission susceptible-forwarding-immune (DT-SFI) dynamics model in phase 1:

The state transition of different populations in phase 1 can be interpreted as follows: an active forwarding user will contact an average number of $\beta_1 N_1$ users per unit time, and the probability of a user being a susceptible user of the posted information is $S_1(t)/N_1$, so an active forwarding user will contact $\beta_1 S_1(t)$ susceptible users. There are $F_1(t)$ active forwarding users of information 1 in total at time t, so $p_1\beta_1 S_1(t)F_1(t)$ susceptible users will choose to forward the information and become new forwarding users, and $(1 - p_1)\ \beta_1 S_1(t)F_1(t)$ will not. As time goes by, $\alpha_1 F_1(t)$ will go to the immune state from the forwarding

period when they do not influence other users as far as information 1 is concerned.

For data fitting purposes, we noted that the Sina Microblog provides important data about any piece of information relevant to COVID-19, the number of cumulative forwarding quantity, given by:

Phase 2: Post New Information During the Quasi–Steady-state Period of the Posted Information

Now we consider that a piece of new information is posted at time t_τ when the posted information is already in the quasi–steady state. We introduce the following indexes:

- *An extensive exposure attractiveness index*: for the individuals in the immune state who have forwarded the posted information but are no longer in their active forwarding period. These individuals are more susceptible to the new yet relevant information, as they had interest in the posted information.
- *A mild exposure attractiveness index*: for the direct immune individuals. These individuals have had exposure to the posted information but had shown little interest in the information.
- *An unexposure attractiveness index*: for those who were never exposed to the first posted information

Accordingly, we introduce three states of the population (N_2) for the newly posted information: the susceptible state (S_2), the forwarding state (F_2), and the immune state (I_2). We summarize the notations in Textbox 1.

Textbox 1. Parameter definitions for large delay model.

Attractiveness parameters, stratified by the exposure to old information

- m_{21}: The extensive exposure attractiveness index that an inactive user of state I_{1+} becomes a forwarding user of state F_2.
- m_{22}: The mild exposure attractiveness index that a direct immune user of state I_{1-} becomes a forwarding user of state F_2.
- m_{23}: The unexposure attractiveness index that a new susceptible user of state S_2 becomes a forwarding user of state F_2.

Transmission parameters associated with the different attractiveness

- β_{21}: The average exposure rate that the inactive users of the old information can contact with the newly posted information.
- β_{22}: The average exposure rate that the direct immune users of the old information can contact with the newly posted information.
- β_{23}: The average exposure rate that the new susceptible users can contact with the newly posted information.
- p_2: The probability that an exposed user will forward the newly posted information.
- α_2: The average rate that a user in the forwarding state of newly posted information becomes inactive to forwarding, where $1/\alpha_2$ is the average duration a forwarding user remains active in forwarding newly posted information.

Each user may have a unique state, with $I_{1+}(t)$, $I_{1-}(t)$, $S_2(t)$, $F_2(t)$, and $I_2(t)$ denoting the number of users in the susceptible, forwarding, and immune state, respectively. We obtain the following LTI DT-SFI dynamics model in phase 2:

The mass action in phase 2 can be interpreted as follows: an active forwarding user will contact an average number of $\beta_{21}N_2$ inactive immune users of the posted information per unit time, and the probability of a user being an inactive immune user is $I_{1+}(t)/N_2$, so an active forwarding user will contact $\beta_{21}I_{1+}(t)$ inactive immune users, among which $m_{21}p_2\beta_{21}I_{1+}(t)F_2(t)$ will choose to forward the new information and $(1 - m_{21}p_2)\beta_{21}I_{1+}(t)F_2(t)$ will not, where $F_2(t)$ is the number of new active forwarding users at time t; an active forwarding user will contact an average number of $\beta_{22}N_2$ direct immune users of the posted information per unit time, and the probability of a user being a direct immune user is $I_{1-}(t)/N_2$, so an active forwarding user will contact $\beta_{22}I_{1-}(t)$ direct immune users, among which $m_{22}p_2\beta_{22}I_{1-}(t)F_2(t)$ will choose to forward the new information and $(1 - m_{22}p_2)\beta_{22}I_{1-}(t)F_2(t)$ will not, where $F_2(t)$ is the number of new active forwarding users at time t; an active forwarding user will contact an average number of $\beta_{23}N_2$ susceptible users of the newly posted information per unit time, and the probability of a user being a susceptible user is $S_2(t)/N_2$, so an active forwarding user will contact $\beta_{23}S_2(t)$ susceptible users, among which $m_{23}p_2\beta_{23}S_2(t)F_2(t)$ will choose to forward the new information and $(1 - m_{23}p_2)\beta_{23}S_2(t)F_2(t)$ will not, where $F_2(t)$ is the number of new active forwarding users at time t.

The forwarding quantity of the newly posted information is given by:

The Public Opinion Reproduction Ratio

Since the newly posted Weibo starts at different times and develops differently under the influence of prior information, we defined the information reproduction ratio as:

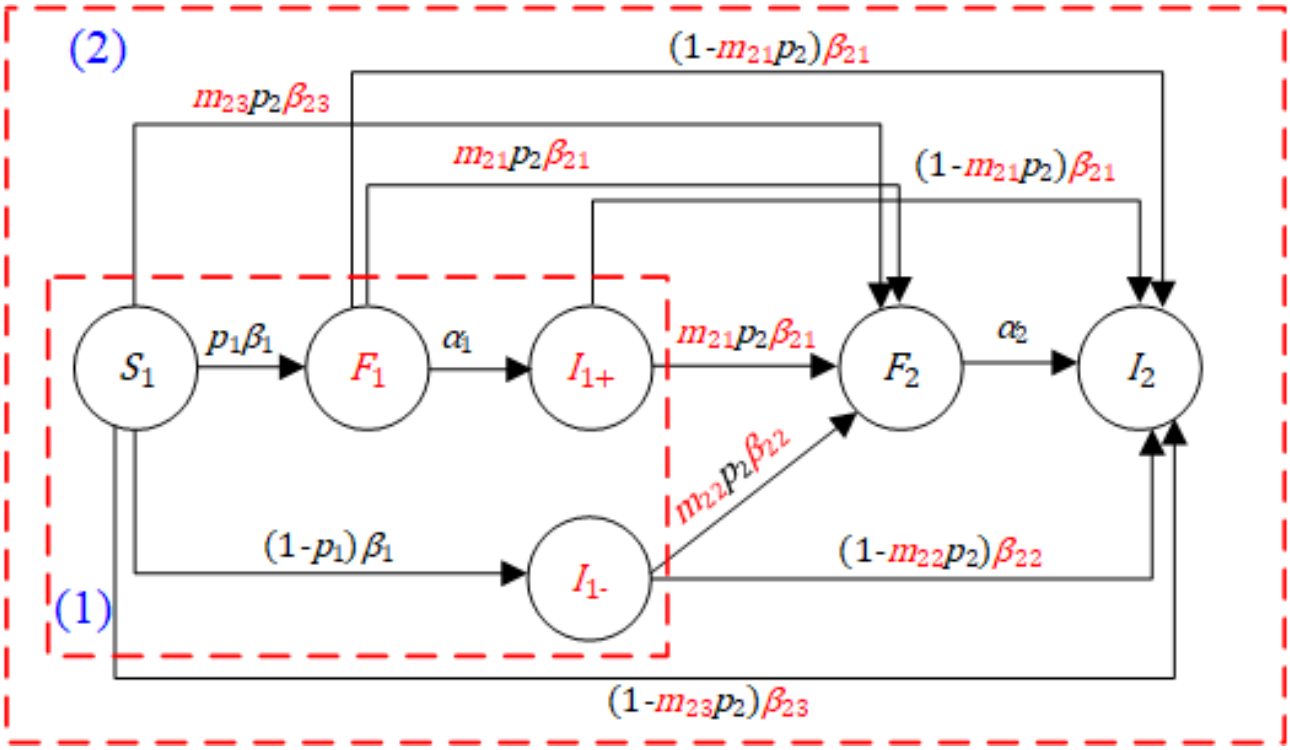
This is the total number of information 2 users generated by introducing a typical information 2 user, at time τ after

information 1 was posted, during their entire period of active forwarding. The initial population for information 2 has been stratified by the exposure of the entire population to information 1 during the time interval [0, τ]. The relative size of [x] to the unity determines if information 2 can generate an information outbreak; since [x] (0) = ($m_{21}p_2\beta_{21}I_{1+,\tau} + m_{22}p_2\beta_{22}I_{1-,\tau} + m_{23}p_2\beta_{23}S_{20} - \alpha_2$) F_2 (0), we concluded that [x] (0)>0 if [x]>1.

Short Delay in Transmission Susceptible-Forwarding-Immune Dynamics Model

Our comprehensive short interval delay in transmission susceptible-forwarding-immune (STI DT-SFI) dynamics model based on the forwarding quantity is shown in Figure 3. In this model, we include two phases. In phase 1, a stand-alone piece of information (information 1) is spreading, corresponding to phase 1 in the LTI DT-SFI model. In phase 2, a piece of newly posted information (information 2) is posted at t_τ during an outbreak period of the posted information. Here, we also divide the population into three groups: S population (S), F population (F_1, F_2), and I population (I_{1+}, I_{1-}, I_2). In particular, we think of the susceptible state of both the posted information and the new information as a whole (S). t_τ is the post time of the newly posted information.

Figure 3. A schematic diagram to illustrate information spreading, when the post time of the newly posted information is during the outbreak period of the posted information.



Phase 1: Post Stand-alone Information

The model is consistent with that of phase 1 of the LTI DT-SFI model.

Phase 2: Posting New Information During the Outbreak Period of the Posted Information

Considering that the new information is posted during the outbreak period of the old information, we developed our phase 2 model to describe the concurrent dynamic process of the two related pieces of information. We considered the difference between the population in active forwarding state or the immune state out of the active period and the population in the direct immune state of the first (old) piece of information. Here, we set the following indexes:

- *An extensive exposure attractiveness index*: for the individuals in the forwarding state, who have forwarded the posted information but are still in their active forwarding period, and the individuals in the immune state, who have forwarded the old information but are no longer in their active forwarding period, to indicate that this population will be attracted by the new information due to the relevance of the two pieces of information
- *A mild exposure attractiveness index*: for the direct immune population to portray that the population will be attracted due to a moderate contact
- *An unexposure attractiveness index*: for the integrated susceptible population to describe that the population will be attracted when they have never read the related information

Assuming that the number of users (N_3) who can contact the information in the process of information propagation on Sina Microblog remains unchanged, we introduced three states of the population of the newly posted information: the susceptible state (S_1) that includes the users who can be exposed to the old information and the new information, the forwarding state of

the new information (F_2), and the immune state (I_2). The parameters are shown in Textbox 2.

Textbox 2. Parameters definitions for short delay model.

Attractiveness parameters, stratified by the exposure to old information

- m_{21}: The extensive exposure attractiveness index that an inactive user of state I_{1+} becomes a forwarding user of state F_2.
- m_{22}: The mild exposure attractiveness index that a direct immune user of state I_{1-} becomes a forwarding user of state F_2.
- m_{23}: The unexposure attractiveness index that a new susceptible user of state S_2 becomes a forwarding user of state F_2.

Transmission parameters associated with the different attractiveness

- β_1: The average exposure rate that the susceptible users can contact the first information.
- β_{21}: The average exposure rate that the inactive users of the old information can contact the newly posted information.
- β_{22}: The average exposure rate that the direct immune users of the old information can contact the newly posted information.
- β_{23}: The average exposure rate that the new susceptible users can contact the newly posted information.
- p_1: The probability that the susceptible users will forward the first information.
- p_2: The probability that the exposed users will forward the newly posted information.
- α_2: The average rate that a user in the forwarding state of newly posted information becomes inactive to forwarding, where $1/\alpha_2$ is the average duration a forwarding user remains active in forwarding newly posted information.

Each user may have a unique state, with $S_1(t)$, $F_1(t)$, $I_{1+}(t)$, $I_{1-}(t)$, $F_2(t)$, and $I_2(t)$ denoting the number of users in the susceptible, forwarding, and immune state when $t>0$, respectively. We obtain the following STI DT-SFI dynamics model in phase 2:

The mass action in phase 2 can be interpreted as follows: an active forwarding user will contact an average number of $\beta_{21}N_3$ inactive immune users and forwarding users of posted information per unit time, and the probability of a user being an inactive immune user and a forwarding user are $I_{1+}(t)/N_3$ and $F_1(t)/N_3$, respectively, so an active forwarding user will contact $\beta_{21}I_{1+}(t)$ inactive immune users and $\beta_{21}F_1(t)$ forwarding users, among which $m_{21}p_2\beta_{21}I_{1+}(t)F_2(t)$ and $m_{21}p_2\beta_{21}F_1(t)F_2(t)$ will choose to forward the new information, however, $(1 - m_{21}p_2)\beta_2 I_{1+}(t)F_2(t)$ and $(1 - m_{21}p_2)\beta_{21}I_1(t)F_2(t)$ will not, where $F_2(t)$ is the number of new active forwarding users at time t. Here, the individuals in the forwarding state and the individuals in the immune state have the same familiarity with the topic content who have forwarded information 1; an active forwarding user will contact an average number of $\beta_{22}N_3$ direct immune users of posted information per unit time, and the probability of a user being a direct immune user is $I_{1-}(t)/N_3$, so an active forwarding user will contact $\beta_{22}I_{1-}(t)$ direct immune users, among which $m_{22}p_2\beta_{22}I_{1-}(t)F_2(t)$ will choose to forward the new information and $(1 - m_{22}p_2)\beta_{22}I_{1-}(t)F_2(t)$ will not, where $F_2(t)$ is the number of new active forwarding users at time t; an active forwarding user will contact an average number of $\beta_{23}N_3$ susceptible users, and the probability of a user being a susceptible user is $S_1(t)/N_3$, so an active forwarding user will contact $\beta_{23}S_1(t)$ susceptible users, among which $m_{23}p_2\beta_{23}S_1(t)F_2(t)$ will choose to forward the new information and $(1 - m_{23}p_2)\beta_{23}S_1(t)F_2(t)$ will not, where $F_2(t)$ is the number of new active forwarding users at time t.

The forwarding quantity of the newly posted information is given by:

The Public Opinion Reproduction Ratio

Considering the initial condition in phase 2, we can obtain the following public opinion reproduction ratio  . The new information entered at time τ during an outbreak period of the posted information, and  $(0) = (m_{21}p_2\beta_{21}F_{1\tau} + m_{21}p_2\beta_{21}I_{1+,\tau} + m_{22}p_2\beta_{22}I_{1-,\tau} + m_{23}p_2\beta_{23}S_{1\tau} - \alpha_2)F_2(0)$. The population will never take off if  $(0) = (m_{21}p_2\beta_{21}F_{1\tau} + m_{21}p_2\beta_{21}I_{1+,\tau} + m_{22}p_2\beta_{22}I_{1-,\tau} + m_{23}p_2\beta_{23}S_{1\tau} - \alpha_2)F_2(0)<0$ due to the decrease of $S_{10\tau}$. It is therefore natural to introduce the following as the STI DT-SFI reproduction ratio:

In the same way, the  of the STI DT-SFI model denotes the comprehensive public opinion generated by the newly posted Weibo starting at the outbreak period of the posted information. When the reproduction ratio <1, it means that the new public opinion will decline. When the reproduction ratio >1, it indicates that the new public opinion will initially grow exponentially.

Statistical Analysis

Data Description

Since the COVID-19 outbreak in China, intensive information that were clearly relevant to each other have been frequently posted. Figure 4 shows the total forwarding quantities of Weibos

during each 1-hour time frame on January 25, 2020, and January 26, 2020 (data acquisition up to February 19, 2020), for the top 10 opinion leaders of this outbreak event in the Chinese Sina Microblog. As illustrated, those pieces of information with high influence were posted frequently by each opinion leader. At the same time, there was a strong correlation among a series of Weibos posted by these opinion leaders during certain periods. Of all the data shown in Figure 4, People's Daily issued five Weibos in 1 hour from 10 PM to 11 PM on January 25, and they were forwarded by a total of more than 300,000 users. Therefore, the frequent release of relevant information by original post owners was a common phenomenon in the COVID-19 information propagation, and understanding its effectiveness is important.

Figure 5 shows the trend of cumulative forwarding users for the three pieces of information in Tables 1-3. It shows that when information A broke out, information B was posted almost immediately. Compared with the information, the outbreak period of information B was shorter and the trend was flatter. Information C was released during the quasi–steady-state period of information B. In comparison with this information, the outbreak period of information C lasted longer; meanwhile, the cumulative forwarding quantity was also larger.

Sequentially releasing two related pieces of information by the same original post owners within the same COVID-19 theme was a common phenomenon. Importantly, different entering times of new information during the spreading process of an old (previously posted) information exhibited different promoting effects on the cross-propagation and cross-promotion of relevant public opinions. Here we focus on users who have been exposed to one posted information that may have a special interest in, and hence are susceptible to, new and relevant information. This represents a remarkable difference from the spread of rumors and other traditional public hot events. Our information cross-propagation DT-SFI models, including the STI DT-SFI dynamics model and the LTI DT-SFI dynamics model, were developed to take into consideration the situations when the relevant information is posted during the outbreak period or during the quasi–steady-state period of the previously posted (old) information.

Data Fitting for the LTI DT-SFI Model

Parameter Estimation

To fit our model with real data from the Sina Microblog, we used the least squares (LS) method to estimate the LTI DT-SFI model parameters and the initial data. In phase 1, the parameter vector is set as $\Theta_1 = (p_1, \beta_1, \alpha_1, S_{10})$, and the corresponding numerical calculation based on the parameter vector for $C_1(t)$ is denoted by (k, Θ_1). The follow LS error function was used in our calculation:

where C_{1k} denotes the actual cumulative forwarding populations of the posted information. Similarly, in phase 2, the vector is set as $\Theta_2 = (\beta_{21}, \beta_{22}, \beta_{23}, m_{21}, m_{22}, m_{23}, p_2, \alpha_2, S_{20})$, and the corresponding numerical calculation based on the parameter vector for $C_2(t)$ is denoted by (k, Θ_2). The following LS error function was used in our calculation:

where C_{2k} denotes the actual cumulative forwarding populations of the newly posted information. Here, n=1, 2 ... represents the different phases, and k=0, 1, 2, ... is the sampling time n=1, 2, 3. We estimated the parameters of our *LTI DT-SFI* model with the data of information B and information C.

Figure 6 reports our data fitting results for information B and information C on the real data given in Tables 2 and 3, where the blue star denotes the actual cumulative number of forwarding users of information B; the red star denotes the actual cumulative number of forwarding users of information C; and the green line and the black line denote the estimated cumulative number of forwarding users of information B and information C, respectively.

Tables 4 and 5 give estimated values of important parameters for information B and information C, respectively. We can see in phase 2, when information C was posted during the quasi–steady-state period of information B, the average exposure rate β_{21} was the largest, indicating that an inactive user of the posted information B was more susceptible to the newly posted information C; the average exposure rate β_{23} was small, indicating that a susceptible user of the newly posted information C contacted the information at a lower rate. In addition, among the three attractiveness indexes, the index m_{22} is the largest, which indicates that information C had the strongest appeal to a direct immune user of information B and has the least attractiveness to an inactive user of the posted information B.

By comparison, there is a difference between the initial time of a new piece of information at the outbreak phase and at the quasi–steady-state phase of the posted information. When the initial time of new information is in the outbreak phase of the posted information, the value of the average immune rate α_2 is generally higher than the value in the quasi–steady-state phase, which is due to the rapid outbreak of information (a large amount of information updates and iterations). The average active duration $1/\alpha_2$ of forwarding users of the new piece of information where users can influence other users to contact information is shorter. Similarly, the average forwarding

probability p_2 of the initial time in the outbreak period is also higher than the value in the quasi–steady-state phase, which conforms to the fact that people are more willing to participate in the discussion successively when exposed to relevant information in the short term. In comparison, the value of average contact rate β_{21} in the outbreak phase is lower than that in the quasi–steady-state phase, indicating that the population who has forwarded information will be larger based on a relatively larger contact population. β_{22} and β_{23} of the initial time in the outbreak period are higher than those of the initial time in the quasi–steady-state phase, indicating that continuous exposure to relevant information in the short term (when the initial time of the new piece of information is in the outbreak phase of a posted information) would attract people who had not participated in the new transmission to forward and spread the information. All average attractiveness indexes of the initial time in the quasi–steady-state phase are larger, which indicates that information that is re-exposed to users after a period of time will inspire their freshness and make them pay more attention to the information itself.

Data Fitting for the STI DT-SFI Model

Parameter Estimation

To use our model to explore some distinctions of the qualitative behaviors for prediction, we used the LS method to estimate the STI DT-SFI model parameters and the initial data of our model. The vector is set as $\Theta_3 = (p_1, \beta_1, \alpha_1, p_2, \beta_{21}, \beta_{22}, \beta_{21}, m_{21}, m_{22}, m_{23}, \alpha_2, S_{10})$, and the corresponding numerical calculation based on the parameter vectors for $C_1(t)$ and $C_2(t)$ are denoted by (k, Θ_3) and (k, Θ_3), respectively. The following LS error function was used in our calculation:

where C_{1k} and C_{2k} denote the actual cumulative forwarding populations of the posted information and the newly posted information; here, n=1, 2, 3 represents the different phases, and k=0, 1, 2, ... is the sampling time n=1, 2, 3. We estimated the parameters of our *STI DT-SFI* model with the data of information A and information B.

In the data fitting of the *STI DT-SFI* model, we used the same method as for the LTI DT-SFI model to fit the data of information A and information B. As shown in Figure 7, we performed data fitting of information A and information B on the real data in Tables 1 and 2, where the pink star denotes the actual cumulative number of forwarding users of information A; the red star denotes the actual cumulative number of forwarding users of information B; the green line and the blue line denote the estimated cumulative number of forwarding users in the early and later period of information A, respectively; and the black line denotes the estimated cumulative number of forwarding users of information B. It can be seen that our STI DT-SFI model achieves accurate estimation.

Table 6 gives some important values of parameter (relevant to the early period of the outbreak) estimation for information A, and Table 7 gives some important values of parameter estimation for the later period data of information A and all data of information B. We can see in phase 2, when information B was posted during the outbreak period of information A, the average exposure rate β_{21} and β_{22} are much larger than β_1 and β_{23}, which indicates that users who have been exposed to information A will contact information B at a greater rate than new susceptible users. In addition, the unexposure attractiveness index m_{23} is the largest among the three attractiveness indexes since the time interval between two information posts is small, and people who have not been exposed to relevant information may have a greater interest in new information; the outbreak of information B has the strongest appeal to susceptible users.

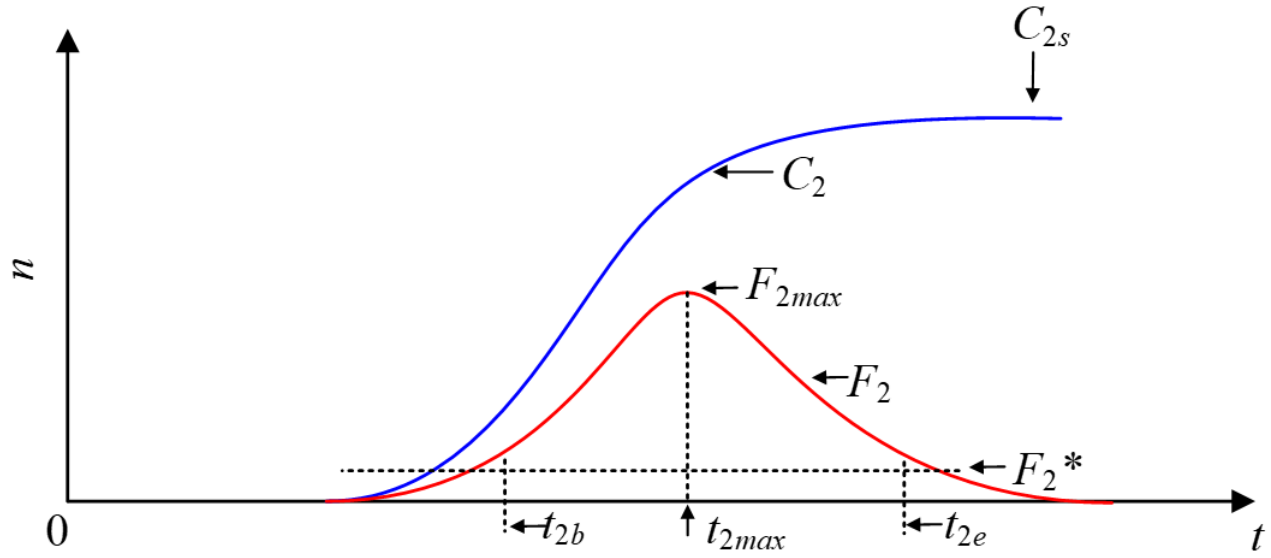
Results

Influencing Factors Analytics: Information Release and Dissemination for the LTI DT-SFI Model

To make a qualitative and quantitative analysis of the delay in transmission, we introduced some additional indexes, shown in Figure 8, and show how these can be used to characterize the cross-propagation. We considered different effects of the posted information on newly posted information when the posted information has reached a quasi–steady state or is still in its outbreak period.

Figure 8. Some summative indices of a newly posted information that cross-propagating with an old information.



- *The outbreak peak F_{2max}*: the maximum of curve F_2, which reflects the peak user values of the newly posted information
- *The final size C_{2S}*: the stable state of curve C_2, which gives the final size of the total number of users of the newly posted information
- *The outbreak time t_{2b}, the end time t_{2e}, and the duration t_{2i}*: the definition depends on the outbreak threshold F_2* set in advance so that $F_2(t_{2b}) = F_2{*}=F_2(t_{2e})$. Here, t_{2b} denotes the outbreak time of the newly posted information, t_{2e} denotes the end time, and $t_{2i} = t_{2e}–t_{2b}$ denotes the duration of the newly posted information transmission. These time indexes will help us judge the start and end of the newly posted information transmission.
- *The outbreak velocity V_{2o} and the declining velocity V_{2d}*: the definition depends on $V_{2o}= (F_{2max}–F_2{*}) / (t_{2max}–t_{2b})$ and $V_d= (F_{2max}–F_2{*}) / (t_{2e}–t_{2max})$ when $F_2(t)=F_{2max}$ and t_{2max} is definite, which reflects the speed of the outbreak and the decline of the newly posted information.

To further analyze the different parameters responsible for the LTI DT-SFI model, we performed an analysis of partial rank

correlation coefficients [36] to evaluate the sensitivity based on 1000 samples for various input parameters against the threshold condition. According to the histogram and scatter diagram of dependence, when the correlation is positive, it means that, with the increase of the value of the parameter, the corresponding index value will increase; on the contrary, when the correlation is negative, the index will decrease as the parameter decreases. Figures 9-12 give the partial rank correlation coefficient results and partial rank correlation coefficient scatterplots with indexes , F_{2max}, $C_{2\infty}$, t_{2b}, t_{2i}, t_{2max}, V_{2o}, and V_{2d} with nine parameters (β_{21}, β_{22}, β_{23}, p_2, α_2, m_{21}, m_{22}, m_{23}, and S_{20}) of the newly posted information in the LTI DT-SFI model, respectively.

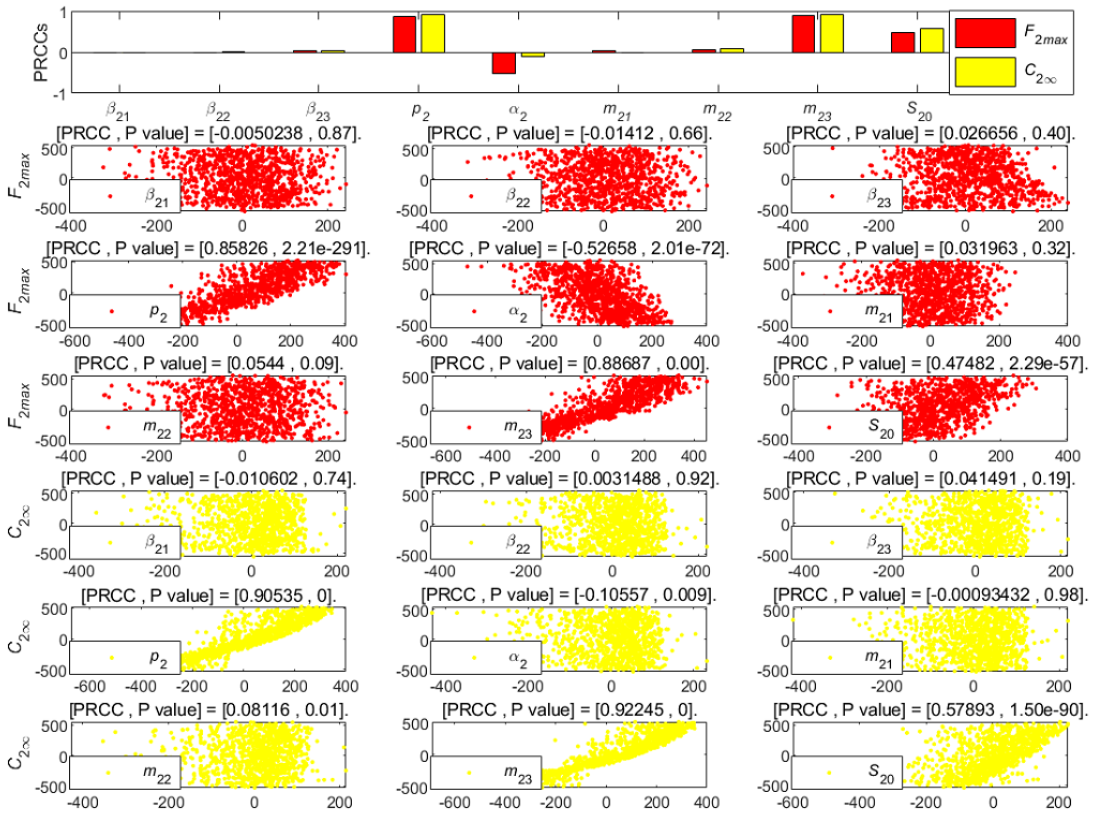

Figure 11. PRCC results and PRCC scatterplots with indexes t_{2max}, t_{2b}, and t_{2i} for different parameters of the newly posted information in the large interval delay in transmission susceptible-forwarding-immune model. PRCC: partial rank correlation coefficient.

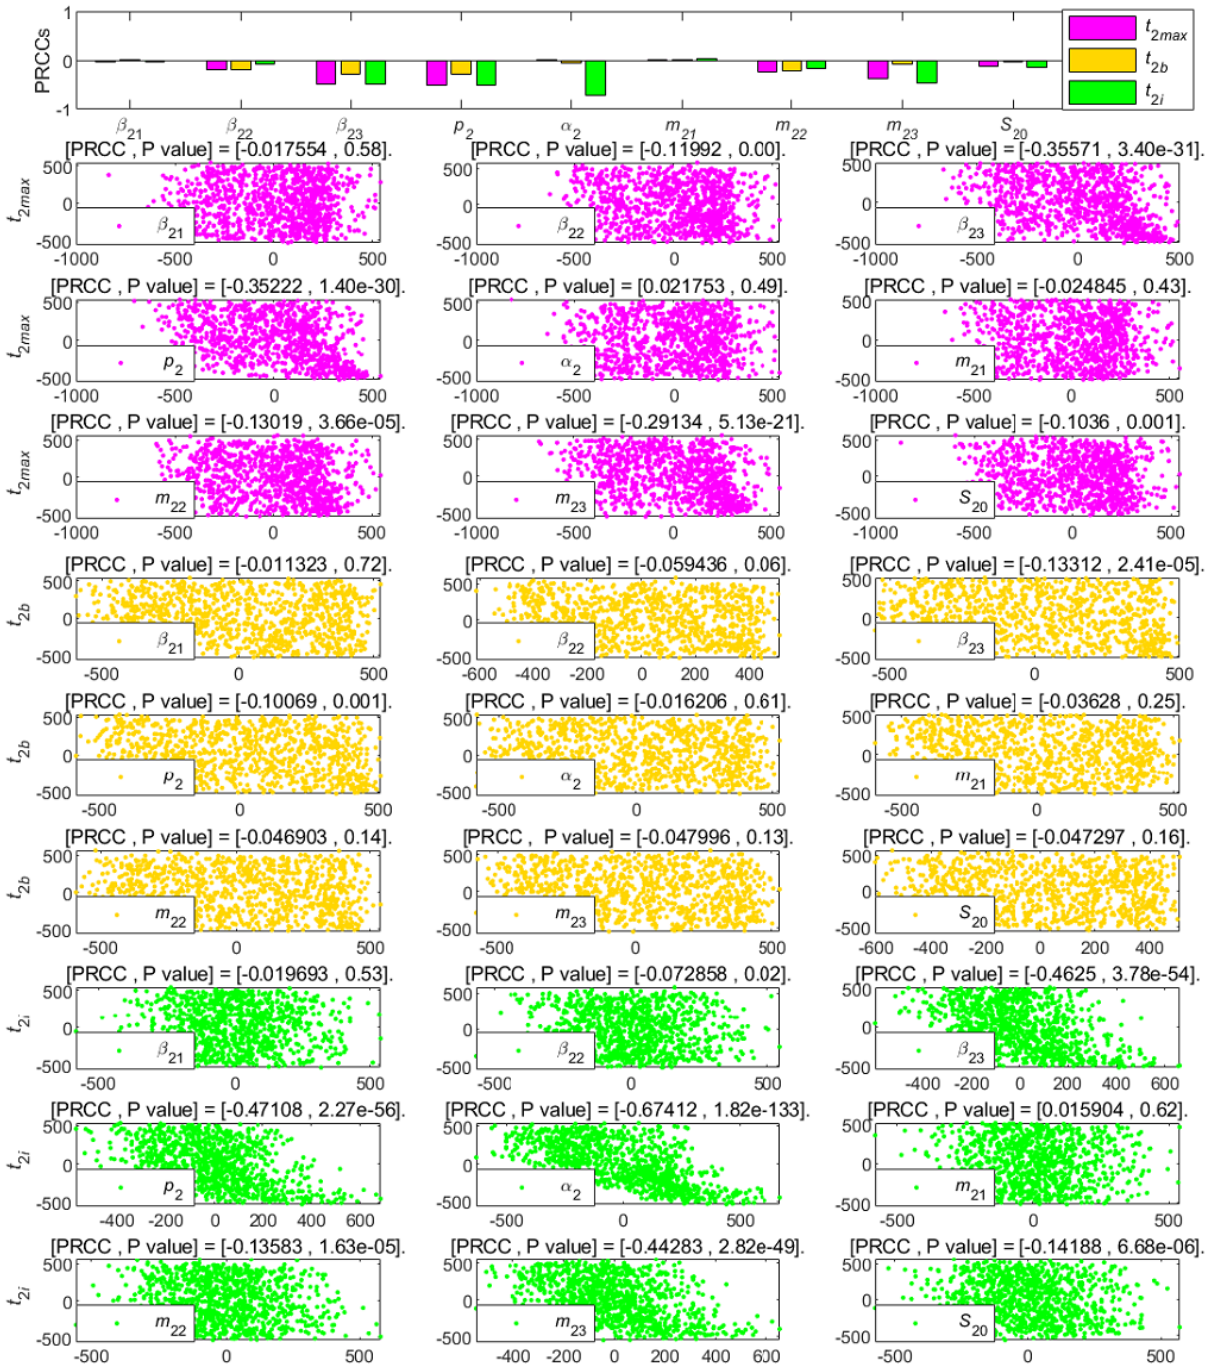

Figure 12. PRCC results and PRCC scatterplots with indexes V_{2o} and V_{2d} for different parameters of the newly posted information in the large interval delay in transmission susceptible-forwarding-immune model. PRCC: partial rank correlation coefficient.

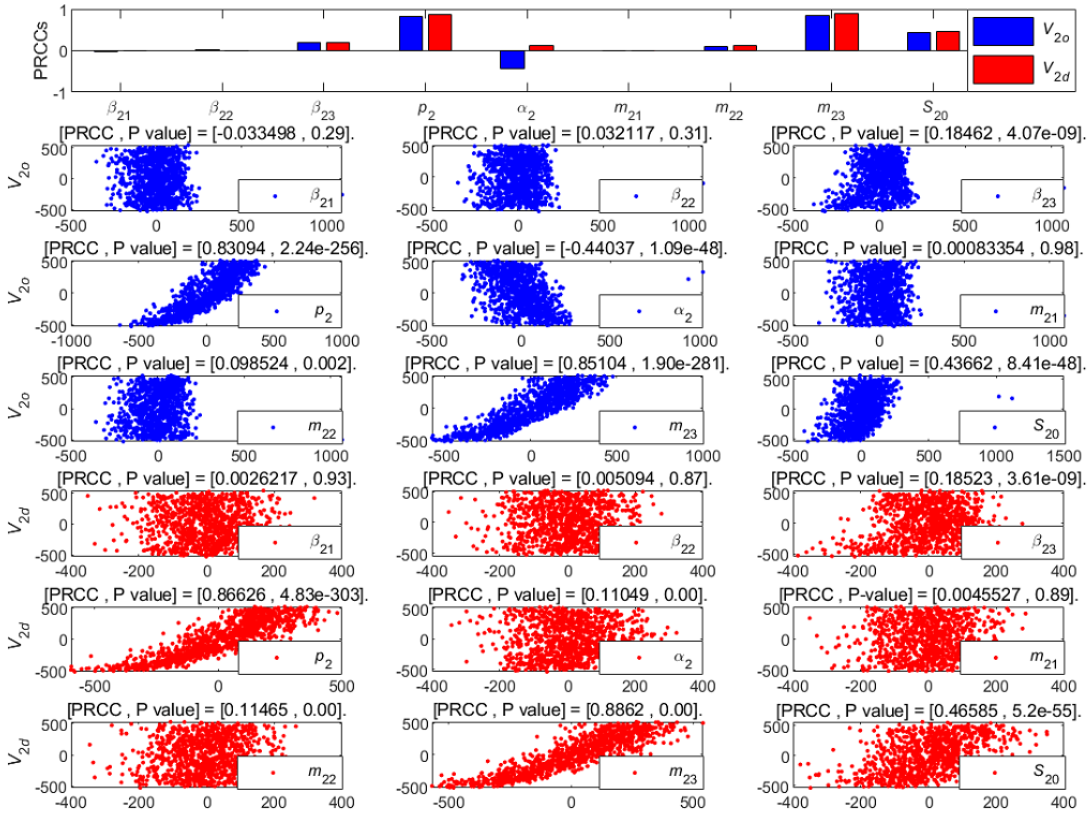

Figure 9 shows the effect of parameters on the public opinion reproduction ratio of the delay in transmission in the LTI DT-SFI model. was strongly positively affected by the average exposure rate β_{22}, the mild exposure attractiveness index m_{22}, the average exposure rate β_{23}, the unexposure attractiveness index m_{23}, and the forwarding probability p_2, and strongly negatively affected by the average immune rate α_2. The positive correlation effects of the parameters β_{21} and m_{21} were relatively weak. Overall, strategies to increase the parameters β_{22}, β_{23}, p_2, m_{22}, m_{23}, and initial value S_{20} or to decrease the α_2 can enhance the transmission capability of the newly posted information.

From Figure 10, the parameters have a similar effect on the forwarding peak F_{2max} and the cumulative forwarding population $C_{2\infty}$. The unexposure attractiveness index m_{23}, the forwarding probability p_2, and the initial value S_{20} of susceptible individuals have a decisive positive influence on the forwarding peak value F_{2max} and the final size $C_{2\infty}$ of delayed information propagation. The effects of the extensive and mild exposure attractiveness parameters that portray the participation of the population of the posted information were very weak. The aforementioned results indicate that the time interval is long between the two delays in transmission information since the new information was posted in a quasi–steady state into the propagation; at this time, most individuals who have been exposed to the posted information have entered the immune state. In addition, most individuals will no longer care about the relevant content due to the possibility of forgetting or leaving the social network platform. The aforementioned conclusions show that when the posted information enters the steady state, the effect of the individuals who have contacted the posted information is not obvious. Therefore, the information transmission can be promoted by influencing the number of the new susceptible population.

Figure 11 shows the effect of parameters on the climax time t_{2max}, the outbreak time t_{2b}, and the duration t_{2i} of the delay in transmission. After mastering the influencing factors of t_{2b} and t_{2i}, the end time of transmission t_{2e} can be calculated. The climax time t_{2max}, the outbreak time t_{2b}, and the duration t_{2i} are negatively affected by parameters β_{23}, p_2, and m_{23} in the same way. In comparison, these parameters have the least impact on t_{2b}, especially m_{23}. The parameter m_{22} had a weak negative correlation effect on each time index, and the parameter α_2 was the main factor to control the duration t_{2i}, which plays a strong negative correlation effect.

From Figure 12, the unexposure attractiveness index m_{23} and the forwarding probability p_2 had major positive correlation effects on the outbreak velocity V_{2o} and the declining velocity

V_{2d}, and the initial value S_{20} of susceptible individuals had a mild positive effect on these two indexes. Moreover, the parameter α_2 had a strong negative effect on the V_{2o}. In addition, the effects of other parameters on the velocities were not important. That is to say, the V_{2o} and V_{2d} will increase accordingly when the parameters m_{23}, p_2, and initial value S_{20} increase. At the same time, the V_{2o} increases with the reduction of parameter α_2. By contrast, the effect of m_{23} on the velocities was greater.

Our LTI DT-SFI model concentrates on the influence of the average exposure rates and attractiveness indexes on the instantaneous forwarding population $F_2(t)$ and the cumulative forwarding population $C_2(t)$ as shown in Figures 13 and 14, respectively, and the variation of parameters over time determines the propagation indexes. By comparing and analyzing the influence of average contact rates and attractiveness indexes in Figures 11 and 12 with the variation of one parameter while fixing other parameters, β_{23} and m_{23} have a similar overall trend of the effects on the instantaneous forwarding population $F_2(t)$ and the cumulative forwarding population $C_2(t)$ of the new information. With the increase of the parameters of β_{23} and m_{23}, the outbreak will accelerate, the instantaneous number of individuals in the forwarding state can reach a higher peak, and the final size will be larger. In addition, the average exposure rate of β_{22} and the mild exposure attractiveness index m_{22} had a weak positive influence on the final size of the cumulative forwarding quantity and had no obvious influence on the propagation times and velocities. In contrast, the average exposure rate β_{21} and the extensive exposure attractiveness index m_{21} had no significant effect on large interval delay in transmission based on forwarding. All the aforementioned key parameters had no significant effect on the outbreak time, climax time, and duration of the long-delayed cross-information transmission based on forwarding, which was also consistent with the results of the partial rank correlation coefficients.

Figure 13. The influence of the average exposure rates on the instantaneous forwarding population $F_2(t)$ and the cumulative forwarding population $C_2(t)$ in the large interval delay in transmission susceptible-forwarding-immune model.

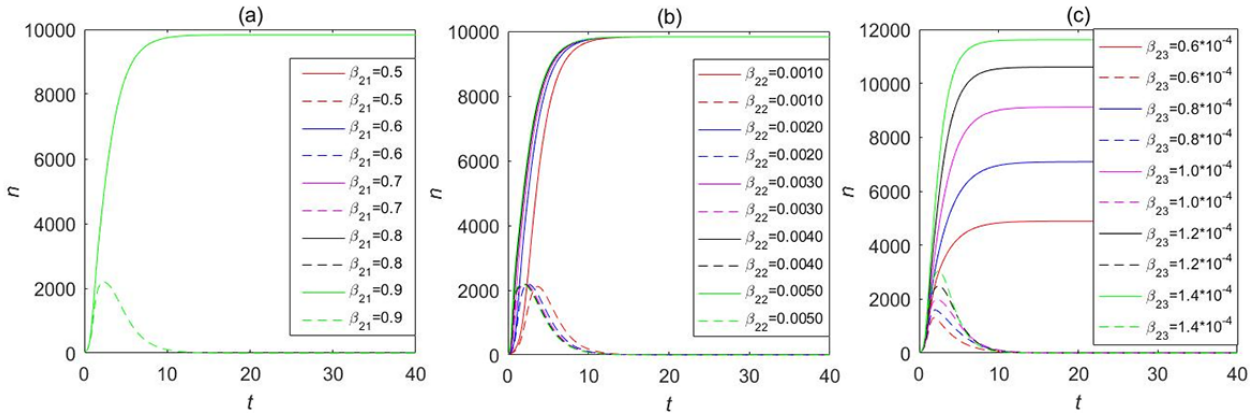

Figure 14. The influence of the attractiveness indexes on the instantaneous forwarding population $F_2(t)$ and the cumulative forwarding population $C_2(t)$ in the large interval delay in transmission susceptible-forwarding-immune model.

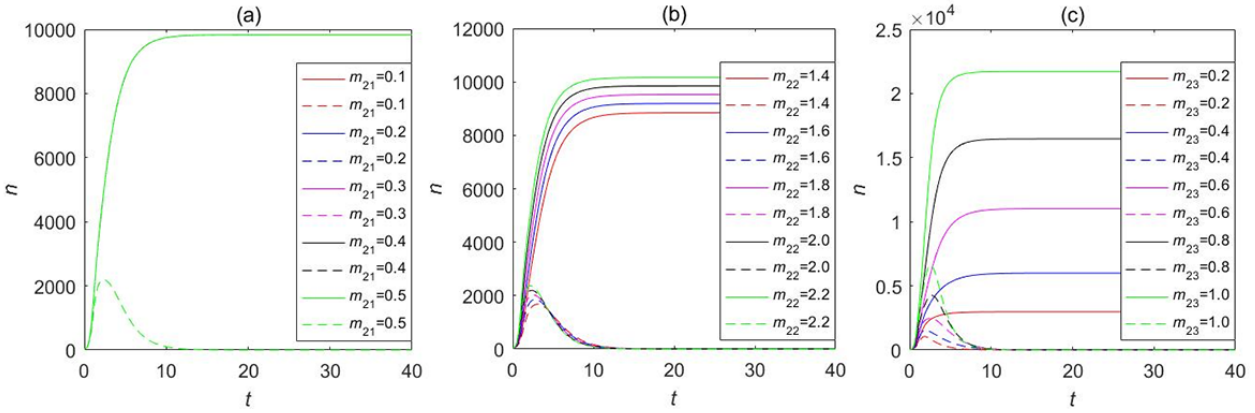

Influencing Factors Analytics: Information Release and Dissemination for the STI DT-SFI Model

To further analyze the impact of different parameters in the STI DT-SFI model for the cross-propagation dynamics, we performed partial rank correlation coefficients to analyze the relationship between the influence and the range of variation of parameters on the indexes. Figures 15-18 give the partial rank correlation coefficient results and partial rank correlation coefficient scatterplots with indexes , F_{2max}, $C_{2\infty}$, t_{2b}, t_{2i}, t_{2max}, V_{2o}, and V_{2d} with nine parameters (β_{21}, β_{22}, β_{23}, p_2, α_2, m_{21}, m_{22}, m_{23}, and S_{10}) of the newly posted information in the STI DT-SFI model, respectively.

Figure 15. PRCC results and PRCC scatterplots with indexes for different parameters of the newly posted information in the short interval delay in transmission–susceptible-forwarding-immune model. PRCC: partial rank correlation coefficient.

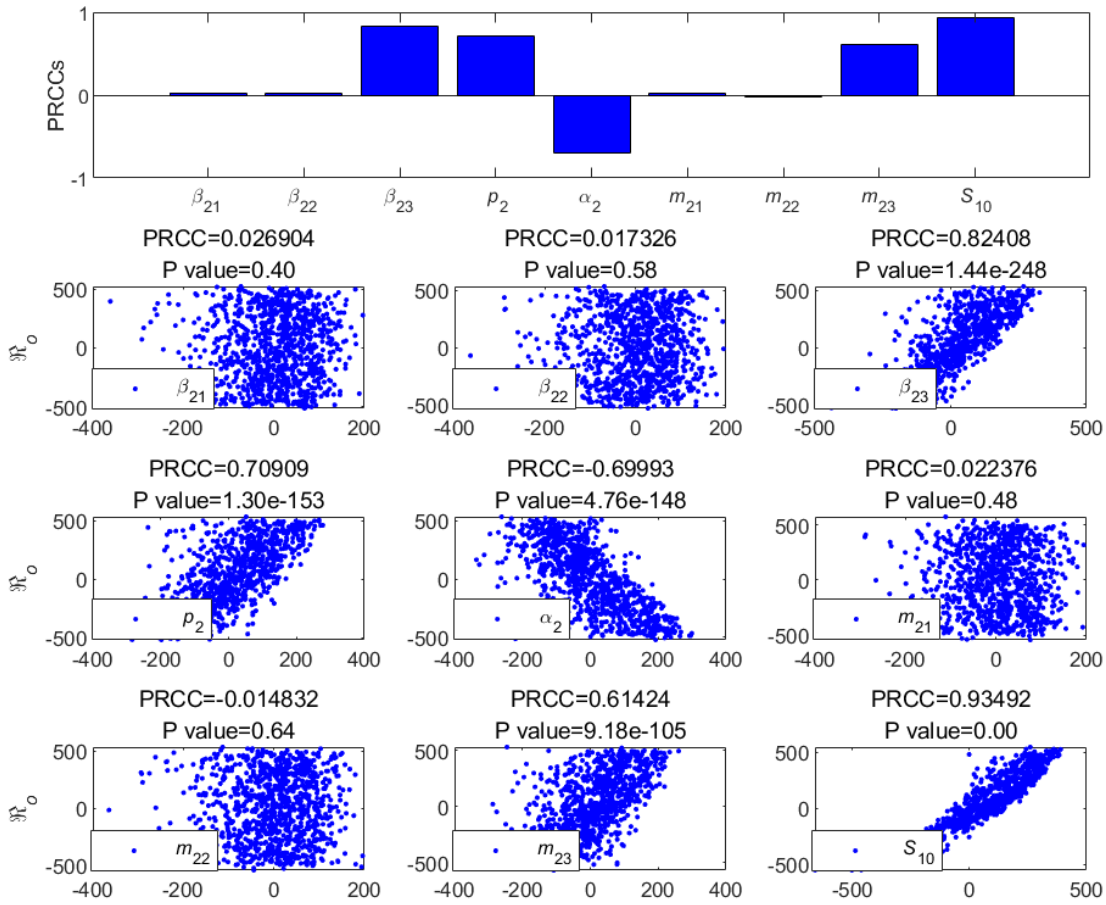

Figure 16. PRCC results and PRCC scatterplots with indexes F_{2max} and $C_{2\infty}$ for different parameters of the newly posted information in the short interval delay in transmission susceptible-forwarding-immune model. PRCC: partial rank correlation coefficient.

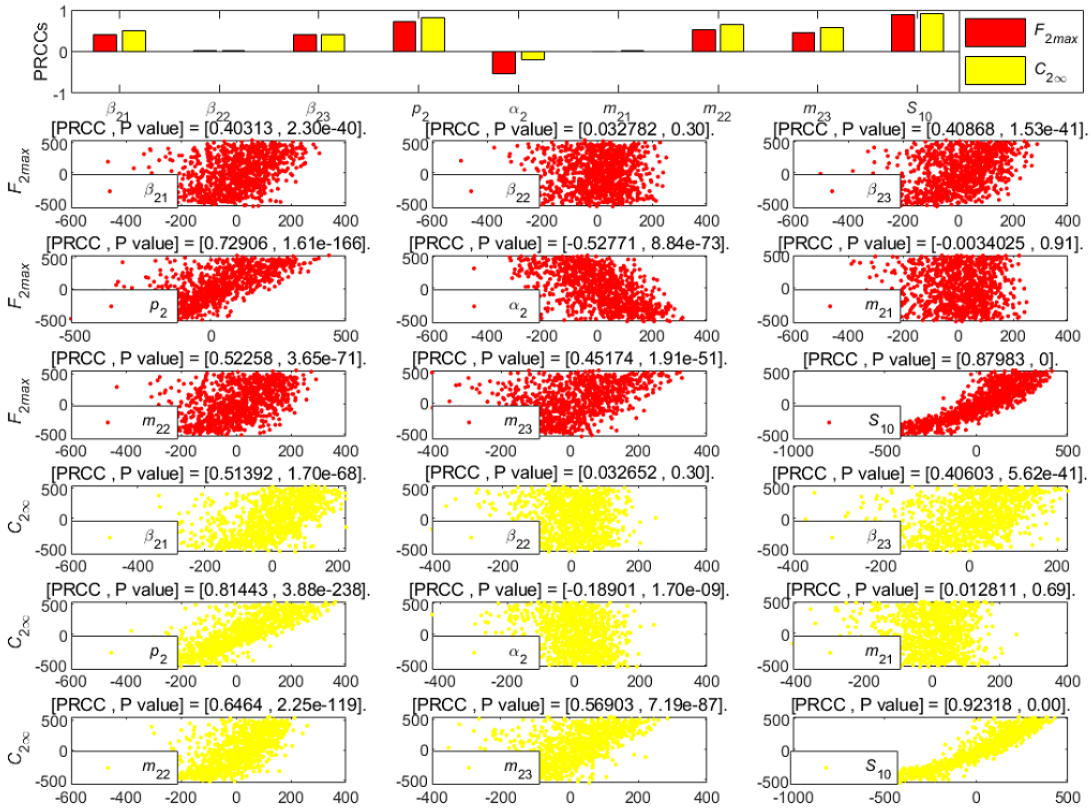

Figure 17. PRCC results and PRCC scatterplots with indexes t_{2max}, t_{2b}, and t_{2i} for different parameters of the newly posted information in the short interval delay in transmission susceptible-forwarding-immune model. PRCC: partial rank correlation coefficient.

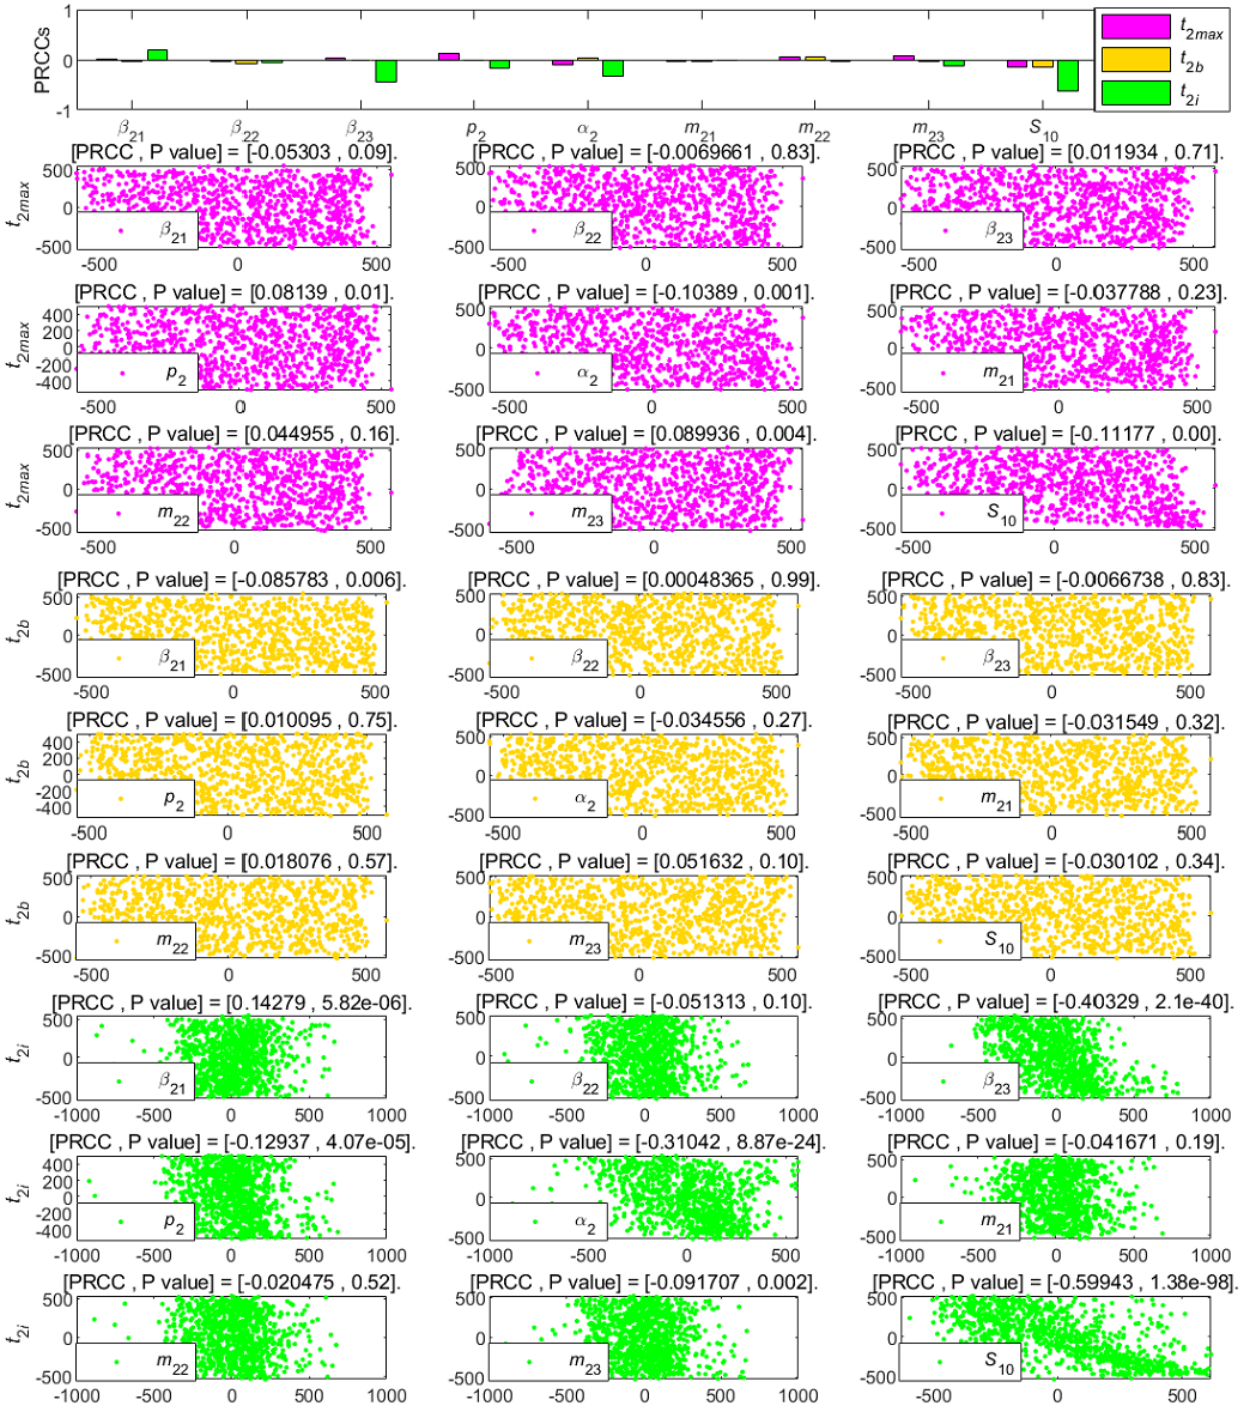

Figure 18. PRCC results and PRCC scatterplots with indexes V_{2o} and V_{2d} for different parameters of the newly posted information in the short interval delay in transmission susceptible-forwarding-immune model. PRCC: partial rank correlation coefficient.

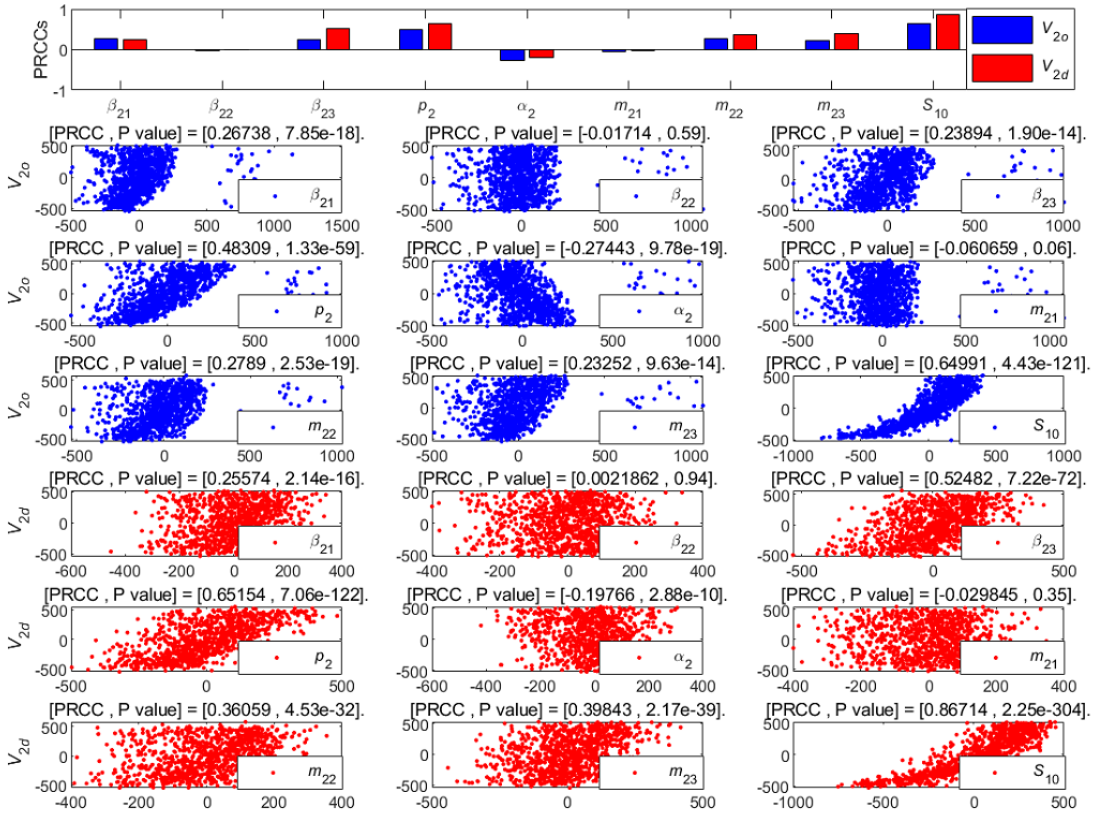

The average exposure rate β_{23}, the unexposure attractiveness index m_{23}, the forwarding probability p_2, and the initial value S_{10} were strong contributions to the public opinion reproduction ratio positively, and the average immune rate α_2 had a strong negative effect on it, as shown in Figure 15. The positive correlation effects of parameters β_{21}, β_{22}, m_{21}, and m_{22} were relatively weak. In general, strategies that can affect the parameters β_{23}, m_{23}, p_2, and the initial value S_{10} to increase or the parameter α_2 to decrease can increase the initial propagation capacity of the newly posted information. On the other hand, we can decrease the parameters β_{23}, m_{23}, p_2, and the initial value S_{10} to reduce the initial propagation ability of the new information.

The average contact rate of β_{21}, β_{22}, the forwarding probability p_2, the mild exposure attractiveness index m_{22}, the unexposure attractiveness index m_{23}, and the initial value S_{10} of susceptible individuals had strong positive impacts on the high peak F_{2max} and the final size $C_{2\infty}$, as shown in Figure 16. In contrast, S_{10} played a major role, and the impact of β_{22} and m_{21} were less significant. The aforementioend results show that individuals who have been exposed to but have not forwarded the posted information are more sensitive to the new information with mild exposure attractiveness due to the understanding of the former information. In addition, the average immune rate α_2 had a strong negative effect on the F_{2max}.

Figure 17 indicates that the influence of each parameter on t_{2max} and t_{2b} were not obvious, and the parameters β_{23}, α_2, and the initial value S_{10} had negative effects on the duration t_{2i}, and the β_{21} had a weak positive effect on it. This means that the average contact rate at which users in the susceptible state can contact the second information is the most important factor affecting the duration t_{2i} of delay in transmission. The smaller the average contact rate is, the longer the duration of new information transmission will be within a certain range, slowing down the development of information transmission.

Figure 18 shows the partial rank correlation coefficients results of the outbreak velocity V_{2o} and the declining velocity V_{2d} of the STI DT-SFI model based on forwarding under multiparameter changes. From the results, the average exposure rate β_{21}, β_{23}, the forwarding probability p_2, the mild exposure attractiveness index m_{22}, the unexposure attraction index m_{23}, and the initial value S_{10} of susceptible individuals make strong positive contributions on V_{2o} and V_{2d}. The average exposure rate β_{22} and the extensive exposure attractiveness index m_{21} had no significant effect on the velocities. That is to say, the outbreak velocity V_{2o} and the declining velocity V_{2d} can be increased with the increase of the parameters β_{21}, β_{23}, p_2, m_{22}, m_{23}, and

the initial value S_{10}. On the contrary, if the parameters decrease, the propagation velocities will slow down.

Here, we also took into consideration the influence of the average exposure rate and attractiveness parameters on the instantaneous forwarding population $F_2(t)$ and the cumulative forwarding population $C_2(t)$ of the STI DT-SFI model as shown in Figures 19 and 20, respectively. The comparative analysis shows that the larger the average contact rate and attractiveness indexes are, the larger the instantaneous forwarding quantity and the cumulative forwarding quantity are. The final size is also affected; the average exposure rate of β_{21}, β_{23}, the mild exposure attractiveness index m_{22}, and the unexposure attractiveness index m_{23} are the main influencing factors of the STI DT-SFI model, and they can play a significant role in the final size of the newly posted information within a certain range. So priority must be placed on controlling these parameters. In addition, the extensive exposure attractiveness index m_{21} has only a small magnitude of effects, while the effect of parameter β_{22} is significant and has a relatively obvious impact. The impact of each parameter on the outbreak timing and increasing and declining velocities is negligible, which is consistent with the results of the partial rank correlation coefficients.

Figure 19. The influence of the average exposure rates on the instantaneous forwarding population $F_2(t)$ and the cumulative forwarding population $C_2(t)$ in the short interval delay in transmission susceptible-forwarding-immune model.

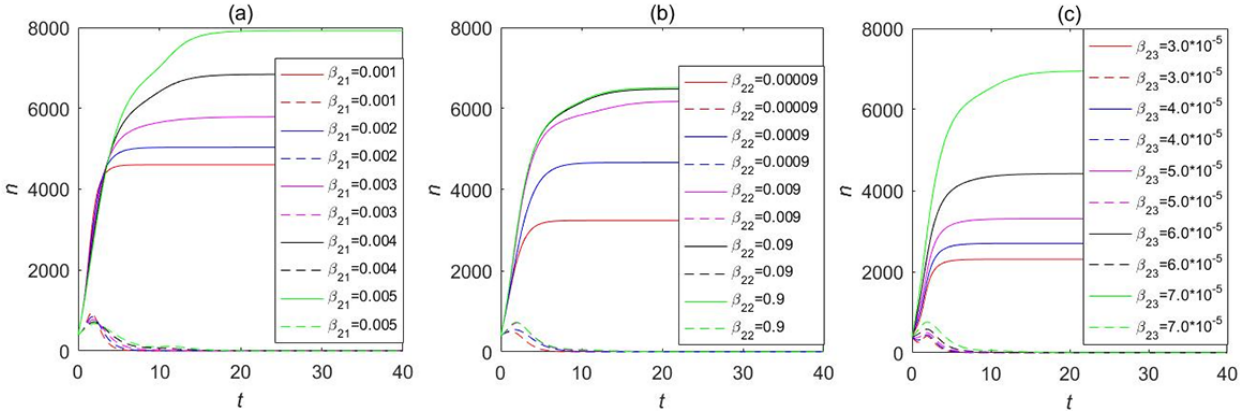

Figure 20. The influence of the attractiveness parameters on the instantaneous forwarding population $F_2(t)$ and the cumulative forwarding population $C_2(t)$ in the short interval delay in transmission susceptible-forwarding-immune model.

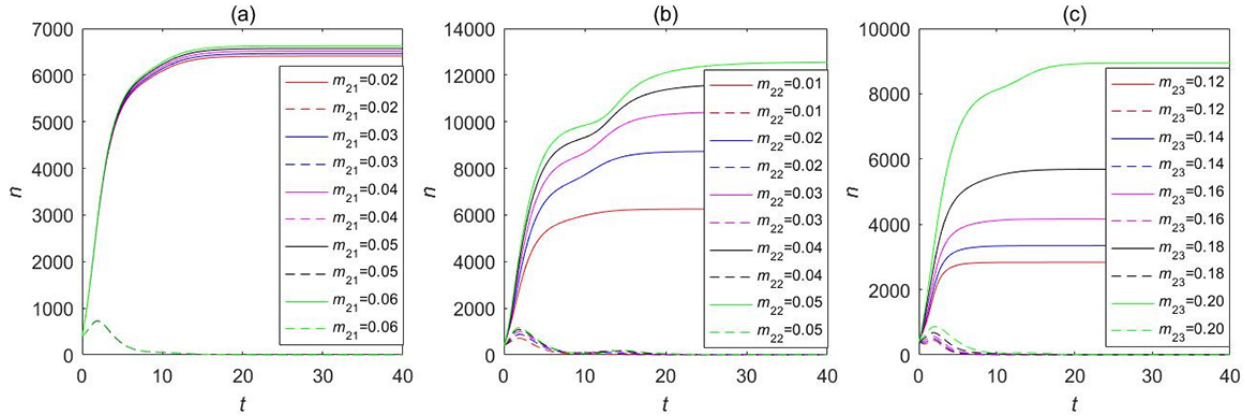

Discussion

Principal Findings

Figure 21 shows the trend of the cumulative forwarding users of information B and information C when the newly posted information is posted during the steady-state period of the posted information in Tables 2 and 3. The time lag with which the newly posted information is posted has a significant impact on the process of public opinion dissemination and the final size of the cumulative number of forwarding users. If the newly posted information is posted during the quasi–steady-state period of opinion propagation, then the earlier the newly posted information is posted, the earlier the cumulative forwarding users will peak, though the final size of the cumulative forwarding users will be close to each other. This, in conjunction with our parameter sensitivity analysis results, shows that for the LTI DT-SFI situation, the unexposure attractiveness index m_{23} and the average exposure rate β_{23} are the key elements to promote the cross-propagation and that, once reaching the quasi–steady state, the timing of posting the new information has an insignificant impact on the final size of forwarding users.

In contrast, Figure 22 shows the trend of the cumulative forwarding users of information A and information B when the newly posted information is posted during the outbreak period of the posted information in Tables 1 and 2. The time lag with which the newly posted information is posted has a noticeable impact on both the dynamic process of public opinion dissemination and the final size of the cumulative number of

forwarding users. If the newly posted information can be posted during the outbreak period of the old information, then the earlier the new information is posted, the greater the cumulative forwarding population and the final size of the cumulative forwarding users will be. This, combined with our parameter sensitivity analysis results, shows that, in the STI DT-SFI case, the mild exposure attractiveness index m_{22}, the average exposure rates β_{21} and β_{23}, and the unexposure attractiveness index m_{23} can all directly influence the interaction between information posted sequentially to increase the "heat" (popularity) of the newly posted information.

Our model-based analysis recommends strategies on how different parameters should be adjusted to achieve the best information dissemination outcomes. For two pieces of relevant information separated by a relative long posting lag, strategies to increase the average exposure rate β_{23} and the unexposure attractiveness index m_{23} are recommendations. These strategies can be achieved if opinion leaders with a large number of followers can participate in the information copropagation. On the contrary, reducing the public's attention to a new piece of information can be achieved by efforts in delaying the posting of the new information or by effectively reducing the potential correlation between the two pieces of information (reducing values of the correlation parameters β_{21}, β_{22}, m_{21}, and m_{22}). Additionally, if our goal is for the final size of the cumulative forwarding users of the new information to not be impacted by the relevant information already posted online, the new information should be posted during the quasi–steady-state period of the posted information.

For two pieces of information with a short interval between posting, we recommend developing strategies to alter the interaction between the information for effectively managing the information transmission indexes we introduced. If we aim to make the new information outbreak faster with a large peak value of forwarding, we should increase the average exposure rate β_{21} and mild exposure attractiveness index m_{22} by persuading the original post owner to post or forward the information earlier during the outbreak period of the posted information, when the posted information has obtained certain public attention, and increase the relevance and attraction of the newly posted information to the forwarding users or immune users of the posted information. Alternatively, we should persuade some opinion leaders to forward the new information along with their insights to β_{23} and m_{23}.

Figure 21. An illustration of a public opinion dissemination process with newly posted information posted with different time lags but during the quasi–steady-state period of the posted information.

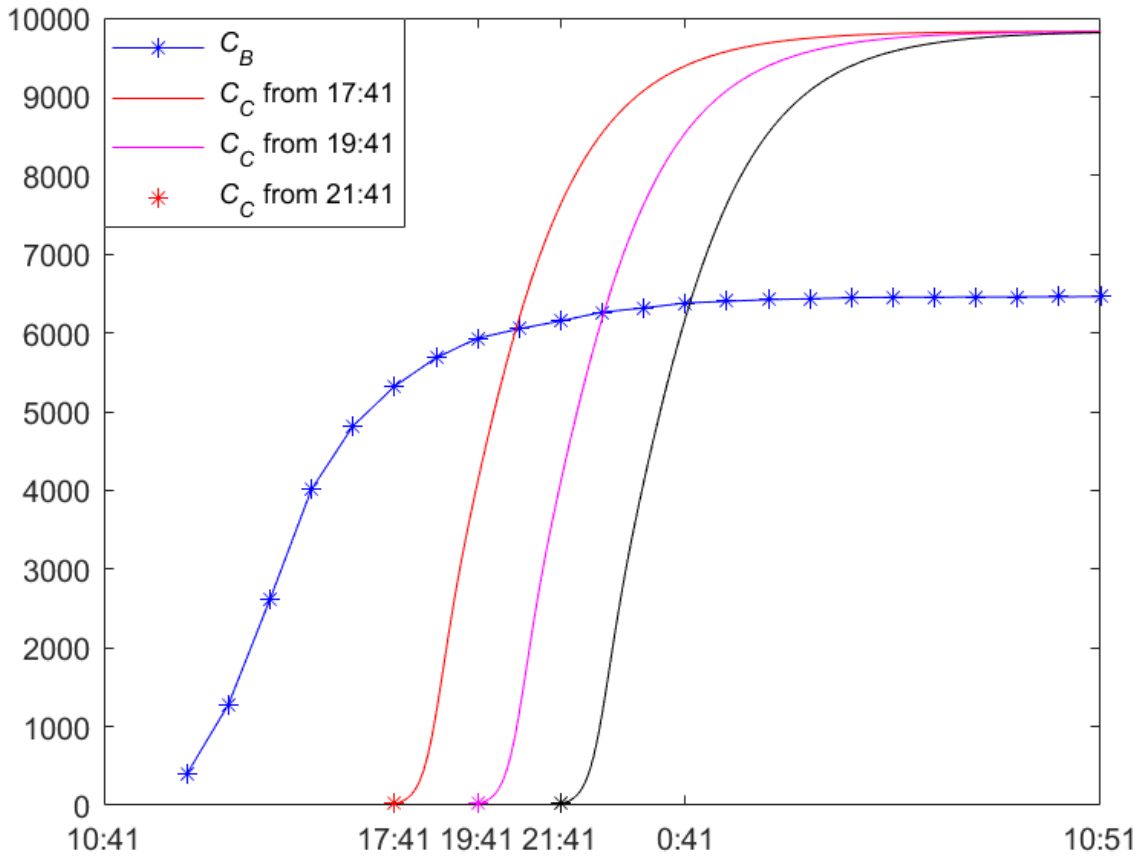

Figure 22. An illustration of a public opinion dissemination process with newly posted information posted with different time lags but during the quasi–steady-state period of the posted information.

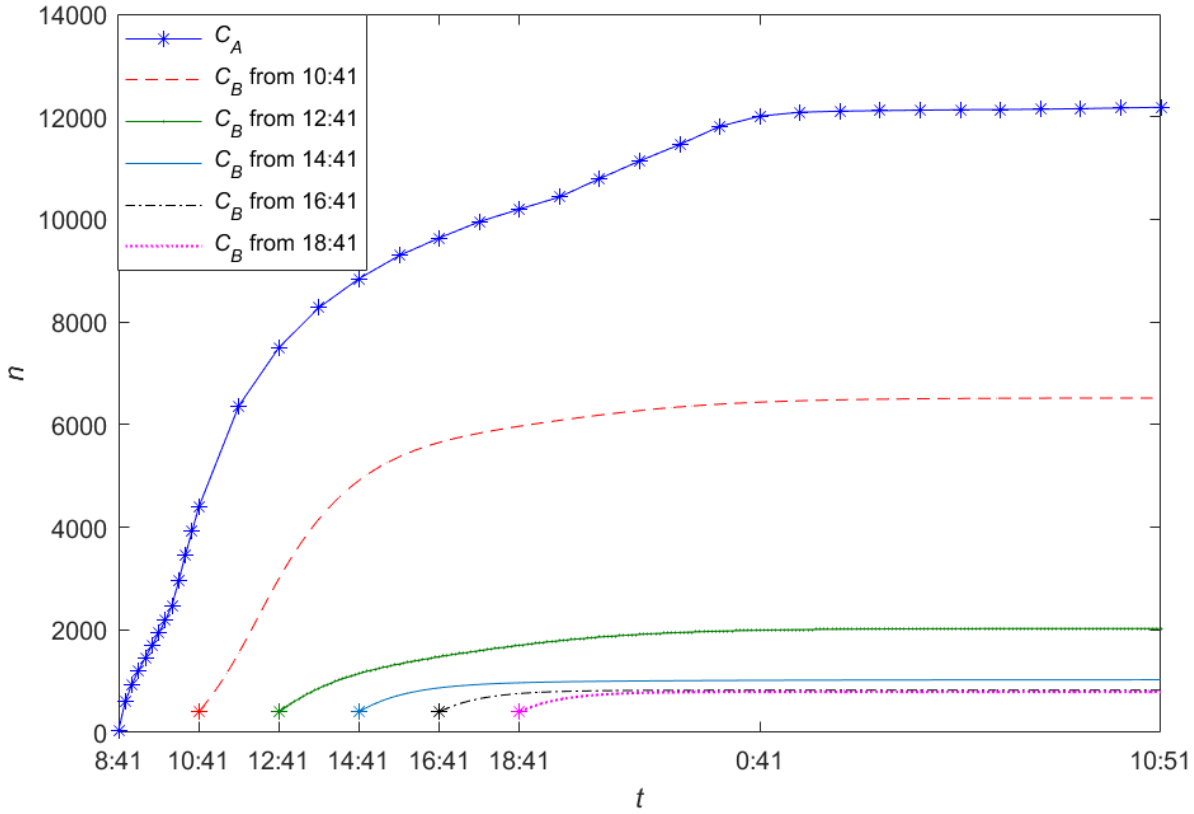

Conclusions

Relevant information is often posted sequentially in fast-evolving public health events such as the COVID-19 pandemic. Consequently, modeling the impact of delay in cross-transmission or copropagation is substantial to identifying the best strategies to communicate key public messages through social media. In this study, we proposed and examined two classes of models, the LTI DT-SFI dynamics model and the STI DT-SFI dynamics model based on the forwarding users in Weibos, and we parametrized our models using real data related to the COVID-19 pandemic in the Chinese Sina Microblog. Our goal is to use these parametrized models to understand the influence of different time lags in the information posting on the copropagation of related information in the microblog.

Our model formulation focused on the transmission mechanism of information in the social network, where a new Weibo may be posted in different phases—outbreak phase or quasi–steady-state phase—of some relevant Weibo already posted. Our goal is to examine the impact of post timing in relation to the old information, the new information on its peak value, and the final size of forwarding users. As we have shown, this impact depends on the correlation of the old and new information, and on the phase of the old information transmission when the new information is posted. We hope that our DT-SFI dynamics models fill in some theoretical gap about optimizing information posting strategies to maximize communication efforts to deliver key public health messages to the public for better outcomes of public health emergency management.

Abstract

Background: During the outbreak of COVID-19, numerous rumors emerged on the internet in China and caused confusion among the public. However, the characteristics of these rumors in different phases of the epidemic have not been studied in depth, and the official responses to the rumors have not been systematically evaluated.

Objective: The aims of this study were to evaluate the rumor epidemic and official responses during the COVID-19 outbreak in China and to provide a scientific basis for effective information communication in future public health crises.

Methods: Data on internet rumors related to COVID-19 were collected via the Sina Weibo Official Account to Refute Rumors between January 20 and April 8, 2020, extracted, and analyzed. The data were divided into five periods according to the key events and disease epidemic. Different classifications of rumors were described and compared over the five periods. The trends of the epidemic and the focus of the public at different stages were plotted, and correlation analysis between the number of rumors and the number of COVID-19 cases was performed. The geographic distributions of the sources and refuters of the rumors were graphed, and analyses of the most frequently appearing words in the rumors were applied to reveal hotspots of the rumors.

Results: A total of 1943 rumors were retrieved. The median of the response interval between publication and debunking of the rumors was 1 day (IQR 1-2). Rumors in text format accounted for the majority of the 1943 rumors (n=1241, 63.9%); chat tools, particularly WeChat (n=1386, 71.3%), were the most common platform for initial publishing of the rumors (n=1412, 72.7%). In addition to text rumors, Weibo and web pages were more likely to be platforms for rumors released in multimedia formats or in a combination of formats, respectively. Local agencies played a large role in dispelling rumors among social media platforms (1537/1943, 79.1%). There were significant differences in the formats and origins of rumors over the five periods (P<.001). Hubei Province accounted for most of the country's confirmed rumors. Beijing and Wuhan City were the main centers for debunking of disinformation. The words most frequently included in the core messages of the rumors varied by period, indicating shifting in the public's concern.

Conclusions: Chat tools, particularly WeChat, became the major sources of rumors during the COVID-19 outbreak in China, indicating a requirement to establish rumor monitoring and refuting mechanisms on these platforms. Moreover, targeted policy adjustments and timely release of official information are needed in different phases of the outbreak.

KEYWORDS

rumor; Internet; COVID-19; epidemic; misinformation; infodemiology; infodemic; social media; communication; public health

Introduction

In December 2019, an outbreak of COVID-19, caused by infection with SARS-CoV-2, emerged in Wuhan, Hubei Province, China, and subsequently became a global pandemic [1-3]. As of July 1, 2020, more than 10.3 million cases had been confirmed in most countries and territories worldwide, with more than 508,000 fatalities [4], seriously threatening the lives and health of the public and jeopardizing the stable economic development and social safety of nations.

Internet public opinion crises characterized by frequent rumors often accompany public health emergencies, especially when information from official authorities is delayed or lacking [5]. Since the advent of Web 2.0 technology, internet social media platforms such as WeChat (similar to WhatsApp) and Weibo (similar to Twitter) have gradually replaced traditional media as the main platforms for the public to express their opinion and participate in social affairs in China. Due to the easy accessibility and convenience of social media, information spreads more rapidly and widely through these platforms than through their conventional counterparts [6]; moreover, the resulting large availability of user-provided content fosters massive recruitment of people around common interests, worldviews, and narratives, thus affecting the evolution of public opinion [7] and further enabling rumors to flourish. In 2013, the World Economic Forum described web-based rumors as “digital wildfire” and highlighted the risks they pose to modern society [8]. The rumor that drinking spirit can prevent infection with SARS-CoV-2 is a typical example of a rumor that spread during the outbreak of COVID-19 in China. From the beginning of the outbreak, social media users started to query about methods of preventing and treating COVID-19, and they rushed to the internet to seek information. Due to strong concerns about their own lives and the lack of awareness of the disease, many microbloggers released messages that misrepresented the causal relationship between COVID-19 and drinking spirit, and their posts became very prevalent [9]. This false message was widely discussed on the internet at the time and caused great confusion and panic. As a result, the government provided an official clarification of the rumor, and various localities promptly refuted the rumor and addressed it through the intervention of public security departments, which prevented the rumor from spreading further.

According to previous research, public opinion events are often caused by the interaction of events, the public, social media platforms, and structural factors of the government [10,11]. Public health emergencies, especially outbreaks of new infectious diseases, are often accompanied by uncertainty about the cause of the emergency. However, the resulting information on the morbidity and mortality of the diseases becomes the focus of public concern from the moment it emerges. Individuals’ perceptions of the threat of diseases tends to be reinforced by their exposure to case data and also by public and private information that is disseminated widely on social media [12]. Simultaneously, the unknown causes of public health emergencies stimulate increased information-seeking behavior in people who are aiming to reduce their uncertainties about the emergent situation [13]. However, in the absence of information, people experience a wide range of emotions in the face of unexpected situations, and the anxiety or fear thus generated can exacerbate the occurrence and dissemination of rumors [14]. The role of government intervention in the development trend of rumors remains uncertain. However, the subject, duration, methods, and level of government intervention have certain influences on the virality of rumors [10]. In addition to the professional measures of epidemic prevention and control, keeping the information accurate and transparent and preventing the spread of rumors are critical parts of the crisis response, reflecting the significance of the establishment of government monitoring-feedback-intervention mechanisms in public health emergencies [15].

Compared with the severe acute respiratory syndrome (SARS) outbreak 17 years ago, the COVID-19 outbreak has sparked more rumormongering. Rumors such as “dual yellow oral liquid inhibited novel coronavirus,” “number of confirmed cases of COVID-19 and deaths in a county,” and “some places have been blockaded or the supermarkets have been closed down” sparked panic among the public, causing people to rush to buy supplies and posing a serious challenge to the governance of internet public opinion in the context of the epidemic. As the challenges grew in the face of the public crisis, the phenomenon of the “infodemic,” an overabundance of accurate or inaccurate information occurring during an epidemic, has escalated to a level that requires a coordinated response. Thus, the emerging research area of “infodemiology,” which can be defined as the science of using epidemiologic methods and terminology to study the distribution and determinants of information in an electronic medium, specifically the internet, with the ultimate aim to inform public health and public policy, has been developed [16] and was effectively used to predict the influenza outbreak in 2006 [17]. Infodemiology data are derived from unstructured, textual, openly accessible information produced and consumed by the public on the internet to demonstrate and explore the opinions, focus, behavior, attitudes, and knowledge of the public [16]. The research field of infodemiology has gradually gained wider use, and it caught the attention of the World Health Organization in the wake of the COVID-19 outbreak [18], encouraging the undertaking of more relevant

studies and effective practices to understand more about internet information.

Thus, in this study, we analyzed rumors collected from rumor-refuting platforms, using the methods of infodemiology from the supply side, to understand the epidemic of rumors and official responses in different periods according to typical events and the disease epidemic. The results of this study could provide evidence-based recommendations for information communication and rumor prevention during subsequent public health emergencies.

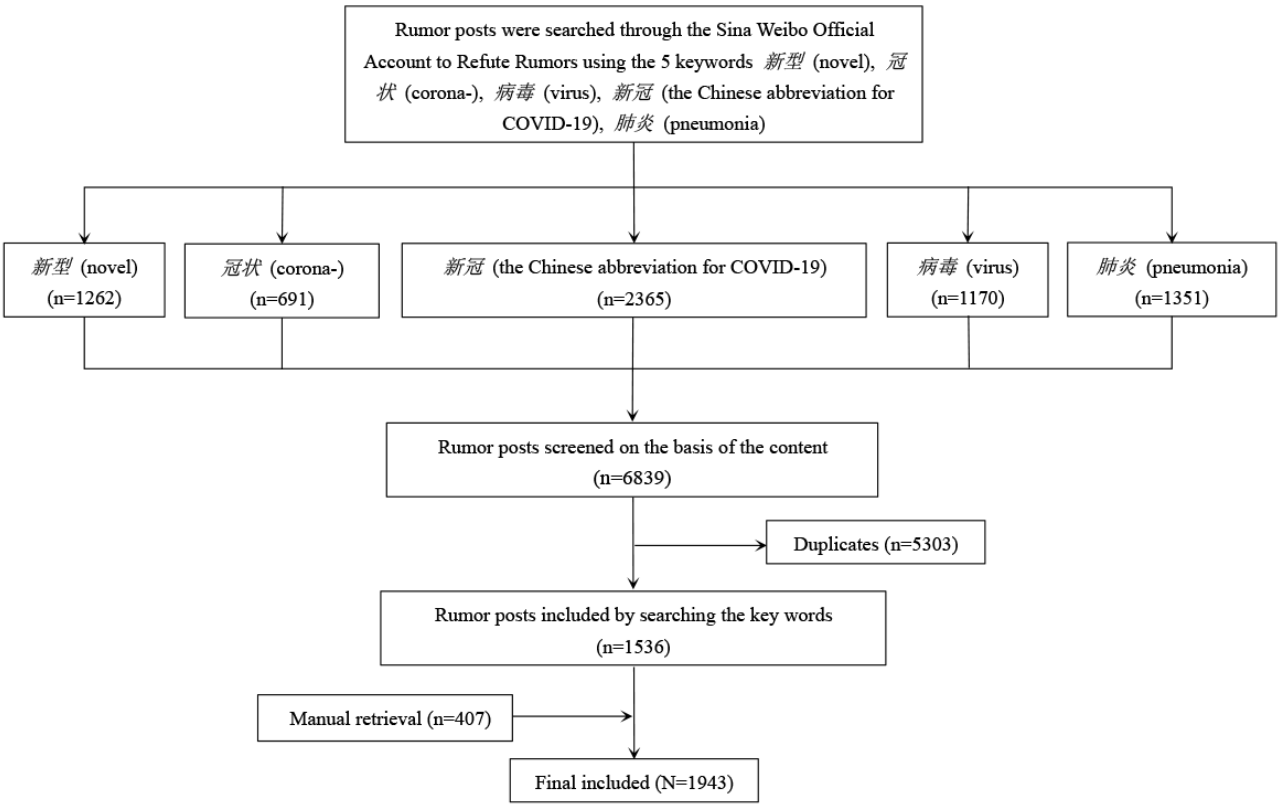
Methods

Data Sources

Between January 20, 2020 (the day the national authority first published the official announcement of human-to-human transmission of COVID-19), and April 8, 2020 (the day the lockdown was lifted in Wuhan), daily reports of identified and confirmed rumors and counterrumors of the COVID-19 outbreak were collected through the Sina Weibo Official Account to Refute Rumors (hereinafter referred to as "the Rumors on Weibo account") [19]. Launched in 2010, this account has been dedicated to rumor-busting and has now become one of the largest accounts in China, with more than 2.16 million registered users and subscribers; it contains a massive amount of information collected from most official platforms, such as the Chinese National Platform to Refute Rumors, WeChat Disinformation Platform, internet media, and web pages of government authorities, to refute rumors. Each post in the Rumors on Weibo account contains a rumor message and related rumor-refuting information.

During the first week of the study period (January 20-27), a small sample of 311 rumor messages was collected via the Rumors on Weibo account, and word frequency analysis was performed on these messages. After a panel discussion, 新型 (novel), 冠状 (corona-), 病毒 (virus), 新冠 (the Chinese abbreviation for COVID-19), and 肺炎 (pneumonia) were selected as the 5 keywords according to their frequency in the rumor posts. A total of 6839 disinformation messages were retrieved on the Rumors on Weibo account based on these keywords during the whole study period, of which 5303 were duplicated; eventually, 1536 rumor messages related to the epidemic were included. Meanwhile, other rumor posts not containing the above keywords were reviewed manually in the Rumors on Weibo account each week. A total of 407 relevant rumor messages, not containing the above 5 keywords, were also retrieved and added to the database (Figure 1). The initial posting time, title, posting platform, geographic location, format of each rumor, rumor-refuting time, and number of retweets of each rumor post were extracted and entered into the database. All the information obtained on the web was in simplified Chinese language and released publicly by the websites; however, no personal identification information was collected.

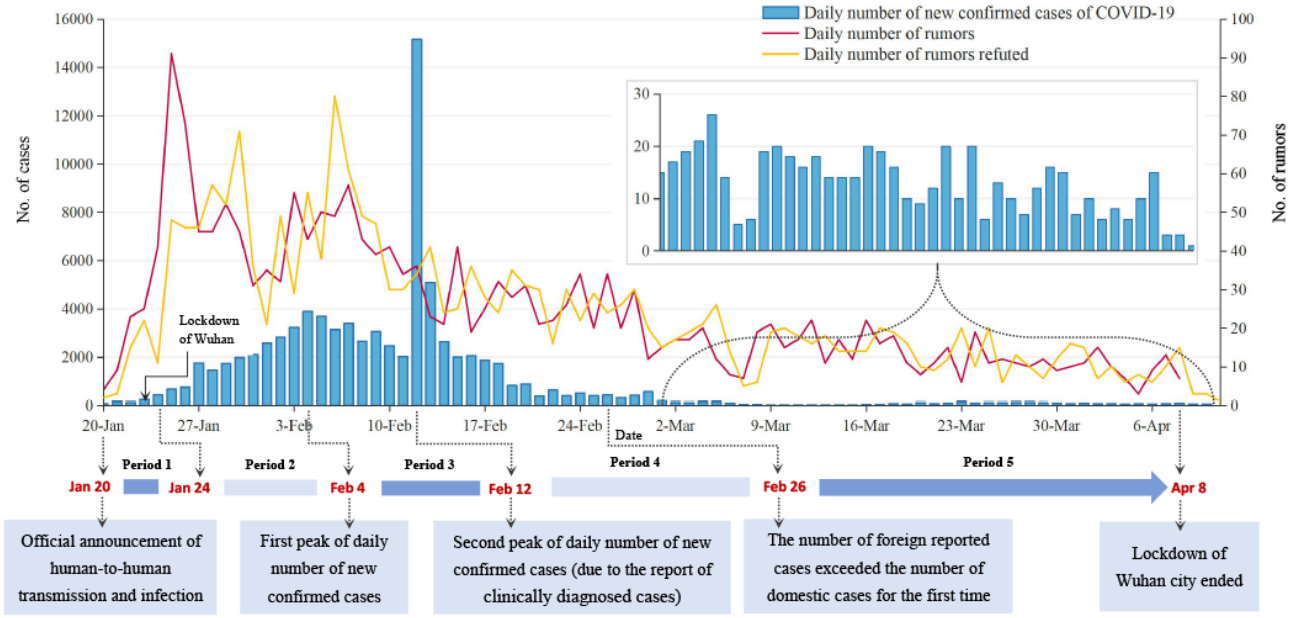
Figure 1. Flowchart of the selection of rumor posts.



Classification of the Five Time Periods

To better reflect the dynamics of the spread of rumors, five time periods were classified based on key events of the disease epidemic that could affect the dissemination of rumors on the internet (Figure 2). The time period between January 20, 2020 (the date of the first official announcement of human-to-human transmission and infection of SARS-CoV-2), and January 24, 2020, was taken as the first period in this study [20]. During this period, the National Health Commission issued a bulletin that COVID-19 had been incorporated into the management of the Prevention and Control of Infectious Diseases Act [21], and many local governments had launched first-level responses in the face of the outbreak. On January 23, the Wuhan government blocked all outbound transportation from the city with traffic suspension and home quarantine within the city [22]. The second period was January 24 to February 4; during this time, the number of new confirmed cases in China was gradually rising, and it reached its highest daily increase on February 4 [23]. From February 5 to February 12 (the third period), there was a steady decrease in the daily report of new confirmed cases. However, the secondary peak of the case numbers was reached on February 12 due to reports of clinically diagnosed cases [24]. From then until February 26 (the fourth period), the domestic epidemic gradually declined; meanwhile, foreign cases surpassed the domestic numbers for the first time by February 26. The fifth period was February 27 to April 8, when the domestic epidemic situation continued to decline and the epidemic situation in Wuhan gradually improved. On April 8, Wuhan government announced that the lockdown of the city had ended [25].

Figure 2. Daily numbers of rumors detected and refuted, the epidemic curve, and key events across five periods of the COVID-19 outbreak in China. The inset shows a magnified view of the number of COVID-19 cases over the last two periods.



Classification and Definition of Information Sources for Rumors

The rumor information sources were divided into the following categories according to their original publishing platforms: chat tools, Weibo, web pages, and others. Chat tools included WeChat and Tencent QQ. Both of these tools are major social media platforms in China that enable people to chat, communicate, and post events or opinions that others can comment on. If a rumor was first published on Weibo, the Twitter-like platform, which enables users to repost or comment, its information source was classified as Weibo. Web pages represented a number of rumors published in the form of web links. “Others” indicated some platforms that could not be classified in any of the above categories, including several mobile apps, such as TikTok, and platforms on which the source of the rumor could not be traced.

Classification and Definition of Rumor Refuters

According to the level of representativeness and influence, the rumor refuters were divided into three main categories: national, local, and other. “National” indicated that the official accounts of the rumor refuters were set up by national departments or institutions for publishing official state news or policies. Accounts established by relevant local agencies for publishing local news were classified as local, and other accounts that could not be classified in either of the above categories were classified as others; these users mainly included certified individual accounts, foreign accounts, and certified accounts of nonstate, nonlocal business firms. Meanwhile, based on the essential attributes and affiliations of different rumor refuters, all of them were further classified as government authorities, news media, and organizations, companies, or individuals. All data were classified based on the classification criteria outlined by two researchers. A third reviewer discussed the different classifications with the two reviewers and finalized the categorization. Some sample accounts are listed in Table 1.

Table 1. The criteria of the categories for the rumor refuters and the sample accounts.

Category of rumor refuter	Definition	Sample accounts
Level of representativeness and influence		
National	Official accounts set up by national departments or institutions for publishing official state news or policy	• CCTV News • Chinese National Platform to Refute Rumors • China Science Communication
Local	Accounts established by relevant local agencies for publishing local news	• Wuhan Release • Nanjing Release • Shanghai Customs
Others	Accounts that could not be classified into the categories above	• Alipay • Doctor Guan
Essential attributes and affiliations		
Government authorities	Official accounts established by government departments for the publication of government-related information	• Wuhan Release • Fuyang Health Committee • Jiangxi Public Security Department
News media	Official accounts of news media websites	• CCTV News • Wuhan Daily News • People's Daily
Organizations/companies/individuals	Accounts of some nongovernmental organizations and corporate and individual accounts.	• Beijing Public Transportation group • Ding Talk • Alipay

Analysis of Most Frequently Appearing Words in Rumors

Rumor word frequency analysis was carried out using Python version 2.7. The jieba package was employed as a text analysis tool for processing the core message of each rumor. The core message of every rumor in our study was summarized by the Rumors on Weibo account, which captured the main point of the content of the entire rumor well. Additionally, the rumors presented in the forms of images, videos, and audio were also translated by extracting the core message of that rumor through the official rumor-refuting account. Accordingly, all the rumor information in this study consisted of brief textual sentences. First, the spaces and newlines were removed from the text; then, all the punctuation marks in the text were replaced with spaces. The processed text was partitioned using the jieba package, and stop words such as "have," "is," "will," "can," and "have been" were removed from the text according to a predefined list of deactivated words. After the data set was created, a corpus of rumors was formed.

Based on the collection and classification of the rumor corpus obtained by preprocessing, the lists of words were filtered and merged according to an expert's opinion, and the data set of rumor features was finally obtained. The weight of every term was calculated using the term frequency–inverse document frequency (TF-IDF) method using the equation below:

The formula is divided into two parts; $(f_k d_k)$ to the left of the equal sign represents the word frequency, which is the number of times a word appears in the text. The higher the number of occurrences of a word, the greater the role it plays in the text. In contrast, $(f_k d_k)$ to the right of the equals sign is the logarithm value of the inverse document frequency. T represents the number of texts in the corpus, and $T(f_k)$ indicates the number of texts containing specific terms in the corpus.

The word cloud of rumors about COVID-19 during the whole study period was visualized using the wordcloud package; moreover, the summary of the top 20 high-frequency keywords of the rumors based on the term frequency–inverse document frequency (TF-IDF) values over each period was used to analyze the changes in the same keyword at different stages, which may further reflect the shifts in the public's focus.

Statistical Analysis

Excel (Microsoft Corporation) was used to record and sort information about the rumors. The epidemic curve, daily number of rumors released and clarified, new confirmed cases of COVID-19, and key events across the five periods were plotted to comprehensively analyze the relationship between the epidemic and the public's focus at different stages. Descriptive analysis of the basic information of the rumors was conducted using SPSS for Windows, version 24.0.0 (IBM Corporation). The geographic distributions of rumor sources and refuters were graphed using the pyecharts package in Python version 2.7. In addition, the cumulative number of cases and rumors in each province was calculated. The Pearson chi-square test and Fisher

exact test were performed to compare different characteristics of the rumors by each category across the five periods. The Spearman rank correlation coefficient was used to explore the relationship between the number of rumors and the epidemic trends if the variables did not satisfy the normal distribution. *P* values were 2-tailed, with statistical significance set at .05.

Results

A total of 1943 rumors were collected from the Rumors on Weibo account in this study between January 20 and April 8, 2020.

Characteristics of Rumors According to the Five Periods

The numbers of rumors published across the periods were 102, 547, 349, 377, and 568, respectively (Table 2). Rumors in the form of texts were predominant (1241/1943, 63.9%), accounting for more than half of the rumors in each time period, followed by rumors in a combination of two or more formats (330/1943, 17.0%). Among the rumor-spreading platforms, chat tools were the most common (1412/1943, 72.7%), with 1386/1943 rumors circulating in WeChat, accounting for the vast majority (98.2%). The proportions of the 1943 rumors circulating from Weibo (n=180, 9.3%), web pages (n=162, 8.3%), and other platforms (n=189, 9.7%) were similar. Additionally, 19.4% (376/1943) and 79.1% (1537/1943) of the rumors were refuted by national and local agencies, respectively. Most rumors were clarified by relevant government authorities (1250/1943, 64.3%), followed by the news media (628/1943, 32.3%).

The epidemic curve and daily number of posted and refuted rumors graphed according to the key events are illustrated in Figure 2. Spearman rank coefficient analysis showed that the daily number of posted rumors was positively associated with the daily number of new confirmed cases (Spearman rank correlation coefficient 0.73, $P<.001$). The median of the response interval between the time when the rumors were initially published and debunked was 1 day, with an IQR of 1-2. Most rumors detected were mainly concentrated between January 24 and February 7, while the majority of the refuting posts were concentrated between January 25 and February 9, with the highest daily reports of posting and refuting rumors occurring on January 25 (n=91) and February 6 (n=80), respectively.

Table 2. Characteristics of rumors across five periods during the outbreak of COVID-19 in China (N=1943).[a] $P<.001$ for all categories.

Characteristic	Time periods (2020)					Total (N=1943)	χ^2 (*df*)
	Jan 20-24 (n=102)	Jan 25-Feb 4 (n=547)	Feb 5-12 (n=349)	Feb 13- 26 (n=377)	Feb 27-Apr 8 (n=568)

[a]The five periods were classified based on key events and the disease epidemic that could affect the dissemination of rumors on the internet from January 20 to April 8, 2020.

[b]Multimedia: video, audio, and news reports.

[c]Combination: two or three formats were combined to disseminate rumors.

[d]Chat tools: WeChat and Tencent QQ.

[e]Others: other platforms that could not be classified in any of the above categories, including several mobile apps such as TikTok, and platforms that could not be traced back.

Characteristics of Rumors on Different Posting Platforms

A comparison of the 1943 rumors categorized by rumor-posting platform is shown in Table 3. Text (1241/1943, 63.9%) was the most common rumor format across different posting platforms, while the image format (114/1943, 5.9%) had the lowest percentage of all rumors. In addition to the texts, there were more rumors disseminated in a combination of formats on Weibo (60/180, 33.3%), while web pages (54/162, 33.3%) and others (42/189, 22.2%) tended to be the initial publishing platforms for rumors in multimedia format. Pearson chi-square tests indicated that there were statistically significant differences in the formats of rumors classified by platform ($\chi^2_9=142.6$, $P<.001$). Local agencies played a large role in dispelling rumors on the rumor-spreading platforms. The rumor refuters of government authorities and news media worked in tandem and complemented each other, and together they dispelled approximately 90% of the rumors on every platform. Fisher exact tests and Pearson chi-square tests suggested that the types of rumor refuters were significantly different across the platforms ($P<.001$).

Table 3. Comparison of different rumor posting platforms between January 20 and April 8, 2020 (N=1943). *P*<.001 for all categories.

Classification	Initial platform of rumor posting, n (%)					
	Chat tools[a] (n=1412)	Weibo (n=180)	Web pages (n=162)	Others[b] (n=189)	Total (N=1943)	χ^2 (*df*)

[d]Combination: two or three formats were combined to disseminate rumors.

[e]N/A: not applicable (*P* value was calculated using Fisher exact test).

Geographic Distribution of Rumor Sources and Refuters

The cumulative numbers of confirmed cases of COVID-19 and rumors generated by province across China as of April 8, 2020, are visualized in Figure 3. The internet rumors spread more actively in the southeast regions. In particular, Hubei Province and its surrounding areas showed the highest numbers of both confirmed cases and rumors in the country. The cumulative number of confirmed cases in Guangdong Province as of April 8 was ranked second in the country, whereas rumor generation in that province was relatively low. Conversely, although Guangxi Province had fewer cases, its number of rumors was among the highest nationwide.

The geographic distributions of the rumor sources and their corresponding refuters are graphed in Figure 4, where the arrow symbols indicate rumor-refuting locations. Beijing and Wuhan were the two main hubs of disinformation refuting during this stage of the COVID-19 epidemic. In Guangdong Province, where the epidemic was relatively severe, more rumors were refuted than spread. Except for the rumors that were clarified locally, rumors circulating within the provinces were often officially refuted by the provincial governments.

Figure 3. Cumulative numbers of confirmed cases of COVID-19 and rumors in each region of China as of April 8, 2020.

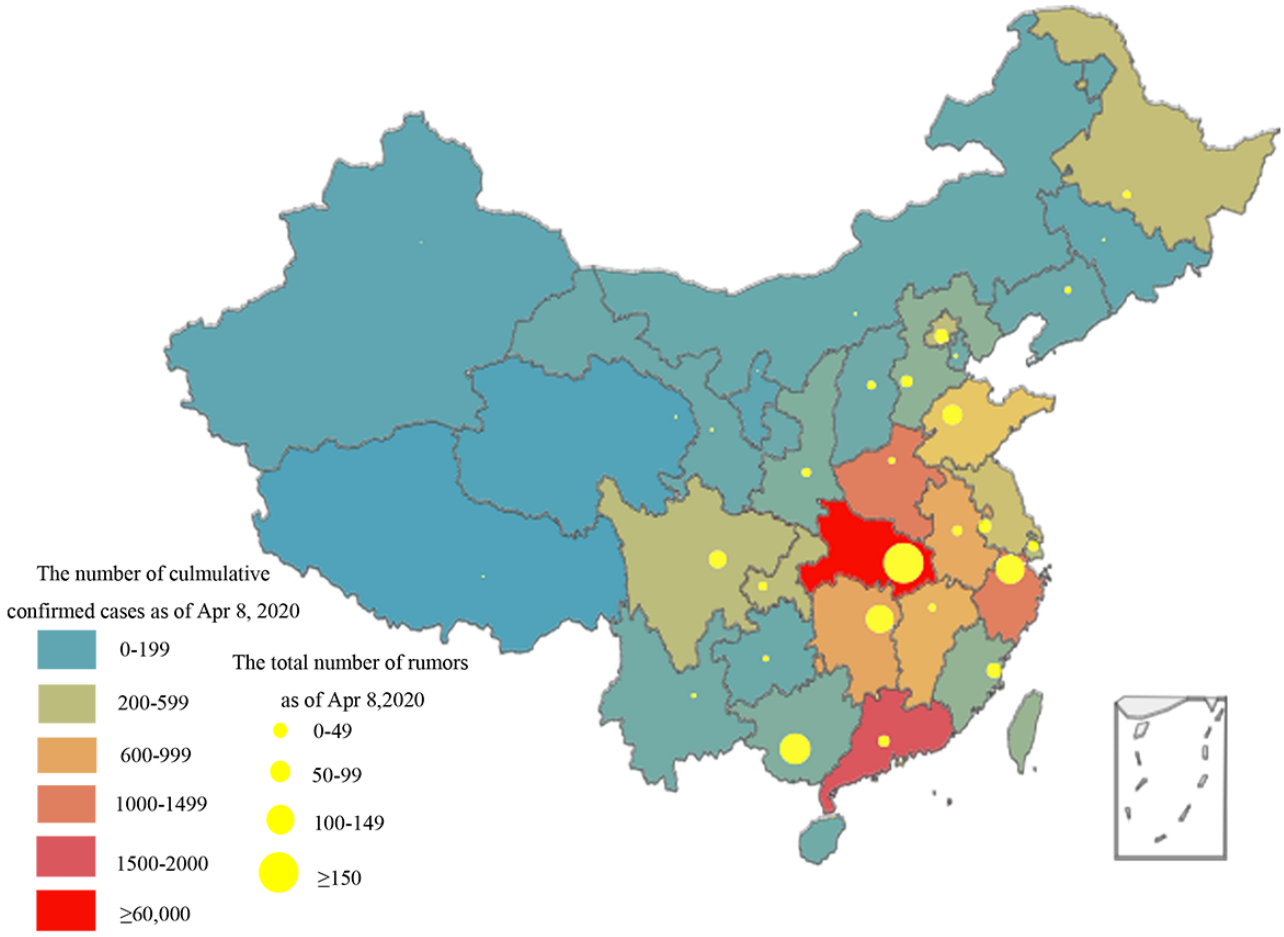

Figure 4. The geographic distributions of rumor sources and refuters during the outbreak of COVID-19 between January 20 and April 8, 2020, in China.

General Focus and Frequent Words of Rumors During the Five Phases

The top 100 most frequent words of the core messages of the rumors throughout the study period and different phases of the outbreak are depicted in Figure 5 (also see Multimedia Appendix 1 for a description of the evolution trends of the top 10 most frequent words, excluding the search keywords, at different periods during the outbreak). The average length of the textual rumors was nearly 19 characters. Overall, 冠状病毒 (coronavirus) and 肺炎 (pneumonia) were the two most common words included in the rumor core message. A majority of the words, such as 病毒 (virus), 新型 (novel), 新冠 (the Chinese abbreviation for COVID-19), and 病例 (case), were associated with COVID-19. In addition, 武汉 (Wuhan), 医院 (hospital), 小区 (residential areas), as terms related to specific locations were also frequently found in the rumors. Meanwhile, some words describing epidemic prevention and control, such as 口罩 (mask), 消毒 (disinfection), and 隔离 (quarantine), were often seen.

Figure 5. The top 100 most frequent words in the core messages of rumors during the outbreak of COVID-19 in China: (A) during the whole study period, (B) from January 20-24, 2020, (C) from January 25 to February 4, 2020, (D) from February 5-12, 2020, (E) February 13-26, 2020, and (F) from February 27 to April 8, 2020.

More details of the top 20 words listed according to their TF-IDF values in the major rumor messages over different periods are presented in Table 4. The top 5 words in the first and second periods were the same. However, the TF-IDF value of each of these words was different; the values in the first stage were higher than those in the second stage. By the third period, 网传 (sourced from internet) had become the top word, while the words 消毒 (disinfection) and 口罩 (mask) had replaced 武汉 (Wuhan) and 感染 (infection) as the fourth and fifth most common words, respectively. In contrast to similar rumors about the epidemic at the other stages, disinformation related to 开学 (schools reopen) began to grow during the fourth and fifth periods. Moreover, as the outbreak of COVID-19 increased outside China, rumors of foreign epidemic situations increased as well.

Table 4. The top 20 keywords in rumors across five periods during the outbreak of COVID-19 in China.[a]

Rank[b]	Time periods (2020)

[a]The five periods were classified based on key events and the disease epidemic that could affect the dissemination of rumors on the internet from January 20 to April 8, 2020.

[b]Keywords are ranked according to the TF-IDF values of the words from high to low.

[c]TD-IDF: term frequency–inverse document frequency.

Discussion

Principal Findings

Based on the official Sina Weibo rumor-refuting platform, nearly 2000 rumors that spread over the internet during the COVID-19 epidemic in China between January 20 and April 8, 2020, were investigated. This is the first domestic research to analyze the distribution, characteristics, spreading trend, and most frequent words of rumors related to the epidemic situation, which will be propitious to provide a scientific reference for the prevention and control of network rumors during unexpected events in the future.

During the study period, the median of the response interval was 1 day, indicating the timeliness of the rumor-refuting measures conducted by the Chinese government during the COVID-19 outbreak. In general, the number of rumors and refuted rumors in the first and second periods of the epidemic showed rapid growth, while both showed fluctuating declining trends in the latter three periods. Notably, after the announcement of the Wuhan lockdown, the rumor posts reached their first peak within three days, suggesting that the rapid rise in the number of rumors over the early period has a strong link with the emergence of landmark events. At this stage, due to the sudden outbreak of COVID-19, the etiology and trend of the disease were totally unclear, and the monitoring mechanism for identifying and refuting disinformation had not yet been perfected; thus, the old rumors were not quickly clarified, while new rumors appeared in rapid succession [26]. The new and old rumors intertwined to reach the peak of rumor growth, obfuscating the truth and increasing the difficulty of epidemic prevention and control [27]. By the middle of the epidemic period, most people had developed a preliminary understanding of the disease after obtaining more official information. At this stage, the rumors were less related to symbolic events and were mainly affected by the trend of the epidemic situation, fluctuating with the increase or decrease in the number of cases. Finally, by the time the disease was under control, most people had grasped a more rational understanding of the situation, with the anxiety and tension over the uncertainties greatly alleviated, leading to a decrease of the number of rumors and their corresponding clarifications. Therefore, the early stages of public emergencies, especially new infectious diseases, are the critical period for web-based surveillance of public response, risk communication, and timely release of information from credible sources, as reflected in a study on avian influenza A (H7N9) [28]. Moreover, risk communication will promote community engagement, decrease rumors to maintain social stability, and reduce threats to public health [29]. Intensive information communication with reference to hot topics of rumors may buy time to control outbreaks and reduce the risk of transmission to humans [30,31]. Additionally, transparent sharing of information in time, particularly of adverse information, and projecting uncertainty explicitly are integral parts of the management of large-scale epidemics and other emergencies [32]. Moreover, during the period of steady decline, continuous internet surveillance of rumors is still required.

Different characteristics of the rumors were analyzed in this study; it was found that internet rumors in the early stage of the epidemic were mainly disseminated in text format, most commonly in the WeChat chat tool. More processed and visualized rumors (eg, in the formats of pictures and multimedia) emerged over the later stages, while the number of rumors increased on other platforms, such as Weibo and web pages. The difference in the main formats of rumor dissemination among different platforms may be related to the openness and information screening mechanisms of each platform. In recent years, WeChat has rapidly become the main social platform in China due to its convenience and accessibility. Compared to other social media, WeChat is a social tool based on realistic relationships and closed-loop communication in a relatively private space, implying the reliability and authenticity of information and invisibly increasing the influence of rumors [33,34]. Therefore, when false news circulates, WeChat lacks self-correction ability due to the trust among acquaintances, and it is also more difficult to completely convince WeChat users that a rumor is false even with rumor-dispelling messages on the internet. However, Weibo and web pages are more open and diverse; uncertain information can be questioned, corroborated, corrected, and supplemented through user-produced content, constantly discarding false information and approaching the truth in positive interactions [35,36]. Moreover, Weibo has established an increasingly comprehensive account for refuting rumors [19]. Eventually, through the questioning of netizens, inaccurate information is replaced by the truth. In recent years, WeChat and other platforms have also taken measures to combat rumors [37]. However, the dissemination of refuting information on WeChat is restricted, mainly because it cannot reach the level of interpersonal communication, leading to small-scale transmission; thus, it can only continue to be shown “to people who do not believe rumors” [38]. Thus, a more comprehensive mechanism to encourage the dissemination of rumor-dispelling information should be developed by relevant departments in the future, accelerating the spread of credible information on WeChat and extending the influence of these departments at the same time.

Analysis of the refuters of rumors showed that during the initial outbreak of COVID-19, rumors were likely to be more nationally focused because they were relatively few in number, and the national-level rumor refuting agencies played a stronger role. When the rumors gradually started spreading locally, local authorities increased their rumor-refuting efforts; combined with the increasing enhancement of self-purification of social media, this eased the pressure on government agencies [28]. Similarly, due to the small scope and influence of rumor spread in chat tools, most were clarified by local government authorities. In contrast, rumors circulating in Weibo elicited more involvement and intervention from higher-level authorities, indicating a larger impact. These findings highlight the significance of coordinating the roles of central and local agencies in the establishment of mechanisms for refuting rumors, improving the feedback mechanisms, and maximizing the self-purification ability of social media.

According to the distribution map of the rumors, Hubei Province was the most active area for rumor breeding, which may be

related to its highly severe epidemic situation. In this study, locations with more cases were likely to generate more rumors, mainly including cities around Hubei, such as Zhejiang and Hunan. However, rumors also circulated in larger quantities in provinces with lower case numbers, such as Guangxi. Accordingly, the timely identification of rumors in regions less affected by public health emergencies is of equal importance to constant internet surveillance in areas that are more severely affected. The cross-regional rumor-refuting plot shows that Beijing was the critical center for rumor clarification. Shanghai and the provincial capitals of Guangzhou, Hunan, Sichuan, and Zhejiang also played vital roles in dispelling rumors during the epidemic, reflecting to some extent that large cities are political and media centers [39].

The high-frequency words in different periods indicated that in the pre-epidemic period, the rumors were mainly related to the disease itself, with numerous descriptions of COVID-19 contained in the core message of the rumors. In the middle of the epidemic, the rumors gradually began to be associated with prevention and control measures due to the official announcement of epidemic initiatives published by departmental agencies. When the domestic epidemic had been effectively controlled, false information about measures such as school reopening and traffic resumption spread across each region, suggesting that people gradually paid more attention to information related to policy adjustment during this period compared to the previous stages [26]. The word 网传 (source from internet) was frequently included in the titles of rumors. The word 确诊 (confirmed diagnosis) continued to appear frequently across different periods, even when the number of daily new confirmed cases had decreased since the third period. Further, when the words 确诊 (confirmed diagnosis) and 病例 (case) were combined in a rumor, the title usually took the form of “multiple cases have been confirmed in a certain place”; thus, the rumors were in a “storytelling” form that was immersive and highly convincing to readers. Such rumors have also been reported in other studies on infectious diseases [28], providing a reference for accurate identification of rumors in the future.

Limitations

There were several limitations to this study. First, this study was a retrospective analysis based on information extracted from an official rumor-refuting account, and it was difficult to avoid omitting some detailed information. In some cases, we could not trace or confirm the platforms or geographic locations where the rumors were initially published. Second, because the information of rumors in this study was refined, the emoticons and function words in the original text were not addressed; this could be considered in future research. Third, not all the rumors could be refuted on this account; instead, the most socially influential rumors were included, which could lead to information loss from the less influential rumors.

Conclusions

Our findings indicate the significance of timely management of and responses to internet rumors during major public crises. In this wave of the COVID-19 outbreak, authorities have taken effective measures to quickly dispel rumors; however, more effort could be made to better address the rumors. WeChat and other chat tools were found to be the most common origins of rumors, suggesting that the early detection and debunking mechanisms of rumors should be strengthened in closed-loop communication environments. In the early stages of the event, authorities should focus on rumors in the form of texts but should also pay more attention to other forms such as multimedia as the event progresses. The words most frequently included in the core messages of the rumors varied over different periods, which may be related to the disease itself, prevention and control measures, and social recovery; this highlights that targeted policy adjustments and timely release of official information in different phases of the outbreak should be required to prevent dissemination of internet rumors. Spread of rumors across borders needs to be controlled regardless of the intensity of the epidemic in the area. Local and national authorities should strengthen joint communication and collaboration in refuting rumors and establish a cooperative refuting mechanism based on the division of functions.

Abstract

Background: It has been widely communicated that individuals with underlying health conditions are at higher risk of severe disease due to COVID-19 than healthy peers. As social distancing measures continue during the COVID-19 pandemic, experts encourage individuals with underlying conditions to engage in telehealth appointments to maintain continuity of care while minimizing risk exposure. To date, however, little information has been provided regarding telehealth uptake among this high-risk population.

Objective: The aim of this study is to describe the telehealth use, resource needs, and information sources of individuals with chronic conditions during the COVID-19 pandemic. Secondary objectives include exploring differences in telehealth use by sociodemographic characteristics.

Methods: Data for this study were collected through an electronic survey distributed between May 12-14, 2020, to members of 26 online health communities for individuals with chronic disease. Descriptive statistics were run to explore telehealth use, support needs, and information sources, and *z* tests were run to assess differences in sociodemographic factors and information and support needs among those who did and did not use telehealth services.

Results: Among the 2210 respondents, 1073 (49%) reported engaging in telehealth in the past 4 months. Higher proportions of women engaged in telehealth than men (890/1781, 50% vs 181/424, 43%; *P*=.007), and a higher proportion of those earning household incomes of more than US $100,000 engaged in telehealth than those earning less than US $30,000 (195/370, 53% vs 241/530 45%; *P*=.003). Although 59% (133/244) of those younger than 40 years and 54% (263/486) of those aged 40-55 years used telehealth, aging populations were less likely to do so, with only 45% (677/1500) of individuals 56 years or older reporting telehealth use (*P*<.001 and *P*=.001, respectively). Patients with cystic fibrosis, lupus, and ankylosing spondylitis recorded the highest proportions of individuals using telehealth when compared to those with other diagnoses. Of the 2210 participants, 1333 (60%) participants either looked up information about the virus online or planned to in the future, and when asked what information or support would be most helpful right now, over half (1151/2210, 52%) responded “understanding how COVID-19 affects people with my health condition.”

Conclusions: Nearly half of the study sample reported participating in telehealth in the past 4 months. Future efforts to engage individuals with underlying medical conditions in telehealth should focus on outreach to men, members of lower-income households, and aging populations. These results may help inform and refine future health communications to further engage this at-risk population in telehealth as the pandemic continues.

(J Med Internet Res 2021;23(2):e23795) doi:10.2196/23795

KEYWORDS

telehealth; telemedicine; coronavirus; COVID-19; chronic disease

Introduction

According to the Centers for Disease Control and Prevention (CDC), people with underlying medical conditions (eg, autoimmune disease, chronic respiratory disease, and cancer) are at greater risk of severe illness from COVID-19 than those without pre-existing conditions [1]. Experts have released multiple guidelines to protect the health and safety of at-risk communities during this pandemic, including instructions to socially distance, stay at home as much as possible, and avoid crowds [1-3]. For communities who must continue health care appointments and treatment regimens during the pandemic, telehealth, or electronic communication and information technologies to support health care [4], has been recommended as a feasible intervention to maintain continuity of care while adhering to social distancing and stay-at-home mandates [1,5-9]. Although telehealth use rapidly increased during the initial spread of COVID-19 [10,11], little information is available regarding telehealth uptake among high-risk populations with underlying medical conditions during this pandemic.

Thus, the purpose of this study is to describe the telehealth use, resource needs, and information sources of individuals with chronic conditions during the COVID-19 pandemic. Data for this study were collected from members of online health communities hosted by the digital publishing platform, Health Union, for patients with chronic conditions (eg, communities for those with migraines, lung cancer, chronic obstructive pulmonary disease, or rheumatoid arthritis) [12]. This paper also explores differences in telehealth use among sociodemographic characteristics to identify those who may be in most critical need of support. Given the importance of understanding an audience's response in health communication evaluation [13] and the fact that increased telehealth efforts are likely to continue both during and beyond the COVID-19 pandemic [11], the information included in this paper may play a helpful role in informing future efforts to engage patients in telehealth practices.

Methods

Data Collection

Data for this study were collected in an online survey distributed through Qualtrics Survey Software (Qualtrics International Inc) to members of 26 online health communities hosted by Health Union. Each community provides patients and caregivers a digital platform to learn about their diagnosis and both provide and receive social support from peers and health care providers [12]. Between May 12-14, 2020, the survey was emailed to 98,983 community members who had previously opted into receiving emails from Health Union. The study team also posted information about the survey on the online health community websites owned and operated by Health Union. To complete the survey, respondents had to be 18 years or older, living within the United States, aware of COVID-19, and diagnosed with one of 26 chronic conditions. The survey included 35 questions assessing telehealth engagement, health information sources and needs during this pandemic, concerns about COVID-19, self-reported chronic condition diagnoses, and demographic characteristics. In this survey, telehealth was defined as "virtual appointments with doctors that may take place over video chat." Upon completion, each participant was entered into a chance drawing to win one of one hundred US $25 e-gift cards.

Measures

Telehealth Engagement and Satisfaction

In this study, telehealth engagement was measured by asking participants to respond "yes" or "no" to the question "Have you had a 'virtual visit' (telehealth) with your doctor / healthcare professional in the past 4 months?" To further assess telehealth practices, participants were asked, "You may have heard about virtual appointments with doctors (sometimes called 'telehealth') that may take place over video chat. Which statements below about telehealth apply to you?" Participants then indicated all statements that applied to them from a list of eight items such as "My doctor has reached out to me about telehealth," "I am interested in telehealth but don't know how to use it," and "I started using telehealth (or will start) because of the pandemic." The full list of item responses can be found in Multimedia Appendix 1.

Among those who had participated in a telehealth visit in the past 4 months, satisfaction was assessed by asking participants to rate their agreement with the following three statements: "I had a positive experience using telehealth," "The technology was difficult to use," and "I feel like the virtual visit was just as good (or better) than an in-person visit." Responses were on a 7-point Likert scale (1=completely disagree to 7=completely agree); in these analyses, "agreement" with each statement was defined as selecting a 6 or 7, while "disagreement" was defined as selecting a 1 or 2.

COVID-19 Information Sources and Needs

COVID-19 Communications With a Health Care Team

To assess how individuals with underlying medical conditions have been gathering information about COVID-19, participants were first asked questions about pandemic-related interactions with their health care team. For example, participants were

asked, "In which of the following ways have you communicated with your doctor/healthcare team about the novel coronavirus (COVID-19)?" and prompted to choose from a list of eight item responses (eg, I reached out, my doctor personally contacted me, or we discussed it at a regular appointment). Among those who had communicated with their health care team, participants were asked, "How have you communicated with your doctor/healthcare professional?" (eg, by phone, portal, or email) and "What did you discuss with your doctor/healthcare provider?" (eg, deciding to temporarily stop or skip medications, monitoring for COVID-19 symptoms, or regular discussion or check-in about my current condition and symptoms). Participants were also asked "What, if anything, have you done – or are you planning to do in the near future -- in response to hearing about the novel coronavirus (COVID-19)?" Item responses included "cancel or postpone regular doctor/healthcare visits"; "have a 'virtual' visit with a doctor/healthcare professional – 'telehealth' – via video chat"; and other items related to health decisions, needs, and information seeking behavior. A complete list of item responses for each of these questions can be found in Multimedia Appendix 1.

Patient Concerns During the COVID-19 Pandemic

To assess patient concerns during the COVID-19 pandemic, participants were asked to indicate their agreement with a series of nine statements on a 7-point Likert scale (1=completely disagree to 7=completely agree). The full list of statements can be found in Multimedia Appendix 1, but examples included "Having a chronic health condition makes me feel particularly concerned about the coronavirus," "I feel like people are not taking the coronavirus seriously enough," and "I feel like I am taking all the right precautions to reduce my risk of getting coronavirus." Participants who reported currently or previously having cancer were asked to rate an additional statement: "Having (or having had) cancer makes me feel particularly concerned about the coronavirus." Agreement with each statement was again defined as selecting a 6 or 7, while disagreement was defined as selecting a 1 or 2.

Other COVID-19–Related Information Sources and Needs

To identify other sources this population has turned to for information during the pandemic, participants were asked, "What sources are you using to learn more about the novel coronavirus (COVID-19)?" and prompted to select all that apply from a list of 15 items (eg, internet search engines, social networking sites, or TV news reports). Finally, participants were asked to indicate the information or support that would be most helpful to them right now by selecting up to three choices from a list of 10 items such as "Information/guidance from my doctor about COVID-19 and my health condition/its treatment," "emotional and/or mental health support," and "Financial support for other necessities/bills (e.g., food, rent, etc.)." The full list of item responses can be found in Multimedia Appendix 1.

Demographic and Disease Characteristics

Participants were asked to indicate their age from a dropdown menu ranging from "Under 18" to "90 or older," with each age in between listed continuously (eg, 18, 19, 20, ...). Participants were also asked to indicate their residence type (ie, rural, urban, or suburban), gender, highest level of education attainment, annual household income, and primary health insurance from categorical lists of item responses (see Multimedia Appendix 1). Participants indicated their chronic condition by selecting all that apply from a list of 25 chronic conditions, or participants were able to respond "none of these." The full list of chronic conditions can be found in Multimedia Appendix 1, but examples include asthma, cystic fibrosis, Chron disease, migraines, and hypertension. Participants were also asked to indicate if they had been diagnosed with any from a list of nine types of cancer or "other" if they had been diagnosed with a cancer that was not listed.

Analyses

Descriptive analyses were conducted to assess telehealth use, resource needs, and information sources among all participants, and *z* tests were used to explore differences between demographic groups. To assess for meaningful differences between demographic groups, age and education were each categorized into three groups (<40 years, 40-55 years, and ≥56 years, and high school, GED [General Educational Development], or less than high school; college degree; trade or vocational training; and some college, graduate, or professional degree), and income was categorized into four groups (<US $30,000, US $30,000-US $54,999, US $55,000-US $99,999, and ≥US $100,000). *Z* tests were also used to explore telehealth use by diagnosis and patient concerns.

Results

Participants

Among those who received information about the survey via email (n=98,983), 1758 (1.8%) people completed it, and an additional 452 people participated after finding information about the survey on one of the health community websites. Of the 2210 total survey respondents, 81% (n=1781) were female, 68% (n=1500) were older than 55 years, and 87% (n=1920) completed at least some college or trade school. The most commonly reported chronic conditions were hypertension (n=863, 39%), hyperlipidemia (n=562, 25%), asthma (n=424, 19%), and migraine (n=420, 19%), and 98% (n=2164) of respondents reported having health insurance. Approximately 30% (n=660) of respondents reported either full- or part-time employment, and 3% (n=75) were currently seeking employment. The remaining respondents were retired (n=849, 38%), stay-at-home parents (n=71, 4%), on disability (n=456, 21%), unemployed and not looking for employment (n=81, 4%), or currently in school (n=18, 1%). Among respondents who reported household incomes (n=1877), the majority (n=1507, 80%) reported annual household incomes under US $100,000. Table 1 displays full demographic and disease characteristics of the study sample.

Table 1. Sample demographic and chronic condition diagnoses.

Demographic	Participants (N=2210), n (%)
Age (years)	
<40	224 (10.14)
40-55	486 (21.99)

Telehealth Engagement and Satisfaction

Among the 2210 survey respondents, 1073 (49%) respondents reported participating in a virtual visit (telehealth) with a doctor or health care provider (HCP) in the past 4 months, while 997 (45%) canceled or postponed regularly scheduled visits with their HCP, and 809 (37%) cancelled or postponed routine medical tests or planned to do so in the near future. Of those who used telehealth services (n=1073), 68% (n=725) agreed with the statement "I had a positive experience using telehealth." Furthermore, 39% (n=420) agreed that "the virtual visit was just as good (or better) than an in-person visit," but 14% (n=145) agreed with the statement "the technology was difficult to use."

As displayed in Figure 1, 40% (n=886) of the 2210 participants started using or planned to use telehealth options because of the COVID-19 pandemic, and 9% (n=194) reported engaging in telehealth options before the pandemic. Almost half of the participants (n=945, 43%) wanted to return to face-to-face appointments in the future, but 27% (n=591) reported a desire to use telehealth even after the pandemic subsides. Finally, 7% (n=162) of participants reported an interest in telehealth but did not know how to use it, while 4% (n=82) had never heard the term "telehealth," and 7% (n=162) reported no interest in using telehealth.

Looking at telehealth use by disease characteristics and patient concerns, patients with cystic fibrosis (n=33/47, 70%), lupus (n=55/82, 67%), and ankylosing spondylitis (n=60/91, 66%) recorded the highest proportions of patients using telehealth in the past 4 months when compared to patients with other diagnoses. When compared to those who did not engage in telehealth, higher proportions of those who used telehealth services reported feeling at higher risk of severe disease due to COVID-19 as indicated by agreeing with the statements "I feel like I am at a greater risk of getting coronavirus because of the medications I take" (341/1073, 32% vs 288/1137, 25%; *P*=.001) and "I feel like I am at a greater risk of having a more severe case of coronavirus because of my general health" (676/1073, 63% vs 659/1137, 58%; *P*=.02). Higher proportions of those who engaged in telehealth also agreed with the statements "Having a chronic health condition makes me feel particularly concerned about the coronavirus" (721/1024, 70% vs 698/1071, 65%; *P*=.01), "I am concerned that I may not have access to my medication/treatment in the future" (194/1073, 18% vs 153/1137, 13%; *P*=.003), and "I feel like people are not taking the coronavirus seriously enough" (646/1073, 60% vs 630/1137, 55%; *P*=.02). Figure 2 displays percentages of those who indicated various concerns by telehealth use status.

Figure 1. Participant's self-reported experience using telehealth (N=2210).

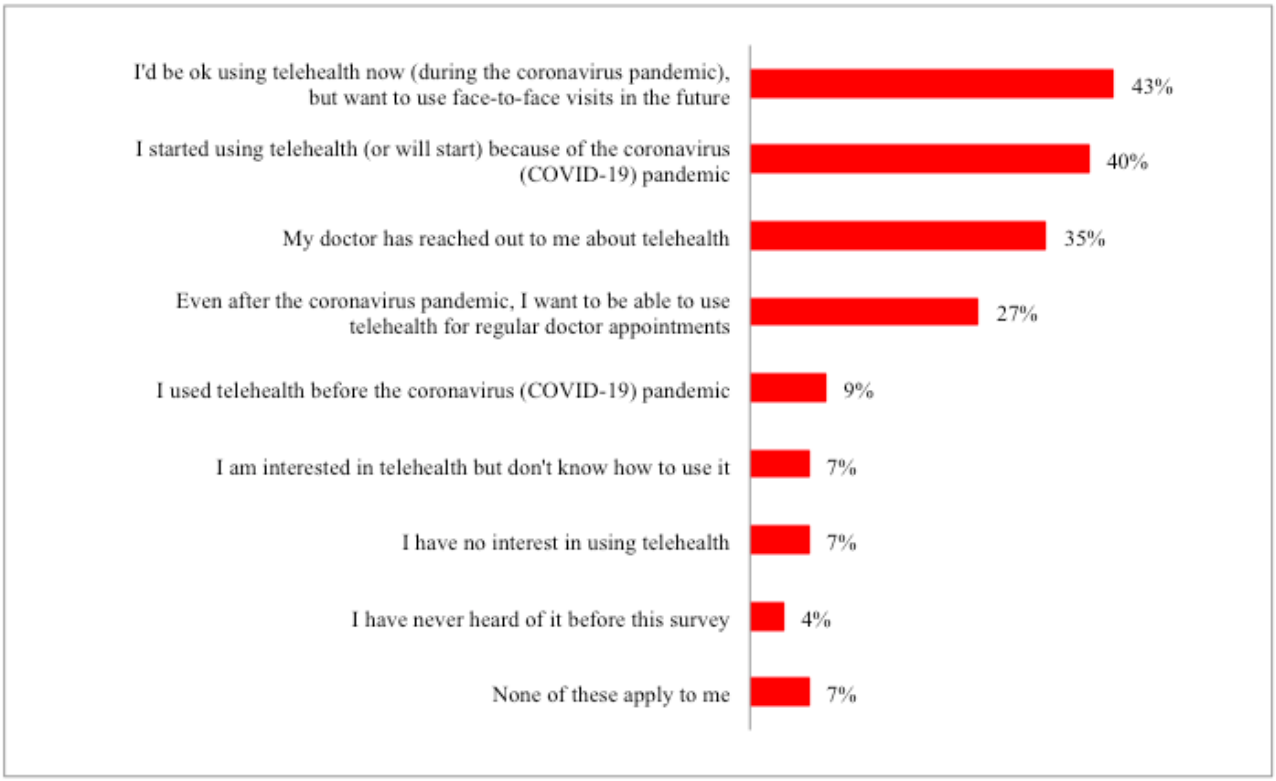

Figure 2. Participant concerns among those who used telehealth and did not use telehealth. *P<.05.

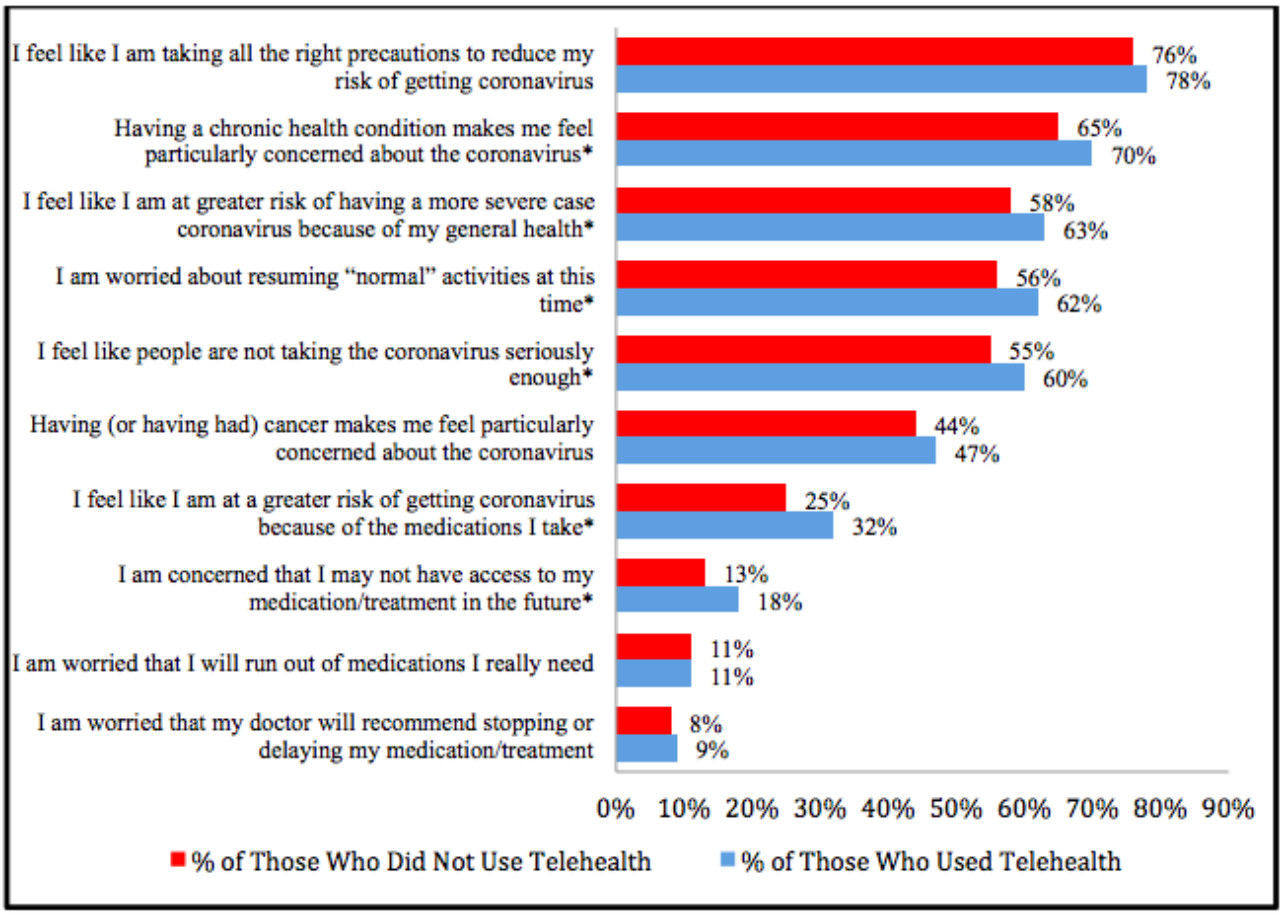

COVID-19 Information Sources and Needs

COVID-19 Communications With a Health Care Team

Of the 2210 participants, 72% (n=1592) reported communicating with their health care team about COVID-19 in some manner. A complete list of the ways in which this discussion was initiated is listed in Multimedia Appendix 2; however, the most highly endorsed responses were "I reached out via phone, online portal, etc." (n=800, 36%) and "My doctor's office sent out information and recommendations (via email, online portal, letter, social media" (n=602, 27%). The most common modes of communication among those who had spoken with an HCP about the virus were by phone (n=1183, 74%), in a telehealth appointment (n=705, 44%), and via online portal (n=680, 43%). Primary topics of these communications were decisions regarding treatment regimens (continuing as prescribed: n=933, 60%; changing: n=181, 12%; or temporarily stopping: n=119, 8%), regular check-ups (n=853, 55%), CDC COVID-19 guidelines (n=660, 42%), and decisions to cancel or delay upcoming appointments and surgeries (n=445, 29%). A complete list of topics discussed can be found in Multimedia Appendix 2.

Other COVID-19–Related Information Sources and Needs

HCPs were not the only source of information respondents turned to in response to hearing about COVID-19. When asked what sources respondents used to learn more about the virus, 63% (n=1389) selected TV news reports, 58% (n=1284) chose news websites, 57% (n=1268) turned to government websites, and 40% (n=892) reported retrieving information through search engines such as Yahoo or Google. In total, 60% (n=1333) of respondents reported that they either already looked up information online or planned to in response to hearing about COVID-19.

When asked what information or support would be most helpful right now, just over half of the survey respondents (n=1151, 52%) answered "understanding how COVID-19 affects people with my health condition," 48% (n=1071) indicated obtaining up-to-date and accurate information about the virus, 24% (n=538) selected emotional or mental health support, and 22% (n=485) indicated that receiving information from their HCP about COVID-19 and their health condition would be helpful. Additionally, 19% (n=412) indicated a need for financial support for life necessities such as food and rent. Significantly higher proportions of those who engaged in telehealth indicated a need for the following types of support than those who did not engage in telehealth: information from the company who makes my medications about COVID-19 and the treatment I take (126/1073, 12% vs 94/1137, 8%; *P*=.006), emotional or mental health support (292/1073, 27% vs 246/1137, 22%; *P*=.002), and financial support for medications and health care costs (167/1073, 16% vs 132/1137, 12%; *P*=.007). Finally, 16% (n=359) of the 2210 respondents indicated no need for additional information or support.

Demographic Comparisons

In this section, we highlight notable trends and differences in telehealth engagement, satisfaction, information sources, and needs between members of various demographic backgrounds. A full list of comparisons can be found in Multimedia Appendix 2.

Telehealth Engagement and Satisfaction

When looking at telehealth engagement across sociodemographic categories, a higher proportion of women engaged in telehealth than men (890/1781, 50% vs 181/424, 43%; *P*=.007), and a higher proportion of those earning household incomes over US $100,000 engaged in telehealth more than those earning less than US $30,000 (195/370, 53% vs 241/530, 45%; *P*=.03). The proportion of those engaging in telehealth also increased across educational attainment levels, such that a greater percentage of those who completed at least some college or trade school engaged in telehealth than those who completed high school or below (706/1454, 49% vs 114/290 39%; *P*=.004), and a greater percentage of those who completed an advanced degree engaged in telehealth than those who completed college or trade school (253/466, 54% vs 706/1454, 49%; *P*=.03). Although 59% (133/224) of those younger than 40 years and 54% (263/486) of those aged 40-55 years used telehealth, a smaller proportion of aging populations did so, with only 45% (677/1500) of individuals 56 years or older reporting telehealth use (*P*<.001 and *P*=.001, respectively). Telehealth use did not significantly differ across residence types (rural, suburban, or urban).

Higher proportions of female telehealth users found the virtual visit to be just as good or better than an in-person visit compared to males (360/890, 40% vs 58/181, 32%; *P*=.04), and a higher proportion of those with a high school degree or below also found the virtual visit to be just as good or better than an in-person visit compared to those with advanced degrees (54/114, 47% vs 91/253, 36%; *P*=.04). When comparing telehealth satisfaction among various income groups, higher percentages of those with lower household incomes (<US $30,000: 100/241, 41%; US $30,000-US $54,999: 86/208, 41%; and US $55,000-US $99,999: 108/266, 41%) also found the virtual visit to be just as good or better than an in-person visit when compared to those earning over US $100,000 annually (59/195, 30%; all *P*=.02). A greater percentage of individuals with advanced degrees disagreed with the statement "the technology was difficult to use" (184/253, 73%) compared to those who reported lower educational levels (at least some college or trade school: 441/706, 62%; *P*=.003; high school or below: 69/114, 61%; *P*=.02). Finally, a greater percentage of those in suburban areas also disagreed with this statement compared to those living in urban areas (372/549, 68% vs 135/224, 60%; *P*=.047).

A significantly larger proportion of those who were 56 years or older reported no interest in using telehealth (128/1500, 9%) compared to younger age groups (25/486, 5% of those aged 40-55 years; *P*=.02; 9/224, 4% of those younger than 40 years; *P*=.02) and desired to return to in-person appointments after the pandemic (675/1500, 45% vs 192/486, 40% of those aged 40-55 years; *P*=.03; and 78/224, 35% of those younger than 40 years; *P*=004). Higher proportions of those 56 years or older also rated the technology difficult to use (107/677, 16%, compared to 12/133, 9% of those younger than 40 years; *P*=.04; and 26/263, 10% of those aged 40-55 years; *P*=.02), but there were no

significant differences between age groups in their agreement with the statement "I feel like the virtual visit was just as good (or better) than an in-person visit." Furthermore, a larger percentage of the older age group were also interested in telehealth but did not know how to use it (125/1500, 8% vs 27/486, 6% of those aged 40-55 years; *P*=.045, and 10/224, 4% of those younger than 40 years; *P*=.04).

COVID-19 Information Sources and Needs

COVID-19 Communications With a Health Care Team

When looking at engagement with a health care team regarding COVID-19 information sources and needs, it may be notable that smaller proportions of those who earned a high school degree or less reported that their doctor's office sent out information and recommendations about the virus when compared to peers who reported higher educational attainment (53/290, 18% vs 397/1454, 27% of those who completed at least some college or trade school; *P*=.001; and 152/466, 33% who held an advanced degree; *P*<.001). Similarly, smaller proportions of individuals with household incomes under US $30,000 (134/530, 25%) and between US $30,000 and US $54,999 (109/428, 25%) reported such a distribution of information compared to those earning at least US $100,000 (122/370, 33%; *P*=.01 and *P*=.02, respectively). Furthermore, higher proportions of those younger than 40 years (113/224, 50%) and between 40 and 55 years (211/486, 43%) reached out to their HCP than those older than 55 years (476/1500, 32%; both *P*<.001). Even when meeting with an HCP, a smaller percentage of those older than 56 years discussed monitoring for COVID-19 symptoms (140/1039, 13% vs 63/350, 18% of those 40-55 years; *P*=.04; and 36/171, 21% of those younger than 40 years; *P*=.009) and what to do if experiencing COVID-19 symptoms (199/1039, 19% vs 106/350, 30% of those aged 40-55 years; *P*<.001; and 52/171, 30% of those younger than 40 years; *P*=.001) compared to younger age groups (see Multimedia Appendix 2).

Other COVID-19–Related Information Sources and Needs

Looking at which COVID-19 information sources were most popular among various demographic groups, government websites (eg, CDC, National Institutes of Health, and local health departments) were the most popular selection among participants younger than 40 years (n=165, 74%), aged 40-55 years (n=329, 68%), and those with annual household incomes over US $100,000 (n=240, 65%). TV news reports were most popular among those 56 years or older (n=1009, 67%), all those earning under $100,000 annually, and all those reporting education levels up to a college degree. They were also the most popular choice regardless of residence type and gender (see Multimedia Appendix 2). Finally, news websites were the most popular choice among those with an advance degree (n=322, 69%).

"Understanding how COVID-19 affects people with my health condition" was of primary interest across all age groups, residence types, education levels, and household incomes, with the exception of those with a high school degree or below, among whom a slightly higher percentage (135/290, 47% vs 134/290, 46%) indicated a general need for up-to-date and accurate information about COVID-19. There were significant differences in information and support needs between age groups such that higher percentages of those younger than 40 years expressed interest in the following resources compared to older age groups: financial support for necessities (69/224, 31% vs 215/1500, 14% of those 56 years or older; *P*<.001); learning how to have food, medication, or supplies delivered (29/224, 13% vs 34/486, 7% of those aged 40-55 years; *P*=.01; and 112/1500, 7% of those 56 years or older; *P*=.005); and emotional or health support (84/224, 38% vs 138/486, 28% of those aged 40-55 years; *P*=.02; and 316/1500, 21% of those 56 years or older; *P*<.001). Conversely, a higher percentage of those 56 years or older stated that they were not in need of any more information or support (280/1500, 19%) compared to those aged 40-55 years (63/486, 13%; *P*=.004) and younger than 40 years (16/224, 7%; *P*<.001).

When examining information and resource needs across other demographic factors, a significantly larger proportion of females also expressed a need for emotional or mental health support than males (465/1781, 26% vs 71/424, 17%; *P*<.001). A smaller proportion of those with an advanced degree expressed a need for financial support compared to those of lower educational attainment, both for medications and health care expenses (44/466, 9% vs 214/1454, 15% of those with some college or trade school; *P*=.004; and 41/290, 14% of those with a high school degree or below; *P*=.047), and for other necessities and bills (59/466, 13% vs 283/1454, 19% of those with some college or trade school; *P*=.001; and 70/290, 24% of those with a high school degree or below; *P*<.001). Finally, the need for information regarding COVID-19 in general and its relation to one's health condition and current treatments tended to increase as household income increased, while financial and food medication delivery information needs tended to decrease (see Multimedia Appendix 2).

Discussion

Principal Results

The purpose of this study is to assess the telehealth use, resource needs, and information sources of individuals living with chronic conditions during the COVID-19 pandemic. According to these results, 45% (n=997/2210) of the study sample either cancelled or planned to cancel appointments with their HCP during times of COVID-19, and nearly half (1073/2210, 49%) engaged in telehealth appointments in the 4 months prior to data collection. Although 40% (886/2210) of participants initiated telehealth care because of the pandemic, 7% (162/2210) responded that they were interested in telehealth and did not know how to use it, 7% (162/2210) reported that they had no interest in using telehealth, 4% (82/2210) reported they had never heard the term prior to taking the survey, and only 35% (780/2210) of patients reported that their doctor reached out to them about telehealth. Thus, as recommendations continue for patients with underlying medical conditions to mitigate possible exposure outside of the home and as practices look to extend telehealth services beyond the pandemic [11], providers need to ensure adequate information is distributed to inform patients about telehealth procedures. A recent survey of 2949 adults living in China found that high-quality communication with a provider prior to

COVID-19 was associated with preventive behavior uptake during the pandemic [14]. Distributing patient-centered, personalized communications about telehealth from HCPs may help increase uptake of telehealth and maintain continuity of care in the future.

It may also be important to note that just under half of survey respondents (945/2210, 43%) were content using telehealth services during the pandemic but desired to return to in-person care in the future. With this in mind, information provided to patients about telehealth may also include information about future plans to return to in-person visits, including public and personal health standards that need to be met to do so. In the interim, providers may also consider implementing recently suggested strategies to enhance feelings of "copresence" or connection between patient and provider during telehealth visits [7,15]. Such strategies include postvisit mood evaluations, one-click responses from health care teams, and encouraging messages, and may help further engage patients, alleviate stress, and maintain continuity of care during the pandemic [7,15].

As telehealth outreach increases, HCPs can optimize virtual visits by addressing patients' top concerns during the pandemic. When asked what support or information would be most helpful, the top-rated responses included information about COVID-19, how it impacts individuals with specific diagnoses and disease regimens, and mental or emotional health support. Experts have already noted the important role telehealth could play in providing remote interdisciplinary care [16], including mental and emotional health services [17] during this global crisis. Thus, telehealth services across multiple disciplines and hospital services, including mental health care, social work, and patient navigation, may prove vital to providing quality care and meeting all information and supportive care needs of patients during COVID-19.

Finally, it is imperative to note which groups may be at highest risk of losing access to care as services shift to digital formats during COVID-19. According to these results, greater proportions of adults younger than 56 years have engaged in and are interested in telehealth than those 56 years or older, which may be unsurprising given the reported digital divide between younger and older generations [18]. This phenomenon has also been reflected in other literature assessing telehealth use both prior to and during the pandemic [19-21]. Although a higher percentage of older adults expressed no interest in telehealth compared to younger age groups, nearly half of those 56 years or older started using telehealth in response to COVID-19, nearly half said they would be willing to participate in telehealth even though they wanted to return to in person in the future, one-third wanted to participate in telehealth even after the pandemic, and only 5% reported being interested but not knowing how to use telehealth. Given the fact that older adults, with or without underlying medical conditions, are at higher risk of serious illness from COVID-19 [1,22-24], particular efforts to communicate the benefits and importance of telehealth during the pandemic and engage this group in telehealth efforts may be vital. Because lower percentages of aging adults reported reaching out to their health care provider about COVID-19, it may also be particularly important for health care providers to initiate conversations about telehealth and pandemic-related information.

Similarly, smaller percentages of participants who reported lower household incomes and educational attainment participated in telehealth when compared to peers of higher income and educational status, realities that have also been noted in previous literature on digital health use [18,20,25]. Other researchers have noted measures HCPs can take to try to ensure telehealth does not exacerbate health inequities during the pandemic (eg, ensuring language interpreter access, recruiting telehealth staff from diverse backgrounds, providing patient trainings in telehealth use, and informing patients about free or discounted broadband access) [25,26]. Thus, future outreach efforts should focus on equitable communication and engagement of patients in telehealth practices.

Limitations

This study presents important information regarding telehealth use, resource needs, and information sources of individuals considered at risk for severe disease during COVID-19 due to underlying medical conditions. This data collection is not without limitations. Given the exploratory nature of this study, many of these measures have not been validated, and the general description of telehealth as a "virtual visit with a doctor/healthcare professional" may not encompass the full scope of telehealth practices taking place during the COVID-19 pandemic. Despite this fact, only 4% of individuals in the study reported that they had never heard of telehealth prior to the study, indicating a general awareness if the terminology among the study population. Because all participants were members of online health communities, the telehealth and information-seeking practices of this sample may also be skewed, as participants may be more comfortable with digital health solutions than the general public.

Finally, at approximately 2%, the response rate for this survey was low, the sample was primarily female (1781/2210, 81%), and the data was skewed toward older populations who rated their conditions with higher severity, which may skew the age analyses presented and limit the generalizability of these results. With this said, the demographic characteristics of this sample do mirror those of the larger sampling frame, given that, among 36,515 survey responses collected from American Health Union members over the previous year, 81% of responses were female and 48% were 60 years or older. By leveraging existing online health communities for data collection, however, this study included a large, national sample of individuals with underlying medical conditions and provides preliminary guidance regarding the telehealth practices and needs of this high-risk population during the COVID-19 pandemic.

Conclusions

These results offer important insight to current telehealth practices and information needs of patients with underlying medical conditions during COVID-19. Although many patients are engaging in telehealth, they continue to seek information about COVID-19, how the virus impacts people with their particular condition and treatment regimen, and support for mental and emotional health during the pandemic. Moving

forward, medical and public health professionals may continue to take an active approach to engaging patients with underlying conditions in available telehealth services, particularly those who are members of lower socioeconomic status and aging populations. Future research will explore changes in telehealth practices and information needs over time by examining data from multiple waves of this survey distributed between March and July of 2020.

Abstract

Background: The COVID-19 pandemic has negatively affected medical education. However, little data are available about medical students' distress during the pandemic.

Objective: This study aimed to provide details on how medical students have been affected by the pandemic.

Methods: A cross-sectional study was conducted. A total of 717 medical students participated in the web-based survey. The survey included questions about how the participants' mental status had changed from before to after the Japanese nationwide state of emergency (SOE).

Results: Out of 717 medical students, 473 (66.0%) participated in the study. In total, 29.8% (141/473) of the students reported concerns about the shift toward online education, mostly because they thought online education would be ineffective compared with in-person learning. The participants' subjective mental health status significantly worsened after the SOE was lifted (P<.001). Those who had concerns about a shift toward online education had higher odds of having generalized anxiety and being depressed (odds ratio [OR] 1.97, 95% CI 1.19-3.28) as did those who said they would request food aid (OR 1.99, 95% CI 1.16-3.44) and mental health care resources (OR 3.56, 95% CI 2.07-6.15).

Conclusions: Given our findings, the sudden shift to online education might have overwhelmed medical students. Thus, we recommend that educators inform learners that online learning is not inferior to in-person learning, which could attenuate potential depression and anxiety.

COVID-19; online education; depression; pandemic; anxiety; medical student

Introduction

The COVID-19 global pandemic has drastically changed our lives, with more than 93 million cases and 2 million deaths reported globally as of January 17, 2021, according to statistics from the World Health Organization [1]. The pandemic led to significant declines in the global economy, and the uncertainty and fears associated with COVID-19 led to increases in mental health disorders. According to a systematic review by Xiong and colleagues, high rates of anxiety, depression, posttraumatic stress disorder, and psychological distress were reported in the general population [2]. Among the people affected, health care workers (HCWs) are considered to be more vulnerable to these issues. A previous cross-sectional study performed in the Asian-Pacific region looked into the psychological impact of COVID-19 on HCWs and noted that the burden of COVID-19 cases might not be related to psychological adversity; however, the increasing number of cases and mortality of COVID-19 continues to threaten the well-being of HCWs [3]. In Japan, more than 300,000 cases have been confirmed as of January 17, 2021, with an explosion in the number of cases in early April, August, and November 2020 [4]. While Japan previously

brought the outbreak under control through active cluster tracing, restriction of mass gatherings, and advocating universal masking and hand hygiene, the country has been experiencing a surge in the number of cases since November 2020, which suggests there were no simple solutions to this issue [5]. After the surge in COVID-19 cases, on April 16, 2020, the Government of Japan declared a state of emergency (SOE) in all 47 prefectures, which lasted until May 25, 2020 [6]. In Okayama, a prefecture in the western part of mainland Japan [7] with approximately 1.9 million people and ranked 20 out of 47 by population among the 47 prefectures, only 2071 confirmed cases had been reported by January 17, 2021. Behind the scenes of successful COVID-19 mitigation, however, those in education-related jobs and medical students struggled with the rapid change in the educational system, as shown in examples from Australia and Spain [8,9].

The SOE was lifted on May 14, 2020, in Okayama based on the low incidence of COVID-19. Okayama University School of Medicine (OUSM), one of the largest national universities in Japan, requested its students to stay home to prevent the spread of COVID-19 within the medical school and the hospital even before the SOE (ie, March 25, 2020). Until the stay-home request was lifted on May 22, 2020, medical students were required to cope with this sudden change in their lifestyle and shifted to online education amid the fear and considerable uncertainty surrounding COVID-19. In the early 2000s, the SARS-CoV outbreak had a devastating impact on academic education, including sudden curriculum changes and rapid integration of information technology [10-12]. Similarly, the current COVID-19 pandemic has provoked significant turmoil in society. In particular, as briefly noted above, mental health problems due to the pandemic have drawn attention worldwide as studies have suggested the need for mental health care interventions during the outbreak [13-18]. Medical students, who essentially need clinical exposure, may have been impacted even further by the pandemic because of the cancellation of clinical rotation. Due to the pandemic that forced educational institutions to eliminate in-person teaching sessions, medical students needed to adapt to new educational environments, such as distance or remote e-learning [19]. While some researchers argued that the COVID-19 pandemic could be an opportunity to catalyze changes in medical education [20], the rapid change in the system and environment might cause significant stress to medical students. Even before the COVID-19 pandemic, the global prevalence of anxiety among medical students was estimated to be 33.8%, and it was the most prevalent in those from the Middle East and Asia [21]. Also, a meta-analysis done in 2016 showed that depression was prevalent in 28.0% of medical students globally. Given the significant psychological distress related to the pandemic [22], the current prevalence of anxiety and depression among medical students might be even higher.

In Japan, medical schools follow an undergraduate medical education system, which is similar to most countries. Students typically enter medical school immediately after high school graduation, often at 18 years old, and they go through 6 years of medical education before graduation. The fundamental philosophy of academic medicine is to provide a quality educational experience. To date, few published studies have investigated the living environment and mental health status of medical students during the COVID-19 pandemic [23-25]. To address this, we conducted a total population survey of OUSM medical students to comprehensively clarify what they require and how they have been mentally affected by COVID-19.

Methods

Study Design, Setting, and Participants

We performed a cross-sectional study that employed an anonymous, self-administered, voluntary web-based survey. Participants included medical students in all years of study at OUSM. We invited all 717 medical students who belonged to the OUSM as of April 1, 2020 (ie, the first day of the academic year in Japan), to participate in the survey. The participants' consent was implied by the completion of the survey.

Our research team developed the survey through consultation with a medical education expert panel at OUSM and through piloting. We conducted a pretest of all the instruments in a sample group of 15 recent medical school graduates, who graduated in April 2020, to confirm their comprehension of the test and to make sure the questions were appropriate to measure psychological distress amid the pandemic. Cronbach α for the instrument developed by the team was .73. Content validity of the survey, as confirmed by the medical education expert panel, showed that the instrument represented the proposed domains (ie, depression and anxiety distress) to be measured in medical students. The survey was administered with Qualtrics (Qualtrics International Inc), a web-based survey platform. We provided survey instructions and instruments in Japanese. We distributed survey links to the students using OUSM official mailing lists. All participants were invited to complete the survey within 1 week (ie, June 8-14, 2020, in Japan Standard Time). No financial incentives were provided for their participation in the survey. The survey included entries on demographics (ie, age, gender, education before entering medical school, employment status on the date of response, changes in employment status due to the COVID-19 pandemic, marital status, living environment, household size, and comorbidities) as well as COVID-19-related items (eg, chance of contracting COVID-19 during the current pandemic), self-learning-associated activities (eg, average amount of time spent self-learning per day), validated depression and anxiety scale instruments, and financial situations. Self-learning is defined as "proactive processes that students use to acquire academic skill" [26]. In this study, the concept of self-learning by participants includes reading medical books, watching webinars, or preparing for shelf exams by themselves. To protect participants' anonymity as much as possible, participants were not prompted to enter their year of study.

Measurements

COVID-19-Related Questions

To evaluate the extent of participants' concerns and preparedness for COVID-19, they were asked the questions listed in Textbox 1.

Textbox 1. Survey questions related to COVID-19.

COVID-19-related questions:

- What do you think the chances are that you will contract COVID-19 during the current pandemic?
- What is your degree of concern about the health status of your family?
- Do you think you have enough information about the symptoms of COVID-19?
- Do you think you have enough information about prevention and treatment of COVID-19?
- Do you feel worried about COVID-19?

To further assess students' concerns, participants were prompted to respond to the following statements:

- I am concerned because my future career formation may be negatively affected due to the COVID-19 pandemic.
- I am concerned because the COVID-19 pandemic may attenuate our relationship to teachers.
- I am concerned because of the disruption to ongoing research or extracurricular activities.
- I am concerned about the shift toward online education.

All questions were evaluated on a 5-point Likert scale, except for the item on the health status of the family, which was evaluated on a 3-point Likert scale. Those who responded with *very concerned* or *concerned* regarding the entry on concern about the shift toward online education were prompted to provide reasons. To describe participants' needs, they were asked to note the types of support they wish to receive from the university if there is a resurgence of COVID-19. These responses were mandatory.

Self-Learning and Related Activities

As noted above, we developed the survey through consultation with a medical education expert panel at our facility. We assumed that several factors might be related to changes in medical students' subjective mental health status. To evaluate subjective mental health status and the average amount of time per day that participants stayed at home, read books, played video games, and learned by themselves, respondents were prompted to answer the following questions, as pertaining to before the SOE order (ie, April 16, 2020) and during the last 2 weeks, with the base date of when participants completed the survey: How many hours a day did you stay at home? How many hours a day did you read books? How many hours a day did you play video games? and How many hours a day did you self-learn?

Depression and Anxiety Disorders

We assessed the presence of depression using the 9-item Patient Health Questionnaire (PHQ-9), a common screening tool for mood disorders. We used the validated Japanese translation of the scale [27]. The total score for the PHQ-9 ranges from 0 to 27, and we defined scores of 10 or more as having *depression*. We screened for anxiety disorders using the Japanese version of the 7-item Generalized Anxiety Disorder scale (GAD-7), which was validated in 2010 [28]. The total score ranges from 0 to 21, and we defined scores of 10 or more as having *anxiety*. We used cut points of 10 or greater in this study because total scores of 10 or more in the PHQ-9 or GAD-7 represent moderate depression or anxiety, respectively. Both instruments ask respondents about their mental health status during the last 2 weeks.

Financial Situation

In Japan, university students typically live on a monthly allowance from parents. According to the latest statistics by the National Federation of University Co-operative Associations, students receive 72,810 Japanese yen (JPY) (approximately US $680) a month on average [29]. Participants were prompted to give their monthly allowance from the following options: *None*, *<30,000 JPY* (US $280), *30,000-49,999 JPY* (US $280-$467), *50,000-69,999 JPY* (US $467-$654), *70,000-99,999 JPY* (US $654-$935), and *≥100,000 JPY* (≥US $935). Respondents were also asked to answer whether they were receiving a scholarship or student loan.

Statistical Analysis

We analyzed the data using JMP statistical software, version 13.1.0 (SAS Institute Inc). We used the Wilcoxon signed-rank test to examine differences in the amount of time participants spent on self-learning-related activities based on nonnormal distribution. For associations between categorical variables containing small sample sizes, we employed the Fisher exact test. To examine the predictive factors of categorical dependent variables, we used univariate logistic regression analyses. The threshold for significance was defined as $P<.05$.

Ethical Approval

This study protocol was approved by the Institutional Review Board of Okayama University Hospital (reference No. 2006-029; approved on June 5, 2020).

Data Availability Statement

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Results

Overview

The response rate to the survey was 66.0%, as 473 out of 717 OUSM students in all 6 years combined completed the survey. Participants' demographic characteristics are summarized in Table 1. Of note, out of 473 respondents, 250 (52.9%) reported that they were engaged in part-time work, while 44 (9.3%)

reported having resigned or lost their jobs due to the COVID-19 pandemic. Out of 473 respondents, 8 (1.7%) and 6 (1.3%) noted that they had a past medical history of anxiety disorders and depression, respectively.

Table 1. Demographic characteristics of the study participants.

Characteristic	Value (N=473)
Age in years (n=471)[a], mean (SD), 95% CI	22.0 (3.3), 21.7-22.3
Gender, n (%)	
Female	161 (34.0)
Male	311 (65.8)
Nonconforming	1 (0.2)
Education before medical school, n (%)	
High school	434 (91.8)
Career college	1 (0.2)
4-year university	31 (6.6)
Master's degree	7 (1.5)
Employment status, n (%)	
Part-time job	250 (52.9)
Schoolwork only: no extra work	221 (46.7)
Self-owned business	2 (0.4)
Resigned or fired due to the pandemic	44 (9.3)
Marital status, n (%)	
Single	467 (98.7)
Married	5 (1.1)
Missing data	1 (0.2)
Living environment, n (%)	
Alone	308 (65.1)
With family	127 (26.8)
With a partner	20 (4.2)
Alone: family or relatives nearby	18 (3.8)
Household size, mean (SD), 95% CI	1.7 (1.3), 1.6-1.8
Comorbidity, n (%)	
None	401 (84.8)
Asthma	37 (7.8)
Anxiety disorder	8 (1.7)
Depression	6 (1.3)
Other	34 (7.2)

[a]Of the 473 respondents, 2 did not specify their age.

COVID-19-Related Survey Items

Table 2 and Figure 1 show respondents' answers to the COVID-19-related survey items. Out of 473 respondents, 81 (17.1%) responded that they were either *likely* or *very likely* to contract COVID-19 during the ongoing pandemic; 275 (58.1%) *agreed* or *strongly agreed* to the prompt "I feel worried about COVID-19." Regarding the breakdown of students' concerns about COVID-19, 182 (38.5%), 121 (25.6%), and 235 (49.7%) out of 473 respondents acknowledged that they were concerned about the negative impacts of COVID-19 on their future career formation, relationship with teachers, and ongoing research or extracurricular activities, respectively, while 141 (29.8%) also reported concerns about a shift toward online education. The reasons for these concerns included the belief that online education may not be as effective as on-site education (92/141, 65.2%), possible resurgence of the COVID-19 outbreak leading to a sudden change in the curriculum (74/141, 52.5%), and decreased clinical exposure (92/141, 65.2%).

Of the 473 participants, 298 (63.0%) answered that they would request financial aid if a stay-home order recurred due to a COVID-19 resurgence, followed by a request for food aid (100/473, 21.1%), technical support for online education (100/473, 21.1%), and mental health care resources, including counseling by therapists or psychologists (85/473, 18.0%).

Table 2. Results of the COVID-19-related survey items.

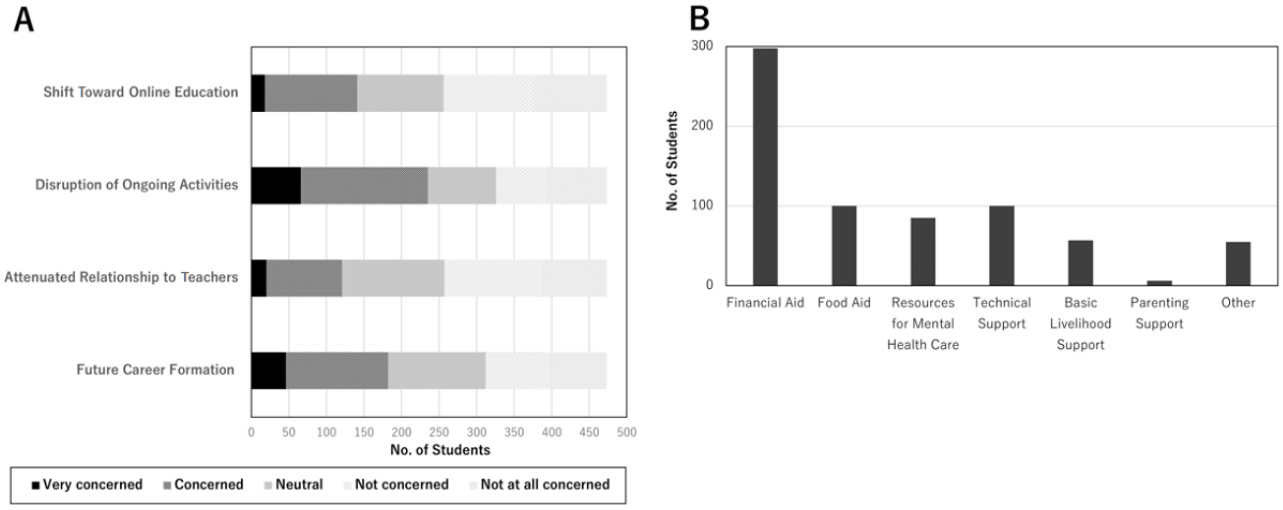
Survey entry and responses	Value (N=473), n (%)
"Chance of contracting COVID-19 during the current pandemic"	
Very likely	15 (3.2)
Likely	66 (14.0)
Neutral	238 (50.3)
Unlikely	121 (25.6)
Very unlikely	33 (6.9)
"Degree of concern about the health status of your family"	
Very concerned	198 (41.9)
Somewhat concerned	237 (50.1)
Not concerned	38 (8.0)
"I have enough knowledge about symptoms of COVID-19"	
Strongly agree	8 (1.7)
Agree	158 (33.4)
Neutral	169 (35.7)
Disagree	116 (24.5)
Strongly disagree	22 (4.7)
"I have enough knowledge about the treatment of COVID-19"	
Strongly agree	6 (1.3)
Agree	65 (13.7)
Neutral	138 (29.2)
Disagree	196 (41.4)
Strongly disagree	68 (14.4)
"I feel worried about COVID-19"	
Strongly agree	46 (9.7)
Agree	229 (48.4)
Neutral	106 (22.4)
Disagree	77 (16.3)
Strongly disagree	15 (3.2)
"Concerned about future career formation due to COVID-19"	
Very concerned	46 (9.7)
Concerned	136 (28.8)
Neutral	130 (27.5)
Not concerned	85 (18.0)
Never concerned	76 (16.0)
"Concerned about attenuated relationship to teachers"	
Very concerned	20 (4.2)
Concerned	101 (21.4)
Neutral	136 (28.7)
Not concerned	129 (27.3)
Never concerned	87 (18.4)
"Concerned about disruption of ongoing research or extracurricular activities"	
Very concerned	66 (14.0)

Survey entry and responses	Value (N=473), n (%)
Concerned	169 (35.7)
Neutral	91 (19.2)
Not concerned	67 (14.2)
Never concerned	80 (16.9)
"Concerned about shift toward online education"	
Very concerned	18 (3.8)
Concerned	123 (26.0)
Neutral	115 (24.3)
Not concerned	121 (25.6)
Never concerned	96 (20.3)
"The reasons for concernabout a shift toward online education" (n=141)[a]	
Online education may not be as effective as on-site education	92 (65.2)
Fear of sudden change in the curriculum	74 (52.5)
Less clinical exposure	92 (65.2)
"What supports do you want from the university?"[b]	
Financial aid (eg, tuition waiver and no-interest student loan)	298 (63.0)
Food aid	100 (21.1)
Resources for mental health care	85 (18.0)
Technical support (eg, free rental of personal computer and pocket Wi-Fi)	100 (21.1)
Basic livelihood support (eg, resources for health maintenance or preventing domestic violence)	57 (12.1)

[a]This survey entry was explicitly answered by participants who answered *very concerned* or *concerned* in response to the item "Concerned about shift toward online education." Multiple answers were permitted.

[b]Multiple answers were permitted.

Figure 1. (A) The breakdown of medical students' educational concerns related to COVID-19. (B) What medical students want from the university upon the second wave the COVID-19 pandemic.



Change in Self-Learning-Related Amount of Time Before and After the SOE

We compared the change in the average amount of time per day that respondents spent at home, reading books, playing video games, and self-learning before the SOE and within 2 weeks prior to the survey completion, after the SOE. As shown in Table 3 and Figure S1 in Multimedia Appendix 1, the participants spent significantly longer on all the activities mentioned above after the SOE compared to before the SOE (P<.001). There were also significant differences in their subjective mental health status before and after the SOE, based on the Wilcoxon signed-rank test (P<.001).

Table 3. Comparison of age-weighted self-learning and related activity times of medical students before and after the national state of emergency (SOE) in Japan.

Measure	Before SOE (N=473)	Last 2 weeks[a] (N=473)	*P* value[b]
Activity (hours/day), mean (95% CI)			
Stay at home	16.1 (15.7-16.6)	18.8 (18.5-19.2)	<.001
Reading books	0.70 (0.58-0.82)	1.1 (0.96-1.2)	<.001
Playing video games	1.5 (1.3-1.7)	2.1 (1.9-2.3)	<.001
Self-learning	2.6 (2.4-2.8)	4.0 (3.7-4.2)	<.001
Subjective mental health status, n (%)			
Very good	85 (18.0)	39 (8.2)	<.001
Good	171 (36.1)	58 (12.2)	<.001
Fair	193 (40.8)	286 (60.5)	<.001
Bad	18 (3.8)	76 (16.1)	<.001
Very bad	6 (1.3)	14 (3.0)	<.001

[a]The base date of the *last 2 weeks* is the date when the participants answered the survey. The survey period was from June 8 to 14, 2020.

[b]*P* values were calculated with the Wilcoxon signed-rank test.

Regression Analyses of Factors Associated With Depression and Anxiety

Of the 473 participants, 75 (15.9%) had PHQ-9 scores of 10 or more and 34 (7.2%) had GAD-7 scores of 10 or more. Table 4 presents all the results from the univariate regression analyses. The odds of being depressed were significantly higher in those who had concerns about a shift toward online education (odds ratio [OR] 1.97, 95% CI 1.19-3.28) and in those who said they would request food aid (OR 1.99, 95% CI 1.16-3.44) and mental health care resources (OR 3.56, 95% CI 2.07-6.15) from the university in the event of the resurgence of COVID-19. Regarding generalized anxiety, the odds were higher in respondents who said they would request food aid (OR 2.50, 95% CI 1.21-5.20) and mental health care resources (OR 3.16, 95% CI 1.51-6.59).

Table 4. Results of univariate regression analyses of factors associated with depression and generalized anxiety in Japanese medical students.

Dependent variable and independent variables	Odds ratio (95% CI)[a]	*P* value
Depression (n=75), PHQ-9[b] score ≥10		
Female vs male	1.08 (0.58-2.01)	.81
Age	1.06 (0.96-1.16)	.45
Concerned about the following[c]:		
Future career formation	1.40 (0.85-2.30)	.18
Attenuated relationship to teachers	1.46 (0.85-2.50)	.17
Disruption of ongoing research or extracurricular activities	0.81 (0.50-1.33)	.41
Shift toward online education	1.97 (1.19-3.28)	.009
Would request the following:		
Financial aid	0.92 (0.55-1.53)	.74
Food aid	1.99 (1.16-3.44)	.01
Mental health care resources	3.56 (2.07-6.15)	<.001
Anxiety (n=34), GAD-7[d] score ≥10		
Female vs male	0.81 (0.37-1.74)	.58
Age	0.96 (0.85-1.09)	.57
Concerned about the following[c]:		
Future career formation	0.75 (0.36-1.58)	.45
Attenuated relationship to teachers	1.43 (0.68-3.03)	.35
Disruption of ongoing research or extracurricular activities	0.53 (0.26-1.09)	.09
Shift toward online education	1.50 (0.73-3.10)	.27
Would request the following:		
Financial aid	1.25 (0.59-2.62)	.56
Food aid	2.50 (1.21-5.20)	.01
Mental health care resources	3.16 (1.51-6.59)	.002

[a]Univariate regression analysis was performed for each dependent variable.

[b]PHQ-9: 9-item Patient Health Questionnaire.

[c]Participants who answered *very concerned* or *concerned* in the respective survey entries listed in Table 2 were considered the *positive concerns group*. On the other hand, those who answered *neutral*, *not concerned*, or *not at all concerned* were considered the *no concerns group* in this analysis.

[d]GAD-7: 7-item Generalized Anxiety Disorder scale.

Prevalence of Financial Hardship

Table 5 and Figure S2 in Multimedia Appendix 1 show the self-reported monthly allowance from parents and situations regarding financial aid. Out of 473 respondents, 332 (70.2%) had a monthly allowance that was lower than the national average (ie, 72,810 JPY; approximately US $680) [29], while 131 (27.7%) received some sort of financial aid for their living and education expenses.

Table 5. Description of the financial situation of Japanese medical students.

Characteristic	Value (N=473), n (%)
Monthly allowance from parents (JPY[a])	
None	127 (26.8)
<30,000	43 (9.1)
30,000-49,999	81 (17.1)
50,000-69,999	81 (17.1)
70,000-99,999	78 (16.5)
≥100,000	63 (13.3)
Financial aid	
None	342 (72.3)
Student loan only	74 (15.6)
Scholarship only	44 (9.3)
Both student loan and scholarship	13 (2.8)

[a]JPY: Japanese yen; according to the Bank of Japan, the exchange rate of 1 US dollar to JPY was 107.39-107.41 on the morning of June 17, 2020.

Discussion

To the best of our knowledge, this study is the first survey of Japanese medical students regarding their life circumstances and challenges due to COVID-19. As of January 17, 2021, Japan has had 307,696 cumulative COVID-19 cases, the second largest number in the World Health Organization Western Pacific region and the 39th largest worldwide [1]. While Okayama has had comparatively fewer cases than other Japanese prefectures, the study results underscore that the pandemic inflicted profound mental health challenges on medical students. We found that approximately 10% of the students with part-time jobs had lost their jobs due to the pandemic. Furthermore, many medical students had concerns regarding their basic life security, demanding support from the university in the form of financial aid, food aid, technical support, and mental health care resources due to the SOE. As shown in previous studies, there may be an increasing prevalence of food insecurity during the pandemic, which might negatively affect the students' mental well-being [30,31]. Regarding students' subjective psychological distress, those who expressed concerns about the rapid shift toward online education and fear around basic life security were more likely to be depressed and anxious after the SOE.

Concerns around future career disruption, attenuated relationships with medical teachers, and disruption of ongoing extracurricular activities were prevalent among the participants, which underlines the considerable uncertainty amid the COVID-19 pandemic (see Table 2). In particular, 63.0% of respondents reported the need for financial aid in the event of a second wave of the pandemic. These data correspond to the fact that more than 70% of participants received no more than the national average monthly allowance from their parents (see Table 5). Contrary to the general notion in Japan that "medical students are financially well-off," many may have experienced financial hardship. Recently, the theory of willpower has gathered public attention. Willpower is defined as the ability to resist short-term temptations to achieve long-term goals or the capacity to override an unwanted thought or impulse [32,33]. As previously studied, the theory is even applicable to students [34]. Financial stability is considered a prerequisite of willpower, which aids appropriate decision making [32]. Combined with previous research findings showing that financial instability could lead to worse mental health outcomes [35,36], educational institutions are expected to develop a strategy to offer financial support to those in need. Although there are no straightforward solutions to address psychological distress amid the pandemic, we encourage educational institutions to provide emergency grant funding and to lobby the national or local government to offer additional funding given the number of students in critical need.

Regarding lifestyle changes and psychological distress, after the SOE was lifted, the participants experienced significantly worse mental health and spent a significantly longer time at home, reading books, playing video games, and learning by themselves (see Table 3) than before the announcement of the SOE. Our results are consistent with prior longitudinal and cross-sectional studies that showed that the COVID-19 pandemic led to a sedentary lifestyle and psychological distress [13,16,17,37]. While longer self-study times and reading books could be the consequences of staying at home longer and might not have detrimental effects on students' well-being, increasing time spent playing video games might be alarming. A previous study suggested that internet addiction is significantly associated with depression and anxiety [38]. As indicated by a previous study, the increase in gaming could be a coping behavior against psychological stress [39].

As for regression analyses of factors associated with depression and anxiety, in our study population, those who said they would request food aid and mental health care resources from the university upon the future resurgence of the COVID-19 outbreak had significantly higher odds of depression and anxiety. Furthermore, concerns around the shift toward online education were identified as factors associated with depression (see Table 4). Surprisingly, 65.2% of those concerned about the shift

toward online education thought online education was less effective than in-person education. While previous studies have reported the utility and noninferiority of online learning compared to offline in-person learning [40,41], this study's results revealed a potential gap in perception regarding the effectiveness of online education between medical students and educators. Educators should not assume that students know the potential benefits of online learning, and it is essential to inform learners that online learning is not inferior to in-person learning, which could attenuate potential depression and anxiety. While in-person communication has become difficult nowadays due to the fear of COVID-19, medical schools may need to reach out to students to find out who among them are suffering from underlying life insecurity and provide multilateral support, including early mental health care interventions. In particular, cognitive behavioral therapy (CBT) has drawn attention as an effective solution to help mitigate psychological distress. Ho et al discussed mental health strategies to support HCWs amid the COVID-19 pandemic, and they noted that CBT could mitigate maladaptive coping behaviors, including self-blame, by enhancing stress-managing skills [42]. In particular, internet CBT (I-CBT) using a learning management platform such as Moodle has been noted as a cost-effective and valid solution to address psychiatric symptoms [43,44]. Further studies are warranted to determine whether I-CBT may also be an effective solution for medical students' psychological distress in Japan.

Although this study's findings might be discouraging, medical students potentially have a role during the COVID-19 pandemic. In several countries including the United States and Vietnam, the mobilization of medical students toward a frontline COVID-19 response has been reported as a considerable help in assisting HCWs while increasing the clinical experience of the students [45,46]. While mobilization of medical students to help in the COVID-19 response needs to be voluntary, this is undoubtedly something that medical students can contribute to the community, health care system, and society. Knowing about good examples from other countries amid the pandemic might help medical students raise their hopes and overcome psychological distress. Educators are encouraged to provide supports to meet individual student needs, and the approach should not be a one-size-fits-all type. A longitudinal nationwide study to follow up with the mental health of medical students is warranted.

Several limitations of this study should be noted. First, due to the single-center, cross-sectional survey design, we may not conclude causal relationships. Second, cross-sectional research contains a limitation in terms of addressing changes over time. While we illustrated the changes in the average amount of time that students spent on self-learning-related activities before and after the SOE in Table 3, a longitudinal study design would be more appropriate to examine the differences in the study cohort. Third, we asked participants to provide their mental health status and amount of time spent on self-learning-related activities before the SOE, approximately 6 weeks before the survey implementation, both of which are subject to recall bias. Fourth, we did not check the convergent and structural validity of the instrument developed by our team. Thus, it should be noted that these scores might not represent hypothesized domains (ie, depression and anxiety). Next, the PHQ-9 and the GAD-7 are self-reported questionnaires that measure psychiatric symptoms, and no clinical diagnoses of depression or anxiety were made. It should be noted that the gold standard for establishing psychiatric diagnosis involves structured clinical interviews and functional neuroimaging [47,48]. Also, PHQ-9 and GAD-7 scores were obtained only after the SOE. Thus, they might not have changed during the period from before the SOE to after. Lastly, due to the nature of the survey topic, those interested in the COVID-19 public health emergency or in mental health may have been more likely to respond, leading to self-selection bias. Despite these limitations, a total population sampling strategy coupled with higher-than-usual response rates [49] contributed to high internal validity.

In conclusion, through this study, we have provided graphical data and evidence regarding the impacts of the COVID-19 pandemic on medical students. In circumstances of considerable uncertainty, both educators and medical students need to be flexible, patient, and resilient. The uncertainty and drastic change triggered substantial psychological distress in students, which was greater than we had assumed. Although Okayama prefecture survived the pandemic with fewer confirmed COVID-19 cases than other prefectures, medical students experienced significant adverse impacts due to the public health emergency. Educational institutions should recognize the prevalence of basic needs insecurity, such as financial difficulties and a shortage of staples, including food. We encourage educational institutions to offer emergency grant funding and lobby the government to provide additional funding at a policy level, given the number of students in critical need. As medical educators, we need to be accountable for the advantages of online education in the field of medicine to alleviate students' psychological distress, in addition to providing multilateral support to those in need, including early mental health care interventions such as I-CBT. While we targeted medical students in a single Japanese national university, the survey results warrant further research and analysis to determine whether the observed distress was amplified by existing anxiety, depression, burnout, etc, or whether it was a wholly COVID-19-related phenomenon. We call for increased research in populations with more COVID-19 cases than in Japan to figure out the challenges that medical students from different cultures and backgrounds have been facing amid the pandemic.

Acknowledgments

We would like to thank the Academic Affairs Division of OUSM for its cooperation in conducting the survey.

Authors' Contributions

YN wrote the manuscript, designed the study, and analyzed the data. KO, KT, MO, HH, and HK analyzed the data and revised the manuscript. FO designed and supervised the research.

Conflicts of Interest

None declared.

Abstract

COVID-19 cases are exponentially increasing worldwide; however, its clinical phenotype remains unclear. Natural language processing (NLP) and machine learning approaches may yield key methods to rapidly identify individuals at a high risk of COVID-19 and to understand key symptoms upon clinical manifestation and presentation. Data on such symptoms may not be accurately synthesized into patient records owing to the pressing need to treat patients in overburdened health care settings. In this scenario, clinicians may focus on documenting widely reported symptoms that indicate a confirmed diagnosis of COVID-19, albeit at the expense of infrequently reported symptoms. While NLP solutions can play a key role in generating clinical phenotypes of COVID-19, they are limited by the resulting limitations in data from electronic health records (EHRs). A comprehensive record of clinic visits is required—audio recordings may be the answer. A recording of clinic visits represents a more comprehensive record of patient-reported symptoms. If done at scale, a combination of data from the EHR and recordings of clinic visits can be used to power NLP and machine learning models, thus rapidly generating a clinical phenotype of COVID-19. We propose the generation of a pipeline extending from audio or video recordings of clinic visits to establish a model that factors in clinical symptoms and predict COVID-19 incidence. With vast amounts of available data, we believe that a prediction model can be rapidly developed to promote the accurate screening of individuals at a high risk of COVID-19 and to identify patient characteristics that predict a greater risk of a more severe infection. If clinical encounters are recorded and our NLP model is adequately refined, benchtop virologic findings would be better informed. While clinic visit recordings are not the panacea for this pandemic, they are a low-cost option with many potential benefits, which have recently begun to be explored.

Challenges in Identifying COVID-19 Clinical Phenotypes

COVID-19 cases are exponentially increasing worldwide; however, clinical COVID-19 phenotypes remain unclear. A clinical phenotype is an observable characteristic (ie, symptom) of a disease in a particular individual. A meta-analysis of COVID-19–related symptom presentations reported that the most frequent clinical symptoms are fever, cough, fatigue, and dyspnea [1]. However, the meta-analysis reported considerable

heterogeneity (I^2=84.9%-96.4%) among studies, potentially suggestive of the extreme heterogeneity among these symptoms at the individual patient level. Other less frequent COVID-19 symptoms include anosmia, dysgeusia, headache, sore throat, rhinorrhea, diarrhea, nausea, and myalgias [2]. However, their clinical implication, prevalence, and importance remain unclear.

A traditional reductionist approach to identifying COVID-19 treatments is not as simple as extrapolating the current knowledge toward our limited SARS-CoV-2 model. Clinical treatments are often based on a set of established biochemical markers, and reports of less frequent symptoms of a disease may reveal a biochemical pathway that can be subjected to pharmacotherapeutic intervention with previously unreported agents. Only laboratory tests can confirm a diagnosis of COVID-19, but such tests are in short supply. This presents an unprecedented need to develop better assessment methods to identify and generate heterogeneity in the clinical profile of COVID-19 and other viral diseases across the entire health care system. The urgency of this need cannot be understated, as it holds a key to understand how to identify and treat COVID-19 more accurately.

Using "Big Data" to Understand the Clinical Manifestations of COVID-19

Natural language processing (NLP) and machine learning may yield a method to rapidly identify individuals at a high risk for COVID-19 and to understand key symptoms upon clinical manifestation and presentation [3]. The existing applications of NLP and machine learning in medical diagnostics are based on a combination of structured (eg, symptom codes, medications, laboratory findings, etc) and unstructured (eg, visit notes, radiology reports, etc) data recorded by clinicians in patients' electronic health records (EHRs). Using NLP and machine learning approaches, data on documented signs and symptoms in the EHR are already being used to identify clinical conditions (computational phenotyping) [4]. Such NLP-based efforts are currently being applied to unstructured text data captured in the EHR from telehealth consultations to develop better screening tools for COVID-19 [5]. Ancillary data can improve the accuracy of computational phenotyping, such as information from disease registries. However, the performance of any model is determined by the quality of data used to generate it, and concerns exist about the fullness of data captured in the EHR.

Limitations of EHR Data

This considerable degree of symptom heterogeneity reported among patients with COVID-19 can deter the accurate documentation of less frequently reported symptoms in the EHR. Documentation inaccuracies in electronic medical records are not a new phenomenon; an analysis of data from 105 clinics indicated that 90% of clinician notes had at least one error, including 636 documentation errors that accounted for 181 charted findings that did not take place and 455 findings that were not charted [6]. Data on such symptoms may not be accurately synthesized into patient records owing to the pressing need to treat patients in overburdened health care settings. In this scenario, clinicians may focus on documenting widely reported symptoms that suggest a diagnosis of COVID-19 albeit at the expense of infrequently reported symptoms because overburdened clinicians are more likely to be affected by cognitive biases such as anchoring and confirmation biases [7]. Additionally, codes of the International Classification of Diseases (10th revision), the mainstay of documentation in electronic medical records, do not adequately capture COVID-19–related symptoms [8]. While NLP solutions can play a key role in generating clinical phenotypes of COVID-19, they are limited by the resulting limitations in EHR data. A comprehensive record of the clinic visits is required—an audio recording may be the solution [9].

Clinical Phenotypes Based on Audio Recordings of Clinic Visits

A small but growing number of health systems routinely obtain audio recordings, and, in some cases, video recordings of clinic visits [9,10]. For example, human scribes are commonly employed to review recordings of clinic visits and make detailed notes, thus reducing the documentation burden on clinicians and improving the accuracy of data entered in the EHR. A recording of the clinic visit represents a more comprehensive and accurate record of patient-reported symptoms. If performed at scale, a combination of data from the EHR and recordings of clinic visits can be used to power NLP and machine learning models, thus rapidly generating a clinical phenotype of COVID-19 and infections with subsequent SARS-CoV-2 strains. In addition to a more comprehensive record of symptoms discussed, recordings also asynchronously collect additional ancillary information such as the type and frequency of cough, which can help improve the precision of phenotyping.

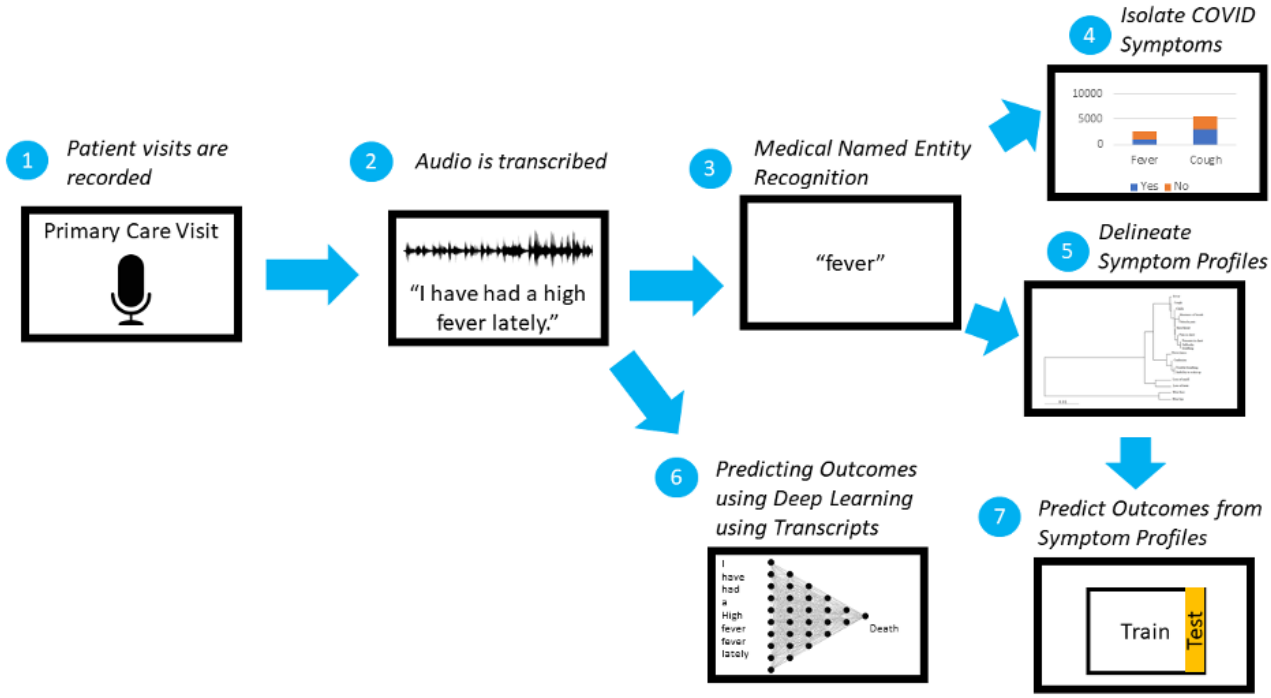
The generation of NLP and machine learning models requires the transcription of vast quantities of conversations of patients being investigated for COVID-19 upon clinic visits (with subsequent confirmatory laboratory tests for the disease) and the annotation of these transcripts by annotators trained to identify symptom mentions. The performance of automated speech recognition algorithms has significantly improved [10], allowing for the real-time use of audio data rather than transcripts of audio data, which are more time-consuming to obtain. Real-time risk assessment is critical when responding to an infectious disease such as COVID-19, since it allows for individuals to identify their risk level and more rapidly self-isolate, thus reducing the risk of disease transmission. Data annotation to generate models that can accurately identify symptoms is not without its challenges, many of which have been summarized by Quiroz et al [11]. It can be difficult for annotators to identify vaguely indicated symptoms from the unstructured natural language used in clinic visit conversations, with a negative impact on model performance. Rigorous training of annotators can help mitigate this challenge; however, such training and annotation is time-consuming and would require a large team of annotators to rapidly meet the immediate need for such an analysis. In addition, model training requires human input and time. Furthermore, the generation of optimal data would require continuous data refinement, wherein records of

suspected cases are replaced by the findings of confirmatory tests so as not to correspond to clinician views or biases.

Implications of the Adoption of Clinic Visit Recordings in Managing COVID-19

We propose the generation of a pipeline from the audio recordings of clinic visits to models based on clinical symptoms and the prediction of COVID-19 incidence (Figure 1). With vast amounts of available data, we believe a prediction model can be rapidly developed to promote accurate screening of individuals at risk of COVID-19. Beyond the challenge of generating a clinical phenotype, an unfiltered account of a patient's clinical experience of the disease allows us to answer other pressing questions, such as those related to understanding the constellation of patient characteristics that may predict a greater risk of a more severe infection. If clinical consultations are recorded and our NLP model is adequately refined, benchtop virologic findings are better informed. Recordings of clinic visits also provide a historic reference, such that we may be better prepared for subsequent pandemics.

Figure 1. Natural language processing pipeline from audio recordings to the establishment of a clinical phenotype of COVID-19.



With the mass transition to telehealth consultations and the availability of guidance for conducting remote assessments of COVID-19 via telehealth at primary care centers [12], an opportunity to capture audio recordings of consultations at scale is now available. An accurate model predicting a higher risk of COVID-19 could be applied to telehealth consultations with the added benefit of reducing the exposure risk among clinicians, patients, and the general public. The use of NLP for remote COVID-19 screening is already emerging; for example, audio recordings of cough sounds are being used to identify individuals with COVID-19 [13,14].

Data From Beyond the Clinic

While recordings of clinic visits are not the panacea for this pandemic, they are a low-cost alternative with many potential benefits that have recently begun to be explored. Beyond audio recordings, video recordings of telehealth consultations can provide additional diagnostic information such as skin appearance [12]. At-home voice-based technologies such as Amazon Alexa, Apple's Siri, and Google Home can also be used, allowing further information from outside of clinic visits to supplement predictive models [15]. For example, the Mayo Clinic has recently added a skill to Amazon Alexa called "Answers on COVID-19," which provides resources on COVID-19 and a virtual questionnaire to determine a person's symptoms and whether the person should get tested for COVID-19 [16].

Considering current accelerated efforts to manage COVID-19, care must be taken to rigorously protect sensitive data, with existing challenges in accessing the corpus of patient recordings needed to generate these models [11]. A data collection method should only be used entirely with an opt-in voluntary framework to preserve privacy and confidentiality; however, this method can help obtain data on COVID-19 symptom exacerbation at a scale unattainable with all traditional methods. This, as is often the case, points toward an evolving learning health system capable of managing computable knowledge.

Abstract

Background: Intimate partner violence (IPV) is one of the leading causes of pregnancy-related death. Prenatal health care providers can offer critical screening and support to pregnant people who experience IPV. During the COVID-19 shelter-in-place order, mobile apps may offer such people the opportunity to continue receiving screening and support services.

Objective: We aimed to examine cases of IPV that were reported on a prenatal care app before and during the implementation of COVID-19 shelter-in-place mandates.

Methods: The number of patients who underwent voluntary IPV screening and the incidence rate of IPV were determined by using a prenatal care app that was disseminated to patients from a single, large health care system. We compared the IPV screening frequencies and IPV incidence rates of patients who started using the app before the COVID-19 shelter-in-place order, to those of patients who started using the app during the shelter-in-place order.

Results: We found 552 patients who started using the app within 60 days prior to the enforcement of the shelter-in-place order, and 407 patients who used the app at the start of shelter-in-place enforcement until the order was lifted. The incidence rates of voluntary IPV screening for new app users during the two time periods were similar (before sheltering in place: 252/552, 46%; during sheltering in place: 163/407, 40%). The overall use of the IPV screening tool increased during the shelter-in-place order. A slight, nonsignificant increase in the incidence of physical, sexual, and psychological violence during the shelter-in-place order was found across all app users (P=.56). Notably, none of the patients who screened positively for IPV had mentions of IPV in their medical charts.

Conclusions: App-based screening for IPV is feasible during times when in-person access to health care providers is limited. Our results suggest that the incidence of IPV slightly increased during the shelter-in-place order. App-based screening may also address the needs of those who are unwilling or unable to share their IPV experiences with their health care provider.

Introduction

Intimate partner violence (IPV) is one of the leading causes of pregnancy-related death [1-3]. In a study of pregnant women who were enrolled in the Nurse Family Partnerships program, 4.7% of participants reported that they experienced IPV during the first 36 weeks of their pregnancy [4]. The documented prevalence of IPV among pregnant women in the United States ranges from <1% to almost 20%, depending on the type of violence and the source of the estimate [5,6]. IPV prevalence estimates using hospital-based samples tend to be higher than population-based studies. This may be due to the higher number of documentation opportunities or the type of screening. Under shelter-in-place mandates, people who experience violence and abuse face restricted access to protective networks, such as health care professionals. Although increases in the number of IPV-related hotline calls have been reported in the media [7,8] and documented in scientific literature [9,10], there is still limited data on the increased number of IPV cases that have been reported to health care systems during the COVID-19 pandemic. Mobile apps that address IPV have been successfully designed [11]. Therefore, such apps may be effective sources of screening and support during the pandemic [12]. During enforced isolation, social networks are restricted. As such, mobile apps may also support the dissemination of IPV risk information to the public. In this study, we examined IPV cases that were reported through a prenatal care app that was prescribed to patients from a large academic health care system. We specifically examined cases from a single US county that were reported 2 months before and after the enforcement of shelter-in-place mandates in 2020.

Methods

Recruitment

In late September 2019, a large academic health system started prescribing the MyHealthyPregnancy app (Apple v.1.4.7 and Android v.1.8) [13] to pregnant patients during their first prenatal appointment. Prior to the COVID-19 pandemic, this app was poised to launch across the entire health care system as a quality improvement initiative. The MyHealthyPregnancy app uses machine learning algorithms to analyze patient-entered data, model each patient's likelihood of experiencing adverse pregnancy events (eg, hypertension and premature delivery), and assess patients' psychosocial risks. The app also offers relevant resources (eg, local women's shelters) to users and notifies their providers about specific risk information in real time (ie, risk information that patients have shared on the app). Furthermore, all app users are notified that their care provider may not see or respond to all risk notifications. The app provides information on immediate actions that users can take to minimize their risks (eg, calling 911, calling their prenatal care provider, or watchfully waiting), based on the seriousness of the identified risks.

All app content was developed in conjunction with a clinical education team that was employed by the health care system. The same team reviewed all app content. The MyHealthyPregnancy app is a product of Naima Health LLC (limited liability company).

The internal protocol for prescribing the MyHealthyPregnancy app involved sending an invitation link to patients' phones and prompting patients to use the app as part of their routine prenatal care. The link allowed users to access a unique code for downloading the app from the Android or Apple app store. By virtue of owning a smartphone, downloading the app, and completing the onboarding process, all users were considered smartphone and internet literate. An individual could not download the app and undergo the onboarding process unless they received a text message–based prescription for the app from their health care provider's office.

The app users included in this study were pregnant residents of Allegheny County, Pennsylvania who were prescribed the MyHealthyPregnancy app during an in-person visit. All app users were offered an opportunity to undergo IPV screening through the app (ie, users received in-app messages that stated "Are you concerned about your safety? Take the pregnancy safety quiz"). Screening was not mandatory, and the screening tool could be accessed from a specific part of the app. We examined data that were collected from January 23 to May 15, 2020, to analyze app-based IPV disclosure before and during the enforcement of local shelter-in-place mandates (ie, approximately 2 months before and after mandate enforcement).

App users consented to the sharing of identifiable data for research purposes and the publication of anonymized aggregate data. Patients did not receive any financial compensation for app use, which was considered a part of routine prenatal care. All analyses were approved by the UPMC health system's quality index review board.

Safety Protocols

App access was protected by a password that was set by the user. The app included a password reset function that required users to input their user ID to receive a personalized text message that provided instructions on how to complete the process. A technical troubleshooting hotline was also available at all times. The IPV screening tool and screening-related notifications used language that was not specific to partner relationships or safety. These notifications were designed to be simple to dismiss, in case there were times when users felt uncomfortable with answering the screening questions. Furthermore, IPV screening data could not be stored or accessed in the app after the screening process was completed, thereby minimizing app users' risk of privacy violations. An icon, which was displayed next to questions about IPV, informed users that positive IPV screening results would be sent to their health care provider. All positive IPV screening results were routinely sent to a UPMC clinical support team.

Measures

The app onboarding process involved answering questions about clinical history (eg, prior preterm births and nulliparity) and demographics. Voluntary, validated screening measures were offered to users after they completed the onboarding process. We used two questions from the Centers for Disease Control and Prevention Behavioral Risk Factor Surveillance System as

measures of physical violence and forced sexual acts. We also used 10 questions from the Women's Experience with Battering scale to quantify psychological abuse [14,15]. Once shelter-in-place mandates were enforced, MyHealthyPregnancy app users were sent a text message that prompted them to use the app to share information about their COVID-19–related protective actions (eg, social distancing) with their care provider. All app users were also offered a COVID-19 triaging tool for assessing their symptoms.

IPV screening is part of the health care system's standard prenatal screening battery. We reviewed the medical charts of patients who screened positively for IPV, to determine whether positive IPV screening tests were documented and to identify all in-person interactions that took place within the system (ie, emergency room, routine prenatal care, specialist care, and physical therapy appointment interactions) during the course of patients' pregnancies.

Statistical Analysis

We compared the IPV screening frequencies and IPV incidence rates of patients who started using the app before the shelter-in-place order, to those of patients who started using the app during the shelter-in-place order, by conducting a two-sample Chi-square test of proportions. IPV incidence rates were then queried against patients' medical charts, to determine whether IPV was documented by a health care provider. Analyses were conducted with R version 3.6.0 (R Foundation for Statistical Computing).

Results

In total, 552 users completed the MyHealthyPregnancy app onboarding process within 60 days prior to the enforcement of shelter-in-place orders (ie, January 23 to March 22, 2020), whereas 407 users completed the onboarding process between the start and end of shelter-in-place enforcement (ie, March 23 to May 15, 2020). Of the 284 respondents who answered all the questions about COVID-19 protective actions, approximately 281 (99%) reported that they adhered to shelter-in-place measures. Frequently performed protective actions included washing hands with soap and water multiple times per day; using hand sanitizer multiple times per day; wearing a face mask; and avoiding public spaces, gatherings, or crowds (eg, not socializing with people who had a high risk of SARS-CoV-2 infection or not frequenting restaurants). Table 1 shows the demographics of patients who completed the onboarding process before and during the shelter-in-place order.

Table 1. MyHealthyPregnancy app user demographics. The demographic distribution of the sample reflects the demographic distribution of the health care system's pregnant population.

Variables	Completed onboarding before the shelter-in-place order (N=552), n (%)	Completed onboarding during the shelter-in-place order (N=407), n (%)
Race/ethnicity		
Black/African American	62 (11)	40 (10)
White	430 (78)	330 (81)
Hispanic/Latinx	13 (2)	3 (1)
Other	45 (8)	33 (8)
Missing data	2 (<1)	1 (<1)
Education status		
No high school or General Education Development diploma	24 (4)	13 (3)
High school or General Education Development diploma	162 (29)	125 (31)
Associate degree	58 (11)	56 (14)
Bachelor's degree	155 (28)	93 (23)
Postgraduate	150 (27)	117 (29)
Missing data	3 (1)	3 (1)
Relationship Status		
Single	20 (4)	21 (5)
Ongoing relationship	159 (29)	115 (28)
Married	369 (67)	269 (66)
Divorced/separated	4 (1)	1 (<1)
Missing data	0 (0)	1 (<1)

The number of patients who used the in-app IPV risk assessment tool did not differ significantly between patients who completed the onboarding process before the shelter-in-place order (252/552, 46%), and those who completed the onboarding

process during the shelter-in-place order (163/407, 40%; two-sample Chi-square test of proportions: 95% CI −12% to −0.01%; *P*=.10). However, the app use rate of patients who completed the onboarding process before the shelter-in-place order was slightly lower than that of patients who completed the onboarding process during the shelter-in-place order. Moreover, the use of the in-app IPV risk assessment across all app users increased from 67% (368/552) to 85% (347/407) during the shelter-in-place order (95% CI 17%-28%; *P*<.001).

Patients who completed the onboarding process during the shelter-in-place order reported that they experienced similar levels of physical violence, sexual violence, and psychological abuse before and during the shelter-in-place order (Table 2). However, after considering all patients who had access to the app during the two time periods (Table 2), we observed a slight, but nonsignificant increase in the incidence of all forms of violence (*P*=.56). Notably, none of the physically at-risk patients (ie, those identified by the app) had any mentions of IPV in their medical chart. However, 24% (4/17) of physically at-risk patients received emergency room care, and 29% (5/17) underwent physical therapy or a prenatal consultation for nonspecific pain or injury.

Table 2. Reports of intimate partner violence and the results of intimate partner violence screening.

Type of intimate partner violence	Before shelter-in-place order			During shelter-in-place order		
	New unique screens vs new unique patients, n/N (%)	New unique positive reports vs new unique patients, n/N (%)	All positive reports vs all reports, n/N (%)	New unique screens vs new unique patients, n/N (%)	New unique positive reports vs new unique patients, n/N (%)	All positive reports vs all reports, n/N (%)
Physical violence[a]	252/552 (46)	2/552 (0.4)	4/461 (0.87)	163/407 (40)	2/407 (0.5)	6/443 (1.4)
Sexual violence[b]	252/552 (46)	2/552 (0.4)	3/461 (0.65)	163/407 (40)	1/407 (0.2)	4/443 (0.9)
Psychological abuse[c]	252/552 (46)	6/552 (1)	6/461 (1.3)	163/407 (40)	3/407 (0.7)	6/442 (1.4)

[a]A 1-item measure (ie, “Has an intimate partner or ex-partner, hit, slapped, kicked, choked, or otherwise physically hurt you in the past month?”).

[b]A 1-item measure (ie, “Has an intimate partner or ex-partner hit, coerced or forced you into sexual activity against your will in the past month?”).

[c]A 10-item measure based on the Women’s Experience with Battering scale (eg, “I try not to rock the boat because I am afraid of what my partner might do”).

Discussion

Principal Results

In this study, we analyzed a stable, prenatal care app–based IPV self-screening tool that was used during shelter-in-place conditions. During the shelter-in-place order, there was a slight, but nonsignificant increase in the incidence of all forms of IPV (*P*=.56). This finding suggests that during times of social isolation (ie, the COVID-19 pandemic), people continue to use technology to disclose their concerns about an increased risk of IPV to care providers [16,17]. However, care providers should take into account the unique needs of pregnant women, to provide them with opportunities for mitigating pregnancy-related risks. It should be noted that even though we observed a nonsignificant, increasing trend in IPV incidence (*P*=.56), new app users’ engagement with the IPV risk assessment tool was stable during both time periods, while overall use went up. One explanation for this is that during the COVID-19 pandemic, people have limited opportunities to seek help outside of home. Therefore, people may be delaying seeking help until abuse starts to escalate.

Given that the people who screened positively for IPV by using an app-based tool were not documented in routine, in-person screening, we believe that the MyHealthyPregnancy app may address the needs of patients who are unable or prefer not to disclose their IPV experiences directly to their care provider. App-based screening may serve as a complementary form of care for those with limited access to health care providers or other social networks. Such technologies may offer patients an additional method for communicating with care providers during times of limited mobility and care access.

Limitations

IPV is serious, and even though it occurs frequently, IPV is rarely reported, even during routine, in-person screening with trusted health care providers. Although our results suggest that there was an increase in the incidence of IPV during the shelter-in-place order, our sample size was not large enough to detect statistically significant differences. This is most likely due to the low rates of disclosure among pregnant women who experience IPV. Although we hope that app-based screening will provide patients with an additional layer of support (ie, by making screening and appropriate resources available at any time), the decision to undergo screening and seek resources is voluntary, and many people may not feel safe or ready to disclose their IPV-related experiences, especially if they are sheltering in place with an abusive partner.

Another limitation of this study is that we were unable to determine whether app-users who screened positively for IPV actually used the resources that were offered through the app. However, we are currently working on a warm handoff system for providing resources to patients who screen positively for IPV and wish to connect with such resources. Although the app users in our study reflect the general population of patients in our health system, it is possible that people who choose not to use the MyHealthyPregnancy app are more likely to experience IPV. This would result in less effective screening. However, we cannot discern this based on our data. It is also possible that app users who experienced IPV, but chose not to disclose it,

reviewed or accessed the universally available support resources that the MyHealthyPregnancy app offers. We hope that this was the case.

Comparison With Prior Work

Regardless of social distancing mandates, the fact that none of the app-detected IPV cases were documented during emergency room visits or other clinical visits highlights a gap in prenatal care [18] that can be filled by implementing app-based technology methods. After shelter-in-place restrictions are lifted, the transition to telemedicine protocols may result in more instances of remote routine screening. Although our results only suggest that pregnant women are more willing to disclose IPV experiences through an app than they are during an in-person encounter, offering app-based IPV risk screening and appropriate resources is one way to address the needs of pregnant people who experience violence during and beyond times of social isolation. Moreover, app-based screening may offer an additional layer of support to patients who would benefit from universally available resources, but do not receive them, even after they present with physical signs of abuse during in-person care visits. This method of screening also allows care providers to anonymously identify the common signs of abuse and violence that patients may present with when seeking care [19] but are missed during in-person visits.

In this study, the number of patients who screened positively for IPV before and during the shelter-in-place period reflects the lower end of national estimates for IPV incidence rates. Therefore, it is unlikely that we identified all instances of IPV among app users (ie, it is possible is that patients who experience IPV do not frequently use smartphones or apps). As such, it is important to take into account that app-based screening alone does not necessarily identify all instances of IPV, especially if an abusive partner controls smartphone use. Our results also suggest that app-based screening may capture a different set of patients who are at risk of IPV, which means that an app-based approach can be used to complement in-person assessments. An app-based approach also provides patients (ie, those who feel that they may be at risk of IPV) with the freedom to engage with screening tools when they feel safe and comfortable.

Abstract

Background: As the COVID-19 pandemic continues, an initial risk-adapted allocation is crucial for managing medical resources and providing intensive care.

Objective: In this study, we aimed to identify factors that predict the overall survival rate for COVID-19 cases and develop a COVID-19 prognosis score (COPS) system based on these factors. In addition, disease severity and the length of hospital stay for patients with COVID-19 were analyzed.

Methods: We retrospectively analyzed a nationwide cohort of laboratory-confirmed COVID-19 cases between January and April 2020 in Korea. The cohort was split randomly into a development cohort and a validation cohort with a 2:1 ratio. In the development cohort (n=3729), we tried to identify factors associated with overall survival and develop a scoring system to predict the overall survival rate by using parameters identified by the Cox proportional hazard regression model with bootstrapping methods. In the validation cohort (n=1865), we evaluated the prediction accuracy using the area under the receiver operating characteristic curve. The score of each variable in the COPS system was rounded off following the log-scaled conversion of the adjusted hazard ratio.

Results: Among the 5594 patients included in this analysis, 234 (4.2%) died after receiving a COVID-19 diagnosis. In the development cohort, six parameters were significantly related to poor overall survival: older age, dementia, chronic renal failure, dyspnea, mental disturbance, and absolute lymphocyte count <1000/mm^3. The following risk groups were formed: low-risk (score 0-2), intermediate-risk (score 3), high-risk (score 4), and very high-risk (score 5-7) groups. The COPS system yielded an area under the curve value of 0.918 for predicting the 14-day survival rate and 0.896 for predicting the 28-day survival rate in the validation cohort. Using the COPS system, 28-day survival rates were discriminatively estimated at 99.8%, 95.4%, 82.3%, and 55.1% in the low-risk, intermediate-risk, high-risk, and very high-risk groups, respectively, of the total cohort (P<.001). The length of hospital stay and disease severity were directly associated with overall survival (P<.001), and the hospital stay duration was significantly longer among survivors (mean 26.1, SD 10.7 days) than among nonsurvivors (mean 15.6, SD 13.3 days).

Conclusions: The newly developed predictive COPS system may assist in making risk-adapted decisions for the allocation of medical resources, including intensive care, during the COVID-19 pandemic.

Introduction

Since the outbreak of unexplained pneumonia in Wuhan, China, in December 2019, which was subsequently identified as COVID-19 caused by the newly discovered pathogen SARS-CoV-2, the COVID-19 pandemic remains active in over 180 countries [1,2]. Globally, as of November 6, 2020, 1,231,017 of a total of 48,534,508 patients with COVID-19 have died, representing an overall infection fatality rate of 2.54% [3,4]. The clinical spectrum of COVID-19 includes asymptomatic or presymptomatic, upper and lower respiratory tract infections and acute respiratory distress syndrome [5-8]. Although the majority of viral infections are self-limiting, COVID-19 cases that are severe (ie, dyspnea, hypoxia, or >50% of lung involvement observed on imaging within 24–48 h) or critical (ie, respiratory failure, shock, or multiple organ failure) are of global concern and require medical resources for intensive care. The proportion of severe or critical COVID-19 cases and the corresponding case fatality rates vary by region and country, ranging from 10%-30% [8-10] to 2%-10%, respectively [3,4].

Most severe or critical cases occur in older patients or those with underlying comorbidities such as cancer, chronic obstructive pulmonary diseases, heart failure, or diabetes [11-13]. The clinical course of patients with COVID-19 also depends on multiple factors, including the immune status of the host, viral load of SARS-CoV-2, genetic diversity of the virus, and underlying diseases. However, details of viral factors and the host immune status (eg, cytokines released) are difficult to analyze in a real-world setting. Therefore, prognosis prediction systems should comprise basic factors such as initial symptoms at diagnosis, vital signs, hemogram parameters, and major underlying comorbidities.

As the global pandemic continues, the ability to detect, in a timely manner, patients with COVID-19 who are at a high risk of death and provide them with intensive care is important. Accordingly, the assessment of disease severity or mortality probability can be used to establish a sustainable strategy. Therefore, in this study, we aimed to develop an easy and simple scoring system that can predict COVID-19 mortality according to the patient's initial presentation and several major underlying comorbidities. Additionally, we investigated the association between the length of hospital stay and disease severity and survival status of patients with COVID-19.

Methods

Study Design and Data Source

This was a nationwide, retrospective cohort study on COVID-19 cases in Korea. For the purpose of this study, COVID-19 cases were defined based on laboratory confirmation of infection and positive results of SARS-CoV-2 reverse transcription polymerase chain reaction assays performed using the testing kits approved by the Korea Ministry of Food and Drug Safety, irrespective of the patient's clinical signs and symptoms [14,15]. Clinical data of patients in this cohort were managed by the Korea Disease Control and Prevention Agency (KDCA) and disclosed to the researchers after application and consent for research purposes in July 2020. The clinical and epidemiological information thus obtained included data of 5628 COVID-19 cases collected between January and April 2020. KDCA is an organization that aims to protect the Korean population from diseases, including emerging infectious diseases such as COVID-19, through national surveillance, health care research, and promotion of policies regarding disease prevention management. Patient data collected for this study included demographic and epidemiological characteristics, hemogram parameters at admission, maximal severity, and clinical outcome obtained from designated hospitals. Patients in the final cohort were randomly allocated to two subcohorts by using a random number generator: two-thirds into the "development cohort" and the remaining one-third into the "validation cohort." The predictive score was developed based on the development cohort, whereas the power of prediction was explored in the validation cohort.

This study was approved by the institutional review board of Seoul St. Mary's Hospital, Seoul, Korea (KC20ZADI0654). Individual patient consent was waived because the data retrieved were anonymous and publicly available.

COVID-19 Management Setting

In Korea, all suspected or confirmed cases of COVID-19 must be reported to the KDCA, as COVID-19 is regarded as a notifiable infectious disease. As a result, all patients with laboratory-confirmed COVID-19 were admitted to designated hospitals or residential treatment centers for isolation, monitoring of symptoms, and treatment. Clinical severity was classified into the following 8 levels according to patient performance, oxygen requirement, and organ failure [16]: (1) no limit of activity, (2) limited activity without oxygen supplementation, (3) requirement of oxygen supply with nasal cannula, (4) requirement of oxygen supply with facial mask, (5) requirement of noninvasive ventilation, (6) requirement of invasive ventilation, (7) requirement of extracorporeal membrane oxygenation (ECMO) for multiple organ failure, or (8) death. Death outcomes were evaluated regardless of maximum severity. Patients that required oxygen supply with invasive ventilation or ECMO were considered as invasive intensive care cases.

Statistical Analysis

Normally distributed numerical variables are presented as mean and SD values. Categorical variables are shown as absolute numbers and their proportions (n, %). The hospital stay durations between two independent groups were compared using Student *t* test. Overall survival was defined as the time from COVID-19 diagnosis to death due to any cause or up to the date of the last follow-up. Death events were censored at the time of hospital discharge for patients who were discharged. Overall survival

rates at 14 days and 28 days were calculated using the Kaplan-Meier method and compared using the Log-rank test.

Within the development cohort, all risk factors with a *P* value <.05 in the univariable analysis were entered into the multivariable model to identify factors associated with overall survival. Multivariable analysis was performed using the Cox proportional hazard regression model. We identified potential variables for the final prediction model based on 2000 bootstrap sampled datasets. When a parameter occurred in 60% or more of the bootstrap models, it was evaluated in the final multiple logistics regression model. We then computed the hazard ratios, 95% CIs, and *P* values for all metrics of the bootstrapped datasets in the final regression model. The final parameters used in the scoring system were defined by a *P* value <.05 in the final regression model. To confirm the risk score for each significant parameter, we adjusted the hazard ratio values to a $\log_e$ scale, followed by the conversion of the respective $\log_e$ scale to a rounded integer point. In the validation cohort, the area under the receiver operating characteristic (AUROC) curve was measured to evaluate the prediction accuracy of the survival rates after 14 and 28 days. An AUROC value above 0.8 was considered reliable. Among the developed risk groups, we compared the length of hospital stay using one-way analysis of variance. For all statistical analyses, we used R statistical software (ver. 3.6.1, R Foundation for Statistical Computing). Statistical significance was set at *P*<.05.

Results

Patient Characteristics

In total, 5628 confirmed COVID-19 cases were reported between January and April 2020. Cases with a postmortem diagnosis (n=7) or lack of clinical course data after diagnosis (n=27) were excluded from the analysis. As shown in Figure 1, a total of 5594 patients with COVID-19 were included in this cohort. Overall, 41.2% (2307/5594) of the patients were male, and 52.2% (2919/5594) were aged 50 years or older. Baseline demographics are summarized in Table 1. In the total cohort, the most frequent age distribution was 50-59 years (1140/5594, 20.4%), followed by 20-29 years (1110/5594, 19.8%) and 60-69 years (905/5594, 16.2%). The most frequently reported symptoms included sputum (1610/5594, 28.8%), fever (1300/5594, 23.2%), and dyspnea (662/5594, 11.8%). Common underlying comorbidities reported were hypertension (1196/5594, 21.4%) and diabetes (686/5594, 12.3%). Moreover, 4% (224/5594) of the patients had dementia and 3.2% (179/5594) of them had cardiac diseases. Distribution of these variables between the development (n=3729) and validation (n=1865) cohorts is presented in Table 1.

[a]Cases that achieved complete cure of cancer were excluded.

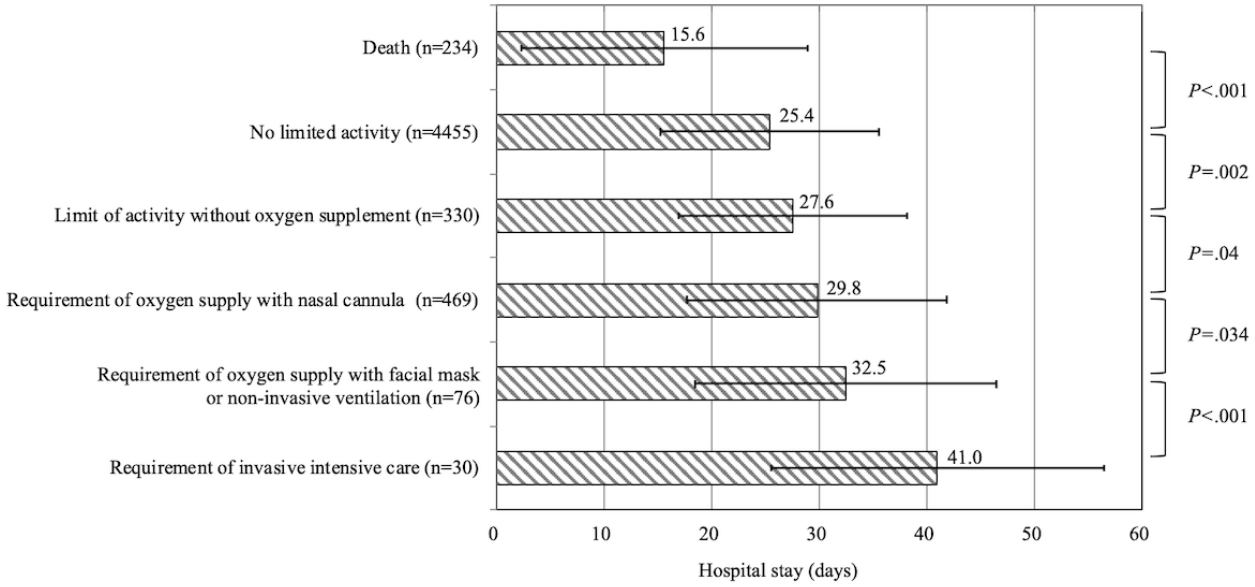
[b]Cases with chronic hepatitis were included in this category.

Clinical Course, Outcome, and Length of Hospital Stay in the Total Cohort

Among the 5594 patients included in the analysis, 234 (4.2%) died after a COVID-19 diagnosis was made, resulting in a cohort case fatality rate of 4.2%. Excluding death, the maximal clinical disease severity during hospitalization was as follows: (1) no limit of activity in 79.6% (4455/5594) of the patients, (2) limited activity without oxygen supplementation in 5.9% (330/5594) of the patients, (3) requirement of oxygen supply with nasal cannula in 8.4% (469/5594) of the patients, (4) requirement of oxygen supply with facial mask or advanced device (such as noninvasive ventilation or high flow oxygen therapy) in 1.4% (76/5594) of the patients, and (5) requirement of invasive intensive care such as invasive ventilation for acute respiratory distress syndrome or ECMO for multiple organ failure in 0.5% (30/5594) of the patients (Figure 2).

Overall, the mean duration of hospital stay was 25.6 (SD 11.0) days. Hospital stay was significantly longer among survivors (mean 26.1, SD 10.7 days) than among nonsurvivors (mean 15.6, SD 13.3 days; P<.001). As shown in Figure 2, the higher the severity of clinical course among survivors, the longer was their hospital stay: no limit of activity, mean 25.4 (SD 10.2) days; limited activity without oxygen supplementation, mean 27.6 (SD 10.6) days; oxygen supply with nasal cannula, mean 29.8 (SD 12.0) days; oxygen supply with facial mask or advanced device, mean 32.5 (SD 14.0) days; and invasive intensive care groups, mean 41.0 (SD 15.4) days.

Figure 2. Maximal COVID-19 disease severity and duration of hospital stay. Hospital stay duration differed significantly according to maximal disease severity; the mean length of hospital stay is indicated.



Analysis of Factors Associated With Overall Survival in the Development Cohort

The univariable analysis identified the following potential factors associated with poor overall survival: age (≥70 or 50-69 years vs <50 years); sex (male); comorbidities such as hypertension, diabetes, dementia, chronic cardiac disease, cancer in active treatment, chronic pulmonary disease, and chronic renal failure; dyspnea, fatigue, mental disturbance, high systolic blood pressure (≥140 mmHg), low diastolic blood pressure (<80 mmHg), tachycardia (heart rate ≥110/min), and fever (≥38°C) at the time of diagnosis; and cytopenia (hemoglobin level <12.5 g/dL, absolute lymphocyte count [ALC] <1000/mm^3, and platelet count <100,000/mm^3), as shown in Table 2.

Table 2. Univariable analysis for potential factors associated with overall survival in the development cohort. All values presented in the table represent data collected at the time of initial COVID-19 diagnosis.

[a]Chronic cardiac disease was a composite variable including heart failure and cardiac disease.

[b]Chronic pulmonary disease was a composite variable including asthma and chronic obstructive lung disease.

COVID-19 Prognosis Score for Predicting Overall Survival

In the bootstrap analysis, we identified that older age (50-69 or ≥70 years) and comorbidities, including dementia, chronic renal failure, presentation of dyspnea, mental disturbance at diagnosis, and ALC <1,000 /mm^3 were significantly associated with poor overall survival. Assigned risk scores obtained by rounding the log_e scale of hazard ratio are shown in Table 3: age (50-69 years, 2 points; ≥70 years, 3 points), underlying dementia (1 point), chronic renal failure (1 point), dyspnea (1 point), mental disturbance (1 point), ALC <1000/mm^3 (1 point). We determined the COVID-19 prognosis score (COPS) based on the risk scores obtained for each patient and summing the respective scores of the 6 parameters. The total COPS ranged between 0 and 8.

We explored the clinical prediction score in the validation cohort using the AUROC curve analysis, which resulted in an AUROC value of 0.918 (95% CI 0.91-0.927) for the 14-day overall survival rate and 0.896 (95% CI 0.872-0.911) for the 28-day overall survival rate, indicating a reliable discrimination through the COPS system (Figure 3). Thereafter, we applied the scoring system to the total cohort, which resulted in a score range of 0-7 points (Figure 4A). This scoring system discriminately classified the patients into 8 groups. The 28-day overall survival rates were predicted as 99.9% (95% CI 99.7-100) in the 0-point group (n=2348), 99.7% (95% CI 99.1-100) in the 1-point group (n=317), 99.6% (95% CI 92.9-99.9) in the 2-point group (n=1511), 95.4% (95% CI 93.9-97.1) in the 3-point group (n=815), 82.3% (95% CI 78.5-86.4) in the 4-point group (n=395), 60% (95% CI 39.2-52.8) in the 5-point group (n=170), 32.9% (95% CI 20.6-52.7) in the 6-point group (n=36), and 50% (95% CI 12.5-100) in the 7-point group (n=2) (P<.001; Figure 4A).

We then determined the risk groups based on the final COPS system; these included low-risk (0-2 points, n=4167), intermediate-risk (3 points, n=774), high-risk (4 points, n=321), and very-high risk (≥5 points, n=98) groups. The 28-day overall survival rates for these groups were as follows: low-risk group, 99.8% (95% CI 99.6-99.9); intermediate-risk group, 95.4% (95% CI 93.9-97.1); high-risk group, 82.3% (95% CI 78.5-86.4); and very-high risk group, 55.1% (95% CI 48.5-62.5) (P<.001; Figure 4B). The developed COPS calculator is available online [17].

Furthermore, a significant increase in the length of hospital stay was observed as the risk group advanced: low-risk group, mean 25.4 (SD 10.4) days; intermediate-risk group, mean 27.2 (SD 10.9) days; and high-risk or very high-risk groups, mean 30.8 (SD 11.9) days (P<.001).

Table 3. The final scoring model in the development cohort. All values presented in the table represent data collected at the time of initial COVID-19 diagnosis.

Figure 3. Receiver operating characteristics curve analysis of the newly developed COVID-19 prognosis score system in the validation cohort. A receiver operating characteristic curve analysis achieved an area under the curve value of (A) 0.918 (95% CI, 0.91-0.927) for 14-day survival and (B) 0.896 (95% CI 0.872-0.911) for 28-day survival.

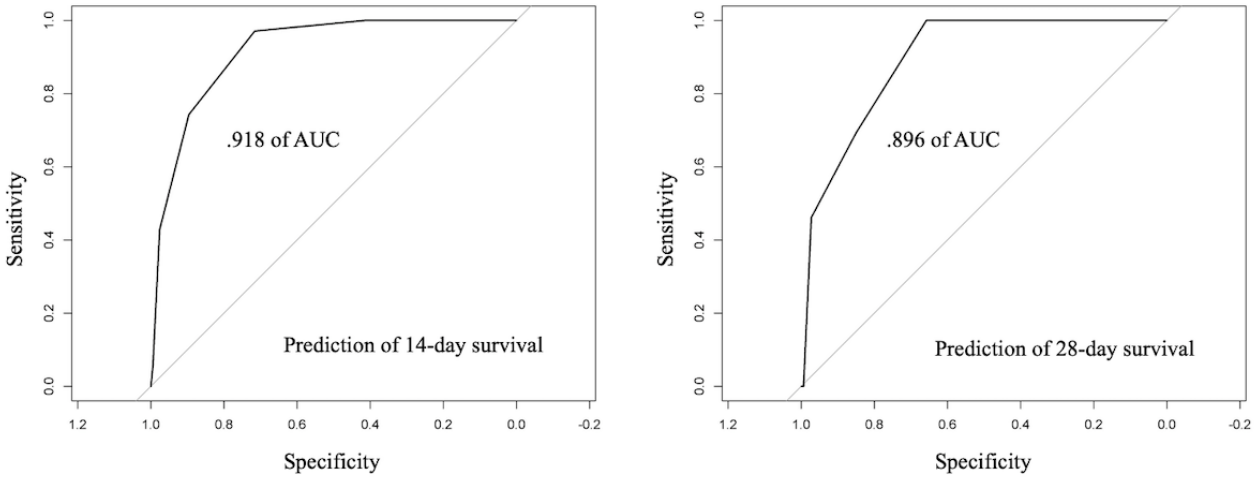

Figure 4. Probability of overall survival in patients with COVID-19 according to (A) each score and (B) the final COVID-19 prognosis score system.

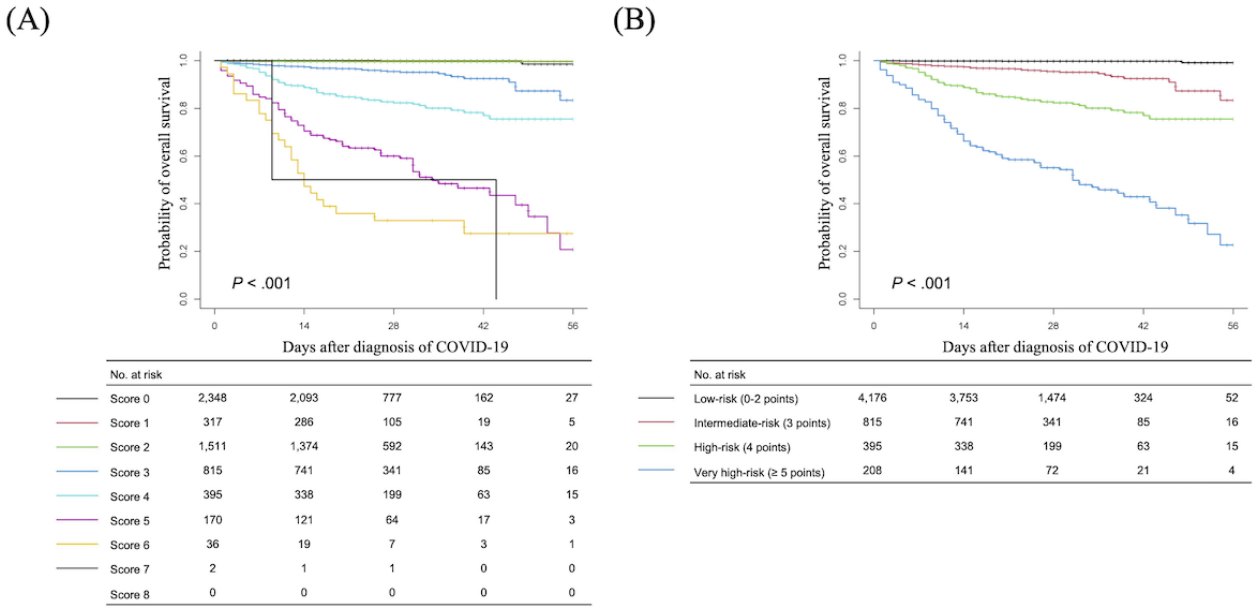

Discussion

In this study, we developed a new scoring system (COPS) to predict the mortality of patients with COVID-19 by using nationwide data of 5594 patients with COVID-19. The COPS system comprises basic demographics, initial symptoms, vital signs, and hemogram results at diagnosis. The risk score was stratified into four risk groups: low-risk, intermediate-risk, high-risk, and very high-risk groups associated with 28-day overall survival rate probabilities of 99.8%, 95.4%, 82.3%, and 55.1%, respectively. The AUROC curve analysis indicated that the prediction ability of the COPS system was excellent in the validation cohort.

Among the comorbidities identified in this study, dementia had the highest impact on mortality (adjusted hazard ratio 3.92) followed by chronic renal failure (adjusted hazard ratio 3.48). Moreover, the prognosis was poor when mental disturbance (adjusted hazard ratio 4.04) was noted at the time of diagnosis or when the patient had underlying dementia (adjusted hazard ratio 3.92). These two factors are related to the presence of SARS-CoV-2 infection clusters in nursing homes or long-term care facilities between February and April 2020 in Korea. Therefore, there is a need to establish screening and infection control strategies for long-term health care facilities [18-21].

In this study, an ALC of <1000/mm^3 was found to affect the survival rate of patients with COVID-19. ALC has been used as a prognostic factor for common respiratory viruses, including respiratory syncytial virus or other viral reactivation in immunocompromised hosts [22]. A recent meta-analysis reported that lymphopenia on admission was associated with poor outcomes in patients with COVID-19 [23]. Further immunological studies on patients with COVID-19 are needed to elucidate the mechanism of lymphopenia and T cell reactivation, as well as cytokines [24].

Regarding disease severity, approximately 87% of patients did not need oxygen supplementation. Approximately 10% of the patients required oxygen supplementation; of these, 25% received oxygen via a simple mask or mechanical ventilators. From the perspective of a national strategy for new infectious disease crisis, it is important to determine the proportion of critically ill patients and the length of hospital stay according to disease severity in order to prepare medical resources, such as critical care beds. This study found that the hospitalization period was significantly longer among survivors than among nonsurvivors. Moreover, among the survivors, the length of hospital stay was directly associated with disease severity.

In this cohort, the infection fatality rate after COVID-19 diagnosis was 4.18% (234/5594). However, until April 30, 2020, the cumulative number of confirmed COVID-19 cases in Korea was 10,765 with 247 deaths, representing an actual mortality rate of 2.29% during the same period [25]. As of November 6, 2020, the total cumulative number of confirmed COVID-19 cases and deaths were 27,195 and 476, respectively, representing an infection fatality rate of 1.75% in Korea [25]. This disparity in mortality rates can be attributed to the fact that not all data were reported at the time this cohort was released. However, considering the large number of patients included in this cohort and collection of most deceased cases, the findings of this study are still meaningful and carry little statistical bias. In addition, remdesivir was not available in Korea during the study period, and infectious disease prevention and control measures were less established in the early phase of the COVID-19 pandemic. Thus, several mass infection episodes might have caused the relatively high mortality rate during the early phase of the pandemic in Korea.

Several studies have attempted to determine predictive factors for severe or fatal COVID-19 cases. A study on risk factors for fatal COVID-19 cases performed in China proposed a scoring system comprising age, procalcitonin, aspartate aminotransferase level, coronary heart disease, and cerebrovascular disease; this system was developed using data of 1590 inpatients with COVID-19 collected until January 2020. The nomogram showed discriminatory power with a C-index of 0.91 to predict survival

[13]. Another study analyzed the risk of intensive care unit admissions and deaths among 4997 individuals under investigation at an academic hospital in New York. The study used age, heart rate, procalcitonin, lactate dehydrogenase, heart failure, and chronic obstructive pulmonary disease to predict care in intensive care units and deaths, yielding an accuracy of 0.74 and 0.83, respectively [26]. In the United Kingdom, a similar study was conducted on 17 million individuals included in the OpenSAFELY database, a near–real-time primary care patient record, which pseudonymously identified 10,926 COVID-19–related deaths. The study found male sex, older age and deprivation, diabetes, and severe asthma as significant risk factors for death [27]. However, the study did not analyze survival and death among patients with a confirmed COVID-19 diagnosis. In addition to studies attempting to predict death in patients with COVID-19, other studies have focused on severity index to predict severe or critical cases [10,28-31]. More recently, a machine learning–based warning system for mortality risk prediction of patients with COVID-19 was reported, and timely risk stratification using multiple laboratory and clinical factors was improved [32].

Compared with the abovementioned studies, our study has a number of strengths. First, the risk factors for death were analyzed using a nationwide cohort comprising a large number of patients with COVID-19, which resulted in a scoring system that can be widely used for triaging laboratory-confirmed COVID-19 cases. Second, the COPS system was developed using easily accessible information, such as age, underlying disease, dyspnea, mental disturbance, and hemogram parameters. We believe that if a scoring system that uses only simple laboratory tests (eg, hemogram parameters) can be developed and still show good predictability, it will prove to be more cost-effective than systems including other biomarkers such as procalcitonin or cytokine levels. Third, the discriminatory power of our system for predicting death probability was excellent. Finally, this study further analyzed the length of hospital stay according to disease severity, which may assist in preparing medical resources based on patient classification. However, this study is limited by the lack of external verification for our scoring model. Therefore, the current model of overall survival for the diagnosis of COVID-19 would need to be validated in a future cohort.

In conclusion, our study provides a simple scoring system based on information collected at diagnosis for predicting mortality among patients with COVID-19 in a timely manner. Early triaging of patients with COVID-19 using the COPS system can provide new insights for risk-adaptive strategies and optimize the use of medical resources.

Acknowledgments

We would like to thank Si-Hyun Park and Seunghoon Han for their help with analyzing the data at Korea Disease Control and Prevention Agency. We acknowledge all the health care workers involved in the diagnosis and treatment of patients with COVID-19 in Korea. We thank Korea Disease Control & Prevention Agency, National Medical Center, and the Health Information Manager in hospitals for their effort in collecting the medical records. This work is funded by the Life Respecting Fund of Seoul St. Mary's hospital and Research Fund of Seoul St. Mary's Hospital, The Catholic University of Korea.

Authors' Contributions

SYC and SSP wrote the manuscript. SSP and MKS collected and analyzed the data and analyzed it. Drafted manuscript was reviewed by YYB, DGL and DWK. DGL and DWK designed the study, conceived the idea, and planned the project. SYC and SSP contributed equally to this work as first authors. DGL and DWK contributed equally to this work as corresponding authors. All authors approved the final version.

Conflicts of Interest

None declared.

Abstract

Background: The emergence of SARS-CoV-2 (ie, COVID-19) has given rise to a global pandemic affecting 215 countries and over 40 million people as of October 2020. Meanwhile, we are also experiencing an infodemic induced by the overabundance of information, some accurate and some inaccurate, spreading rapidly across social media platforms. Social media has arguably shifted the information acquisition and dissemination of a considerably large population of internet users toward higher interactivities.

Objective: This study aimed to investigate COVID-19-related health beliefs on one of the mainstream social media platforms, Twitter, as well as potential impacting factors associated with fluctuations in health beliefs on social media.

Methods: We used COVID-19-related posts from the mainstream social media platform Twitter to monitor health beliefs. A total of 92,687,660 tweets corresponding to 8,967,986 unique users from January 6 to June 21, 2020, were retrieved. To quantify health beliefs, we employed the health belief model (HBM) with four core constructs: perceived susceptibility, perceived severity, perceived benefits, and perceived barriers. We utilized natural language processing and machine learning techniques to automate the process of judging the conformity of each tweet with each of the four HBM constructs. A total of 5000 tweets were manually annotated for training the machine learning architectures.

Results: The machine learning classifiers yielded areas under the receiver operating characteristic curves over 0.86 for the classification of all four HBM constructs. Our analyses revealed a basic reproduction number R_0 of 7.62 for trends in the number of Twitter users posting health belief–related content over the study period. The fluctuations in the number of health belief–related tweets could reflect dynamics in case and death statistics, systematic interventions, and public events. Specifically, we observed that scientific events, such as scientific publications, and nonscientific events, such as politicians' speeches, were comparable in their ability to influence health belief trends on social media through a Kruskal-Wallis test (P=.78 and P=.92 for perceived benefits and perceived barriers, respectively).

Conclusions: As an analogy of the classic epidemiology model where an infection is considered to be spreading in a population with an R_0 greater than 1, we found that the number of users tweeting about COVID-19 health beliefs was amplifying in an epidemic manner and could partially intensify the infodemic. It is "unhealthy" that both scientific and nonscientific events constitute no disparity in impacting the health belief trends on Twitter, since nonscientific events, such as politicians' speeches, might not be endorsed by substantial evidence and could sometimes be misleading.

COVID-19; social media; health belief; Twitter; infodemic; infodemiology; machine learning; natural language processing

Introduction

Beginning in December 2019, the outbreak of SARS-CoV-2 rapidly evolved into a global pandemic [1-3]. As of the writing of this paper, over 40 million cases and 1 million deaths from 215 countries or regions have been confirmed [4]. However, spreading faster than the virus is information. Sylvie Briand, Director of Infectious Hazards Management at the World Health Organization (WHO)'s Health Emergencies Programme, pointed out "We know that every outbreak will be accompanied by a kind of tsunami of information, but also within this information you always have misinformation, rumors, etc." [5]. The WHO used the term *infodemic* to describe the overabundance of information and misinformation occurring during the COVID-19 pandemic. Though the term infodemic was first coined in 2002 [6], the concerns over infodemics have recently become dramatic with the amplification effect from social media. The WHO held the first Infodemiology Conference in June 2020 as the phenomenon had escalated to a level that required a coordinated response [7]. Even though we cannot avoid an infodemic, we can still manage it. Previous studies and commentaries proposed several perspectives to detect and fight the COVID-19 infodemic [5,8-10]. However, one of the critical points absent from these studies is an investigation of health beliefs. Understanding how the general public's health beliefs are expressed and altered can facilitate our management of both the pandemic and infodemic. In conjunction, it is also essential to evaluate any concurrent or ongoing interventions.

The health belief model (HBM) quantifies health beliefs [11-13]. The HBM was developed to investigate people's beliefs about health problems. It consists of the following four core constructs that can be tailored for given hypotheses: (1) perceived susceptibility, (2) perceived severity, (3) perceived benefits, and (4) perceived barriers. The HBM has been widely used to investigate individual opinions toward diseases and interventional approaches, such as HIV risk behaviors [14], human papillomavirus (HPV) vaccines [15], and the gender difference in food choices [16]. In those cases, the HBM was employed to evaluate people's beliefs toward the given health problem and their perceived benefits or barriers of action, for which each of the core constructs of the HBM is assessed based on the corresponding definitions. During pandemics, researchers have employed the HBM to investigate the health beliefs toward public interventional policies, such as stay-at-home orders [17]; to analyze public health communication on Instagram during the Zika outbreak [18]; to examine public perceptions of physical distancing [19]; and to guide community pharmacists in their communication with patients [20]. However, because these are survey-based or merely commentary studies, results are limited to the analyzed population and, therefore, may be biased. In this study, we expanded and diversified our study population by using crowdsourcing data from one of the mainstream social media platforms, Twitter, in order to investigate the health beliefs of the general public toward COVID-19 and its potential treatments.

In addition to quantifying health beliefs, we aimed to identify factors influencing fluctuations in public opinions. For instance, the pandemic dynamics (ie, the number of cases and deaths due to COVID-19) constitute one of the leading factors influencing attitudes toward the pandemic. Additionally, interventional government policies may also impact the opinions of the general public. Furthermore, it is reasonable to believe that health belief–related posts can also be self-regulated as a consequence of their nature to induce or soothe panic for readers. Potential treatments trigger massive discussions as well, such as the debate over the appropriate use of the antimalarial drug hydroxychloroquine (HCQ) or chloroquine (CQ), advocated for by the then American President as a "game changer," which was then subsequently discarded. Public attitudes regarding potential treatments may be altered by public events, such as the news or politicians' speeches. Furthermore, rapidly emerging scientific publications can also influence the point of view of the general public. In this paper, we aim to identify factors that impact health beliefs on social media, which may serve as a probe for identifying better strategies to manage both the pandemic and the infodemic.

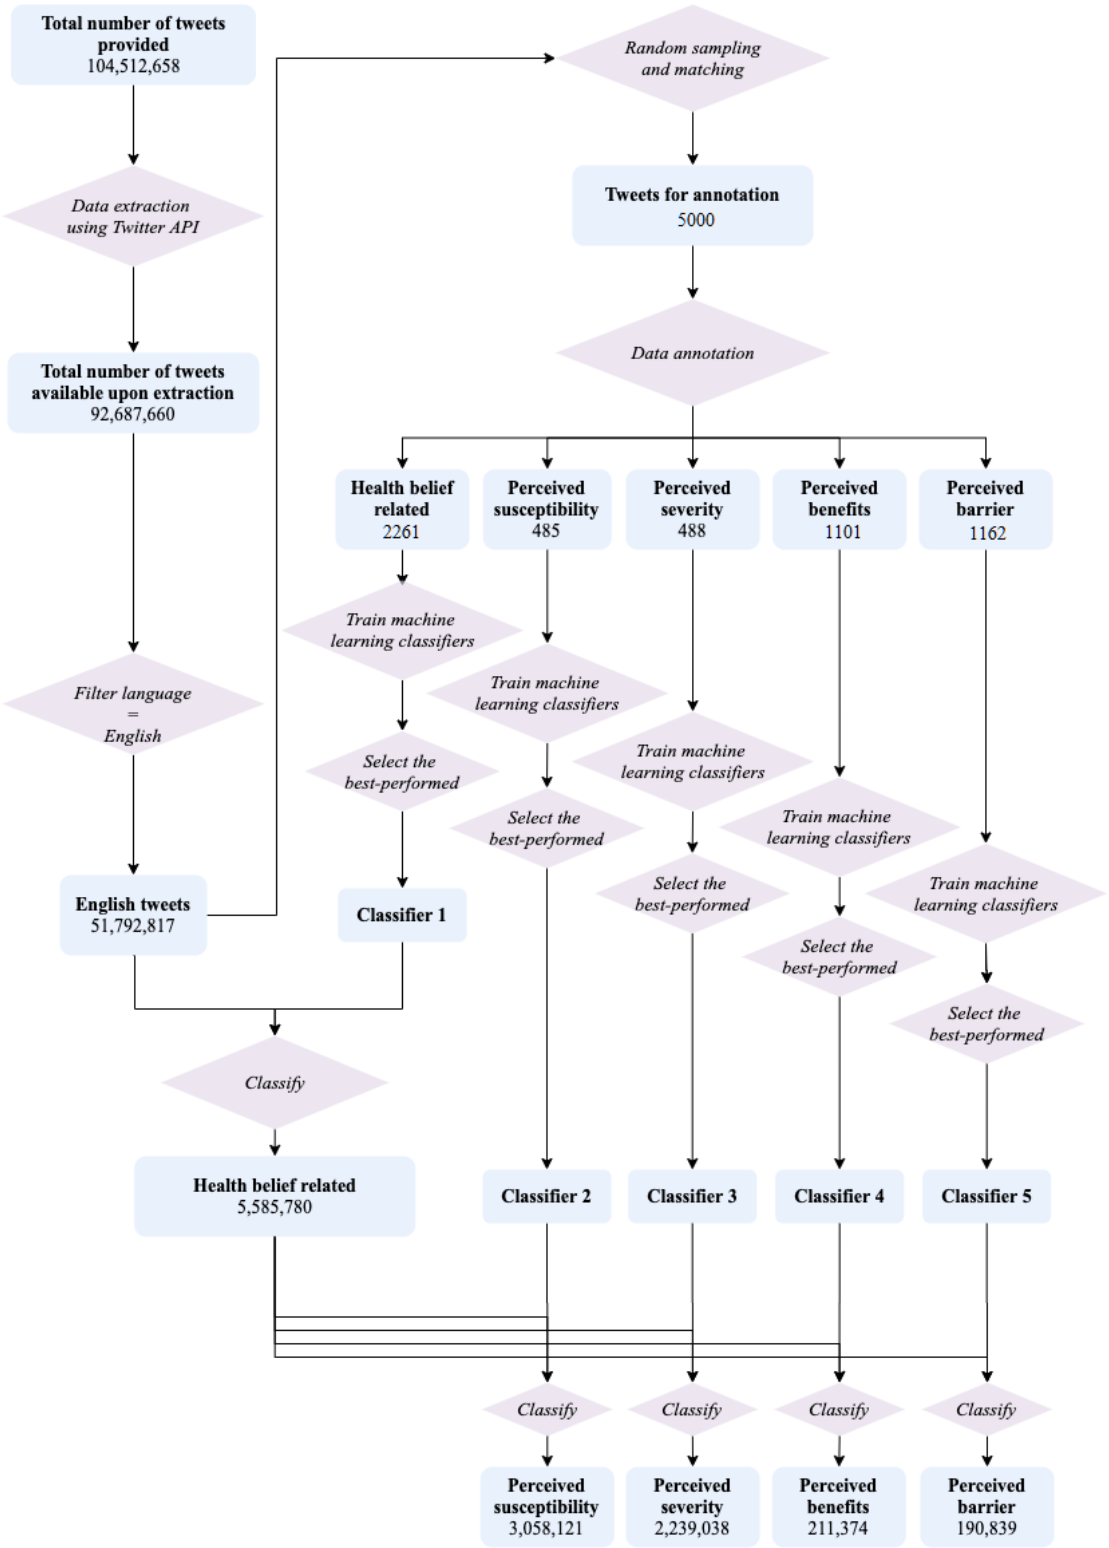
Contributions of this study include the following:

1. An evaluation of utilizing a mainstream social media platform, Twitter, to facilitate a comprehensive understanding of health beliefs toward COVID-19 and potential treatments.
2. A publicly available data set annotated by multiple professionals for studying the health beliefs related to COVID-19 and potential treatments.
3. Identification and comparison of factors that influence health beliefs toward COVID-19 and potential treatments, HCQ or CQ in particular.
4. An extendable framework for monitoring the general public's health beliefs during a pandemic and infodemic, which could be feasibly transferred to facilitate the management of future infodemic outbreaks, such as when COVID-19 vaccines become available to the public.

Methods

The entire workflow of data extraction, filtering, and classification is illustrated in Figure 1.

Figure 1. The workflow of data selection, data annotation, and machine learning classifier training and implementation. API: application programming interface.



Data

We used version 15.0 of the COVID-19 Twitter chatter data set constructed by the Panacea Lab [21], which collected all COVID-19-related tweets between January 6 and June 21, 2020. The provided data set only contains the identifiers of corresponding tweets, so we used the application programming interface (API) provided by Twitter to extract the full content of each tweet. The Social Media Mining Toolkit provided by the Panacea Lab was used to hydrate the data set [22]. There is no limitation regarding the days prior to the extraction. A language filter (ie, "lang" attribute in the tweet object = "en") was then applied to identify tweets written in the English language.

Data Annotation for Constructing the Health Belief Model

We employed the HBM to quantify health beliefs. As mentioned above, it consists of the following four core constructs that can be tailored for given hypotheses: (1) perceived susceptibility, (2) perceived severity, (3) perceived benefits, and (4) perceived barriers. The HBM was developed to investigate people's beliefs about health problems and has been widely used to investigate individual opinions toward diseases and interventional approaches, such as HIV risk behaviors [14], HPV vaccines [15], and the gender difference in food choices [16]. Specifically, for perceived benefits and barriers, we focused on HCQ or CQ, the antimalarial drug advocated for by the then American President as a "game changer," which was then subsequently discarded. Tweets were labeled as positive or negative for being related to HBM, meaning they could be mapped to at least one of the four aforementioned constructs. Thus, each tweet could potentially have up to five labels. The annotation process was performed by three senior PhD students in biomedical informatics (HW, YLi, and MH). All annotators classified the first 500 tweets individually, then reconciled different opinions and built final annotation rules. The definitions for each construct of the HBM are described in Table 1 with example tweets. Based on the rule, HW and YLi annotated the rest of 5000 tweets independently and evaluated the agreement using the Cohen κ score [23]. Finally, MH resolved the divergent annotations between HW and YLi with further consideration. We made the data set with the 5000 annotated tweets available for researchers [24]. To protect the privacy of Twitter users and per Twitter's policy, we did not include any tweet content in the data set. Instead, each tweet's unique identifier (ie, tweet ID) was provided.

Table 1. Health belief model (HBM) constructs, definitions, and example tweets.

Construct	Definitions of the construct	Example tweet
Perceived susceptibility	The assessment of the risk of getting COVID-19 infection	"Across the UK, 194,990 people had tested positive for coronavirus as of 9am on Tuesday, up from 190,584 at the same point on Monday. Find out how many cases there are in your area."
Perceived severity	The assessment of whether COVID-19 is a sufficient health concern	"US Recorded 1,297 Coronavirus Deaths in Past 24 Hours."
Perceived benefits	The benefits of HCQ[a] and CQ[b] in prevention or treatment of COVID-19	"Dr. Zelenko In NY has now treated 699 Coronavirus patients with 100% success using Hydroxychloroquine."
	Positive statements or reports about HCQ and CQ	
Perceived barriers	The side effects of HCQ and CQ	"Family of New York woman blames hydroxychloroquine combo for fatal heart attack."
	The unaffordable cost of HCQ and CQ	
	The inaccessibility of HCQ and CQ	
	Negative statements or reports about HCQ and CQ	
HBM related	Can be mapped to at least one of the four constructs above	Any of the above tweets are examples for this construct

[a]HCQ: hydroxychloroquine.

[b]CQ: chloroquine.

Machine Learning Classifiers

We trained machine learning classifiers on the annotated data, evaluated the performance, and automatically classified the 50 million tweets. The entire annotated data set was split into a training data set and a testing data set with a ratio of 8:2. Feature selection was applied by ignoring terms with a document frequency of less than 0.01 or greater than 0.99. Terms with only letters were considered, but terms were ignored when there were numbers or special characters. Before vectorization, we removed all the URLs; unified all the contractions, punctuation marks, and white spaces; and converted all terms to lowercase in the corpus. The free-text tweets were vectorized using both bag-of-words and term frequency–inverse document frequency (tf-idf) algorithms. A list of English stop words provided by the natural language toolkit [25] was used to rule out unrelated words. Next, 5-fold cross-validation was performed to select the best-suited classifier for the task. The machine learning classifiers that we experimented on included Ridge classifier; perceptron; passive-aggressive classifier; k-nearest neighbors classifier; random forest; support vector machine with linear kernel and l1 or l2 penalty; support vector machine with radial basis function, polynomial, or sigmoid kernel; stochastic gradient descent classifier with l1 or l2 or elastic net penalty; multinomial naïve Bayesian classifier; Bernoulli naïve Bayesian classifier; and logistic regression. Performance across classifiers was evaluated using the area under the receiver operating characteristic (AUROC) curve, and the classifier that yielded the highest AUROC was chosen (see Multimedia Appendix 1, Tables S1-S5). In total, five classifiers were built to construct the final HBM. First, a classifier was trained to classify whether a tweet was HBM related or not. Then, we collected all the tweets that were identified as HBM related for the following task. Lastly, we built four classifiers to label each core construct of the HBM separately.

The entire pipeline was built with Python 3.6.8 (Python Software Foundation). The bag-of-words algorithm, machine learning classifiers, and model evaluations were implemented with the scikit-learn, version 0.22.1, package [26].

The Overall Trend of Health Beliefs in Tweets

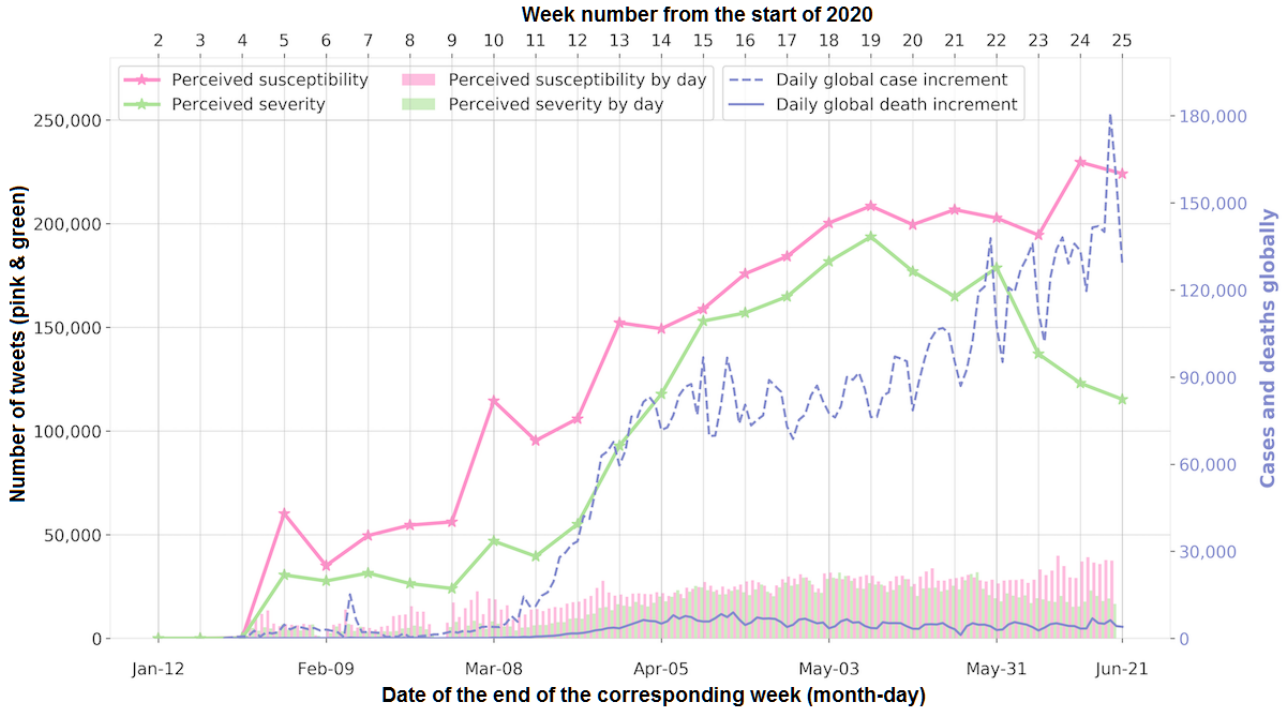
To quantify whether the information spread constituted an infodemic, we applied one of the classic measurements in

epidemiological models: the basic reproduction number, R_0. We employed the susceptible-infectious-recovered (SIR) model [27], for which the detailed calculation can be found in the Multimedia Appendix 1. In our case of an infodemic, we considered the users who tweeted about COVID-19 as the susceptible population; among this population, *being infected* meant a user tweeted about health beliefs defined in our HBM scope, and *recovering* then indicated that a user stopped tweeting about health beliefs. Thus, *contact with infected individuals* could be considered as reading health belief–related tweets posted by other users.

The Trend of Health Belief Toward the Disease

There are two core constructs in the HBM that focus specifically on the disease of interest: perceived susceptibility and perceived severity. We visualized these two constructs together with the dynamics of the pandemic in Figure 2. We observed a similar pattern in COVID-19 case dynamics and the number of tweets regarding perceived susceptibility, as well as in the dynamics of COVID-19 deaths and the number of tweets indicating perceived severity. For the first pair, we observed an earlier increase in the number of perceived susceptibility tweets prior to a surge in COVID-19 cases, while for the second pair, there was a delay in the increase of COVID-19 deaths compared with the number of perceived severity tweets. To investigate how many days the trend dynamics of health belief discussions followed or postponed the actual case or death increases, we calculated the Spearman correlation coefficient under various time lags (ie, for a 1-day lag, the correlation between the number of tweets and the COVID-19 situation was calculated by moving the COVID-19 trend 1 day forward). Moreover, we conducted a change point analysis using the dynamic programming algorithm [28] to detect the significant turning point of the trends.

Figure 2. Dynamics of perceived susceptibility and severity with COVID-19 case and death trends. The pink and green lines with "star" marks reflect the weekly cumulative number of tweets for perceived susceptibility and severity, while the pink and green bars on the x-axis indicate the daily number of tweets related to perceived susceptibility and severity. The global case and death dynamics have been available since January 22, 2020.



The Effect of Interventions

To evaluate the impact of interventions on the infodemic and the pandemic, we further investigated the lockdown in the United States. Because we were analyzing only tweets written in the English language, and there were systematic official lockdowns issued in the United States, we chose to study the effect of US-based interventions on health beliefs. The location information is not available for each tweet. We analyzed 136,641 tweets where the *place* was available—a variable in the tweet object that, when present, indicates that the tweet is associated with a place—and subsequently identified 54,164 tweets corresponding to the United States. We investigated the effect of interventions by visualizing the trends along with the timeline of lockdowns in the United States.

News in the Top Topics

To understand major topics in the tweets related to health beliefs, we extracted the top 10 phrases from the tweets each week. We considered unigrams and bigrams in this case. The frequency of each phrase was not only calculated as the count; instead, we used the tf-idf score to find the highlighted topics of each week. A higher tf-idf score is obtained if a given word or phrase frequently appears in one document but only appears in a small number of documents.

The Influence of Scientific and Nonscientific Events

To evaluate the difference between the impact of scientific and nonscientific events on health beliefs, we conducted a Kruskal-Wallis test. The Kruskal-Wallis test was chosen since there was no reasonable assumed distribution for the influence

of the two types of events, and the two groups being compared had different sample sizes. We collected events associated with HCQ and CQ on the internet during the study period with no exclusion criteria. All the events were classified as scientific events if they were based on scientific evidence or endorsed by authorities, while all remaining events were treated as nonscientific events. To quantify the influences, for each event, we calculated the sum of the number of tweets that expressed perceived benefits or perceived barriers regarding HCQ and CQ on the day of the event and the day after.

Results

Data and Machine Learning Classifiers

The data set contained identifiers for 104,512,658 unique tweets, of which 92,687,660 were still available upon extraction. After applying the language filter, our final set for analysis consisted of 51,792,817 English tweets. The Cohen κ score for interrater reliability of data annotation was 0.94 for identifying whether a given tweet was HBM related and was around 0.9 for the annotation of all four individual HBM constructs (see Table 2). Random forest was found to be the best-performing classifier for the HBM-related classification and three of the HBM constructs (ie, perceived susceptibility, perceived benefits, and perceived barriers), while the passive-aggressive classifier was found to be the most suitable choice for classifying whether a tweet indicated perceived severity. The AUROC curves for HBM-related and the two disease-related constructs were all above 0.9, while AUROC curves for the two treatment-related constructs were around 0.86 (see Table 2).

After classification, 5,585,780 tweets were HBM related, among which 3,058,121 (54.75%) tweets expressed perceived susceptibility of COVID-19, 2,239,038 (40.08%) tweets expressed perceived severity of COVID-19, 211,374 (0.04%) tweets expressed perceived benefits of HCQ or CQ, and 190,839 (0.03%) tweets expressed perceived barriers toward HCQ or CQ. To further ensure the validity of the classification, we performed additional spot checks on the final results; examples can be found in Multimedia Appendix 1.

Table 2. Performance of machine learning classifiers.

Construct	Cohen κ[a]	Classifier[b]	AUROC[c] curve	Accuracy	Precision[d]	Recall[e]	F1 score[f]
Perceived susceptibility	0.92	Random forest	0.97	0.94	0.92	0.85	0.88
Perceived severity	0.88	Passive-aggressive	0.92	0.90	0.88	0.77	0.81
Perceived benefits	0.92	Random forest	0.87	0.79	0.78	0.78	0.78
Perceived barriers	0.92	Random forest	0.86	0.77	0.77	0.77	0.77
HBM[g] related	0.94	Random forest	0.90	0.84	0.84	0.84	0.84

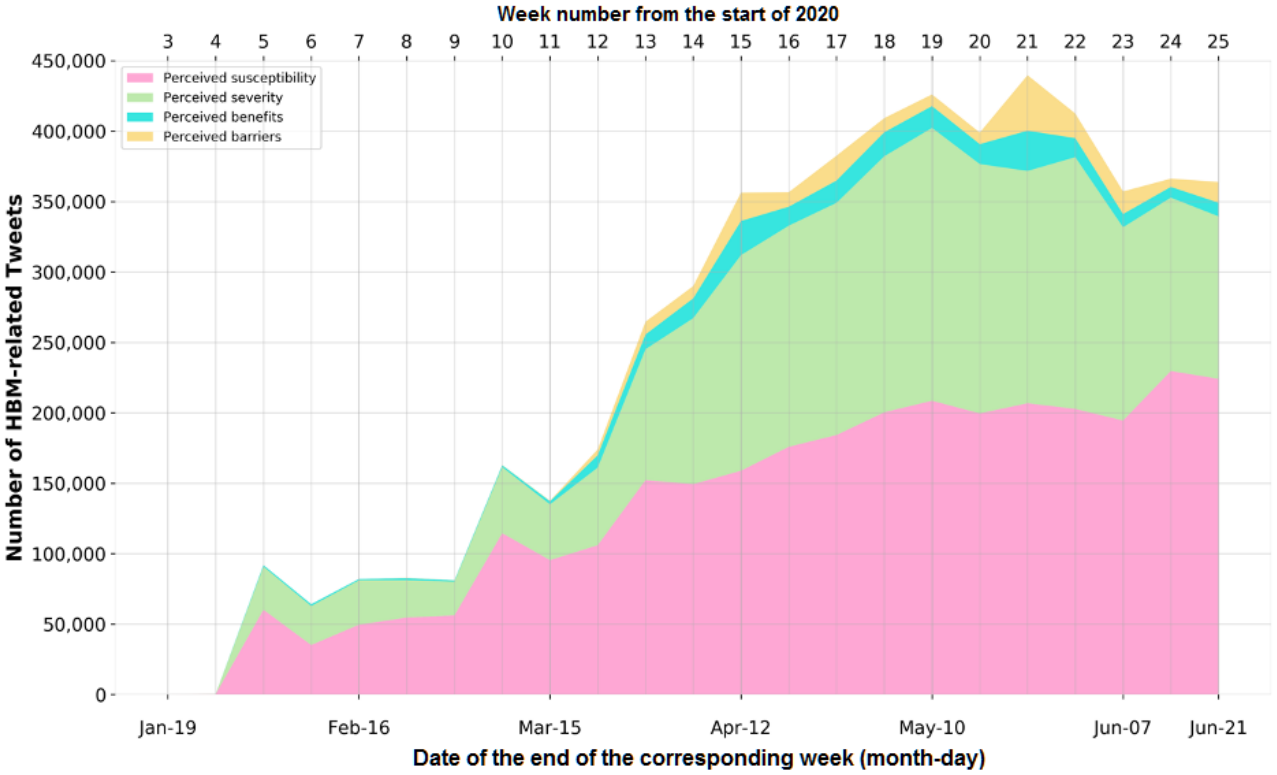
The Overall Trend of Health Beliefs in Tweets

The visualization of the overall trend of health beliefs is shown in Figure 3, with the number of tweets that fell into each core construct of the HBM. Each construct was displayed in a different color chronologically, starting from the third week of 2020, and stacked together to show the total number of HBM-related tweets. A dramatic increase can be observed from January to June, which indicates an increasing number of discussions regarding personal health beliefs. The R_0 was 7.62 for the users who tweeted about health beliefs in our data.

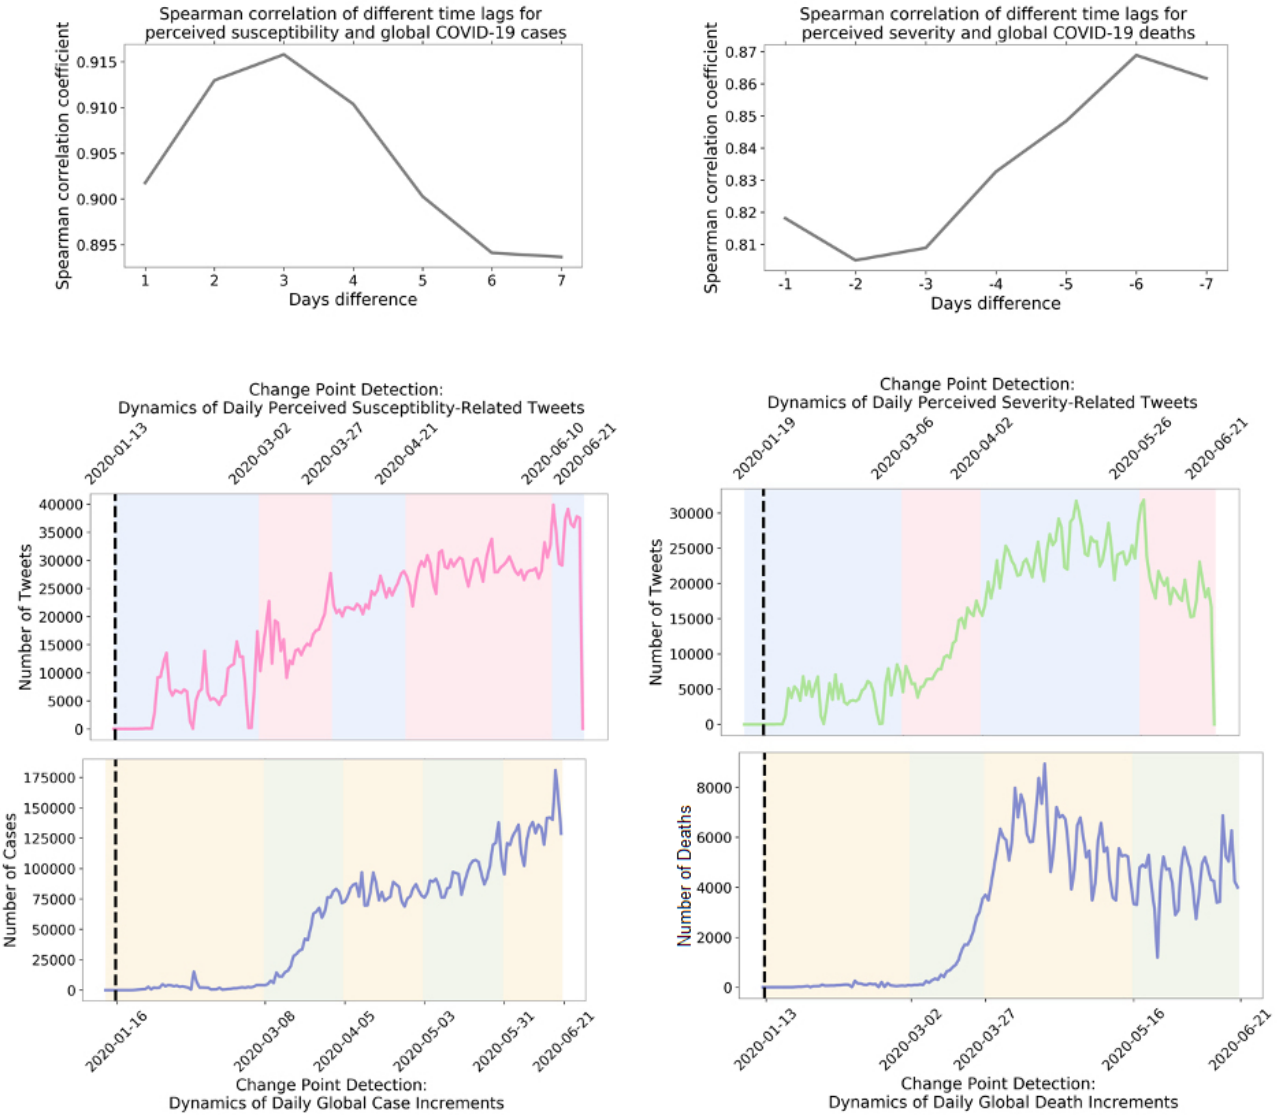
Figure 3. Stacked area chart for the four core constructs of the health belief model (HBM) from January 19 to June 21, 2020.



The Trend of Health Belief Toward the Disease

The left panel of Figure 4 displays the strongest correlation (ie, 0.92) between perceived susceptibility–related tweets and the global case increment when imposing a 3-day lag (ie, moving the trend of COVID-19 cases 3 days forward so that the number of perceived susceptibility tweets on January 13, 2020, will be aligned with the number of COVID-19 cases on January 16, 2020). The patterns detected by the change point analysis depicted by color in Figure 4 also show similarities within the pair. For the second pair (ie, perceived severity and COVID-19 death trend in the right-hand panel of Figure 4), the strongest correlation was found at –6 days (ie, 0.87), which indicates that changes in the perceived severity were lagging the actual death dynamics by 6 days (ie, the strongest correlation was found when moving the death trend 6 days backward). The change point analysis unraveled similar patterns between the trends of perceived severity and COVID-19 deaths.

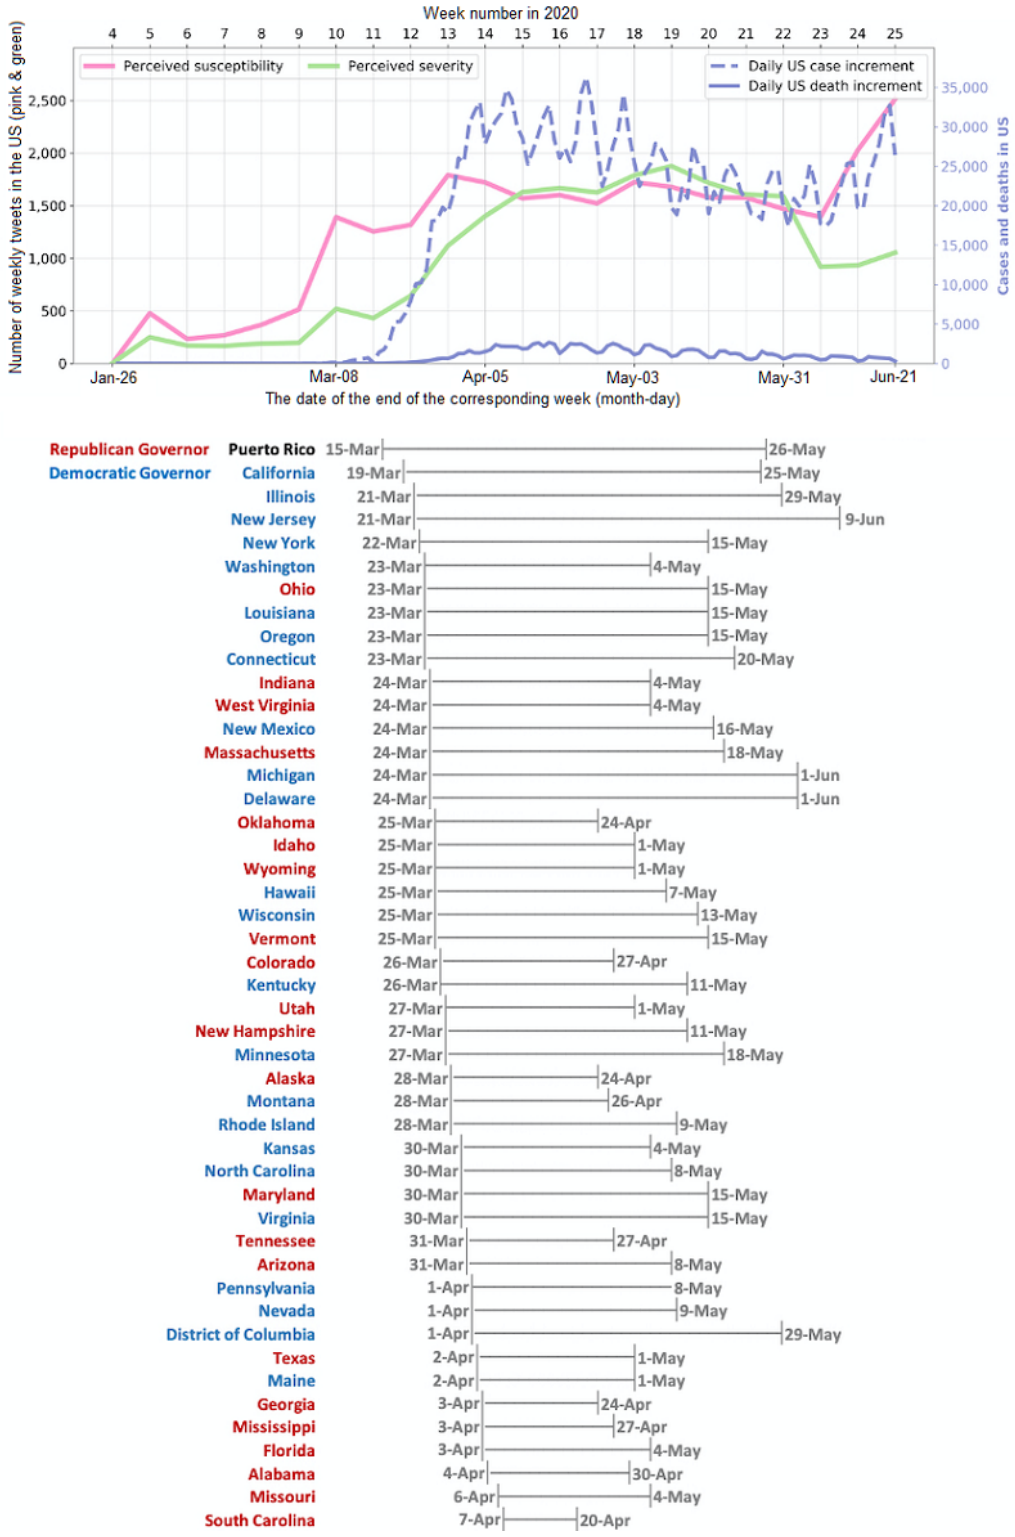
Figure 4. Correlation between perceived susceptibility–related tweets and COVID-19 case dynamics. Each pair of the lower four graphs are staggered according to the time differences that achieve the highest correlation in the top graphs: 3 days and –6 days, respectively. The pink and blue as well as the yellow and green shades depict the change points detected from the change point analysis.



The Effect of Interventions

We visualized the trends of perceived susceptibility and perceived severity along with the daily case and death dynamics in the United States in Figure 5. Meanwhile, lockdown information for each state is also listed by the timeline. Decisions made by Republican or Democratic governors are colored red and blue, respectively. The Republican states South Dakota, North Dakota, Iowa, Nebraska, and Arkansas did not announce official lockdowns and are not included in this figure. The official documents of lockdown and reopen decisions for each state are listed in Multimedia Appendix 1, Table S6.

Figure 5. Dynamics of health beliefs related to COVID-19 and the trend of case and death fluctuation in the United States with lockdown status. The lower half of the figure shows the official lockdown circumstances in each US state by each governor. The lines corresponding to each state represent the start and end date of the official lockdowns. The Republican states South Dakota, North Dakota, Iowa, Nebraska, and Arkansas did not announce official lockdowns and are not shown in this figure. The full reference for each state can be found in Multimedia Appendix 1, Table S6.



News in the Top Topics

Top 10 topics, which where all changed to lowercase, according to the tf-idf scores are shown in Figure 6, where a darker shade of the cell indicates a higher tf-idf score. The featured phrases that were closely related to the news during the corresponding time periods are highlighted in purple.

Figure 6. Top 10 topics of each week. Top phrases for each week are organized horizontally in each row. The blue shade in each cell indicates the term frequency–inverse document frequency (tf-idf) score of the phrase; the higher the tf-idf score, the darker the shade. The phrases that were likely associated with news are highlighted in purple.

The Influence of Scientific and Nonscientific Events

The list of events that we collected is shown on the right-hand side of Figure 7, while the trends of perceived benefits and barriers are shown on the left-hand side. We observed that both scientific and nonscientific events were associated with fluctuations in health beliefs. The scales of the fluctuations observed varied over time. There were more nonscientific events around the two most massive spikes, but scientific events were majorly distributed along the timeline where many gentle fluctuations could be found. The Kruskal-Wallis test showed no significant difference between the influence of scientific and nonscientific events for both perceived benefits and barriers (H=0.078, P=.78; and H=0.002, P=.92, respectively). Full references for each event can be found in Multimedia Appendix 1, Table S7.

Figure 7. Dynamics of health beliefs related to hydroxychloroquine (HCQ) and chloroquine (CQ) with correlated scientific and nonscientific events. Scientific events are those that have concrete scientific evidence or are endorsed by authorities, while nonscientific events account for the rest. The full reference for each event can be found in Multimedia Appendix 1, Table S7. Discussion

Principal Findings

Through the utilization of natural language processing (NLP) and machine learning, we employed the HBM to identify tweets associated with health beliefs. Through further evaluation of HBM-related tweets, our findings demonstrated that trends in health beliefs were correlated with dynamics in positive case and mortality rates. Additionally, we observed a decline in perceived disease susceptibility during government-issued lockdowns, while perceived severity appeared unaltered. Lastly, our study identified top news events, scientific and nonscientific, that may play a role in altering health beliefs. These findings lay the groundwork to better understand how the general public's COVID-19-related health beliefs are influenced by case and mortality rates, government policies, current news, and significant events. Through careful study of these observations, we may better implement management strategies to combat the pandemic and the infodemic.

In commonly used models for infectious diseases, infection is considered to be spreading in a population when R_0 is greater than 1, and the epidemic is harder to control with a larger value of R_0. Therefore, given the R_0 of 7.62, it is reasonable to conclude that an infodemic is ongoing in our study population.

It is interesting that health beliefs involving perceived susceptibility increased in advance of the actual evolvement of the pandemic. Because we observed the basic reproduction number R_0 of 7.62, suggestive of an infodemic, these findings may suggest that the volume of information regarding COVID-19 affects Twitter users' perspectives regarding the risk of infection. In the early stages of the pandemic, before mortalities were observed, it is possible that less severity was assumed. Over time, perceived severity may have increased as the number of deaths cumulated. Strong correlations between perceived susceptibility and perceived severity regarding the case and death dynamics may suggest that the ongoing situation of the pandemic is a significant impact factor affecting health beliefs.

From the line chart in Figure 5, we observed a dramatic increase in daily cases between week 11 and week 14. There was also an upward trend in perceived susceptibility starting from week 11, which began decreasing by week 13. This phenomenon is interesting when we take the lockdown situation into consideration, as starting from week 13 was when most of the states were under the government-issued lockdown. Thus, official interventions were observed to potentially mitigate the general public's perceived susceptibility of COVID-19. Meanwhile, we saw the growth of the number of confirmed cases slowing down during this same period. Interestingly, we failed to see a decline in perceived severity even when almost all the states were under quarantine. Previously, we showed that perceived severity was found to most strongly correlate with mortality; thus, it is reasonable that lockdown policies did not ease such health concerns, perhaps owing to the fact that while lockdowns slow down the spread of infection, they do not offer complete protection, especially in the absence of viable medications or treatment strategies.

As shown in Figure 6, for the first 3 to 4 weeks, topics predominately covered confirmed cases worldwide when the global pandemic was not yet affirmed by the authorities. In the following weeks, the terms *cruise ship* [29] and *li wenliang* [30] came into the spotlight. In early February, a large and notable cluster of COVID-19 cases occurred on the Diamond Princess cruise ship. Dr Wenliang Li, the Chinese doctor who tried to raise the alarm about a possible outbreak of a disease that resembled SARS-CoV-2 in Wuhan, China, died of the infection on February 7 , 2020. During weeks 8 and 9, when the COVID-19 outbreak heightened in Italy [31] and Iran [32], topics related to these countries began trending. On March 18, 2020 (ie, week 12), then President Trump announced that he was taking HCQ as prophylaxis for COVID-19 [33] and triggered massive discussions. In fact, starting at week 13, discussions involving HCQ and CQ began to dominate. Lastly, we were initially surprised to observe other topics like *george floyd* [34] in the health belief–related tweets. However, this topic is related to many events where people gathered that happened while many states were still under lockdown, possibly provoking health concerns. Through this analysis, we suspect that the news from all sources may penetrate into discussions regarding health beliefs and, thus, may influence health beliefs. Therefore, the news that we consume every day may inadvertently be a substantial factor that affects our health beliefs, which may contribute to and even exacerbate the infodemic on social media.

We observed that speeches by politicians could have dramatic impacts on the health beliefs of the general public who read the news. However, politicians' speeches do not necessarily recapitulate scientific facts or evidence and could sometimes be misleading [35]. Thus, we expect to rely more on scientific sources, such as publications with scientific evidence or announcements made by health authorities, for more accurate and reliable information regarding the pandemic. However, it is uncertain whether scientific events or nonscientific events have a more profound influence on altering the health beliefs of the general public.

The results from the Kruskal-Wallis test imply that scientific events and nonscientific events did not significantly differ from one another in regard to their effect on health beliefs within the given period (ie, January 6 to June 21, 2020). We found it surprising that scientific events did not appear to be significantly associated with altering the health beliefs toward potential treatments in our data set. This might be due to the public's distrust in science arising from the many uncertainties involving the pandemic or the instances of being delivered conflicting information, such as "Don't wear masks" to "Wear masks all the time." To better cope with COVID-19 circumstances, everyone in society, online and offline, should be aware of the overabundance of information and its potential impact on health beliefs. Thus, it is essential to be prudent to screen the authenticity of each piece of information.

Limitations and Future Work

We have identified some limitations in this study. The tweets analyzed in this study covered the English language, and there might be divergences across different languages that were not addressed. Although English tweets constitute the largest proportion among all the tweets, the number of tweets in other languages or undefined languages are still considerable [36]. We hope to expand the analysis to a multilingual setting in future work. Additionally, although we did not cover every potential treatment at this stage, our framework is extensible to assess the influence on health beliefs of additional treatments or interventions, such as vaccines. In fact, we plan to apply similar approaches to investigate health beliefs in COVID-19 vaccines once they are available to the general public. Furthermore, we likely have not considered other factors that may contribute to alterations in health beliefs.

This analysis used data extracted from one social media platform, Twitter, which may also introduce bias. Users' health beliefs may not represent those of the entire population, since not everyone uses Twitter. More social media platforms will be incorporated in future work, such as Facebook, Instagram, and Reddit. Additionally, it would be interesting to compare our crowdsourcing results with health beliefs obtained through hospital-administrated surveys from patients with COVID-19 and their caretakers.

Technically, this study employed the very classic text classification methods, which used a combination of the bag-of-words model and machine learning classifiers. Yet, the

experiments showed that they worked well (ie, AUROC curve over 0.9) on the given data. Deep learning architectures were not discussed in this study, mainly because there is no guarantee that deep learning models always work better than simple machine learning classifiers. Meanwhile, deep learning models bear higher technical barriers, which compromise the accessibility for people from other domains. Deep learning models are also known to demand considerable energy [37], so we were also trying to trade off the energy-performance balance. However, it is definitely worth a whole other study to discuss various NLP techniques for the classification task. For future studies, we are also interested in investigating the performance of various NLP techniques on the current text classification tasks.

Conclusions

Our data suggest that we are not only fighting a pandemic but also an infodemic. The excessive information disseminated on social media platforms and other sources is closely related to the dynamics of the general public's health beliefs. The dynamics of the pandemic, news, scientific and nonscientific events, and even the related tweets already published on social media platforms may influence the health beliefs of the general public on social media to some extent. Our findings provide clues and evidence for more effective management of the infodemic associated with the COVID-19 pandemic.

Acknowledgments

HW, YLi, and YLuo conceived of the presented idea. HW, YLi, and MH contributed to the data annotation and validation. HW carried out all the experiments and conducted all the data analyses. HW wrote the manuscript and designed the tables and figures with support from MH and YLi. AN provided clinical insights and contributed to the results interpretation. YLuo advised and supervised the entire project. We thank Twitter for providing the API for developers to retrieve tweets for this research.

Abstract

Background: The initial symptoms of patients with COVID-19 are very much like those of patients with community-acquired pneumonia (CAP); it is difficult to distinguish COVID-19 from CAP with clinical symptoms and imaging examination.

Objective: The objective of our study was to construct an effective model for the early identification of COVID-19 that would also distinguish it from CAP.

Methods: The clinical laboratory indicators (CLIs) of 61 COVID-19 patients and 60 CAP patients were analyzed retrospectively. Random combinations of various CLIs (ie, CLI combinations) were utilized to establish COVID-19 versus CAP classifiers with machine learning algorithms, including random forest classifier (RFC), logistic regression classifier, and gradient boosting classifier (GBC). The performance of the classifiers was assessed by calculating the area under the receiver operating characteristic curve (AUROC) and recall rate in COVID-19 prediction using the test data set.

Results: The classifiers that were constructed with three algorithms from 43 CLI combinations showed high performance (recall rate >0.9 and AUROC >0.85) in COVID-19 prediction for the test data set. Among the high-performance classifiers, several CLIs showed a high usage rate; these included procalcitonin (PCT), mean corpuscular hemoglobin concentration (MCHC), uric acid, albumin, albumin to globulin ratio (AGR), neutrophil count, red blood cell (RBC) count, monocyte count, basophil count, and white blood cell (WBC) count. They also had high feature importance except for basophil count. The feature combination (FC) of PCT, AGR, uric acid, WBC count, neutrophil count, basophil count, RBC count, and MCHC was the representative one among the nine FCs used to construct the classifiers with an AUROC equal to 1.0 when using the RFC or GBC algorithms. Replacing any CLI in these FCs would lead to a significant reduction in the performance of the classifiers that were built with them.

Conclusions: The classifiers constructed with only a few specific CLIs could efficiently distinguish COVID-19 from CAP, which could help clinicians perform early isolation and centralized management of COVID-19 patients.

COVID-19; clinical laboratory indicators; community-acquired pneumonia; classifier; classification algorithm

Introduction

COVID-19 caused by SARS-CoV-2 infection, which was discovered in early December 2019, has become a global pandemic. As of August 3, 2020, COVID-19 has become widespread in 215 countries, areas, or territories worldwide; it has caused infection in more than 17.9 million people and has resulted in the deaths of more than 686,000 people [1]. The World Health Organization has stated that the spread of COVID-19 may be impeded by early detection, isolation, and the implementation of a robust health care system [2,3]. Nevertheless, the published data indicate that the initial symptoms of COVID-19 in patients are very similar to those in patients with the common cold or influenza. COVID-19 patients exhibit different clinical symptoms, and some of them do not have any symptoms [4-7]. sars-cov-2 infection has a long incubation period, with a median incubation period of 5 to 7 days, which is the chief risk factor for community infection [6,8]. Community-acquired pneumonia (CAP) and COVID-19 have similar clinical and imaging features, but their treatment and infectivity are very dissimilar. Distinguishing COVID-19 from CAP is very important to prevent the spread of COVID-19 and to provide specific treatment.

Some characteristic spectra demonstrated by clinical laboratory indicators (CLIs) of COVID-19 patients have been utilized as auxiliary clues for diagnosis [9]. Previous studies have demonstrated that increased procalcitonin (PCT), lymphocytopenia, and thrombin activation can all be utilized as auxiliary diagnostic indicators of COVID-19 and poor prognostic factors [9-11]. However, they are also correlated with CAP [12-15]. Thus, in accordance with the changes in these indicators, it is impossible to differentiate COVID-19 from CAP. The changes in the neutrophil to lymphocyte ratio, the peak platelet to lymphocyte ratio, lactate dehydrogenase (LDH), C-reactive protein (CRP), and interleukin-6 (IL-6) are considered to be associated with the progression and prognosis of COVID-19 [9], but using the information from the CLIs to give clinicians correct guidance is still a great challenge.

Classifiers established by machine learning (ML) algorithms based on various clinical features, biomarkers, and CLIs are increasingly widely utilized in disease diagnosis and risk prediction [16]. During the COVID-19 pandemic, ML was also widely used to predict, classify, assess, track, and control the spread of SARS-CoV-2 [17,18]. ML can improve diagnostic performance compared with hand-selected biomarkers by selecting relevant biomarkers and more consistently capturing both their relative importance to prediction and their interactions among one another [19]. In this study, we used CLIs to build classifiers with different ML algorithms to distinguish COVID-19 patients from CAP patients; we found that only the feature combinations (FCs) with many specific CLIs rather than the FCs with the most significantly differential CLIs between the two groups could build high-performance classifiers (HPCs).

Methods

Collection of Patients' Electronic Medical Record Data

The electronic medical records of patients who were admitted to Gong An County People's Hospital, China, and diagnosed with COVID-19 or CAP from December 2019 to March 2020 were retrieved. The information regarding each patient's age, sex, clinical symptoms upon admission, medical history, epidemiological history, computed tomography (CT) imaging features, and CLIs were sorted out for retrospective analysis. Only the laboratory test results during admission were included. It was specified that all patients' data were to be kept confidential, and this data were only to be utilized for comprehensive analysis. No personal information about any patient was mentioned in the paper. This study was approved by the ethics committees from the Guangdong Provincial Hospital of Chinese Medicine (approval No. ZE2020-049-01) with a waiver of informed consent due to the retrospective nature of the study.

Data Description

Diagnosis and clinical classification of COVID-19 were performed according to the *Chinese Clinical Guidance for COVID-19 Pneumonia Diagnosis and Treatment (7th edition)* [20]. A total of 61 patients with COVID-19 and 60 patients with CAP were enrolled according to the discharge diagnosis on their electronic medical records. There were 3 mild, 47 common, 6 severe, and 5 critical types, which were categorized into two groups for further analysis as follows: COVID19-COM (3 mild and 47 common types) and COVID19-SV (6 severe and 5 critical types). They were matched by age and sex and did not significantly differ in terms of medical history. The main clinical symptoms between CAP and COVID-19 groups were not significantly different.

Primary Analysis

The descriptive analysis of all CLIs was performed between groups or subgroups. Between-group or between-subgroup differences were tested using the *statsmodels* module from Python (Python Software Foundation) [21]. The Student *t* test was performed when the distribution of the variables conformed to the normal distribution; otherwise, the Mann-Whitney *U* test was used. The chi-square test was used to detect differences in baseline data between two groups or subgroups. A value of $P<.05$ was considered to be significant.

Feature Selection and Data Preprocessing

The CLIs with a missing value ratio greater than 20% were excluded. Only the CLIs with a significant difference between the two groups were selected and used to generate 1,807,780 nonrepetitive random FCs, consisting of one to eight CLIs, by using the *combinations* iterator in the *itertools* module from Python [22]. Next, an FC was selected from the FC list one by one to form a new data sheet with the dependent variable (ie, disease type), and 1,807,780 new data sheets were eventually formed. For each new data sheet, the rows with missing values were removed. The remaining rows were then divided into *training_dataset* and *test_dataset* using scikit-learn, version 0.23.1 (*train_test_split* function with *test_size* = 0.25,

random_state = 0). The training data set was used to build the classifier, and the test data set was used to assess the performance. The feature values were standardized using the *StandardScaler* function in the scikit-learn module before constructing the logistic regression (LR) classifier.

Construction of Classifiers With ML Algorithms in the Scikit-Learn Module

Scikit-learn is a Python module integrating a wide range of state-of-the-art ML algorithms for medium-scale supervised and unsupervised problems [23]. The LR classifier, the random forest classifier (RFC), and the gradient boosting classifier (GBC) have been typically used to construct classifiers in prediction of disease risk, progression, prognosis, and so on [24]. The LR classifier in the *sklearn.linear_model* is also known as logit regression, maximum-entropy classification, or the log-linear classifier. In this model, the probabilities describing the possible outcomes of a single trial are modeled using a logistic function [24]. The RFC in the *sklearn.ensemble* module is one of the averaging algorithms in ensemble methods and is a perturb-and-combine technique specifically designed for trees. In the random forest algorithm, each tree in the ensemble is built from a sample drawn with replacement from the training data set. Furthermore, when splitting each node during the construction of a tree, the best split is found either from all input features or from a random subset of size setting with the parameter *max_features*. In practice, the variance reduction due to the introduction of randomness in the classifier construction is often significant, hence, yielding an overall better model [25,26]. The GBC algorithm, using the *sklearn.ensemble* function, is a boosting method, in which base estimators are built sequentially. To reduce the bias of the combined estimator, one has to combine several weak models to produce a powerful ensemble. The GBC algorithm builds an additive model in a forward stage-wise fashion, and it allows for the optimization of arbitrary differentiable loss functions [27,28].

In this study, the classifiers were respectively constructed using the LR classifier, RFC, and GBC in the scikit-learn module with the training data set. The model parameter settings were kept as default, except that *random_state* was modified to "0" for all models and *class_weight* was modified to "balanced" for the LR classifier and RFC models. The performance of the classifiers was evaluated with the test data set by calculating the recall rate (ie, sensitivity), specificity, accuracy, and area under the receiver operating characteristic curve (AUROC), using the *sklearn_metrics.recall_score*, *sklearn_metrics.precision_score*, *sklearn_metrics.accuracy_score*, and *sklearn_metrics.auc* functions, respectively. Gini importance was computed using the *feature_importance* function to measure the importance of each feature in the RFC and the GBC. The higher the Gini importance value, the more important the feature [29]. All the above analyses were performed in Python, version 3.7 (Python Software Foundation).

Results

Basic Characteristics of CAP Group and COVID-19 Group

No significant differences in age and sex were found between CAP and COVID-19 groups (see Table 1); however, the proportions of males in the CAP and COVID-19 groups were 55% (33/60) and 66% (40/61), respectively, and were higher than those of females in both groups. No significant difference in the medical history between the two groups (see Table 1) was observed. Also, no significant difference was found in the proportions of the main clinical symptoms between the two groups, such as fever, cough, fatigue, muscle soreness, and loss of appetite (see Table 1). The average hospitalization days for CAP patients were remarkably lower than those for COVID-19 patients (P<.001). In the CAP group, some patients with pulmonary CT also had imaging features that included patchy hyperdense shadow (11/60, 18%), ground-glass shadow (4/60, 7%), and fibrotic lesion (6/60, 10%). Nonetheless, the chief imaging features of pulmonary CT in the COVID-19 group were patchy hyperdense shadow (25/61, 41%) and ground-glass shadow (9/61, 15%), and many patients (7/61, 11%) had both patchy hyperdense shadow and ground-glass shadow (see Table 1). Among the 61 patients suffering from COVID-19, 3 (5%) had mild symptoms, 47 (77%) had common symptoms, 6 (10%) had severe symptoms, and 5 (8%) had critical symptoms. Fever and cough were the principal symptoms in the early stage of COVID-19, and these accounted for 70% (43/61) and 64% (39/61) of the cases, respectively (see Table 1). Among the CAP patients included in the analysis, no cases of death were found during hospitalization; however, 3 of the 5 (60%) severely ill patients in the COVID-19 group, who were aged 36, 49, and 74 years, died during hospitalization. The 36-year-old patient who died underwent interventricular septal repair in childhood.

Table 1. Comparison of baseline information between COVID-19 patients and community-acquired pneumonia (CAP) patients.

Baseline characteristic	CAP patients (n=60)	COVID-19 patients (n=61)	*P* value
Sex (male), n (%)	33 (55)	40 (66)	.27
Age (years), mean (SD)	55.72 (18.10)	50.23 (16.95)	.09
Hospitalization days, median (IQR)	9 (7-12)	21 (13-26)	<.001
Medical history, n (%)			
Hypertension	14 (23)	16 (26)	.83
Diabetes	2 (3)	6 (10)	.27
Liver disease	2 (3)	3 (5)	.99
Heart disease	3 (5)	5 (8)	.72
Exposure history	Unclear	54 (89)	N/A[a]
Familial aggregation infection[b]	Unclear	22 (36)	N/A
Initial symptoms, n (%)			
Fever	36 (60)	43 (70)	.26
Cough	44 (73)	39 (64)	.33
Myalgia	4 (7)	7 (11)	.53
Poor appetite	5 (8)	11 (18)	.18
Fatigue	33 (55)	24 (39)	.10
Days from onset of symptoms to admission, median (IQR)	Unrecorded	3 (1-7)	N/A
Imaging features, n (%)			
Patchy high-density opacity	11 (18)	25 (41)	.009
Ground-glass opacity	4 (7)	9 (15)	.24
Fibrotic lesion	6 (10)	3 (5)	.32
Patchy high-density opacity and ground-glass opacity	0 (0)	7 (11)	.01
Death cases, n (%)	0 (0)	3 (5)	N/A

[a]N/A: not applicable; groups could not be compared because there were no values for the CAP group.

[b]There were more than 2 cases of infection after aggregation with family members or relatives.

Characteristic Profile of the CLIs in COVID-19 and CAP

Even though most CLIs had a similar variation trend in both CAP and COVID-19, the extent of change was different. Among more than 60 evaluated CLIs, there were significant differences in 25 CLIs between the two groups (see Table 2). A decrease of lymphocyte, red blood cell (RBC) count, hematocrit or packed-cell volume (PCV), hemoglobin concentration, and mean corpuscular hemoglobin concentration (MCHC) and an increase of neutrophil ratio, prothrombin time (PT), micro-CRP (mCRP), and PCT were observed in both COVID-19 and CAP patients. Furthermore, the neutrophil ratio and levels of PT, mCRP, and PCT in CAP were remarkably higher than those in COVID-19. Levels of lymphocyte, RBC count, PCV, hemoglobin concentration, and MCHC in CAP were significantly lower than those in COVID-19 (see Figure 1). Various erythrocyte-related CLIs—RBC count, PCV, hemoglobin concentration, and MCHC—significantly decreased in both CAP and COVID-19, but there was a greater reduction in CAP patients (see Figure 1). The RBC distribution width–standard deviation (RDW-SD) and RBC mean corpuscular volume (MCV) also indicated prominent differences between CAP and COVID-19 (see Figure 1).

Table 2. Differences in clinical laboratory indicators (CLIs) between patients with community-acquired pneumonia (CAP) and COVID-19.

CLI	CAP patients (n=60)		COVID-19 patients (n=61)		*P* value
	n (%)	Mean (SD)	n (%)	Mean (SD)	
Procalcitonin (ng/mL)	43 (72)	0.629 (0.838)	55 (90)	0.134 (0.184)	<.001
Monoamine oxidase B (U/L)	35 (58)	4.569 (1.748)	53 (87)	3.538 (1.592)	.001
Myoglobin (ng/mL)	14 (23)	39.179 (29.421)	23 (38)	65.794 (87.039)	.04
Micro–C-reactive protein (mg/L)	41 (68)	63.943 (64.530)	13 (21)	22.568 (29.577)	.004
Prothrombin time (seconds)	30 (50)	12.780 (0.873)	53 (87)	12.460 (1.107)	.04

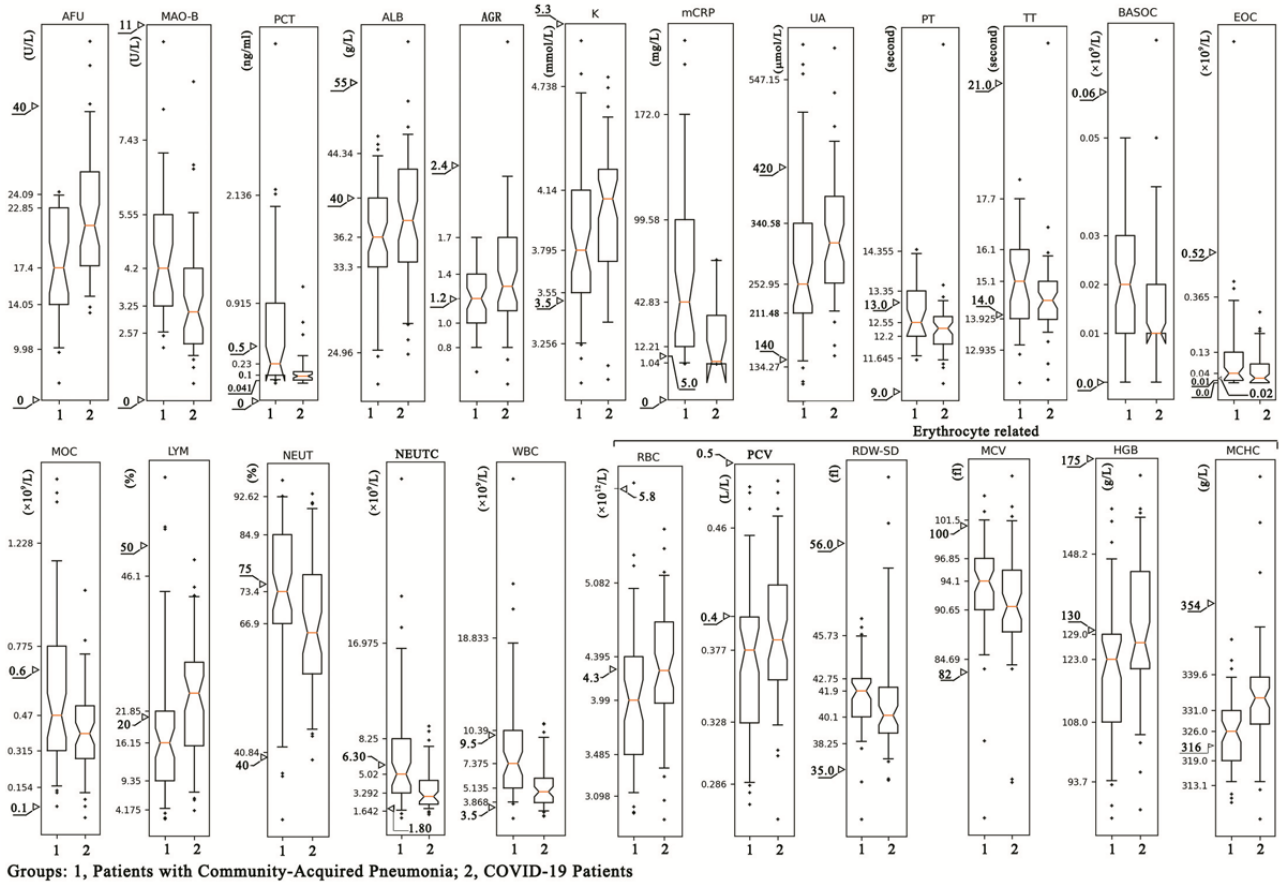
Mean red blood cell volume (fL)	55 (92)	93.255 (6.662)	56 (92)	91.241 (6.501)	.01
Mean corpuscular hemoglobin concentration (g/L)	55 (92)	325.473 (8.360)	56 (92)	334.482 (13.559)	<.001
Red blood cell distribution width–standard deviation (fL)	55 (92)	41.476 (2.573)	56 (92)	41.141 (4.082)	.01

Figure 1. The statistical distribution of the plasma level of the clinical laboratory indicators (CLIs) with a remarkable difference between COVID-19 and community-acquired pneumonia (CAP). The statistical distribution was presented with a box and whisker plot. The horizontal lines within the boxes indicate the median value. The vertical lines extending below and above the boxes represent 5%-95% percentile values. The scale on the y-axis represents the values of the 5th, 25th, 50th, 75th, and 95th percentiles of the CLI in the CAP group. The triangles represent the upper and lower limits of the normal reference range of the laboratory index. AFU: α-L-fucosidase; AGR: albumin to globulin ratio; ALB: albumin; BASOC: basophil count; EOC: eosinophil count; HGB: hemoglobin concentration; K: potassium; LYM: lymphocyte; MAO-B: monoaminoxidase B; MCHC: mean corpuscular hemoglobin concentration; mCRP: micro–C-reactive protein; MCV: mean (red blood cell) corpuscular volume; MOC: monocyte count; NEUT: neutrophil ratio; NEUTC: neutrophil count; PCT: procalcitonin; PCV: packed-cell volume (hematocrit); PT: prothrombin time; RBC: red blood cell count; RDW-SD: red blood cell distribution width–standard deviation; TT: thrombin time; UA: uric acid; WBC: white blood cell count.



Comparing the COVID19-COM and COVID19-SV subgroups, 26 CLIs demonstrated a remarkable difference (see Table 3). In comparison with the COVID19-COM subgroup, LDH, aspartate aminotransferase, fibrinogen content, mCRP, and erythrocyte sedimentation rate increased acutely in the COVID19-SV subgroup, whereas prealbumin, carbon dioxide binding capacity, lymphocytes, and lymphocyte count decreased in the COVID19-SV subgroup (see Multimedia Appendix 1).

An orderly increase of α-L-fucosidase (AFU), myoglobin, uric acid, and MCHC and an orderly decrease of thrombin time, monocyte count, eosinophil count, RBC MCV, and RDW-SD were observed in CAP, COVID19-COM, and COVID19-SV patients, indicating that these CLIs may be used to distinguish CAP from COVID-19 and may suggest the probability of severe COVID-19 progression (see Multimedia Appendix 2).

Table 3. Difference in clinical laboratory indicators (CLIs) between patients with common and severe types of COVID-19.

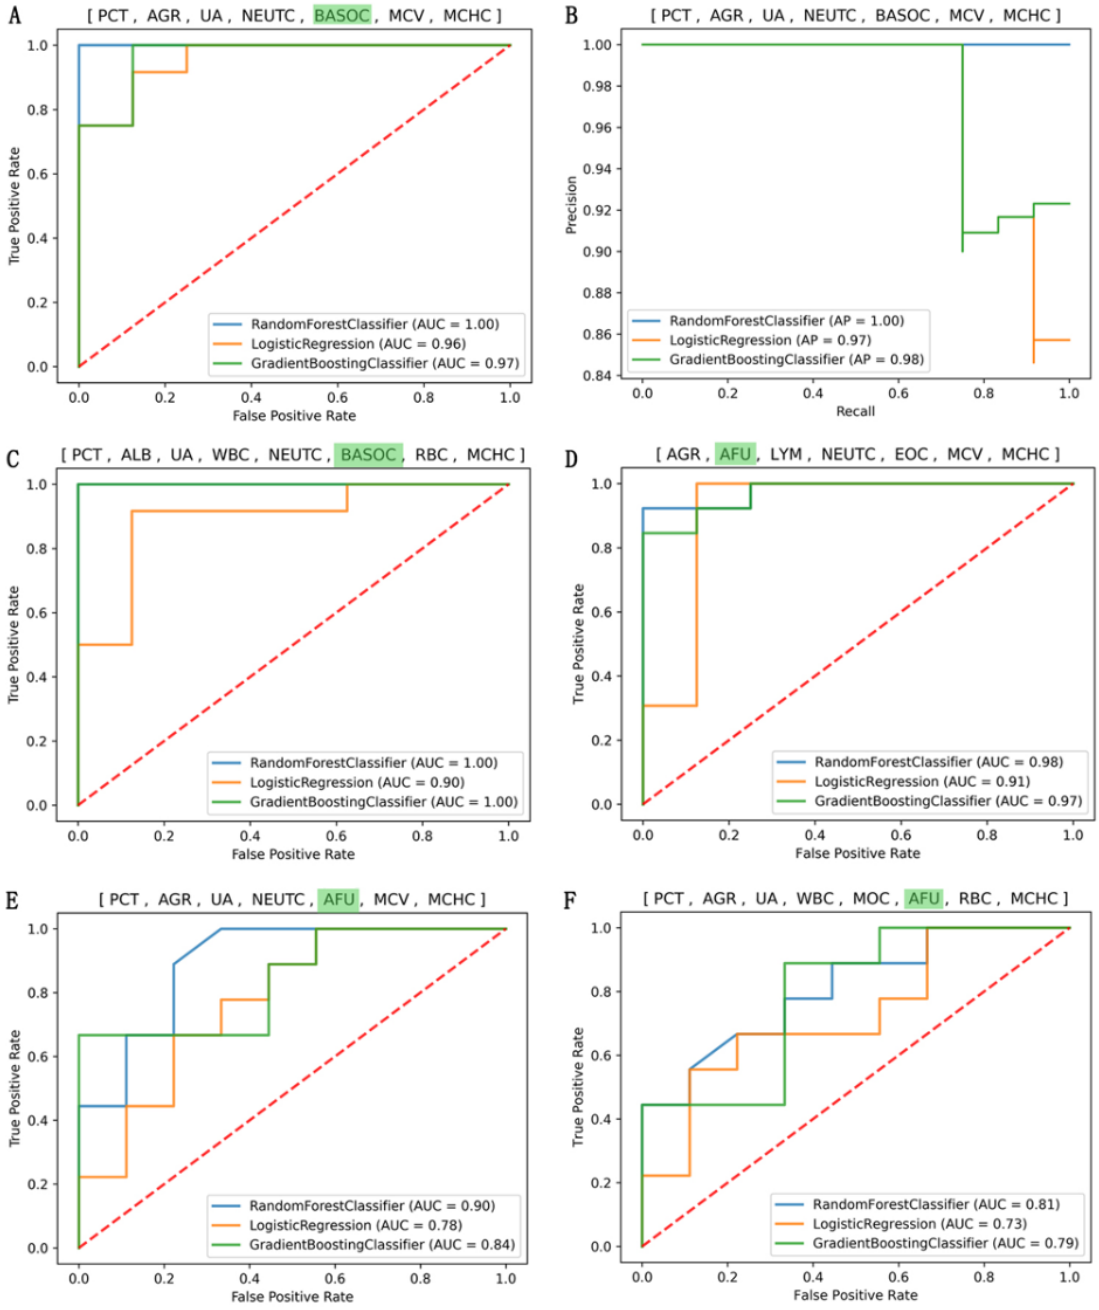
CLIs	Patients with a common type of COVID-19 (n=50)		Patients with a severe type of COVID-19 (n=11)		*P* value
	n (%)	Mean (SD)	n (%)	Mean (SD)	
Procalcitonin (ng/mL)	44 (88)	0.112 (0.170)	11 (100)	0.224 (0.217)	.01
N-terminal pro-B-type natriuretic peptide (pg/mL)	29 (58)	366.053 (549.429)	11 (100)	534.782 (398.067)	.03
Hypersensitive C-reactive protein (mg/L)	41 (82)	23.332 (34.483)	11 (100)	72.458 (60.805)	.002
Lactate dehydrogenase (U/L)	26 (52)	214.896 (73.319)	8 (73)	314.750 (118.755)	.02
D-dimer (mg/L)	42 (84)	0.834 (1.115)	11 (100)	5.133 (10.399)	.005
Myoglobin (ng/mL)	16 (32)	49.221 (60.505)	7 (64)	103.674 (127.354)	.02
Cardiac troponin (ng/mL)	16 (32)	0.011 (0.003)	7 (64)	0.033 (0.041)	.02
Creatine kinase (U/L)	27 (54)	81.296 (47.153)	8 (73)	202.125 (195.052)	.02
Fibrinogen content (mg/dL)	42 (84)	411.905 (104.363)	11 (100)	467.455 (76.500)	.03
Aspartate aminotransferase (U/L)	46 (92)	29.413 (15.756)	10 (91)	45.600 (18.969)	.004
γ-glutamyl transpeptidase (U/L)	44 (88)	46.046 (41.609)	10 (91)	80.000 (44.229)	.007
Albumin (g/L)	44 (88)	38.602 (6.267)	10 (91)	34.440 (4.558)	.02
Albumin to globulin ratio	44 (88)	1.436 (0.507)	10 (91)	1.120 (0.230)	.02
Indirect bilirubin (μmol/L)	44 (88)	9.482 (3.841)	10 (91)	7.960 (4.336)	.048
Prealbumin (mg/L)	41 (82)	180.171 (83.374)	9 (82)	125.556 (68.182)	.03
β2-microglobulin (mg/L)	41 (82)	1.978 (0.430)	9 (82)	2.528 (1.015)	.01
Carbon dioxide binding capacity (mmol/L)	41 (82)	25.420 (2.537)	9 (82)	22.733 (2.018)	.002
Potassium (mmol/L)	44 (88)	4.057 (0.414)	11 (100)	3.876 (0.251)	.04
Erythrocyte sedimentation rate (mm/h)	30 (60)	55.433 (41.639)	7 (64)	87.000 (35.081)	.02
Neutrophils (%)	45 (90)	64.496 (13.286)	11 (100)	75.519 (14.001)	.02
Lymphocytes (%)	45 (90)	25.711 (10.932)	11 (100)	17.073 (9.750)	.01
Eosinophils (%)	45 (90)	1.236 (1.388)	11 (100)	0.391 (1.038)	.009
Eosinophil count ($\times 10^9$/L)	45 (90)	0.062 (0.076)	11 (100)	0.014 (0.039)	.003
Lymphocyte count ($\times 10^9$/L)	45 (90)	1.255 (0.558)	11 (100)	0.835 (0.383)	.008
Packed-cell volume (hematocrit) (L/L)	45 (90)	0.395 (0.050)	11 (100)	0.368 (0.036)	.03
Red blood cell distribution width–coefficient of variation (%)	45 (90)	12.658 (1.171)	11 (100)	12.873 (0.781)	.03

Classifiers Constructed From the FCs With Seven to Eight CLIs Could Accurately Distinguish COVID-19 From CAP

The performance of the classifiers gradually improved as the number of CLIs in the FCs increased from one to eight. However, when the number of CLIs in the FCs reached eight, the performance of the classifiers constructed by these FCs no longer significantly improved. The performance of the LR classifier algorithm constructed with the FCs with eight CLIs (ie, 8-CLI combination) was even slightly lower than those constructed by the FCs with seven CLIs (ie, 7-CLI combination). A total of 43 FCs, including five 7-CLI combinations and 38 8-CLI combinations, were determined according to the recall rate. The AUROCs of the classifiers constructed with the LR classifier, RFC, and GBC algorithms were greater than 0.85 (see Multimedia Appendix 3, Table S1). The AUROC and precision-recall curves of the classifiers constructed with the RFC, LR classifier, and GBC algorithms from the representative 7-CLI combination (ie, PCT, albumin to globulin ratio [AGR], uric acid, neutrophil count, basophil count, RBC MCV, and MCHC) showed very high performance and precision in COVID-19 prediction; their AUROCs were 1.0, 0.97, and 0.96, respectively (see Figure 2, A), and their average precision values were 1.0, 0.97, and 0.98, respectively (Figure 2, B). The AUROCs of the classifiers constructed with the RFC, LR classifier, and GBC algorithms from the representative 8-CLI combination (ie, PCT, albumin, uric acid, WBC [white blood cell] count, monocyte count, basophil count, RBC count, and MCHC) were 1.0, 0.90, and 1.0, respectively (see Figure 2, C). The AUROCs of the classifiers constructed with the three algorithms from the 7-CLI combination (ie, agr, afu, lymphocytes, neutrophil counts, eosinophil count, RBC mcv, and mchc) were 0.98, 0.91, and 0.97, respectively (see Figure

2, D). Feature importance results showed that basophil count was the least important in the above two representative CLI combinations, and AFU was the most important in the CLI combinations (see Figure 3). However, when basophil count was substituted with AFU in the two above-mentioned CLI combinations, the performance of the classifiers constructed with the new CLI combinations decreased (see Figure 2, E and F). PCT and AFU were not observed to be in the same CLI combination from which an HPC could be constructed. The evidence above and the fact that only 43 FCs with seven or eight CLIs could be used to build HPCs suggested that only the FCs with specific CLIs can establish HPCs to distinguish COVID-19 from CAP.

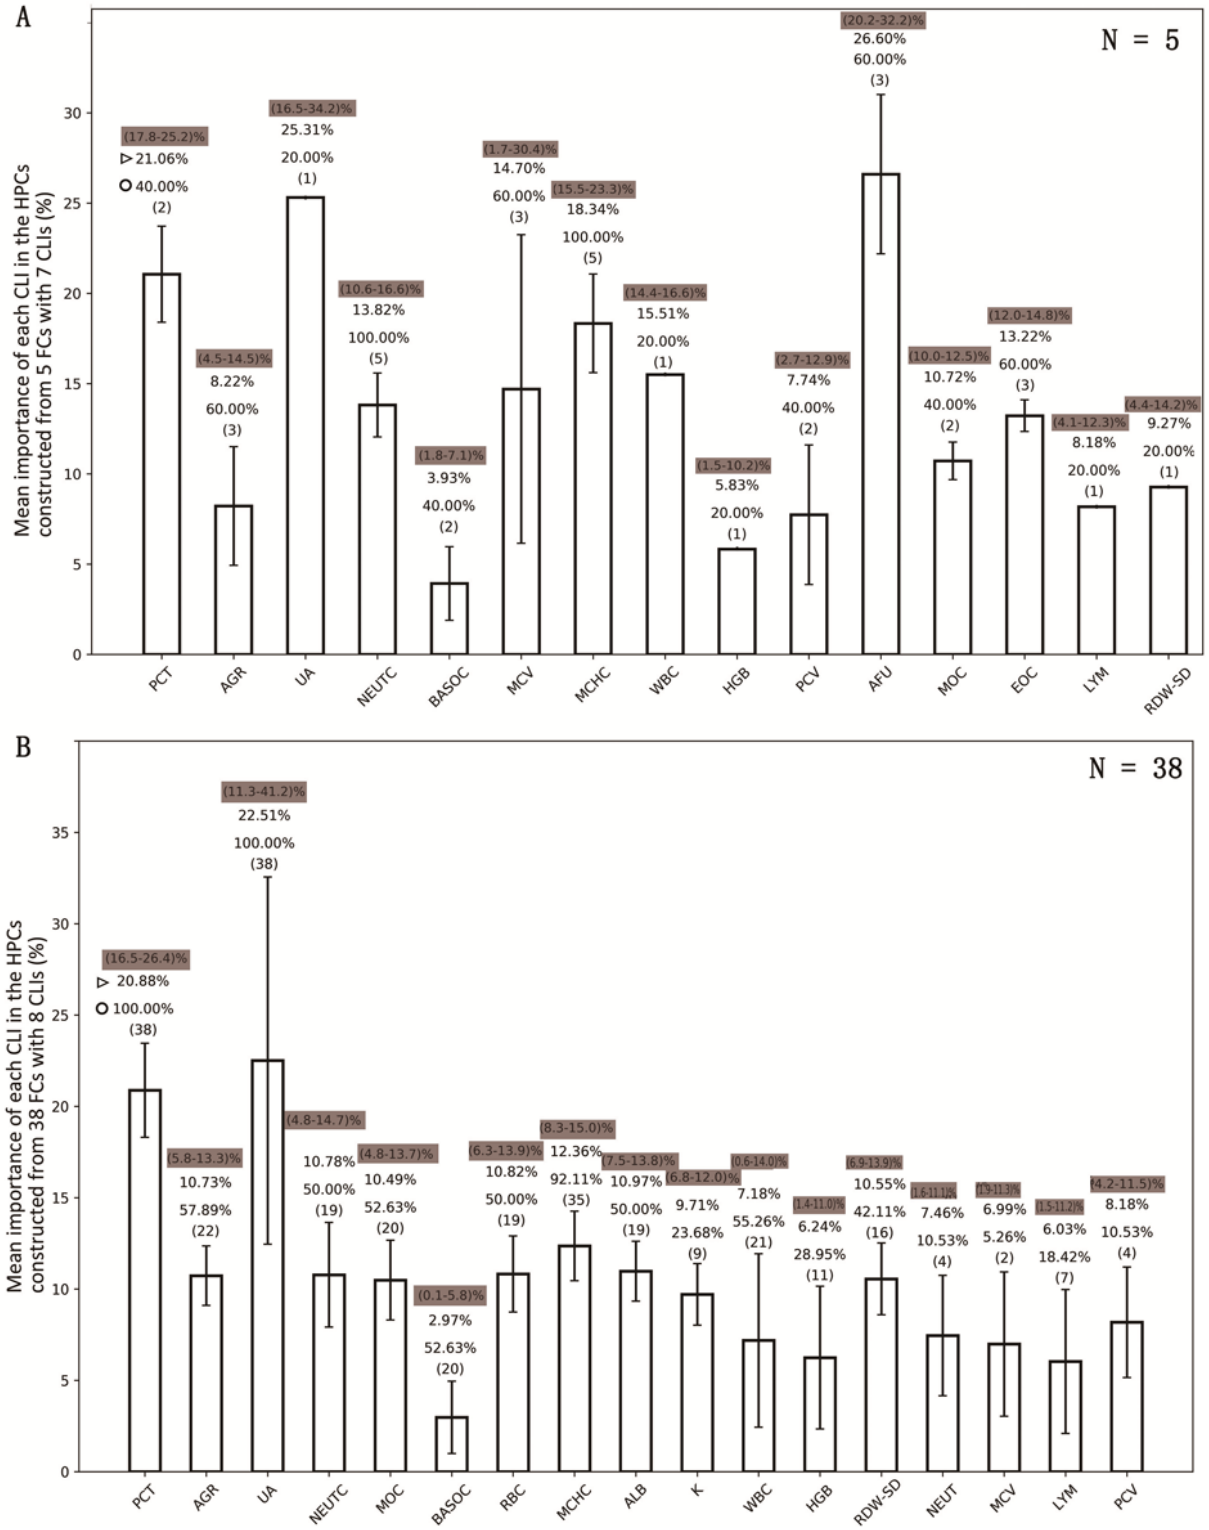
Figure 2. Area under the receiver operating characteristic curve (AUROC) and precision-recall curve plotted for the COVID-19 vs community-acquired pneumonia (CAP) classifiers built with various feature combinations (FCs) of different clinical laboratory indicators (CLIs). At the top of each image is the CLI combination for constructing classifiers using three different classification algorithms. AFU: α-L-fucosidase; AGR: albumin to globulin ratio; ALB: albumin; BASOC: basophil count; EOC: eosinophil count; LYM: lymphocyte; MCHC: mean corpuscular hemoglobin concentration; MCV: mean (red blood cell) corpuscular volume; MOC: monocyte count; NEUTC: neutrophil count; PCT: procalcitonin; RBC: red blood cell count; UA: uric acid; WBC: white blood cell count.



The importance of different CLIs in classifiers varied greatly, and the importance of the same CLI varied greatly among classifiers constructed by different FCs (see Figure 3). In the HPCs constructed with the 7-CLI combinations, the average feature importance of AFU (26.60%) was the highest, followed by uric acid (25.31%) and PCT (21.06%) (see Figure 3, A). However, in the HPCs constructed with the 8-CLI combinations, the average feature importance of uric acid (22.51%) was the

highest, followed by PCT (20.88%) and MCHC (12.36%) (see Figure 3, B). PCT and MCHC were very important to each classifier because they were included, respectively, in 100% (38/38) and 92% (35/38) of the 8-CLI combinations (see Figure 3, B) and in 40% (2/5) and 100% (5/5) of the 7-CLI combinations (see Figure 3, A). Uric acid was also included in all 8-CLI combinations, but its feature importance varied from 11.3% to 41.2% in different classifiers (see Figure 3, B).

Figure 3. Usage rate and the feature importance of each clinical laboratory indicator (CLI) in the high-performance COVID-19 vs community-acquired pneumonia (CAP) classifiers. (A) The mean feature importance of each CLI in the high-performance classifiers (HPCs) constructed with the 7-CLI combinations. (B) The mean feature importance of each CLI in the HPCs constructed with the 8-CLI combinations. The histogram is represented by mean (SD). The numbers with the shadow backgrounds represent the minimum and maximum values of the feature importance of the CLI. The number indicated with the triangle symbol represents the mean feature importance of CLI in all classifiers. The number indicated with the circle represents the usage rate of the CLI in the HPC. The number in the parentheses indicates how many CLI combinations are capable of constructing the HPCs containing the CLI. AFU: α-L-fucosidase; AGR: albumin to globulin ratio; ALB: albumin; BASOC: basophil count; EOC: eosinophil count; FC: feature combination; HGB: hemoglobin concentration; K: potassium; LYM: lymphocyte; MCHC: mean corpuscular hemoglobin concentration; MCV: mean (red blood cell) corpuscular volume; MOC: monocyte count; NEUT: neutrophil ratio; NEUTC: neutrophil count; PCT: procalcitonin; PCV: packed-cell volume (hematocrit); RBC: red blood cell count; RDW-SD: red blood cell distribution width–standard deviation; UA: uric acid; WBC: white blood cell count.



Discussion

Principal Findings

The main highlight of this study is that only a few of the common CLIs were required to establish the classifier models to accurately distinguish COVID-19 from CAP. The HPCs could only be constructed by combining several specific CLIs. Among the nearly 2 million FCs with one to eight CLIs, only 43 FCs could be used to construct HPCs with a recall rate greater than 0.9 and an AUROC greater than 0.85 to distinguish COVID-19 from CAP.

Comparison With Prior Work

We have established many COVID-19 versus CAP HPCs with FCs consisting of only CLIs, and almost no similar research results on distinguishing COVID-19 from CAP have been reported. However, many studies have used CLIs to build ML models to help with COVID-19 diagnosis. The prediction performance of these models varied: the accuracy of these models in predicting COVID-19 was between 0.8 and 0.96 [30-32]. In addition, most of the reported ML models for the diagnosis or prediction of COVID-19 have involved more types of variables, such as CT results, clinical symptoms, and CLIs [17,32,33]. Although most of these COVID-19-related ML models were built with more than two ML algorithms, not all models constructed with each algorithm showed high performance. The methods of feature selection that were used in these studies included the recursive feature elimination algorithm [31], causal explanation models [17], and the least absolute shrinkage and selection operator regression [32]. These methods can extract the features that are closely related to the target phenotype, but whether the classifier constructed by the combination of these features has the best performance needs to be determined. The optimized FCs in this study were selected by evaluating the recall rate and AUROC for each FC with one to eight randomly selected CLIs from the differential CLIs between COVID-19 and CAP groups and by constructing classifiers using each FC with the LR classifier algorithm. The FCs that were preliminarily screened were used to build classifiers with RFC and GBC algorithms; finally, only the FCs capable of building the HPC simultaneously with the LR classifier, RFC, and GBC algorithms were selected for the final model construction.

Limitations

As reported earlier, many inflammatory factors, including IL-6 and interleukin-10 (IL-10), are closely related to COVID-19 and have diagnostic value, but neither IL-6 nor IL-10 were detected in the patients of this study. Menni et al [18] reported that loss of smell and taste is a strong predictor for COVID-19. Deviations and omissions may exist in the patients' self-reported clinical symptoms. Thus, we did not take into account the clinical symptoms when building the classifiers. The possibility that other indicators are more important in constructing COVID-19 versus CAP classifiers was not ruled out. In addition, the sample size included in this study was relatively small, and the classifiers need to be optimized with larger samples before it can be used to distinguish COVID-19 from CAP in practice.

The Rationality of the Research Results

Out of the 43 FCs, 40 contained PCT and MCHC. The feature importance of PCT in each classifier is very high, suggesting that PCT may be a good blood marker to efficiently distinguish COVID-19 from CAP. PCT is one of the markers of lower respiratory tract bacteria and other infections. The US Food and Drug Administration approved the monitoring of the beginning and the entire duration of antibiotic treatment for suspected lower respiratory tract infections based on serum PCT levels [12]. However, the elevation of serum PCT in COVID-19 patients was also reported in many studies [34]. The increase of PCT is a remarkable characteristic of patients with COVID-19 [34]. Increased serum PCT levels in both COVID-19 and CAP patients indicated that the distinction of COVID-19 from CAP could not be made simply on the basis of the increase in PCT. Compared with the normal reference values of the CLIs, the serum levels of most of the CLIs increased or decreased simultaneously in both COVID-19 and CAP patients. Thus, providing references for the diagnosis of COVID-19 or CAP directly in regard to the rise or decrease of the CLIs is difficult. However, we found that the ML classifiers constructed with the FCs with many certain CLIs could distinguish COVID-19 from CAP effectively, suggesting an advantage of ML algorithms in disease classification or diagnosis.

The COVID-19 versus CAP classifiers with the highest performance also involved PCT, MCHC, uric acid, albumin, neutrophil count, monocyte count, basophil count, RBC count, and WBC count, proposing the importance of these CLIs in differentiating COVID-19 from CAP. Few studies have reported the changing trend of MCHC in patients with COVID-19 or CAP, but the results of this study showed that MCHC decreased in both groups and was significantly lower in the CAP group than in the COVID-19 group. The reason for the decrease of MCHC may be closely related to the reduction of iron due to inflammation [35]. The IQRs of uric acid in both COVID-19 and CAP groups were within the normal reference range, but the IQR was significantly higher in the COVID-19 group than in the CAP group. Elevated uric acid is an independent risk factor of renal injury or renal dysfunction; the underlying mechanisms of uric acid elevation are very complicated [36]. The significant difference in uric acid between COVID-19 and CAP may be interpreted as follows: individuals with higher uric acid may be more susceptible to COVID-19 than those with lower uric acid levels. Uric acid exists in all 8-CLI combinations that are capable of constructing high-performance CLIs and has a high feature importance in the classifiers, suggesting that uric acid is another important marker that can distinguish COVID-19 from CAP. Zhou et al reported that albumin significantly decreased in severe and critical COVID-19 patients [37]. Serum albumin level is a good prognostic marker in CAP. A decreased albumin level is closely associated with a higher risk of mortality in patients with CAP [38]. Although albumin decreased remarkably in both COVID-19 and CAP groups, there was still a significant difference between the two groups; the decrease in the CAP group was more obvious than that in the COVID-19 group, which could contribute to the differentiation of COVID-19 from CAP. AFU contributed high feature importance in the HPCs constructed from 7-CLI combinations

due to the significant difference in AFU between COVID-19 and CAP. An increase of serum AFU has a certain diagnostic value for primary liver cancer [39]. Thus, the higher AFU in the COVID-19 group than in the CAP group may be explained by the fact that liver injury is more common in COVID-19 than in CAP or that the diversity in AFU levels determines the difference in susceptibility to COVID-19.

Recommendations

Both PCT and AFU contributed high feature importance in the HPCs constructed from the FCs containing PCT or AFU, but the performance of the classifiers constructed from the FCs containing both PCT and AFU decreased remarkably. This result indicated that intrinsic dependence exists among some CLIs that undergo synergistic changes in individuals and can be used to construct HPCs. The internal relationship between CLIs is very complex and difficult to deconstruct. Therefore, the following method may be effective: random selection of different CLIs to construct classifiers with different classification algorithms, followed by the evaluation of the performance of each classifier, and, finally, the discovery of the FCs with certain CLIs that can be used to accurately distinguish COVID-19 from CAP.

Conclusions

The patients suffering from COVID-19 and CAP have their own characteristic profiles of CLIs, and some FCs consisting of seven or eight specific CLIs could build COVID-19 versus CAP HPCs. The usage rate and the feature importance of the CLIs in the HPCs indicated that PCT, MCHC, uric acid, albumin, AGR, neutrophil count, RBC count, monocyte count, and WBC count are the most important indicators that can distinguish COVID-19 from CAP.

Acknowledgments

We are very grateful to Associate Professor Benrong Liu of the Second Affiliated Hospital of Guangzhou Medical University for his guidance in data analysis. We are also very grateful to the doctors and nurses of Gong An County People's Hospital for their hard work to prevent as well as control COVID-19.

Authors' Contributions

XZH (huangxz020@gzucm.edu.cn) and YX (yujuanxiong@gzucm.edu.cn) share corresponding author duties for this article. XZH and YX made substantial contributions to the study concept and design. YX and PFK were in charge of drafting the manuscript. WD and WH were responsible for obtaining ethical approval, collecting data, and confirming the accuracy of the data. ZZL, QZZ, and YW performed the data analysis and interpretation. All authors agreed on the final version for submission to the journal.

Abstract

Background: Transition to digital pathology usually takes months or years to be completed. We were familiarizing ourselves with digital pathology solutions at the time when the COVID-19 outbreak forced us to embark on an abrupt transition to digital pathology.

Objective: The aim of this study was to quantitatively describe how the abrupt transition to digital pathology might affect the quality of diagnoses, model possible causes by probabilistic modeling, and qualitatively gauge the perception of this abrupt transition.

Methods: A total of 17 pathologists and residents participated in this study; these participants reviewed 25 additional test cases from the archives and completed a final psychologic survey. For each case, participants performed several different diagnostic tasks, and their results were recorded and compared with the original diagnoses performed using the gold standard method (ie, conventional microscopy). We performed Bayesian data analysis with probabilistic modeling.

Results: The overall analysis, comprising 1345 different items, resulted in a 9% (117/1345) error rate in using digital slides. The task of differentiating a neoplastic process from a nonneoplastic one accounted for an error rate of 10.7% (42/392), whereas the distinction of a malignant process from a benign one accounted for an error rate of 4.2% (11/258). Apart from residents, senior pathologists generated most discrepancies (7.9%, 13/164). Our model showed that these differences among career levels persisted even after adjusting for other factors.

Conclusions: Our findings are in line with previous findings, emphasizing that the duration of transition (ie, lengthy or abrupt) might not influence the diagnostic performance. Moreover, our findings highlight that senior pathologists may be limited by a digital gap, which may negatively affect their performance with digital pathology. These results can guide the process of digital transition in the field of pathology.

KEYWORDS

COVID19; digital pathology; Bayesian data analysis; probabilistic modeling

Introduction

Digital pathology (DP) intends to use computer workstations and digital whole slide imaging to diagnose a pathological process [1-4]. A complete transition from classical to digital pathology is usually a "soft" procedure, taking months or even years to be completed [4-9]. We planned a digitalization of our department, and we were testing several technical aspects related to digital transition. By February 2020, most of our staff pathologists and residents had used digital whole slide imaging for educational or scientific purposes, but the situation radically changed in March 2020. With the COVID-19 pandemic and the subsequent guidelines adopted by the Italian national government and the medical direction of our hospital, we were forced to reduce the presence of staff in the laboratory. Taking advantage of the ongoing digitalization, we decided to adopt DP to sustain smart work.

Most of the reported discordances between diagnoses in DP and those by the gold standard (ie, evaluation of a glass slide under a microscope) are less than 10% [10], and none of these reports were made under an abrupt transition in diagnostic approach. These discrepancies could be attributed to several factors that could be pathologist dependent (eg, career level or individual performance) or pathologist independent (eg, specimen type or the task to be undertaken during the diagnostic procedure). Discerning the relative effect of these features (that could be really small)—even in a carefully designed experimental setting—might be challenging. Probabilistic modeling (and Bayesian data analysis, in general) allows the detection of small effects [11-13]. Moreover, the employment of multilevel hierarchical modeling permits the transfer of shared information among data clusters, resulting in balanced regularization; thus, it reduces overfitting and improves the out-of-sample predictive performance [11,14-18].

In this study, we aimed to (1) quantitatively describe how abrupt transition to DP might affect the quality of diagnosis, (2) model the possible causes via probabilistic modeling, and (3) qualitatively gauge the perception of this abrupt transition.

Methods

A detailed description of the study methods is described in Multimedia Appendix 1 [15,16,19-24].

Ethics Approval

No ethics approval was required for this study. The study participants (ie, pathologists and residents) agreed to—and coauthored—the study.

Study Participants

This study involved 17 participants who were divided into the following 4 groups or career levels, based on their pathology experience: (1) senior (pathologists with >20 years of experience, n=2), (2) expert (pathologists with 10-20 years of experience, n=5), (3) junior (pathologists with <10 years of experience, n=6), and (4) resident (1st year, n=1; 2nd year, n=3). Each of the 17 participants evaluated 25 digital cases, with a total of 425 digital images examined in the study. Overall, 1445 questions were examined (ie, 85 questions per participant) in the study.

Study Design

In addition to their own diagnostic tasks, which were not considered in this study, the pathologists and residents received (1) a set of digital cases within the area of general surgical pathology, (2) specific questions to be addressed while reviewing the cases, and (3) a survey about their digital experience.

Sets of Digital Cases

We set up 5 sets of digital cases representing 3 different specialties (breast: n=2; urology: n=1; and gastrointestinal: n=2) and assigned them to each study participant. Each test comprised 5 cases, represented by one or more slides of a single case that was previously diagnosed using conventional microscopy by the referral pathologist at our institution. The information reported about the original diagnosis was considered as the gold standard. To cover a spectrum of conditions overlapping the routine situation, we considered biopsy and surgical specimens (specimen type). Cases were digitalized using the Aperio AT2 scanner (Leica Biosystems) and visualized using the WebViewer APERIO ImageScope (version 12.1). The slides used for the tests were from 8 nontumoral and 17 tumoral cases. Of the tumoral cases, 7 tumors were benign and 10 were malignant; all malignant tumors were infiltrative and equally distributed between grade 2 and grade 3; 14 cases were biopsy and 11 were surgical.

Study Questionnaire

Participants answered (all or some) of the following questions (ie, categories of diagnostic task), for each case: (1) Is it neoplastic or negative for neoplasia? (2) Is it a malignant (in situ or infiltrative) or a benign neoplasia? (3) What is the histopathological diagnosis? (4) What is the histotype of the lesion? (5) What is the grade of the lesion? Questions 1 and 3 were answered for all cases, question 2 was answered only for neoplastic lesions, and questions 4 and 5 were answered for malignant neoplasms.

Statistical Analysis

To model data clusters, we used a varying effects, multilevel (hierarchical) model [14-16]. The rate of wrong answers (W_i) was modeled as a Bernoulli distribution:

$$W_i \sim Binomial\ (\ 1, p_i\ )$$

For each pathologist (PID), their career level (LEVEL), the specific diagnostic question (CATEGORY), the specimen type (SPECIMEN), and the subspecialty of the case (SPECIALTY), we used the logit link function and modeled the varying intercepts as follows:

The prior distribution for the intercepts and SD values were as follows:

$$\alpha_j \sim Normal\ (\ \square\ ,\ \sigma_\alpha\ ),\ \text{for}\ j = 1..17$$

$\beta_j \sim Normal\ (0, \sigma_\beta)$, for $j = 1..4$

$\gamma_j \sim Normal\ (0, \sigma_\gamma)$, for $j = 1..5$

$\delta_j \sim Normal\ (0, \sigma_\delta)$, for $j = 1..2$

$\varepsilon_j \sim Normal\ (0, \sigma_\varepsilon)$, for $j = 1..3$

$\sigma_\beta \sim Exponential\ (1)$

$\sigma_\gamma \sim Exponential\ (1)$

$\sigma_\delta \sim Exponential\ (1)$

$\sigma_\varepsilon \sim Exponential\ (1)$

The hyperpriors for the hyperparameters average pathologist and σ_α were set as follows:

$\sim Normal\ (0, 1.5)$

$\sigma_\alpha \sim Exponential\ (1)$

The SD value for was set at 1.5 since it produces a flat (weakly regularizing) prior after logit transformation [16,18]; moreover, we used an exponential distribution to model SD, because this assumes the least, for maximum entropy reasons [16,25-28], given the fact that σ is a nonnegative continuous parameter. To assess the validity of priors, we run prior predictive simulation of the model [16,29,30] (see Table S1 in Multimedia Appendix 1, and Multimedia Appendices 2 and 3). To limit divergent transitions, we reparametrized the models with a noncentered equivalent form [31,32]. Models were fit using Stan (a probabilistic programming language) and R [33,34]. Full anonymized data and custom code can be found in the public repository SmartCovid hosted on Github [35].

Study Survey

The survey was inspired by previous published works [36-38]. Briefly, the survey included 17 questions in a randomized order for all the pathologists, covering 3 fields: (1) attitude towards DP, (2) confidence in using DP solutions, and (3) satisfaction with DP. The survey was sent at the end of the digital experience. Pathologists were requested to answer the questions using a Likert scale, with scores ranging from 1 (strongly disagree) to 5 (strongly agree). The results were reported as the proportion of pathologists who assigned each single value of the Likert scale.

Results

Quantitative Description

The pathologists answered 1345 of the total 1445 questions (100 missing answers in total), of which 1228 (91.30%) corresponded to the original diagnoses and were considered correct. Table 1 depicts the errors among each group of the 5 different categories recorded, and Figure 1 highlights the median (IQR) values of those categories. Considerable variation was observed among the performances of each pathologist, ranging from an error rate of 0.01 (1/67, Pathologist #4) to 0.32 (26/81, Pathologist #13), with a collective median error of 0.07 (IQR 0.04-0.11). This performance variation was tapered once the same data were considered after filtering among the different career levels, yielding the same median of 0.07, but a narrower IQR of 0.07-0.10. Moreover, some diagnostic tasks were more error prone than others; for instance, histotyping of the lesions had a very low rate of errors 0.01 (2/160), whereas grading was a more error-prone task with an error rate of 0.18 (27/147). The specimen type also resulted in different error rates, with surgical specimens easier to diagnose, with an error rate of 0.06 (40/716), than biopsy specimens, with a 2-fold error rate at 0.12 (77/629).

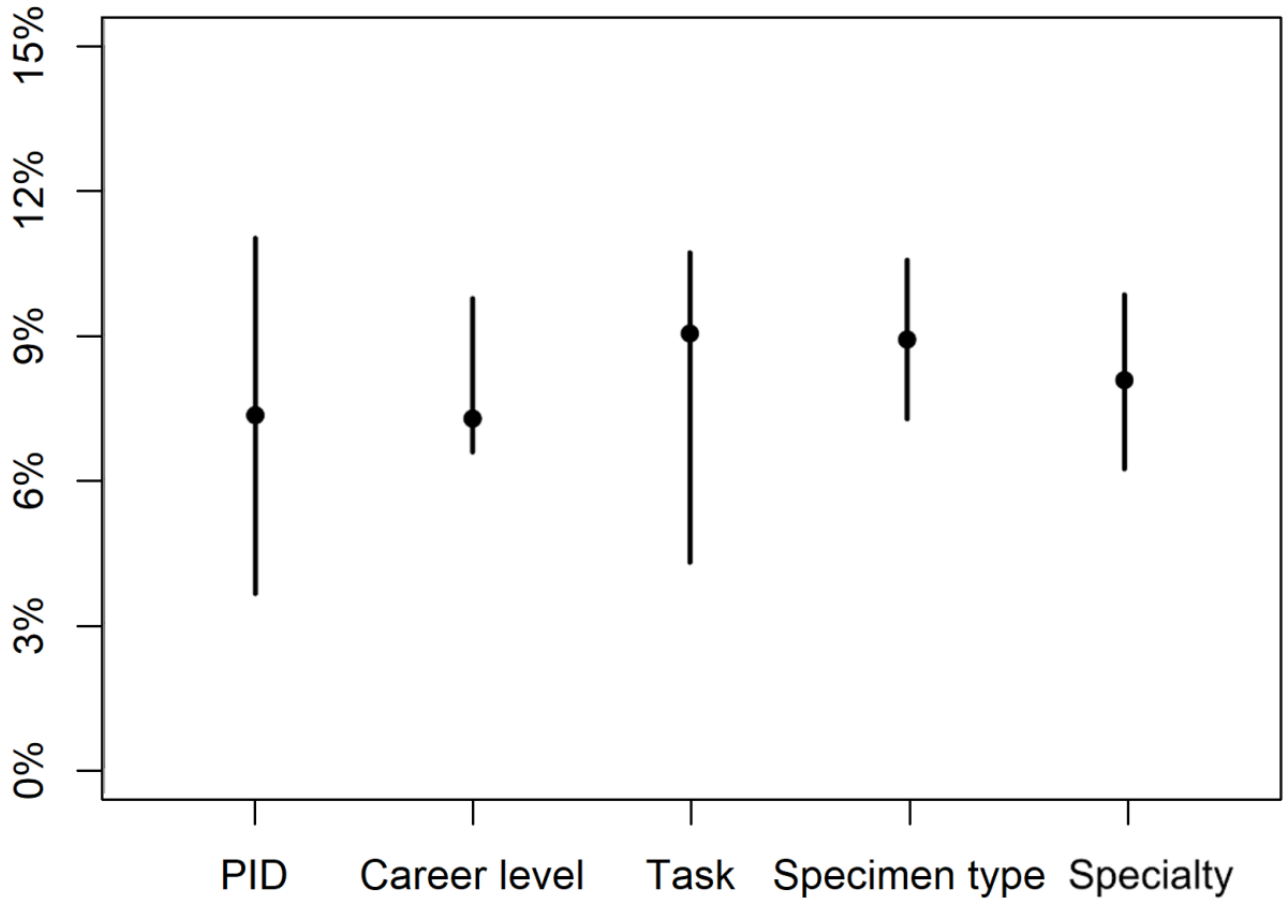
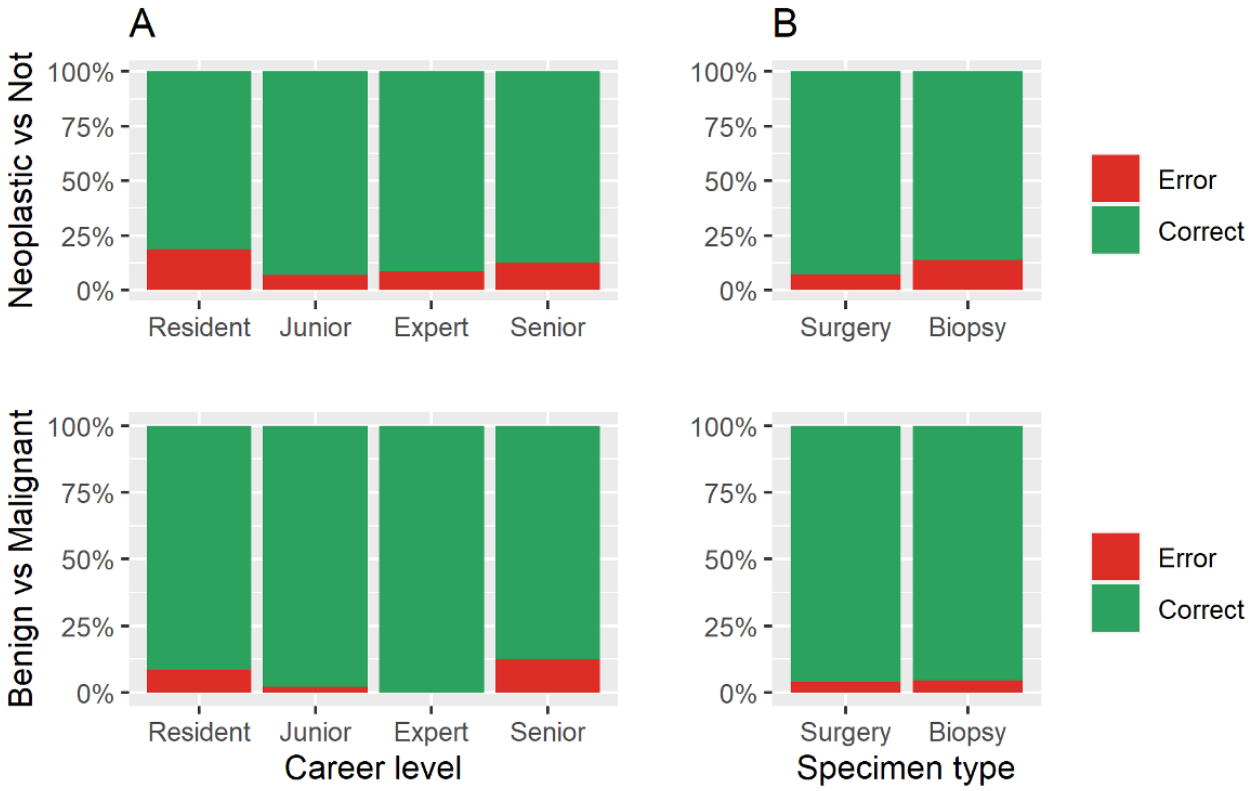
Figure 1. Error rates among different categories. This dot-bar plot depicts the median (IQR) values of error rates among different categories. The error rates showed the widest IQR among individual pathologists (PID), whereas the least IQR was noted for the career level and the specimen type (biopsy vs surgical).



Differences in error rates for two important tasks—differentiation between neoplastic and nonneoplastic processes and that between benign and malignant neoplastic processes—were observed among pathologists at different career levels and for different specimen types. The same error profile was observed across career levels, although the former task had a higher error rate (Figure 2A). However, even though the differentiation of a neoplastic process from a nonneoplastic one might be more challenging on a biopsy specimen, the distinction between a benign and malignant neoplasm was done with the same error rate regardless of the specimen type (Figure 2B). Differences in the prevalence of errors among individual pathologists and those at different career levels, as well as across diagnostic tasks, specimen type, and case subspecialty, are further highlighted in Multimedia Appendices 4 and 5.

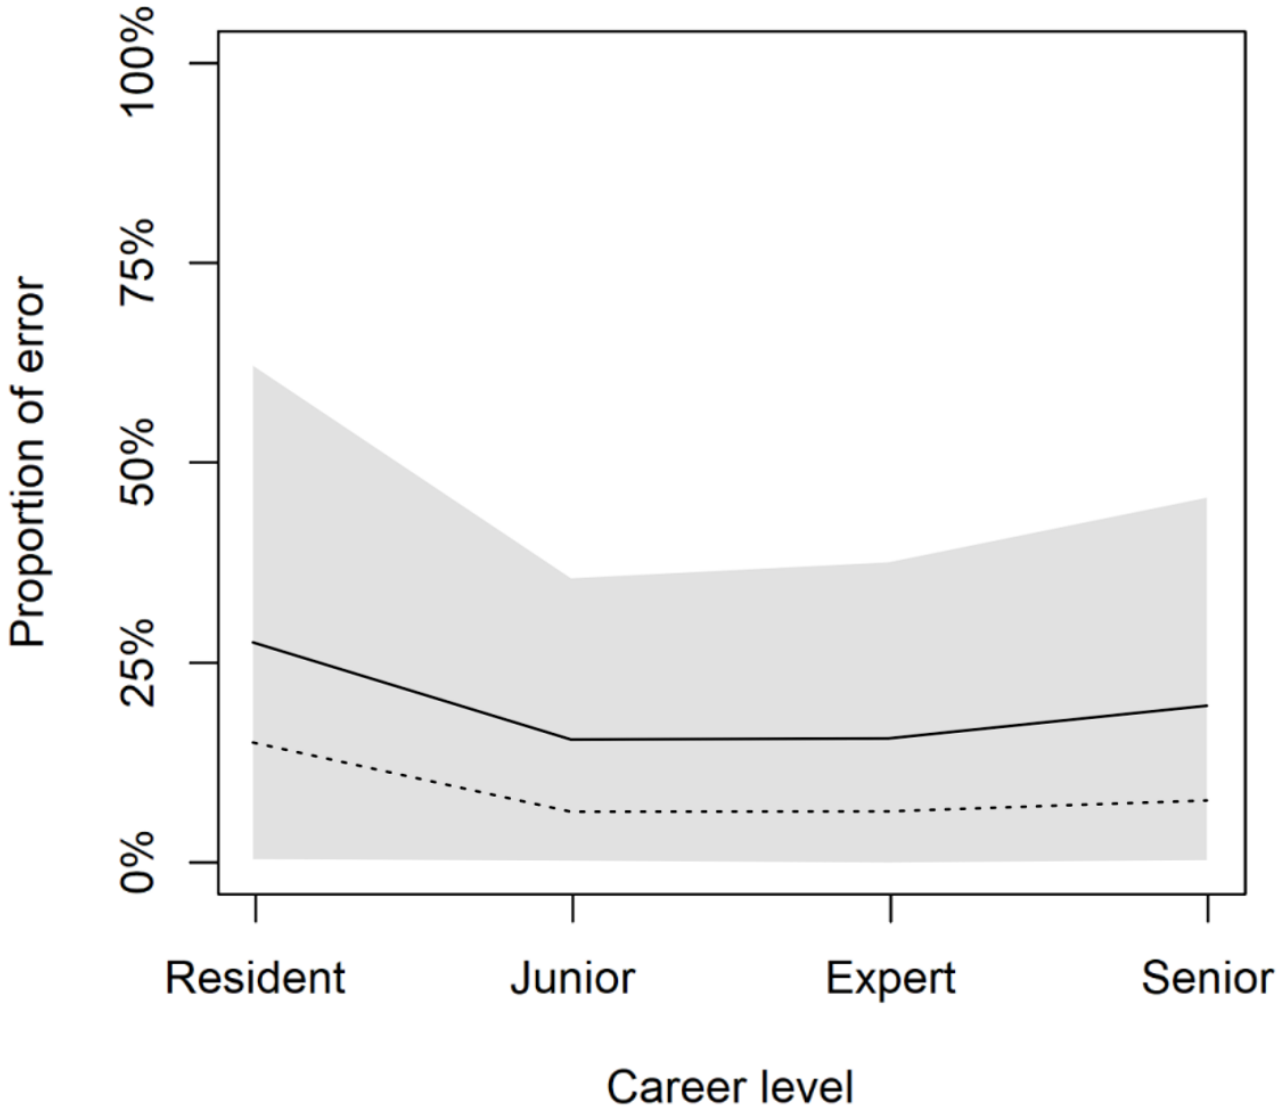
Figure 2. Raw proportion of errors across (A) career levels and (B) specimen types in performing two important tasks: differentiation between neoplastic and nonneoplastic processes and between malignant and benign tumors.



Prediction of Average Pathologist Performance

Diagnostics of the model's fit are shown in Multimedia Appendices 6, 7, and 8. The analysis reported a good overall performance: the average pathologist showed a negative mean coefficient of -1.8 with most of the posterior probability mass below 0 (given the model structure, positive values reflect the probability of making errors; Table S2 in Multimedia Appendix 1). The pathologists' individual performances and their career levels were the variables that showed less variance in predicting the error rate, whereas the specimen type, case subspecialty, and the particular type of task collectively showed more variance (Multimedia Appendix 9). Hence, we simulated the performance of an average pathologist at different career levels; this prediction shows better performance among pathologists at intermediate career levels of career (Figure 3).

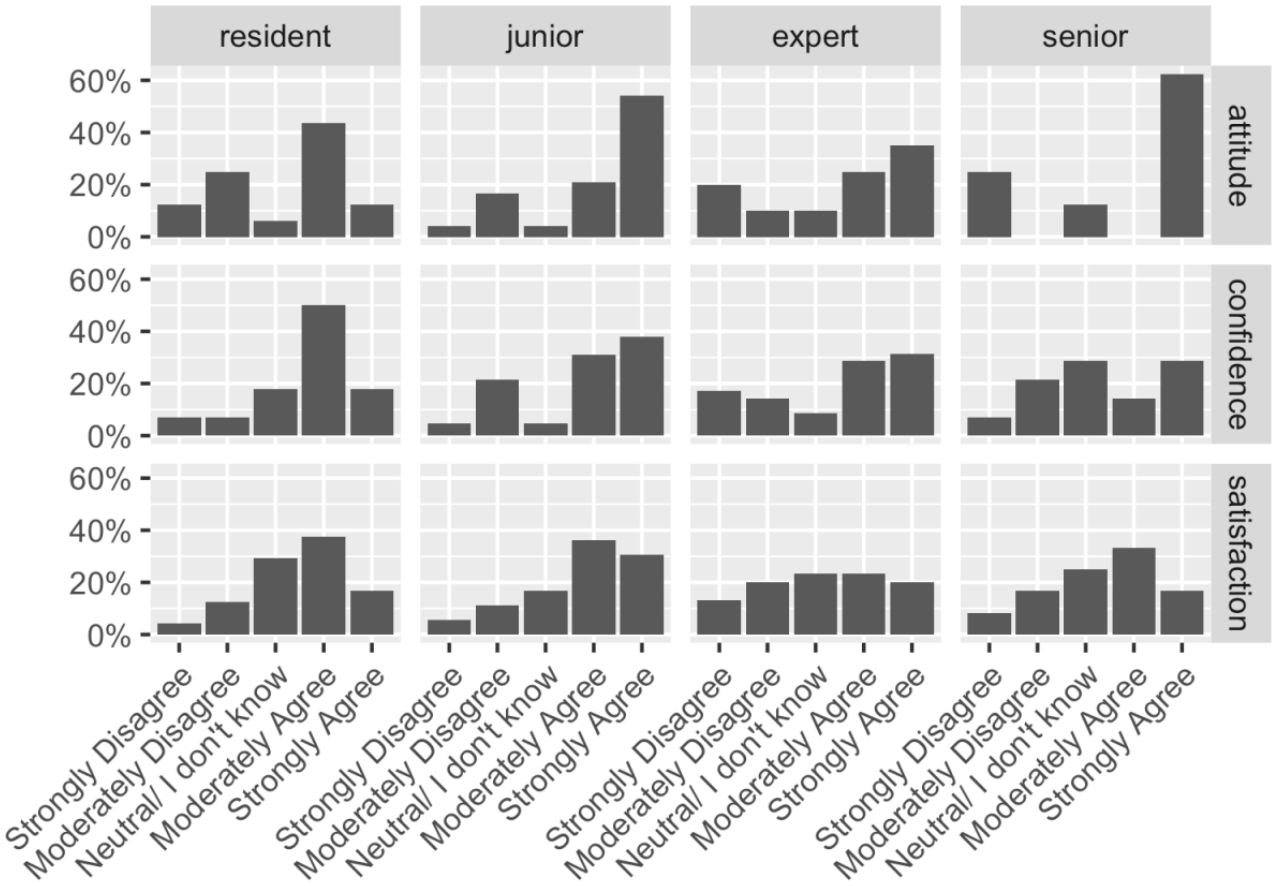
Figure 3. Prediction of average pathologist performance. Pathologists of intermediate levels of career perform better on average. The graph depicts the posterior predictive distributions for the multilevel model. Solid lines represent posterior mean values; shaded regions represent 89% high-posterior density interval; and dashed lines represent raw data.



Survey Results

Most pathologists reported a very good score (ie, 4 or 5 indicating they "moderately agree" and "strongly agree," respectively) for their attitude toward DP (44/68, 64%), confidence in DP (75/119, 63%), and satisfaction with DP (56/102, 54.9%). A detailed analysis of these parameters showed that the residents reported the highest value for confidence, junior pathologists reported the highest values for attitude and satisfaction, whereas expert and senior pathologists reported relatively lower levels of confidence in and satisfaction with DP (Figure 4).

Figure 4. Overview of the psychological aspect of the study. This series of graphs summarize the results of the survey conducted among pathologists at different career levels (residents, junior, expert, and senior) to evaluate their attitudes toward, confidence in, and satisfaction with digital pathology solutions.



Discussion

Principal Findings

Our study showed an overall discordant rate of 9% among diagnoses performed using digital slides and those performed using the gold standard (ie, conventional microscopy). However, when we considered the different diagnostic tasks, this rate dropped to less than 5% in the category "benign versus malignant tumor", which is probably the most clinically impacting category among the other diagnostic tasks. A systematic review of 38 pertinent studies published before 2015 reported a 7.6% overall discordance rate between digital and glass slide diagnoses. Among these studies, 17 studies reported a discordant rate higher than 5%, and 8 reported a discordant rate higher than 15% [39]. A later reanalysis of the same series fixed the overall discordance rate to 4% and major discrepancies to 1% [40]. A more recent review, covering studies published until 2018, reported a disagreement ranging from 1.7% to 13% [10]. Two multicentric, randomized, non-inferiority studies reported major discordant rates of 4.9% [41] and 3.6% [42] between diagnoses done by digital and glass slides. Furthermore, a study from a single, large academic center reported an overall diagnostic equivalency of 99.3% [43]. The same group was also the first to report about the use of DP during COVID-19 with an overall concordance of 98.8% [44]. Thus, despite our challenging approach to DP, the diagnostic performance we recorded was consistent with previous reports—a result that further supports the transition to DP.

In our study, a high proportion of errors was generated in small biopsy specimen type (12.2%) and diagnostic tasks involving tumor grading (23%). These results are consistent with those of the review by Williams et al [40]. The latter showed that 21% of all errors concerned grading or histotyping of malignant lesions, whereas 10% of the errors could be ascribed to the inability to find the target.

Moreover, recent studies have consistently reported high, intermediate, and low discordant rates for bladder, breast, and gastrointestinal tract specimens, respectively [41,42]—a finding suggesting intrinsic difficulties of specific areas. In contrast, we observed 4%, 8%, and 12% of discrepancies for urology, gastrointestinal tract, and breast specimens. This result could be attributed to a nonrandom selection of the cases and might represent a study limitation, biasing the value of the coefficients of specific parameters of the case subspecialty, similar to those of diagnostic tasks and the specimen type. However, these characteristics were excluded in the posterior predictive simulation, which was intended to represent how the different career levels might impact the pathologists' performance, after adjusting for all other factors.

As compared by the study by Hanna et al [44], our readiness to undertake digital diagnostic tasks was far from being mature in March 2020, and this study was specifically designed to identify

and illustrate the effects of such a sudden adoption of DP—something that had never been investigated before. Our results suggest that this abrupt transition might not influence the adoption of and performance with DP. However, different factors seem to be involved. In particular, data concerning major discrepancies between diagnoses using DP and gold standard methods disclosed an interesting feature. Both in the distinction of neoplastic versus non-neoplastic lesions and of benign versus malignant tumors, the worst results obtained were among residents and senior pathologists–2 contrasting categories in terms of pathologists' working experience. Therefore, these survey results might suggest an explanation to this paradoxical result: senior pathologists felt ready to diagnose a pathological process using a digital approach (ie, positive attitude) but were less prepared to use digital devices (ie, low confidence). Residents, in turn, had a high predisposition to using a digital device (ie, high confidence) but also had some concerns about diagnosis of a pathological process (ie, poor attitude). The hypothesis that senior pathologists were limited by a digital gap was supported by another finding: once they decided a lesion was malignant, they demonstrated the best performance with regard to tumor grading. By contrast, residents made several errors, likely due to their limited working experience. Lastly, even if expert pathologists showed a good diagnostic performance, they had the lowest level of satisfaction in DP. This result suggests that DP can be adopted rapidly for practical purposes. However, it also highlights a critical point of the process that needs to be addressed, possibly with adequate training or user-friendly equipment, and warrants further investigations.

Conclusions

Our study describes how the abrupt transition to DP affected the quality of diagnoses and qualitatively gauged the psychological aspects of this abrupt transition. Moreover, our study model highlighted the potential causes for these challenges and might inform what could be expected in other laboratories. In conclusion, the exceptional conditions dictated by the COVID-19 pandemic highlighted that DP could be adopted safely for diagnostic purposes by any skilled pathologist, even abruptly.

[PNG File , 111 KB - jmir_v23i2e24266_app8.png]

Multimedia Appendix 9
Model coefficients. Graphical representation of the coefficients for the model parameters conditional on the data. The lowest box depicts the coefficients for the hyper-parameter $\bar{\alpha}$ (alpha_bar) and the variances – the σ (sigma_a, b, [...] e) – of the categories of clusters modeled. All other boxes depict the distributions of the mean value for each element of the category considered. From top to bottom: the first box depicts the parameters of the pathologists' performance; the second, the parameters regarding the career level; the third, the diagnostic category analyzed; the fourth, the specimen type; and the fifth, the case subspecialty. Interpretation of the model at the parameter level is not possible because they combine in a very complicated way: prediction (ie, see how the model behave on the outcome scale, Figure 4 in the manuscript) is the only practical way to understand what the model "thinks".

Abstract

Background: For the clinical care of patients with well-established diseases, randomized trials, literature, and research are supplemented with clinical judgment to understand disease prognosis and inform treatment choices. In the void created by a lack of clinical experience with COVID-19, artificial intelligence (AI) may be an important tool to bolster clinical judgment and decision making. However, a lack of clinical data restricts the design and development of such AI tools, particularly in preparation for an impending crisis or pandemic.

Objective: This study aimed to develop and test the feasibility of a "patients-like-me" framework to predict the deterioration of patients with COVID-19 using a retrospective cohort of patients with similar respiratory diseases.

Methods: Our framework used COVID-19–like cohorts to design and train AI models that were then validated on the COVID-19 population. The COVID-19–like cohorts included patients diagnosed with bacterial pneumonia, viral pneumonia, unspecified pneumonia, influenza, and acute respiratory distress syndrome (ARDS) at an academic medical center from 2008 to 2019. In total, 15 training cohorts were created using different combinations of the COVID-19–like cohorts with the ARDS cohort for exploratory purposes. In this study, two machine learning models were developed: one to predict invasive mechanical ventilation (IMV) within 48 hours for each hospitalized day, and one to predict all-cause mortality at the time of admission. Model performance was assessed using the area under the receiver operating characteristic curve (AUROC), sensitivity, specificity, positive predictive value, and negative predictive value. We established model interpretability by calculating SHapley Additive exPlanations (SHAP) scores to identify important features.

Results: Compared to the COVID-19–like cohorts (n=16,509), the patients hospitalized with COVID-19 (n=159) were significantly younger, with a higher proportion of patients of Hispanic ethnicity, a lower proportion of patients with smoking history, and fewer patients with comorbidities (P<.001). Patients with COVID-19 had a lower IMV rate (15.1 versus 23.2, P=.02) and shorter time to IMV (2.9 versus 4.1 days, P<.001) compared to the COVID-19–like patients. In the COVID-19–like training data, the top models achieved excellent performance (AUROC>0.90). Validating in the COVID-19 cohort, the top-performing model for predicting IMV was the XGBoost model (AUROC=0.826) trained on the viral pneumonia cohort. Similarly, the XGBoost model trained on all 4 COVID-19–like cohorts without ARDS achieved the best performance (AUROC=0.928) in predicting mortality. Important predictors included demographic information (age), vital signs (oxygen saturation), and laboratory values (white blood cell count, cardiac troponin, albumin, etc). Our models had class imbalance, which resulted in high negative predictive values and low positive predictive values.

Conclusions: We provided a feasible framework for modeling patient deterioration using existing data and AI technology to address data limitations during the onset of a novel, rapidly changing pandemic.

Introduction

The SARS-CoV-2 virus, which causes the disease COVID-19, has infected almost 107 million people worldwide and is responsible for more than 2.3 million deaths [1]. Around the globe, patients with COVID-19 have a broad range of symptoms and disease severities. However, patients with COVID-19 demonstrate several symptoms that are striking in their commonality and nonspecificity to other well-known respiratory infections, such as pneumonia, influenza, and acute respiratory distress syndrome (ARDS) [2-5]. In fact, initial reporting of the disease indicated that most patients present with pneumonia- or influenza-like illnesses [6,7].

COVID-19 shares symptoms with other respiratory illnesses; from these diseases, we can learn about the clinical progression of patients, including the progression of patients presenting with severe hypoxemia followed by rapid deterioration, which often requires advanced life support such as invasive mechanical ventilation (IMV). Worldwide, the pandemic has left health systems struggling with capacity limits, especially regarding intensive care units (ICU) and mechanical ventilators [8,9]. Patients with COVID-19 remain on mechanical ventilation for an average of 10 to 20 days, further limiting the availability of this scarce resource [10,11]. Furthermore, an earlier study showed a high mortality rate of up to about 60% among critically ill patients [12]. The severity of cases has put great pressure on health systems, leading to a shortage of intensive care resources. Thus, understanding who will become critically ill and consume scarce resources as a result of this emerging disease can improve resource, hospital, and societal planning, and increase the number of lives saved.

However, given the novelty of COVID-19 and lack of clinical experience, the health care community is grappling for robust clinical data to learn about the disease. Under the appropriate assumptions, artificial intelligence (AI) may help with the planning of COVID-19 responses and guide clinical decisions in this time of uncertainty. Given the number of patients that may become infected with COVID-19, it is essential to understand who will be more likely to develop severe illness and need scarce resources at the time of presentation to the health care system, and AI can help with this determination. Indeed, AI technologies related to COVID-19 outcomes are emerging, as indicated in a recent published systematic review, with a majority of these studies conducted in China [13]. Predictive models using rule-based scoring tools and machine learning approaches have been applied to predict clinical deterioration in hospitalized patients and support health care providers in triaging patients when resources are limited [14-19]. However, there are many concerns and barriers to making this a reality [20], including uncertainty in the risk factors associated with disease progression, a limited number of patients whose data can be used to train and test models, and no public data sets available to test and validate models outside of a single health care setting. Of the COVID-19 AI studies published thus far, many have been designed and developed retrospectively on a small number of patient cases, limiting their validity and generalizability to other populations [15,21,22].

To help guide clinical decisions during the COVID-19 pandemic, we developed a framework to bootstrap AI models for outcomes of patients with COVID-19 using COVID-19–like cohorts to develop and train AI models to predict IMV within 48 hours and mortality using features associated with outcomes of patients with COVID-19. The COVID-19–like cohorts included patients diagnosed with bacterial pneumonia, influenza, viral pneumonia, and ARDS between 2008-2019. We tested the models' performances on hospitalized patients with COVID-19. This framework may be particularly important in a novel and accelerated outbreak where clinicians and health care systems are forced to make difficult decisions without past experience of the specific disease at hand. In the void created by a lack of clinical experience with COVID-19, AI trained with data from COVID-19–like disorders may be an important way to bolster clinical judgment and decision making.

Methods

Study Design and Data Source

This retrospective study used data from electronic health records (EHRs) of patients admitted to the Stanford Healthcare Alliance (SHA) from January 1, 2008, to July 11, 2019. SHA is an integrated health system that includes an academic hospital, a community hospital, and a primary/specialty health care alliance. This study received approval from the institute's Institutional Review Board (IRB). All source codes for this work are available at the Stanford Digital Repository [23].

Study Cohorts

This study included two retrospective cohorts: a COVID-19–like cohort (n=16,509) and a COVID-19 cohort (n=159).

COVID-19–like Cohort

The COVID-19–like cohort used for model training included patients hospitalized with a diagnosis of bacterial pneumonia, influenza, viral pneumonia, unspecified pneumonia, or ARDS, using International Classification of Diseases codes (ICD-9 and ICD-10; Table S1 in Multimedia Appendix 1), between January 1, 2008, and July 11, 2019. These diseases were selected because of their similarity to COVID-19 in clinical manifestation, histological features, and disease progression [4,7,24]. Patients

with complete missing lab data were excluded from the study (n=1712, 10.4%). For patients with multiple ICD codes for different conditions, the following rule was applied for disease categorization: influenza → viral pneumonia → bacterial pneumonia → unspecified pneumonia. Among these COVID-19–like cohorts, those who developed ARDS formed a separate COVID-19–like cohort.

COVID-19 Cohort

We included adults with a confirmed COVID-19 diagnosis who were hospitalized between March 1, 2020, and July 11, 2020. A confirmed COVID-19 diagnosis was defined as either a positive SARS-CoV-2 RNA detection test or a diagnosis code for COVID-19 (Table S1 in Multimedia Appendix 1). All patients were observed throughout their hospital encounter.

Data Collection

Patient demographics and clinical information were captured from EHRs. We selected the most relevant features identified from the literature [2,3,5], including demographics, existing comorbid conditions, smoking history, symptoms at initial presentation, coinfection with other respiratory pathogens, and laboratory values (Textboxes 1-3). The patient's existing comorbidities, including cardiovascular disease, diabetes, cancer, hypertension, chronic respiratory disease, respiratory failure, and kidney disease, were determined over a 3-year period prior to hospital admission for the retrospective cohort. Laboratory values 2 weeks prior to and during the hospital stay were extracted for the retrospective and COVID-19 cohorts. Laboratory values on the day of IMV were excluded to ensure the values were not taken after IMV.

Textbox 1. Features included in the invasive mechanical ventilation and mortality model development (demographics and clinical characteristics).

Demographics and clinical characteristics

- Age at admission (years)
- Gender
- Race/ethnicity
- Ever smoked (all life before admission)

Comorbidity present (3 years before admission)

- Cancer
- Chronic respiratory disease
- Cardiovascular disease
- Hypertension
- Type 2 diabetes
- Respiratory failure
- Kidney disease
- Alzheimer disease
- Cirrhosis

Symptoms (15 days before admission)

- Cough
- Dyspnea
- Tachypnea (respiratory rate >20)
- Hypoxemia (oxygen saturation ≤90%)
- Rhinorrhea
- Nose congestion
- Fever (temperature >37 C/98.6 F)
- Sputum
- Pharyngitis (sore throat)
- Headache
- Fatigue
- Conjunctivitis
- Diarrhea
- Anosmia
- Myalgias

Textbox 2. Features included in the invasive mechanical ventilation and mortality model development (laboratory findings).

Laboratory findings

- White blood cell count, K/μL
- Lymphocyte count, K/μL
- Alanine aminotransferase, U/L
- Aspartate aminotransferase, U/L
- Creatinine, mg/dL
- Lactate dehydrogenase, U/L
- Creatine kinase, U/L
- Cardiac troponin, ng/mL
- D-dimer, ng/mL
- Prothrombin time, seconds
- Serum ferritin, ng/mL
- Procalcitonin, ng/mL
- Platelet count, K/μL
- C-reactive protein, mg/dL
- Total bilirubin, mg/dL
- Blood urea nitrogen, mg/dL
- Albumin, g/dL
- Oxygen saturation, mm Hg
- Fraction of inspired oxygen, %
- Sodium, mmol/L
- Potassium, mmol/L

Textbox 3. Features included in the invasive mechanical ventilation and mortality model development (coinfections).

Coinfection (15 days before admission)

- Adenovirus
- Chlamydia pneumoniae
- Coronavirus
- Influenza A
- Influenza B
- Metapneumovirus
- Mycoplasma pneumonia
- Parainfluenza 1
- Parainfluenza 2
- Parainfluenza 3
- Parainfluenza 4
- Rhinovirus/enterovirus
- Respiratory syncytial virus

Outcome

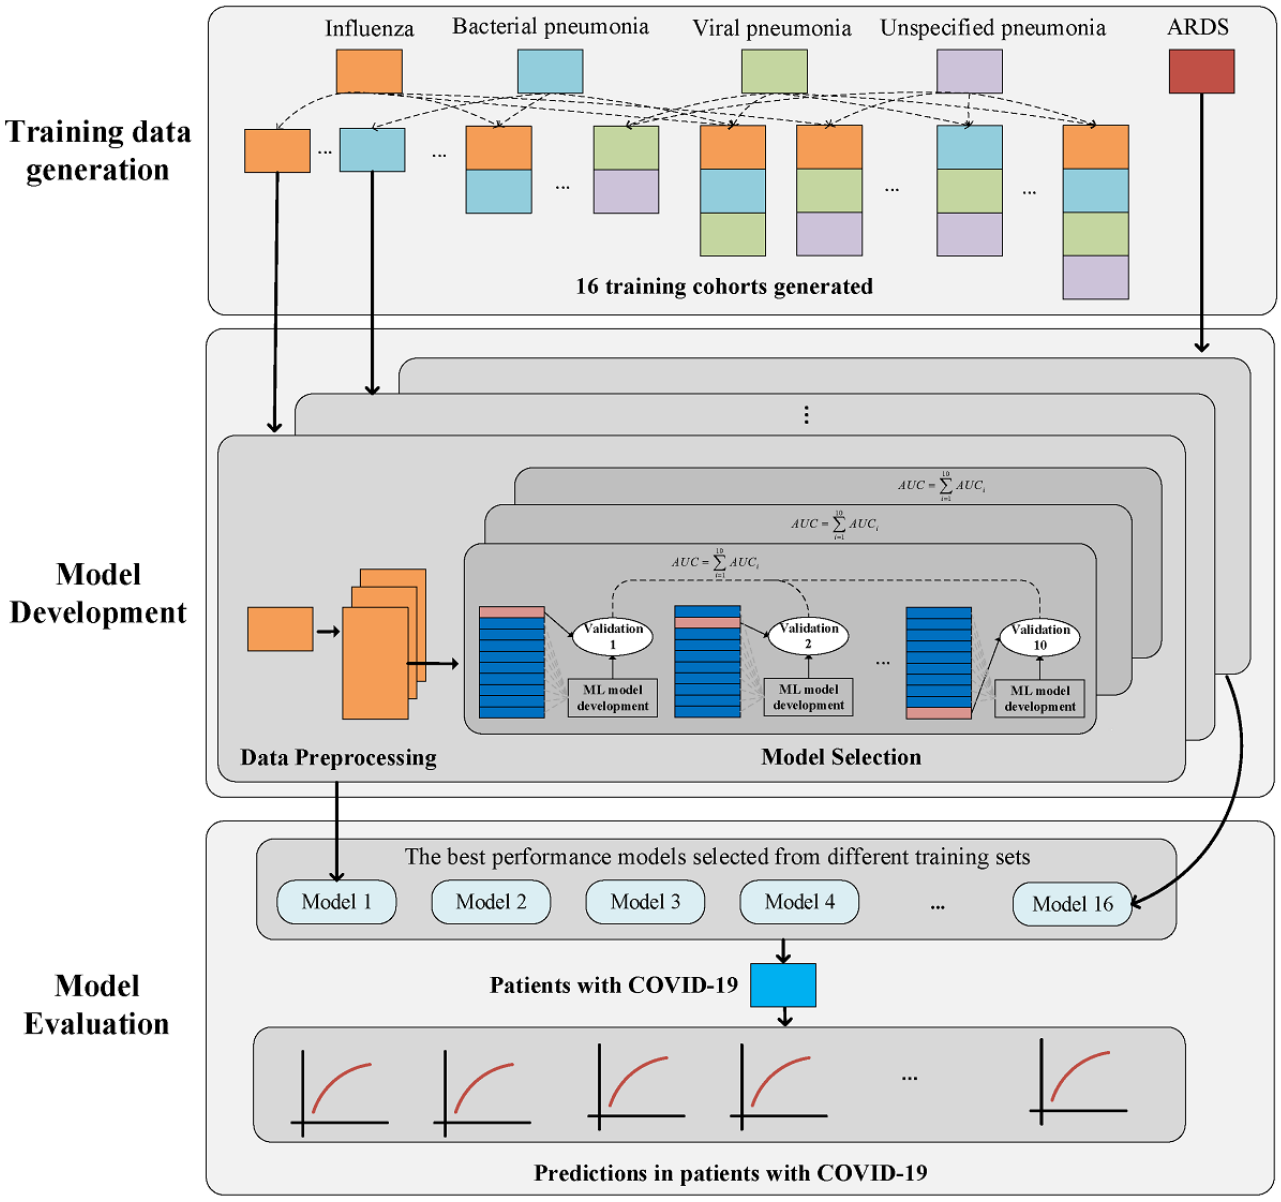
The outcome of interest was IMV in the next 48 hours and all-cause mortality. In the COVID-19–like cohort, the need for IMV in 48 hours was identified from the EHRs using the presence of IMV date and time. This time point was selected due to the rapid deterioration of disease conditions observed in patients with COVID-19. Deceased individuals who did not receive IMV during their hospital stay were considered nonintubated patients. All-cause mortality was identified using

the death date recorded in the EHRs, including those who died during their hospital stay and within two weeks of hospital discharge.

Artificial Intelligence Framework

We developed a three-step framework to bootstrap machine learning models to predict IMV and mortality among hospitalized patients with COVID-19. Figure 1 illustrates the study design framework, including training data generation, model development, and model evaluation.

Figure 1. The methodological framework for selecting training data cohort, model development, and model evaluation for predicting intubation and mortality.



Training Data Generation

To determine the most appropriate COVID-19–like cohort for the prediction task, we explored different combinations of the 4 COVID-19–like cohorts (influenza, bacterial pneumonia, viral pneumonia, and unspecified pneumonia), including any single disease, any two diseases, any three diseases, and all four diseases combined to construct 15 training cohorts. Due to the differences between patients with COVID-19 and patients with ARDS, these COVID-19–like patients who developed ARDS were considered as an additional exploratory cohort to examine whether or not it could contribute to better prediction for the patients with COVID-19. Since we selected the best-performing machine learning model from each COVID-19–like cohort, 16 models were developed from the 16 COVID-19–like cohorts.

Model Development

Data Preprocessing

Features with missing values in the training set were imputed as –1. Due to the unbalanced data in training cohorts (Table S2 in Multimedia Appendix 1), oversampling approaches were used to generate synthetic samples for the minority class and to balance the positive and negative training set. These approaches included synthetic minority oversampling technique

(SMOTE), borderline SMOTE, support vector machine (SVM) SMOTE, and random undersampling methods. Random undersampling was initially applied to trim the number of examples in the majority class to twice that of the minority group (positive cases), then the oversampling method was used to synthesize the minority class to balance the class distribution [25].

Model Training

Each of the 16 preprocessed COVID-19–like cohorts were split into 70% training and 30% validation sets with stratified random sampling. We derived four machine learning algorithms, including SVM and three tree-based ensemble algorithms (decision tree, AdaBoost, and XGBoost). We selected three decision tree–based algorithms because they have previously been applied to predict clinical events in patients with respiratory diseases based on EHR data [16,26,27]. We included models that were frequently applied for clinical prediction of severe patient outcomes [16,26,28]. In total, two steps were involved in model training: (1) using the training data set, a 10-fold cross-validation strategy was used to train the machine learning models, while grid search technique was used to search all combinations of hyperparameters and determine the best hyperparameters, and (2) using all training data, the models were retrained with the best hyperparameters (obtained in step 1). The validation data were used to monitor the performance of the model to avoid overfitting in training data. The final model was derived when the performance of the model on the validation data set did not improve after 20 training iterations. The detailed processes of model training are presented in Figure S1 in Multimedia Appendix 1.

Model Evaluation

COVID-19–like Cohorts

The performance of the models on the training cohorts was compared using the area under the receiver operating characteristic curve (AUROC). The default threshold of 0.5 was selected for interpreting probabilities to class labels. For IMV, to be a true positive, the model had to predict the need for IMV within 48 hours with a risk score of ≥0.5, and the patient had to receive IMV within this time interval. If the risk score was ≥0.5 and the patient did not receive IMV in 48 hours, the patient was treated as a false positive. The inverse strategy was applied for true negative and false negative cases. For mortality, patients who died during the hospital course or within two weeks after discharge with a risk score of ≥0.5 were considered as true positives. The inverse strategy was applied for the true negative and false negative mortality cases. To interpret the model, feature importance for predicting IMV and mortality were presented using SHapley Additive exPlanations (SHAP) values [29].

COVID-19 Cohort

The best training cohort was selected based on model performance (ie, AUROC) on the COVID-19 cohort. To determine the feasibility of models trained on COVID-19–like cohorts to identify patients at high risk of IMV within 48 hours and all-cause mortality, we calculated the AUROC, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for patients with COVID-19.

Statistical Analysis

Descriptive statistics were used to compare the characteristics of the COVID-19–like and COVID-19 populations. An independent *t* test or Mann-Whitney *U* test were used wherever appropriate for comparing continuous features. The Pearson chi-square test was used for categorical features, and the Fisher exact test was used when the number in the cell was <5. Algorithms were developed using the training cohort and assessed on the independent validation cohort, which played no role in model development, by calculating the PPV and AUROC. Algorithms were further tested on the independent COVID-19 cohort. A threshold of 0.50 was set for each model, and PPV and all other threshold-dependent performance metrics were derived at this alert rate. As the PPV is threshold dependent, AUROC was also compared among models. We chose to present AUROC values because they are a threshold-independent measure of discrimination. Statistical significance for primary analysis was set at $P<.05$. All tests were two-tailed.

Results

Cohort Description

There were a total of 16,509 patients in the COVID-19–like cohorts, and 159 patients in the COVID-19 cohort (Table 1). Compared to the COVID-19–like cohorts with pneumonia and/or influenza, patients with COVID-19 were significantly younger (mean 56.9 [SD 20.3] years versus mean 65.8 [SD 19.3] years, $P<.001$), less often White (27% versus 58.2%, $P<.001$), and more often Hispanic (46.5% versus 13.6%, $P<.001$). In addition, patients with COVID-19 had a significantly smaller proportion of ever-smokers (29.6% versus 41.3%, $P=.003$) and fewer patients with COVID-19 had comorbidities (37.1% versus 67.1%, $P<.001$). There were significant differences in IMV rate and time to IMV between the COVID-19–like patients and patients with COVID-19; the patients with COVID-19 had a lower IMV rate (15.1% versus 23.2%, $P=.02$) and shorter time to IMV (2.9 [SD 3.9] days versus 4.1 [SD 7.3] days, $P<.001$). Additionally, we observed a significantly lower mortality rate in patients with COVID-19 compared to the COVID-19–like cohorts ($P<.001$).

[a]Percentages may not add up to 100 due to missing values.

[b]The *P* value was calculated between the total of 4 retrospective COVID-19–like cohorts and the COVID-19 cohort.

[c]Comorbidities include cardiovascular disease, diabetes, cancer, hypertension, chronic respiratory disease, respiratory failure, kidney disease, Alzheimer disease, and cirrhosis.

Tables 2 and 3 compare symptoms at presentation and laboratory results during a hospital course between the COVID-19–like cohort and patients with COVID-19. Patients with COVID-19 experience a wider range and greater number of symptoms compared to the COVID-19–like cohort with pneumonia and influenza ($P<.05$). The average clinical laboratory results during hospitalization were also different (Table 3). The median laboratory values of D-dimer, lactate dehydrogenase, and ferritin elevated in hospitalized patients with COVID-19. Compared to the retrospective cohort of hospitalized patients with pneumonia and influenza, patients with COVID-19 had significantly higher values for lymphocyte count, platelet count, aspartate aminotransferase, albumin, lactate dehydrogenase, and ferritin, and lower values for white blood cell count, bilirubin, blood urea nitrogen, D-dimer, procalcitonin, creatinine, and prothrombin time.

Table 2. Comparison of symptoms at admission of the COVID-19–like cohort and patients with COVID-19.

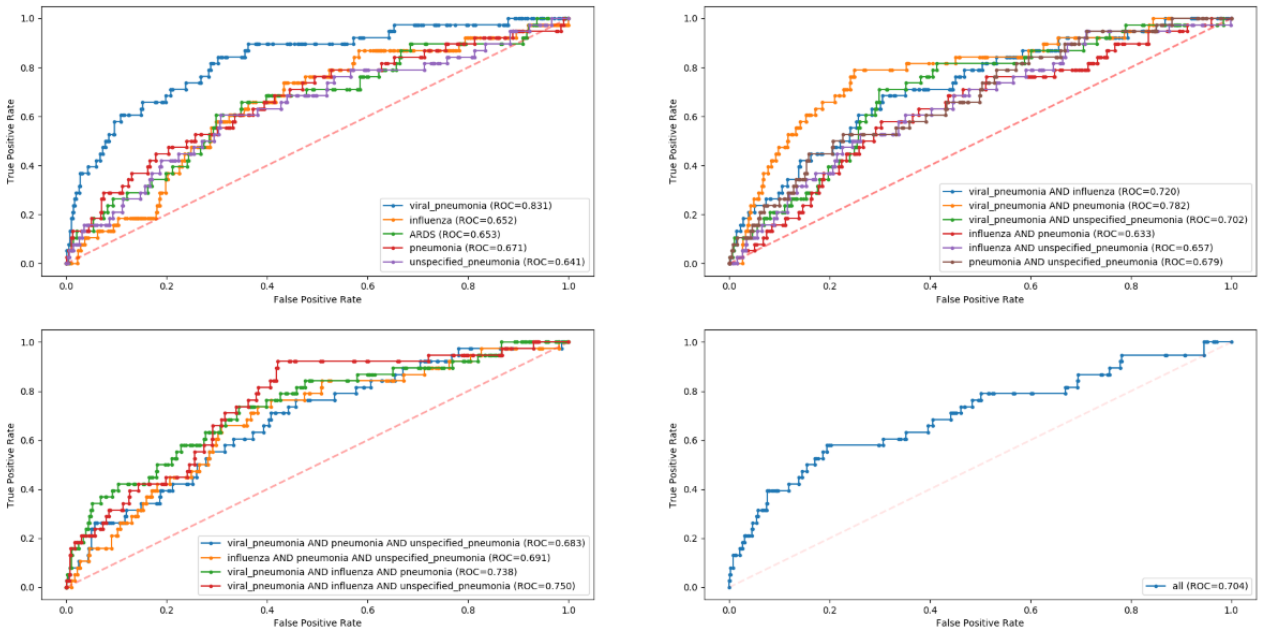
Model Performance: Predicting 48-Hour IMV

The AUROCs of all models for predicting 48-hour IMV risk are illustrated in Figure 2. Algorithm discrimination and other performance metrics for the COVID-19–like cohorts are presented for each model in Table S3 in Multimedia Appendix 1. At the prespecified threshold of 0.5, the XGBoost classifiers achieved the highest AUROCs (range 0.772-0.905) compared to other machine learning classifiers in each of the 16 training

cohorts for prediction of 48-hour risk for IMV. The best PPVs ranged between 0.583 and 0.767, and all models had an accuracy of 0.724 or higher and specificity of 0.786 or higher. The model trained with the influenza cohort was one of the worst-performing models, with an AUROC of 0.772 and PPV of 0.583 for IMV.

Figure 2. Receiver operating characteristic curves for model performance on predicting 48-hour invasive mechanical ventilation risk in the COVID-19 cohort, stratified by COVID-19–like cohorts. ARDS: acute respiratory distress syndrome; ROC: receiver operating characteristic.

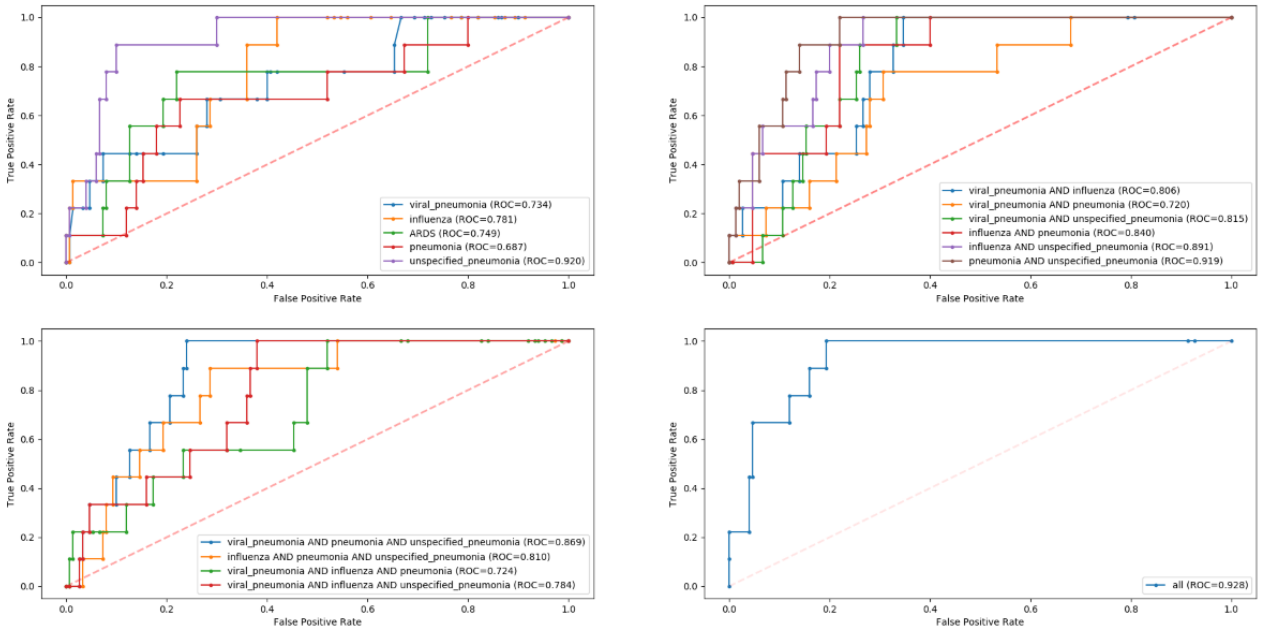


The pretrained models for 48-hour IMV prediction performed worse on the COVID-19 cohort than on the COVID-19–like cohorts. The model with the best performance on the new COVID-19 cohort was the XGBoost model trained on the viral pneumonia cohort (AUROC=0.826). The accuracy, precision, and sensitivity of the best model were 0.948, 0.423, and 0.289, respectively. Performance metrics for each model are presented in Table S4 in Multimedia Appendix 1. For negative cases at the patient-day level, the mean risk score was 0.09 (SD 0.124), with a minimum of 0.002 and a maximum of 0.859. For positive cases, the mean risk score was 0.31 (SD 0.23), with a minimum of 0.012 and a maximum of 0.823. At the patient level, the best-performing model was able to predict IMV in 48 hours for 7 of the 24 intubated patients with COVID-19. The model failed to predict the need for IMV in 48 hours for 17 patients (71%). Among the non-IMV patients, two were predicted to be at high risk of requiring IMV, although they were never intubated during hospitalization. Further details of the model hyperparameter optimization for predicting IMV can be found in Tables S5 and S6 in Multimedia Appendix 1.

Model Performance: Predicting All-Cause Mortality

Figure 3 and Table S7 in Multimedia Appendix 1 present detailed results of model performance for mortality prediction on the COVID-19–like cohorts. The XGBoost classifiers outperformed other machine learning classifiers in each of the 16 training cohorts for all-cause mortality prediction, with AUROC values ranging from 0.679 to 0.748.

Figure 3. Receiver operating characteristic curves for model performance on predicting inpatient mortality in the COVID-19 cohort, stratified by COVID-19–like cohorts. ARDS: acute respiratory distress syndrome; ROC: receiver operating characteristic.



Mortality prediction was better when testing on the COVID-19 cohort, with AUROC values ranging from 0.687 to 0.928. The best-performing model for the COVID-19 cohort was the XGBoost model trained on all 4 COVID-19–like cohorts (AUROC=0.928). The accuracy, precision, and sensitivity of the best model were 0.925, 0.286, and 0.222, respectively. The worst-performing model for the COVID-19 cohort was trained by using the pneumonia cohort, and achieved an AUROC of 0.687. Other results are presented in Table S8 in Multimedia Appendix 1. For all-cause mortality prediction at the patient level, the best-performing model predicted 22% of the deaths at the time of hospital admission. Further, our model predicted 5 deaths among the 109 patients discharged alive at the time of hospital admission.

Manual Chart Review

Manual chart review of 24 false positive and false negative cases was performed by author HC. Among the seven false positive cases for IMV prediction, one patient received IMV; however, this was not entered as structured data in the EHRs, therefore it was marked as a false positive for the model. Furthermore, two patients were extremely ill and close to receiving IMV. In the 17 false negative cases, 6 patients experienced rapid clinical deterioration in less than 24 hours or sometimes within 12 hours, and another 6 patients received scores that were close to the threshold. Additionally, our model incorrectly predicted the risk of death in 12 patients, including 5 false positive and 7 false negative cases. Based on the chart review, we confirmed that 3 of the 5 false positives were true false positives, while for the other two, the patients' conditions were severe and they were identified by the clinician as having a higher risk of death.

Algorithm Variable Importance

To identify the most salient features driving model prediction, we calculated SHA*P* values for the best-performing model. Among the top features, elevated fraction of inspired oxygen, total bilirubin, white blood cell count, lymphocyte count, D-dimer, and cardiac troponin, and lower albumin, oxygen saturation, and platelet count favored the classifier to predict an IMV event. Other important features from the best prediction model are in Figure 4. For mortality, being older and having higher blood urea nitrogen, potassium, and high-sensitivity cardiac troponin, and low albumin, oxygen saturation, and platelet count were the most influential factors in driving mortality prediction. Other important features associated with increased mortality risk included elevated total bilirubin and lower platelet count (Figure 5).

Figure 4. SHapley Additive exPlanations (SHAP) scores for identifying important features for prediction of invasive mechanical ventilation, including demographic information, vital values, and laboratory values. The color indicates whether the value of the feature is high (red) or low (blue).

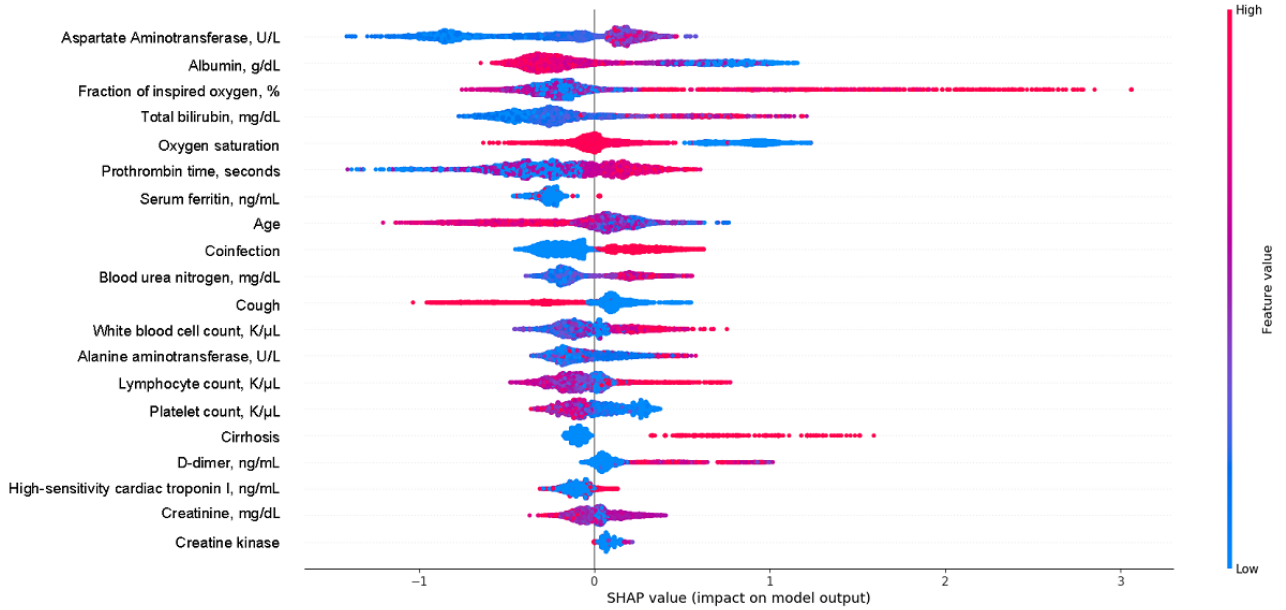


Figure 5. SHapley Additive exPlanations (SHAP) scores of the mortality prediction model. The color indicates whether the value of the feature is high (red) or low (blue).

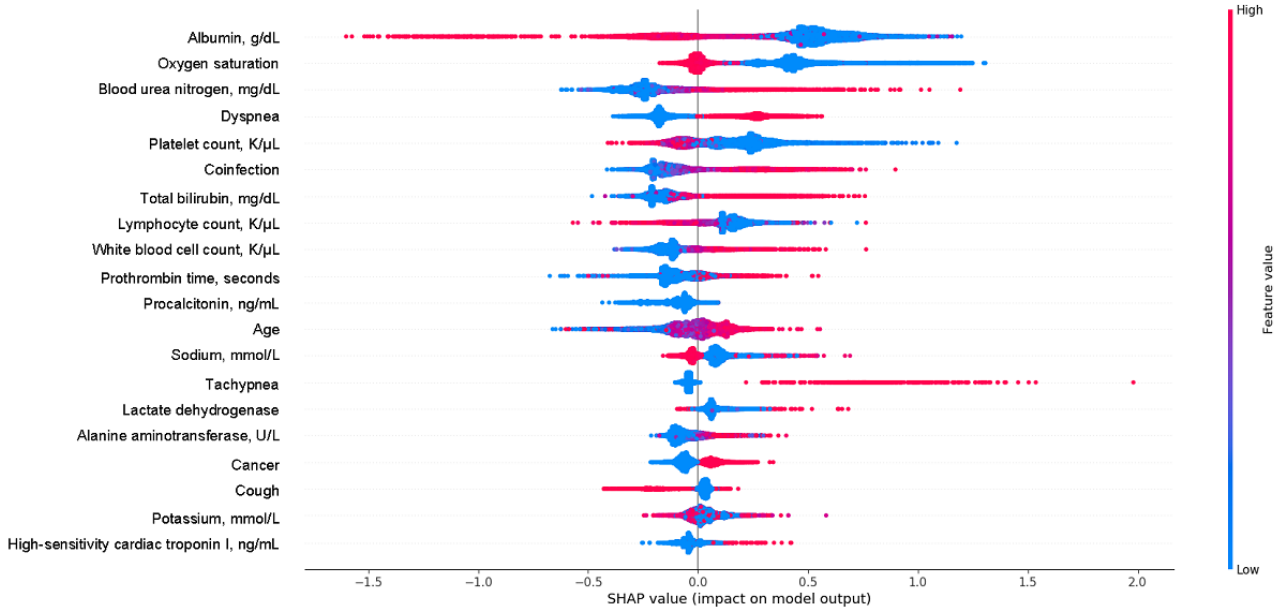

Discussion

Principal Findings

In the clinical care of well-established diseases, literature and research are supplemented by the clinical judgment that is formed and refined through repeated episodes of care. Given the novelty of COVID-19, there is a lack of research evidence and clinical experience to inform clinical practice and guide care decisions. AI-enabled clinical decision support tools are promising to fill this gap and bolster clinical decision making. Early studies suggest that the disease manifestation, symptoms, and clinical course of COVID-19 resemble that of other respiratory infections, particularly pneumonia, influenza, and ARDS [5,30-32]. Due to the lack of robust, unbiased, representative data to train an AI model, we designed a framework to bootstrap existing retrospective data from COVID-19–like cohorts to predict IMV and all-cause mortality.

Our findings regarding the study cohort are consistent with previous international studies comparing patients with COVID-19 with patients previously hospitalized with other respiratory illnesses. The patients hospitalized with COVID-19 in our health system were younger and had fewer comorbidities than the COVID-19–like patients [33]. Patients with COVID-19 were less likely to have ever smoked compared to the COVID-19–like cohort. In addition, racial and ethnic minorities have been disproportionately affected by the disease, and we show similar trends in our health care system [32,34]. In addition to the variations in demographics and clinical outcomes, we

observed differences in symptoms at admission and laboratory values during the hospital stay. Importantly, significant differences were observed in IMV rates, time to IMV, and mortality rates between the two cohorts, with lower IMV and mortality rates in the patients with COVID-19 than in the COVID-19–like cohort, yet faster deterioration, as indicated by a shorter duration from admission to IMV.

The models, in general, performed well in the COVID-19–like cohorts, but less optimally in the COVID-19 cohort. Although the AUROC values of the best IMV and mortality prediction models in the COVID-19 cohort were good, the PPVs of both models were low, although the NPVs were high. Overall, the two models underestimated risk scores in patients with COVID-19. This can be explained by several factors. First, symptoms, laboratory values, and the proportions of missing data were different between COVID-19–like patients and patients with COVID-19, despite them sharing similar clinical manifestations and symptoms. Second, unlike the COVID-19–like cohorts, patients with COVID-19 had a broad spectrum of clinical manifestations, with critical courses that may involve fast deterioration and the need for IMV within 24 hours; thus, patients may have had limited signs of severe disease progression 48 hours prior to IMV. On the other hand, several clinical circumstances may affect clinical decisions. Clinicians may be reluctant to put patients on a ventilator due to the complexity of and complications associated with this invasive procedure. Patients or family members might also be hesitant to consent to the procedure out of fear of losing control [35]. Sometimes, patients have a Do Not Intubate code status, indicating they do not want to receive IMV in the event of a life-threatening situation. All these factors challenge the performance of our model, particularly the PPV. The model made a positive prediction for patients who require IMV, yet patients may not receive it in the end due to the factors mentioned above, and these are therefore considered false positives.

Traditional machine learning evaluation criteria, such as AUROC and PPV, were used to assess the performance of predicting the risk of IMV and all-cause mortality at the patient-day level; however, there is a lack of standard criteria to evaluate the model at the patient level when there are also multiple day-level data. When reporting the patient-level prediction results, a “strict” criterion was selected: the model correctly predicted the case only when the alarm occurred at 48 hours before IMV. If the prediction occurred too early or too close to IMV, it was considered wrong for that patient. If correct cases were determined as at least one alarm before IMV for those who were finally intubated and no alarm for non-IMV patients, the model performance would be greatly improved. The use of different standards for analyzing patient-level results can have clinical significance. For example, if a patient is predicted to be intubated during hospitalization, the provider needs to be reminded to pay more attention to avoid the rapid deterioration of the patient’s condition. Therefore, our framework provides important insight into the deterioration of patients with COVID-19 and the timing of that deterioration. Further studies are needed to explore evaluation criteria for this novel, emerging disease.

The performances of our COVID-19–like models suggest that the deterioration in the COVID-19 population in our health system is more similar to viral pneumonia than other respiratory illnesses. These results support our evolving understanding of the clinical characteristics of this disease state and support evidence that patients with COVID-19 are less like ARDS patients than was originally believed [36]. Although the scientific community has been shifting practices of treating the ventilation needs of patients with COVID-19 away from mimicking ARDS treatment, this work may be the first indication that there is a detectable demographic and pathophysiologic difference in the presenting characteristics of COVID-19 as well as the response to therapy.

This work has several clinical applications. It is notable that this model could make for an excellent screening tool for clinical deterioration in the inpatient setting because the model has a high positive likelihood ratio and high specificity. This indicates that a positive result truly indicates an increased probability of clinical respiratory decline for those admitted to hospital with COVID-19, even if the individual PPV for that “patient-day” is low. The implementation of this model would allow for enhanced monitoring of patients likely to require advanced respiratory support, especially during surge settings when there is a strain on staffing with advanced infectious disease or pulmonary training.

Although there is lower ability to predict patients in need of IMV within 48 hours or all-cause mortality at the “patient-day” level with great precision, this work can also be used to identify patients who are not at risk of clinical escalation. This means that this model can be used as a screening tool in our population, offering providers some confidence in the current level of care being appropriate rather than using valuable hospital resources on enhanced monitoring for patients who are less likely to need advanced medical management for respiratory failure. Such information can help with resource allocation and help providers triage patients who are less likely to become critically ill. Given the extreme stress and burden the COVID-19 pandemic has placed on the health care system, particularly on frontline workers, identifying patients who may need less focused attention may reduce some of the burden for health care systems that are already stretched thin. We anticipate that this work could be implemented across health care systems and therefore provide all codes and software needed to deploy these models. The external validation of our framework across systems could help in elucidating the clinical course of COVID-19 by refining the model in populations over time.

Limitations

While we envision many possible applications of our framework, we also recognize several limitations. First, our data come from a single health care system, and the results may not generalize to other health care systems that may have a different patient population or clinical practice. External validation would be required to reinforce our conclusions. Second, the sample sizes of the COVID-19–like and COVID-19 cohorts are different, which may bias our comparison in terms of demographics and clinical characteristics. However, despite this difference, these patients share similar clinical manifestations, histological

features, and disease progression. Third, our data set contained a relatively small number of deaths, and the model performance on the COVID-19 cohort could be unstable based on the limited number of patients. Future work is needed to validate the mortality prediction in other settings. Finally, the prediction of the risk of mortality used data from admission, limiting the performance of the model. Despite these limitations, important lessons have been learned from our experience of using pretrained machine learning models for disease severity prediction. It is feasible to pretrain a model using an unseen disease-like cohort but this requires special caution. First, selecting the most appropriate cohort, one which is similar to the clinical manifestation, pathological features, and disease progression of the targeted disease population, is essential for developing a successful machine learning model. Second, based on the nature of the disease and the type of data that are available, determining the right time frame for your machine learning model is crucial. We failed to predict whether or not a patient with COVID-19 would need IMV during their hospital stay using data obtained at hospital admission. Predictions may be hampered by the rapid deterioration seen in some patients with COVID-19 and changes in laboratory results.

Conclusions

In conclusion, our work demonstrates the feasibility of using existing data infrastructure and AI technology to guide critical care resource allocation in the early stages of a disease outbreak when not many cases have been observed and there is a lack of training data. Although the spread of COVID-19 has been exponential worldwide, most individual health care systems do not have a comprehensive, diverse, readily available data set of patients with COVID-19, which is necessary to develop, train, and validate essential AI models that may be used to guide clinical care. To date, many COVID-19–related AI models distributed through the scientific community have been trained and "validated" on only a handful of patients. However, given the lack of knowledge related to COVID-19, there is an urgent need to learn as much as possible about the disease, even if from small nonrepresentative populations. The framework we describe provides a strategy to mitigate this lack of data by identifying how and what we can learn from other COVID-19–like diseases. As we will likely deal with another wave of COVID-19 cases and other pandemics in the future, having a framework to rapidly design and train predictive models will have eminent value. Although using these COVID-19–like cohorts to learn about and predict outcomes of patients with COVID-19 may not be ideal, they provide an unbiased pathway to help guide clinical decisions when faced with this novel disease.

Abstract

Background: Misdiagnosis, arbitrary charges, annoying queues, and clinic waiting times among others are long-standing phenomena in the medical industry across the world. These factors can contribute to patient anxiety about misdiagnosis by clinicians. However, with the increasing growth in use of big data in biomedical and health care communities, the performance of artificial intelligence (Al) techniques of diagnosis is improving and can help avoid medical practice errors, including under the current circumstance of COVID-19.

Objective: This study aims to visualize and measure patients' heterogeneous preferences from various angles of AI diagnosis versus clinicians in the context of the COVID-19 epidemic in China. We also aim to illustrate the different decision-making factors of the latent class of a discrete choice experiment (DCE) and prospects for the application of AI techniques in judgment and management during the pandemic of SARS-CoV-2 and in the future.

Methods: A DCE approach was the main analysis method applied in this paper. Attributes from different dimensions were hypothesized: diagnostic method, outpatient waiting time, diagnosis time, accuracy, follow-up after diagnosis, and diagnostic expense. After that, a questionnaire is formed. With collected data from the DCE questionnaire, we apply Sawtooth software to construct a generalized multinomial logit (GMNL) model, mixed logit model, and latent class model with the data sets. Moreover, we calculate the variables' coefficients, standard error, *P* value, and odds ratio (OR) and form a utility report to present the importance and weighted percentage of attributes.

Results: A total of 55.8% of the respondents (428 out of 767) opted for AI diagnosis regardless of the description of the clinicians. In the GMNL model, we found that people prefer the 100% accuracy level the most (OR 4.548, 95% CI 4.048-5.110, *P*<.001). For the latent class model, the most acceptable model consists of 3 latent classes of respondents. The attributes with the most substantial effects and highest percentage weights are the accuracy (39.29% in general) and expense of diagnosis (21.69% in general), especially the preferences for the diagnosis "accuracy" attribute, which is constant across classes. For class 1 and class 3, people prefer the AI + clinicians method (class 1: OR 1.247, 95% CI 1.036-1.463, *P*<.001; class 3: OR 1.958, 95% CI

1.769-2.167, *P*<.001). For class 2, people prefer the AI method (OR 1.546, 95% CI 0.883-2.707, *P*=.37). The OR of levels of attributes increases with the increase of accuracy across all classes.

Conclusions: Latent class analysis was prominent and useful in quantifying preferences for attributes of diagnosis choice. People's preferences for the "accuracy" and "diagnostic expenses" attributes are palpable. AI will have a potential market. However, accuracy and diagnosis expenses need to be taken into consideration.

Introduction

The phenomenon of uneven allocation and distribution of high-quality doctor resources has existed for centuries with the history of the modern medical industry, which brings about a series of problems such as gaps in diagnosis accuracy, speed, or accessibility in rural areas. According to a recent study, over 12 million patients in the United States have experienced one or more misdiagnoses, and the misdiagnosis rate is 5.08% [1]. Some developing countries still face the problem of scarcity of doctors. The World Health Organization (WHO) has suggested that 2.5 doctors per 1000 people are needed to guarantee primary health care [2]. However, it has been reported that there were only 1.9 doctors per 1000 people in 2017 in China, and 45% of WHO member countries still have less than 1 doctor per 1000 people [3]. Therefore, new medical technology, such as artificial intelligence (AI) technologies, urgently needs to be improved.

The recent outbreak of an epidemic caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is a severe threat to public health. The COVID-19 pandemic, with lockdowns and unprecedented restrictions on movement, brings a newer angle to the importance of AI diagnosis. With big data growth in biomedical and health care communities, AI is increasingly applied to antiepidemic medical practice.

Medical AI can be classified into eight main fields: medical imaging and diagnosis, medical research, medical risk analysis, drug mining, virtual nurse assistant, prognostics and health management, mental health, and nutrition [4,5]. AI diagnosis and treatment technologies have become increasingly mature and are expected to become mainstream. As far as we know, there is no clear proof of how health outcomes or costs interdepend and correlate [6-8], although AI diagnosis was assumed certainly to be the higher cost-performance option from a medical angle. Such a lack of proof of clear superiority of either diagnosis method gives prominence to the patients' and medical institutions' preferences. Thus, the acceptability may be enhanced by choosing and adapting a diagnostic program to cater to patients' preferences.

In addition, the Ministry of Industry and Information Technology of China demanded an increase in the praxis of artificial intelligence in the precise prevention and control of epidemics [9]. AI algorithms combine chest computed tomography imaging reports with clinical symptoms, medical history, and laboratory examination to rapidly diagnose patients as infected by SARS-CoV-2. The AI system slightly reduced misdiagnosis by radiologists [10]. The COVID-19 detection neural network, a deep learning model, can precisely detect SARS-CoV-2 and distinguish it from other pneumonia [11]. Artificial neural network modeling of SARS-CoV-2 morbidity across the United States illustrated that a single-hidden-layer multilayer perceptron could interpret nearly 65% of the correlation with ground truth for the prognostication [12].

A few studies [13,14] have focused on the effect of outpatient waiting time, diagnosis time, follow-up after diagnosis, etc in patients' decision making and concluded that these factors play a vital role in patients' trade-off and relative policy making. However, with the development of AI in medicine and rise of AI diagnosis, patients start shifting their focus to the accuracy and expense of AI diagnosis. Thus, we aim to fill the gap that exists because almost no studies focus on the effects of accuracy or other attributes of AI diagnosis and clinicians in patients' choice.

The objectives of this paper are to measure the extent of patients' preferences for a range of characteristics of an AI diagnosis scheme in China and to determine what characteristics are more attractive and make AI a better alternative to defeat traditional medical methods. A technique that is in common use for visualizing preferences is the discrete choice experiment (DCE), in which different alternatives with various attributes are given in the form of a questionnaire to people who are invited to choose options. In this paper, we will construct and make a comparison of these three models: mixed logit (MXL) model, generalized multinomial logit (GMNL) model, and latent class model (LCM). Moreover, the importance of attribute levels and preference heterogeneity must be compared and reported when people are considering any AI diagnosis service.

Methods

Overview

We designed multiple choices in different scenarios consisting of 6 different randomly selected attributes using conjoint-related techniques. Questionnaires were created by Sawtooth software's Lighthouse Studio modules (version 9.8.1) for general interviews and choice-based conjoint (CBC) scenario design. Respondents were aged 18 to 85 years. Meanwhile, in this data analysis section, we aimed to visualize and measure the percentage weight and importance of different attributes with selected models. From the perspective of public health, McFadden's conditional logit [15], which is also known as multinomial logit (MNL) [16], is widely applied to organize, analyze, and predict

the data we had and help with further analysis of statistical significance. However, the foundation of using this model is that we acquiesce that unobserved heterogeneity of preference does not exist across respondents. Therefore, we then need to introduce a MXL model [17] and a GMNL model [18], both of which take unobserved heterogeneity of preference into account. The LCM [19] might also be an appropriate model to apply here, since it divides the data into various groups with fixed segmented size and the evident probability of latent membership [20]. With different latent classes, we can clearly distinguish the most important attributes or attributes' levels of each class and summarize these attributes with a significant percentage weight.

Principle of DCE

Random utility theory [21] is the basic principle of DCE. The principle assumes that all the choice selectors have *M* different choice alternatives, and each choice alternative corresponds to a utility *W*. The utility *W* is consistent with a combination of fixed and random utility. The stationary utility *U* can be explained by some observable elements *x*, while the random factor ε represents the influence and interference unobserved utility and possible error. The goal of choice selectors is to choose the best combination with the supreme utility; then the probability of each combination alternative being selected can be expressed as a function of its fixed utility: $P = F(U)$. The specific form of the function depends on the distribution of random effects. In most model settings, the utility that is optical, U_v, will be expressed as a linear combination of elements *x*, that is, $U_v = \beta x$. β is a coefficient, and its value and significance level can be estimated from the observation data.

Selection of Attributes

Based on the relevant literature [22-24], we have assumed that the patients' preference or satisfaction with the medical choices mainly depends on some specific features that make up the essential attributes of our experiment. Moreover, we performed a pilot test to get the attributes and levels that we need in our research. Patients in the outpatient queue of the First Affiliated Hospital of Jinan University (Guangzhou Overseas Chinese Hospital) and the First Affiliated Hospital of Sun Yat-sen University were interviewed and invited to have a discussion of what attributes patients are most likely to attach importance to. In addition, the possible attributes' levels are hypothesized and set in a certain sequence in our questionnaire; for instance, accuracy ranks from 0% to 100%.

Therefore, in our questionnaire, six attributes have been contained for our experiment: (1) diagnostic method; (2) outpatient waiting time before being asked; (3) diagnosis time; (4) accuracy (ratio of correct diagnosis); (5) follow-up after diagnosis (whether the outpatient doctor/AI doctor can follow up and follow up at any time); and (6) diagnostic expenses. Every attribute and its levels are presented in Table 1.

Table 1. 6 different attributes hypothesized and their levels in discrete choice experiment questionnaire.

Diagnosis methods	Levels
Diagnostic methods	Clinicians' diagnosis; AI diagnosis + clinicians' confirmation; AI diagnosis
Outpatient waiting time	0 min; 20 min; 40 min; 60 min; 80 min; 100 min

Questionnaire and DCE Design

The questionnaire contains two sections. In the first section, which is also known as demographic questions, we aim to allocate the respondents' basic information: age, gender, and highest education level. In the second section, we use the CBC function in Sawtooth software to create various combinations of scenarios for respondents to choose from.

When we use the factorials method [25] to analyze the attributes to give the combinations of scenarios, we encounter several obstacles. Since we have 6 attributes that give 3240 (3×6×3×5×2×6) possibilities, we assume that we have 6 random questions and 100 sets, which also gives 600 different combinations. The difficulty is how to extract 600 representative combinations from 3240 combinations and obey two basic principles [26] at the same time: (1) balance and (2) orthogonality. Balance means each attribute level appears equally often within an attribute, and level 1 in attribute 1 equals level 2 in attribute 2. Orthogonality means each pair of levels appears equally often across all pairs of attributes. However, it is almost unrealistic to handle such a huge task. Therefore, we use Sawtooth software to help us select suitable combinations. We set six random tasks, one fixed task, and two concepts per task (excluding "None Option"). Meanwhile, we set the sample size 500 and assume that 5% of respondents would choose "None Option" and finally design the test.

The standard error of almost all the attributes' levels is <0.05. Since the expense is a continuous variable of which the standard error could be slightly higher than 0.05, a sample size of 500 should be sufficient for our experiment. One of the CBC tasks of the DCE questionnaire has been presented in Table 2.

Table 2. An example scenario of choice-based conjoint in the questionnaire.

Attributes	Doctor A	Doctor B	None
Diagnostic methods	AI diagnosis	Clinicians' diagnosis	
Outpatient waiting time (min)	0	20	
Accuracy (%)	80	60	
Follow-up after diagnosis	No	Yes	
Diagnostic expenses (¥)[a]	150	200	
Which method would you choose?	Choose Doctor A	Choose Doctor B	No choice

[a]A currency exchange rate of ¥1=US $0.15 is applicable.

Data Collection Procedure

We sent our website link containing our DCE questionnaire through social media apps such as Facebook and WeChat. In addition, we gave respondents some rewards such as Mi bands or a small cash payment if the respondents could fully complete the questionnaire.

Statistical Analysis

GMNL Model and MXL Model

With collected data, some models can be applied in our analysis; first is the GMNL model. We do not use the MXL model or the scaled-multinomial logit (S-MNL) model here since the GMNL model, which is developed by Fiebig (2010) [27], nested a MXL model and scaled multinomial model. Meanwhile, the GMNL model could accurately describe consumers' preferences and heterogeneity. According to Fiebig et al, the probability of respondent i choosing alternative j in choice situation t is given as follows:

Here, β_i is a vector of an individual-specific parameter and the individual coefficients of independent variables can be described as follows:

$$\beta i = \sigma i\beta + \{\gamma + \sigma i(1-\gamma)\}\eta i$$

where the β is a constant vector, the "effect" σ_i in our model is a parameter of individual-specific scale, and γ is a parameter that decides how σ_i and η_i are different in some degrees. With this equation, when σ_i equals 1, our GMNL model will become an MXL model. Meanwhile, when the variance of η_i becomes 0, our GMNL model will turn into a S-MNL model. When σ_i equals 1 and variance of η_i equals 0 are both satisfied, the GMNL model will transform into an MNL model. Sawtooth will be needed to help run the coefficients of all attributes, standard errors, and *t* ratios to calculate *P* values. Differences between attributes are also needed to calculate the odds ratios. We calculate the odds ratio using the following equation:

$$odds\ ratio = exp\ (current\ effect - reference\ effect)$$

LCM

In addition, the LCM will be applied. LCM is a latent variable model because the latent variable is discrete. According to Greene and Hensher (2003) [28], the principle of LCM is that the observable attributes and latent heterogeneity decide the individual behavior. The heterogeneity changes with the unobserved factors. This model is used to sort individuals into a set of classes with a certain segmented size and scale, and different effects of each class have been estimated for different attributes. As well, the LCM will help us measure the differences and similarities of preference across classes of respondents. Attributes' importance and part worth utilities will also be needed for visual analysis and comparison of attributes and deciding which attribute is the most essential from the people's perspective. Additionally, the average maximum membership probability will help predict the certainty of the class into which respondents are divided.

Results

Respondents

428 participants (aged 18-85 years) who provided complete data were included in the analysis. Among those with complete data, 206 (48.1%) were male and 222 (51.9%) were female, while 2 of them were pregnant women.

Attributes' Levels and Utility Report

The average utility values of all the attributes' levels were measured using the Utility Scaling Method with zero-centered differences. The highest utility levels of the six hypothesized attributes are "AI diagnosis + clinicians' confirmation" (of "diagnosis method"), "20 min" (of "outpatient waiting time"), "15 min" (of "diagnosis time"), "100%" (of "accuracy"), "Yes" (of "follow-up"), and "¥0" (of "diagnostic expenses"), respectively. The most important attribute is "accuracy," meaning that the majority of respondents ranked that attribute (Table 3).

Table 3. The utility report of different attributes' levels.

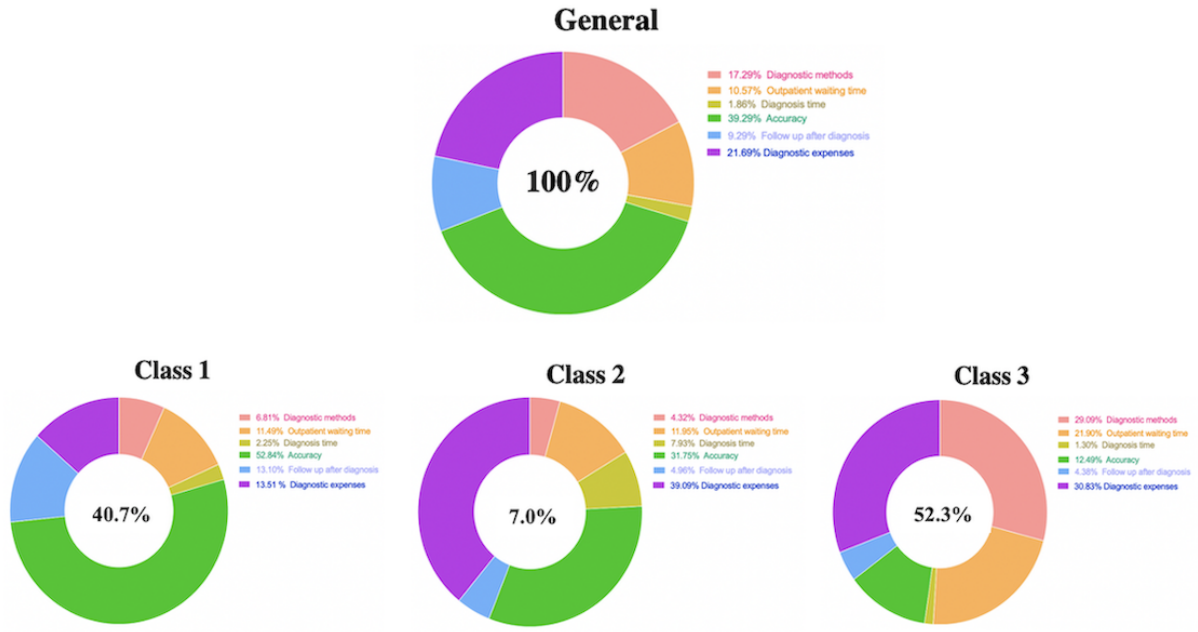
Logit Result of DCE and Attributes' Percentage Importance

In general, it is obvious that attribute "accuracy" was the most important factor and most preferred when facing the diagnosis. As is presented in Figure 1, the percentage importance of attribute "accuracy" was 39.29%, which undoubtedly shows the position of accuracy of diagnosis in people's minds. Attributes "diagnostic expenses" and "diagnostic method" ranked second and third, respectively.

Figure 1. Percentage importance of attributes in general condition and latent class condition.



The results of the logit analysis of all attributes' levels are presented in Table 4. For the diagnosis method, the coefficient of level "AI + clinician" is positive, which means that the level "AI + clinician" is positively correlated with people's preference and utility. In addition, the coefficients of levels "0 min," "20 min," and "40 min" (of "outpatient waiting time") are positive, and others are negative. It is clear that people have a preference for shorter outpatient waiting time. For other attributes' levels, people prefer to choose the higher accuracy level, greater possibility to follow up after diagnosis, and lower diagnosis expense. However, for the attribute "diagnosis time," people unexpectedly prefer a longer diagnosis time rather than the "0 min" option.

Table 4. The result of logit analysis of preference in general (N=428).

[a]A currency exchange rate of ¥1=US $0.15 is applicable.

For the *P* value of these attributes' levels, we assume that if the *P* value of a level is less than .05, then this level is statistically significant; when the *P* value of a level is less than .001, then this level is extremely statistically significant. We found that "AI + clinician" and "AI diagnosis" for "diagnosis methods" are extremely statistically significant; "20 min" of outpatient waiting time is extremely statistically significant; "60 min" and "80 min" are statistically significant; "60%," "70%," "90%," "100%" of "accuracy" are extremely statistically significant; both levels of attribute "follow up after diagnosis" are extremely statistically significant. "¥0'" of attribute "diagnostic expenses" is extremely statistically significant, and all the other levels of diagnostic expenses are statistically significant.

The odds ratio is a commonly used indicator in case-control epidemiological studies. In our analysis and calculation results (Table 4), we find that some odds ratios of the attributes' levels compared to the reference level are greater than one, which means that the probability of people's choosing of these levels is higher than the previous one or the reference. Taking the level "Clinician" of attribute "diagnostic methods" as the reference, level "AI + clinician" has an odds ratio of 1.559 (95% CI 1.446-1.682). The odds ratio of level "20 min" (of "outpatient waiting time") is 1.136 (95% CI 1.014-1.274) with the reference of level "0 min." Levels "15 min" and "30 min" (of "diagnosis time") have odds ratios 1.077 and 1.067, respectively, with the reference of level "0 min" (95% CI 0.999-1.162 and 0.984-1.143, respectively). All the levels of the attribute

"accuracy" were greater than one, which means the preference weights increase with the accuracy. Meanwhile, all the odds ratios of expense compared to the reference are smaller than zero, which refers to a preference of "free diagnosis" for the majority of people.

Latent Class Analysis Result

We compared these potential models and selected the model that maximized the area under the receiver operating characteristic curve and minimized the Akaike information criterion (AIC) [29,30] and Bayesian information criterion (BIC) [31] to penalize for model complexity. According to AIC, 5 classes should be the best choice for our model. However, if we must choose with BIC, then a 2-class option should be the most appropriate one, since 2-class has the lowest BIC. Under such circumstances, we compare ABIC, which means sample size–adjusted BIC [32] and involves sample size value. After comparing, the 3-class option has the lowest value of ABIC. Therefore, the most suitable number of latent classes in our model was 3 (Table 5 and 6). First of all, we divided all 428 respondents into 3 classes with segment sizes of 174 (40.7%), 30 (7.0%), and 224 (52.3%). The average maximum membership probability is around 0.87 and the percent certainty was 35.30, which is relatively low, meaning that there was not much uncertainty according to the respondents divided into classes.

For class 1, *t* ratios for attributes "diagnostic expenses," "'accuracy," and "follow-up after diagnosis" were significant across all treatment modalities. Attribute "accuracy" was the most important factor for patients with 52.8%, followed by "diagnostic expenses" and "follow-up after diagnosis" with percentage importance 13.51% and 13.10%, respectively (Figure 1). Meanwhile, the span of percentage weights of "accuracy" is obvious (Figure 2), from −2.33 to 2.52. Meanwhile, the span of attribute "diagnostic expenses" is from −0.819 to 0.423. The preference weights of "diagnostic expenses" decrease with the increasing of the expenses. The preference weight of attribute "follow-up after diagnosis" is from −0.602 to 0.602. This is −0.602 for "No follow-up" and 0.602 for "follow-up", which is symmetrical. In addition, the odds ratio of level "AI + clinicians" was 1.247 (95% CI 1.036-1.463), meaning that the majority of patients prefer durable treatments over a single treatment. As well, all the levels of attribute "diagnosis time" with the reference level "0 min" are larger than one. At the same time, the odds ratio (Table 7) of the levels of attribute "accuracy" increases with the accuracy rate, meaning that people's preference weight increases with the accuracy.

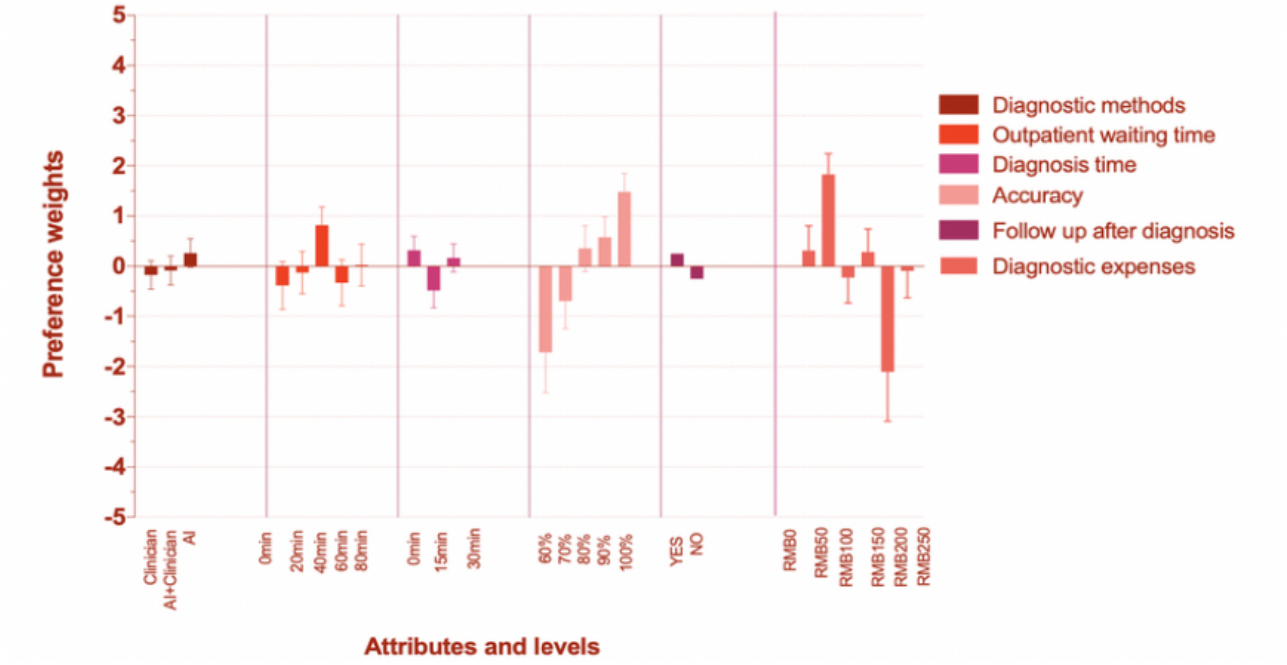
[a]OR: odds ratio.

[b]N/A: not applicable.

[c]A currency exchange rate of ¥1=US $0.15 is applicable.

For class 2, the attribute "accuracy," as well as "diagnostic expenses," was relatively important. Meanwhile, "diagnostic expenses" was (surprisingly) the most important for respondents among the attributes with a percentage weight of 39.09%, followed by "accuracy" with a percentage of 31.75% (Figure 1). The span of the percentage weights of these two attributes has been presented in Figure 3. The percentage weights for attribute "accuracy" were from −1.717 to 1.480, and −2.10 to 1.830 for "diagnostic expenses" (Figure 3). From *P* values, we find that almost all the levels are not statistically significant except the "100%" level of "accuracy" and level "¥50" of "diagnostic expenses." The odds ratio (Table 7) displays that the AI method is the best of three methods. The odds ratio of levels of "outpatient waiting time" are all greater than 1, and patients' preference weight still increases with the increasing of "accuracy" as in class 1. For attribute "diagnostic expenses," only the level "¥50" has an odds ratio greater than 1.

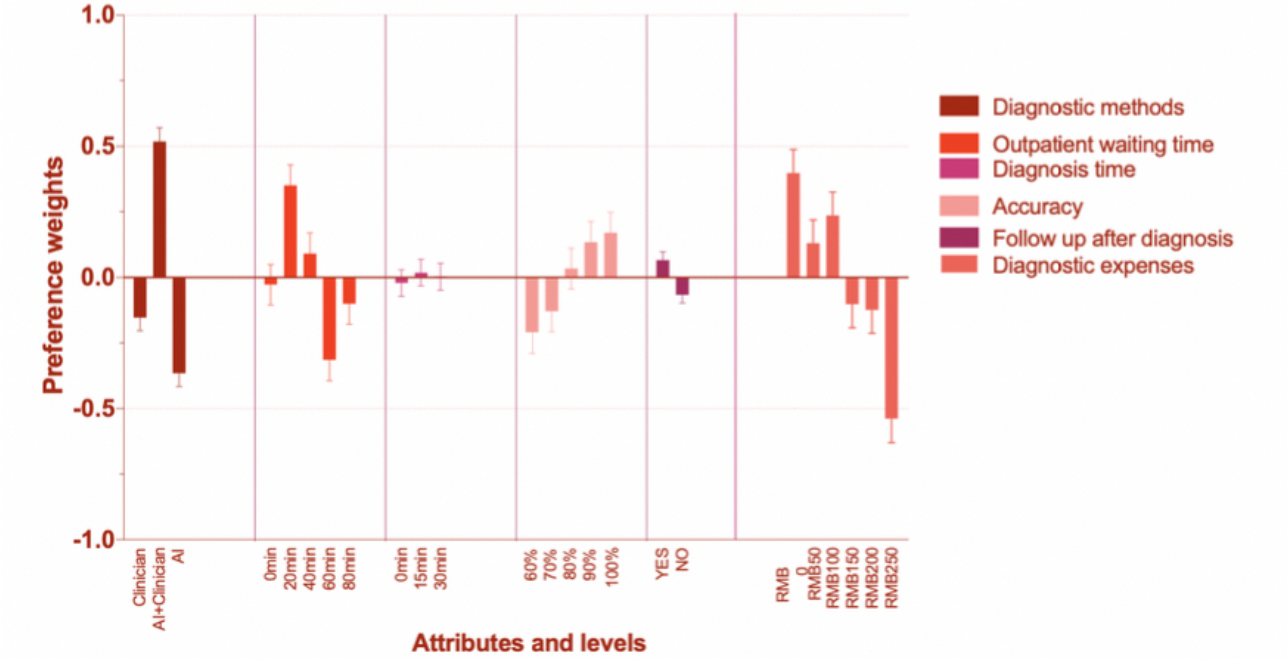
Figure 3. Latent class percentage weights in class 2. AI: artificial intelligence; RMB: yuan renminbi.



For class 3, attributes "diagnosis method" and "outpatient waiting time" were more statistically significant across all the attributes. For respondents in this class, the percentage importance of "diagnosis method" and "outpatient waiting time" were 29.09% and 30.83%, respectively (Figure 1). From Figure 4, we find that the span for diagnostic methods is from −0.364 to 0.518. Meanwhile, the span for diagnostic expenses is from −0.538 to 0.397. In addition, the odds ratio of level "AI + clinicians" of attribute "diagnostic method" was 1.985 (95% CI 1.769-2.167), which is greater than 1, meaning that respondents in class 3 also prefer durable diagnosis mode rather than single mode, similar to the condition of class 1. All of the odds ratios of levels of attributes "outpatient waiting time" and "accuracy" are greater than 1. Meanwhile, the odds ratio continues increasing with the increase of accuracy, the same condition of the previous two classes.

For these 3 latent classes, attribute "accuracy" is the most preferred factor in two classes (class 1 and class 2), while "diagnostic expenses" is the most preferred factor in class 3. In addition, the odds ratio of levels of attribute "accuracy" always increases with the increasing of accuracy rate, meaning that people's preference will always grow with the increase, and higher accuracy is always preferred.

Figure 4. Latent class percentage weights in class 3. AI: artificial intelligence; RMB: yuan renminbi.



Discussion

Principal Findings

Several different models were used in our study to research people's preference for various attributes, including a GMNL model and LCM; both models presented with their own merits and shortcomings.

For the GMNL analysis and the utility report, we found that "accuracy" was the most important thing for respondents and most of the levels of attributes "diagnostic methods" and "accuracy" were statistically significant. From the odds ratio, most of the respondents have a preference for the AI diagnosis plus clinicians' confirmation with outpatient waiting time of 20 minutes, diagnosis time of 15 minutes, and 100% accuracy. We would expect that the outpatient waiting time of 0 minutes and diagnosis time of 0 minutes should be preferred. However, the preferred choice was not 0 minutes. We assume that some people believe that a longer diagnosis time can give them more credibility and a feeling of safety. Furthermore, the odds ratio of 1.559 for "AI diagnosis + clinicians' confirmation" was evidently higher than only "AI diagnosis," which reflects that, for now, the vast majority of people still cannot totally trust the AI diagnosis due to the factors of AI uncertainty. AI diagnosis acting in concert with clinicians will significantly guarantee the accuracy. Another defect of AI diagnosis is that patients follow up after diagnosis, which means that patients who cannot receive follow-up have no alternatives but to head to clinicians as outpatients, which indirectly results in missing the best patient treatment time. That also leads to huge inconvenience to both patients and clinicians. Those who have an evident preference for only AI diagnosis may as a result of freshness and relatively higher diagnosis time of AI method, with sacrifice of accuracy in their mind. Thus, we can still consider the clinicians' diagnosis to remain irreplaceable, at least in the short term. The limitation of the GMNL model was also obvious; some respondents with preferences for other diagnostic methods and different diagnosis expenses cannot be reflected.

From the LCM, our study finds that respondents who are divided into 3 classes show different preferences and different patient profiles. There was slight heterogeneity compared to the GMNL model. Specifically, respondents in class 1 and class 2 still attach importance to "'accuracy"; however, respondents in class 3 mostly pay attention to "diagnostic expenses." Although medical insurance and accessibility are quite advanced today, some patients hardly get access to basic medical diagnosis or treatment, particularly in some underdeveloped or remote areas in China. Some old people would rely on their own self-healing function or immune system [33] rather than go to the hospital due to their outdated concepts of unaffordable diagnosis and treatment expenses. Therefore, the acceptability of AI diagnosis or even modern medical techniques among old people is palpably lower than among new generations in China due to the concepts of cost. In addition, we hypothesized that the numbers of hospitals in remote areas is undoubtedly lower than those in urban or advanced areas, which results in the people living in remote areas having to undertake the transportation time and cost. The long transit time and cost could also sometimes be fatal to these people since that would also force them to stay at home and miss the most appropriate diagnosis and treatment time. To sum up, the promotion and spread of AI diagnosis cannot ignore the need to set a suitable diagnosis price or give some discount and bonus according to the wealth status of patients.

Several previous studies [13] have found that most patients believe the outpatient waiting time plays a vital role in their decision-making behavior when faced with various choices of hospitals and clinicians. In addition, few studies [14] have attached importance to the quality and quantity of follow-up after clinical diagnosis. However, all of these studies ignored the effect of diagnosis accuracy and diagnosis expense in patients' trade-offs. Especially in the era of artificial intelligence, there are few studies addressing the accuracy of AI versus human clinicians rather than the outpatient waiting time or other factors. With diagnostic accuracy, clinically, the AI system can be programmed to probe and mark out some cancer indications such as prostate cancer and is more accurate than experts [34]. The clinical application could reduce pathology workload in this epidemic and in future clinical work. An AI system with expert-level grading performance might contribute a second opinion, aid in standardizing grading, and provide expert advice in areas with poor sanitation. As cloud computing capabilities come closer to life, overcomes limited memory, and central processing unit power [35]. We believe ever more and more people will trust the rapid diagnostic capabilities of AI. There is a lot of SARS-CoV-2–related scientific research undertaken to use AI to combat this pandemic by deploying new methods in the development of vaccines and drugs, as well as for public awareness [36]. Relying on the advantages of AI for medical auxiliary diagnosis, image analysis, remote consultation, etc during the outbreak of COVID-19, many AI devices have been used in first-line medicine. Moreover, AI is reducing cross infection. It has played an important role in therapeutic innovation. Health QR Code, which is a fusion of AI and big data, is a mobile phone app for everyone and uses red, yellow, and green colors to provide simple and effective intelligent services for personnel communication and economic and trade exchanges in the China in the "postepidemic era."

AI will continue to play an increasingly important role in controlling the public health crisis to save lives and economic recovery. AI contact tracing based on mobile communication technology becomes more mature [37]. The AI systems combining computed tomography and clinical symptoms can help to quickly diagnose SARS-CoV-2 patients [10]. A surrogate rapid diagnosis technique that is based on a deep learning neural network can be applied for discovering SARS-CoV-2 by analyzing the visual chest radiography imaging of patients [38].

Limitations

Limitations for Our DCE

Theoretically, the larger the sample size is, the smaller the changes we will find in the DCE; however, due to various reasons related to the pandemic, we applied convenience sampling in the data collection procedure. Thus, our sample size is relatively small and underrepresentative. Furthermore, the other significant shortcoming of our DCE data is that our

statistics do not stand for the point of view of all the people in China or other people worldwide due to the limited transmission of our questionnaire. We did not set the diseases as acute or chronic, which is an exogenous factor that will affect people's choice of waiting time.

Limitations for AI Diagnosis Propaganda

With AI diagnosis, there exists a requirement for rapid delivery and logistics of medicine. Furthermore, the conceptual propaganda for AI diagnosis and treatment are still not in place, particularly in some rural areas and among some old people with relatively traditional medical concepts. Confidence and trust in the AI diagnostic method still have a long way to go.

Conclusion

Segments of patients' preferences for these diagnosis options seem to be homogenous and convergent. All the attributes hypothesized and attributes' levels are evidently not ignorable during the implementation and widespread use of AI diagnosis techniques. People's preference for "accuracy" was obvious across different classes. Although "online treatment" has become more common today, accuracy has been sacrificed in exchange for so-called convenience, which is totally unwise. In addition, AI diagnosis technique developers as well as technology sellers, including hospitals, should take diagnosis expense into consideration and make pricing rules more flexible in the light of areas' economic development and individual patients' wealth status.

AI will definitely have a potential market and bright future, especially in the ongoing COVID-19 pandemic, since the AI diagnostic technology can ease the requirements of professional clinicians worldwide, particularly in rural areas.

Abstract

Background: During the COVID-19 pandemic in Canada, Prime Minister Justin Trudeau provided updates on the novel coronavirus and the government's responses to the pandemic in his daily briefings from March 13 to May 22, 2020, delivered on the official Canadian Broadcasting Corporation (CBC) YouTube channel.

Objective: The aim of this study was to examine comments on Canadian Prime Minister Trudeau's COVID-19 daily briefings by YouTube users and track these comments to extract the changing dynamics of the opinions and concerns of the public over time.

Methods: We used machine learning techniques to longitudinally analyze a total of 46,732 English YouTube comments that were retrieved from 57 videos of Prime Minister Trudeau's COVID-19 daily briefings from March 13 to May 22, 2020. A natural language processing model, latent Dirichlet allocation, was used to choose salient topics among the sampled comments for each of the 57 videos. Thematic analysis was used to classify and summarize these salient topics into different prominent themes.

Results: We found 11 prominent themes, including strict border measures, public responses to Prime Minister Trudeau's policies, essential work and frontline workers, individuals' financial challenges, rental and mortgage subsidies, quarantine, government financial aid for enterprises and individuals, personal protective equipment, Canada and China's relationship, vaccines, and reopening.

Conclusions: This study is the first to longitudinally investigate public discourse and concerns related to Prime Minister Trudeau's daily COVID-19 briefings in Canada. This study contributes to establishing a real-time feedback loop between the public and public health officials on social media. Hearing and reacting to real concerns from the public can enhance trust between the government and the public to prepare for future health emergencies.

Introduction

The World Health Organization declared COVID-19 to be a global public health emergency on March 11, 2020 [1]. Canada confirmed its first COVID-19 case on January 25, 2020, and a total of 189,387 cases of COVID-19 in Canada were reported as of October 14, 2020 [2]. On March 12, 2020, Quebec was the first province to declare a state of emergency [3], and the government established preventive measures such as transportation restrictions, quarantine rules, and social distancing requirements [4,5]. In Canada, Prime Minister Justin Trudeau started providing a daily briefing on the government's updated policies and actions for stopping the spread of COVID-19 on March 13, 2020. For example, Prime Minister Trudeau announced an interest-free moratorium on student loan payments and closure of the United States–Canada border on March 18, 2020; announced the Canada Emergency Response Benefit (CERB) on March 25; and announced the Canada Emergency Student Benefit (CESB) through independent public entities (eg, lowering of the interest rate by the Bank of Canada) or federal government programs (eg, CERB and CESB) on April 22 [6].

Since the COVID-19 outbreak, social media has become the most accessible source for obtaining news and health information and for exchanging opinions. Given their self-isolation, people extensively post opinions, express emotions, and exchange ideas about COVID-19–related policies on the web [7]. In this study, we analyzed the YouTube comments under Prime Minister Trudeau's daily briefing videos. YouTube is the first web-based video sharing platform. With more than 2 billion users and 1 billion hours of videos watched every day, YouTube has become one of the largest video sharing platforms worldwide, and it has played an essential role in public communication during the COVID-19 epidemic [8]. Comments on YouTube have provided rich data for public discourse and sentiment research. Existing studies examine the impact of YouTube videos and comments on epidemic diseases (eg, Ebola virus, Zika virus) and show that YouTube videos and comments are essential channels for disseminating health information [9-11]. Basch et al [9] coded the source and contents of the 100 most widely viewed videos about the Ebola virus on YouTube. They found that these videos have been viewed 73 million times and included contents about the death toll of the virus and how it was transmitted. Pathak et al [11] evaluated 198 YouTube videos about the Eloba outbreak in 2014. They found that most of the videos were useful, and they demonstrated that YouTube is a useful health information source during global health emergencies. In contrast, Bora et al [10] concluded that videos could potentially spread misinformation during global public health emergencies, and trustworthy videos from health organizations or universities were scarce. Khatri and colleagues [12] analyzed content about COVID-19 on YouTube by reviewing 72 videos in English and 42 videos in Mandarin; they demonstrated that YouTube is an important platform for health information dissemination.

This study has two goals. The first is to examine whether YouTube comments are a useful source of public opinions and priorities on COVID-19; the second is to identify public responses and discourses related to Prime Minister Trudeau's COVID-19 policies in Canada over time. According to Bora et al [10], we purposively selected trustworthy videos published by the official YouTube channel of the Canadian Broadcasting Corporation (CBC). More specifically, this study examines and tracks public discourse under Prime Minister Trudeau's daily COVID-19 briefing videos posted on YouTube (N=57) from March 13 to May 25, 2020, in Canada. This paper contributes to understanding the undermeasured public responses to Prime Minister Trudeau's COVID-19–related policies in Canada. Real-time and longitudinal analysis of public responses and concerns can help public health authorities recognize Canada's public priorities.

Methods

We followed the text mining pipeline, including data preparation and data analysis [7]. Data preparation included data sampling, collection, and preprocessing. Data analysis included unsupervised machine learning and thematic analysis. The unit of analysis was each unique comment posted under Prime Minister Trudeau's daily briefing videos from March 13 to May 25, 2020.

Sampling

We used a purposive sampling approach. Our sampling frame was Prime Minister Trudeau's COVID-19 daily briefing videos, which were published on the official CBC channel on YouTube [13] starting on March 13, 2020. Our sampling frame included 58 daily briefing videos posted from March 13 to May 22, 2020 (57 videos included comments; 1 did not receive any comments).

We present the characteristics of these videos in Multimedia Appendix 1, including publication dates; titles and descriptions of the videos; and numbers of views, likes, dislikes, and associated comments that each video received up to May 25, 2020. For example, on March 22, 2020, the daily briefing with the title "PM Trudeau announced that the $82-billion financial package was just the first step, and more financial funds will come" received the highest number of comments (n=2413) among the daily briefing videos published in March. The video titled "The term 'New Normal' to describe daily routine during the COVID-19 pandemic and the numbers would take months of continued, determined effort" had the highest number of comments (n=2087) in April. The video titled "Trudeau urged world leaders to pull together for the COVID-19 vaccine" received the highest number of comments (n=2653) in May.

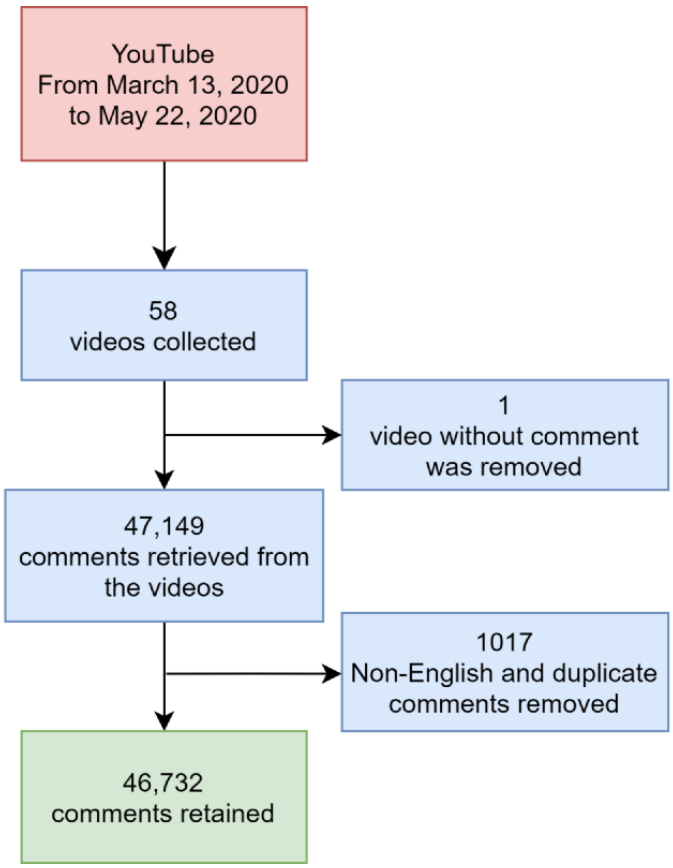
Data Collection

The data set of the study consisted of all the comments posted by YouTube users under each of the 57 videos. We used YouTube's open application programming interface to collect all the comments under each of Prime Minister Trudeau's daily briefing videos on May 25, 2020. We coded the information retrieval script in Python, version 3 (Python Software Foundation). We retrieved a total of 47,149 comments from these 57 videos. After removing 1017 non-English and duplicate comments, 46,732 comments remained as our final data set, as shown in Figure 1. The following information associated with each of the 46,732 comments was collected: (1) a unique ID

related to each comment; (2) the full comment text; (3) metadata associated with the comment, such as the reply count (number of replies that comment received), like count (number of the likes that comment received), published date and time of the comment, and deidentified username. The collected 46,732 English comments included both the first level comment and its associated "replyTo" (comment posted in reply to another comment) from 17,211 YouTube users.

We treated the set of comments published under each video as a separate document for the topic modeling (eg, documents 1-57). Thus, we obtained a total of 57 documents for topic modeling.

Figure 1. Data preprocessing chart.



Preprocessing of the Raw Data

We preprocessed the raw data to ensure data analysis quality. Preprocessing is an important task for analyzing YouTube comments, as it cleans the data by diminishing its complexity to provide better results [14]. Our data preprocessing included the steps below.

1. We removed handles (@user) and their content, as they did not contribute to the analysis.
2. We removed all non-English characters (non–American Standard Code for Information Interchange [ASCII] characters) because this study focused on English messages.
3. We removed words that did not make sense, such as "#newYork sdaaawd asjdasd @!!!!" We used the Nostril evaluator [15] to detect nonsense comments and pronunciations. Nostril incorporates a large table of n-gram frequencies to support its probabilistic assessment of text strings. For the comments labeled as "nonsense" by Nostril, we also checked their pronunciations (ie, vowels and phones). The detected nonsense comments were removed from the analysis.
4. We removed stopwords to ensure better results [16]. Stopwords (eg, the, a, an, in) are frequently occurring words that do not carry any information or orientation. We used the Natural Language Toolkit suite of Python libraries to filter out the stopwords to save space in our database and shorten the processing time.
5. We applied a stemmer. A stemmer is a rule-based process of stripping the suffixes (eg, "ing," "ly," "es," "s") from words. A large number of conjugates were removed.

Data Analysis

Unsupervised Machine Learning

We used latent Dirichlet allocation (LDA) [17] to generate prominent topics. LDA is a generative probabilistic model based on the hierarchical Bayesian that mines the underlying set of topics on a corpus of text. LDA has been applied to COVID-19–relevant topics on social media. For example, Xue et al [7] examined Twitter posts related to the COVID-19 pandemic. Obadimu and colleagues [18] applied LDA to recognize the toxicity of comments on YouTube. In this study, we treated the collected YouTube comments as a document and applied LDA topic modeling with the gensim Python library. For each identified topic, we used WordNetLemmatizer to extract popular unigrams and bigrams. The pyLDV library was used to visualize the findings.

Qualitative Analysis

The thematic analysis enabled us to interpret the patterns, topics, and themes from the unsupervised machine learning processes [19,20]. Two authors independently assigned topics based on the bigrams and representative comments related to each of the videos. Then, they reviewed all the identified topics and their representative unigrams, bigrams, and comment examples from the 57 videos and assigned themes across these topics. The research team examined the initial coded themes and considered whether they reflected the identified topics. The team discussed the themes and provided names to ensure that they reflected the identified salient topics.

Results

Descriptive Results of the Videos

Our sampling frame included 57 of Prime Minister Trudeau's daily briefing videos published on the CBC YouTube channel between March 13 and May 22, 2020. We describe the statistics of the videos in Table 1, including the numbers of views, likes, dislikes, and comments of the 57 videos. For example, on average, these videos were viewed 364,487 times and received an average of 830 comments and 1826 likes.

Table 1. Descriptive statistics of the collected videos (N=57).

Characteristic	Range	Mean (SD)
Number of views	74,924-839,921	364,487 (205,984)
Likes	492-4405	1826 (1059)
Dislikes	290-2750	676 (344)
Comments	197-2653	830 (544)

Figure 2 shows the view counts of Prime Minister Trudeau's daily briefings over time. The view counts peaked on March 20 and gradually decreased after April, when Prime Minister Trudeau declared that the government would close the border to stop the spread of COVID-19 [21].

Figure 2. The number of views for the sampled daily briefing videos over time (n=56).

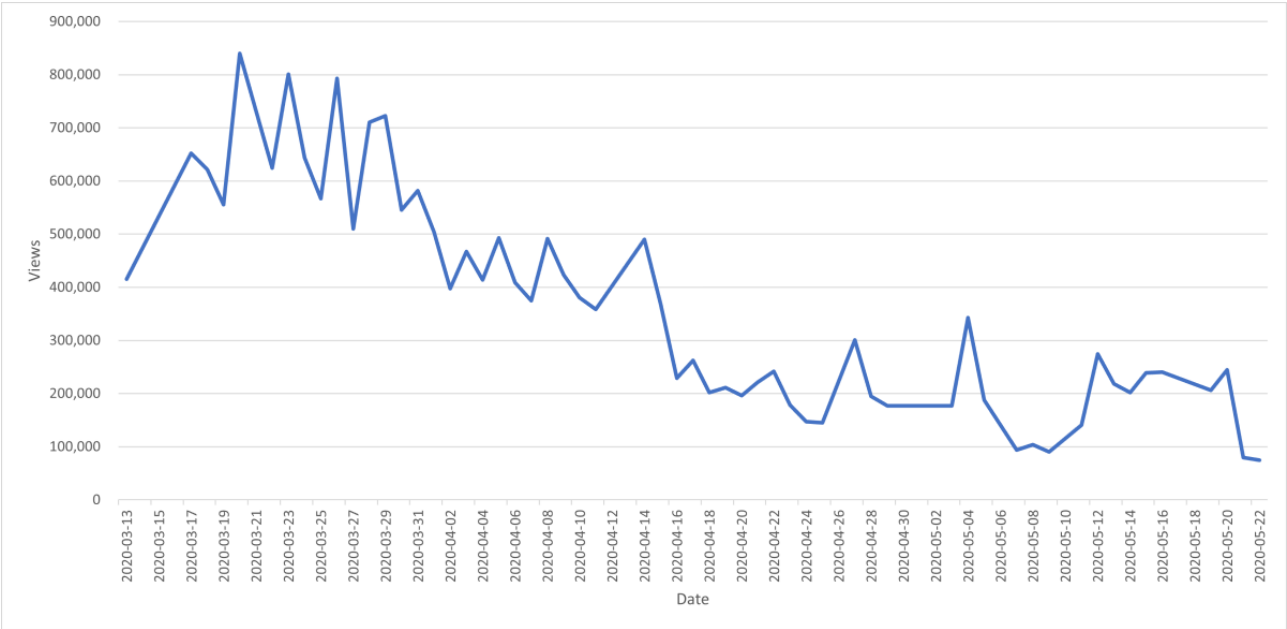


Figure 3 shows that the numbers of likes were higher than the numbers of dislikes on most of the days, except for May 4 and May 9, 2020. The daily briefing on May 4 urged all world leaders to work together and fight for a COVID-19 vaccine. Additionally, this video received the highest number of comments. Prime Minister Trudeau stated that Canadians would receive more financial benefits on May 9, 2020; this video received more dislikes than likes.

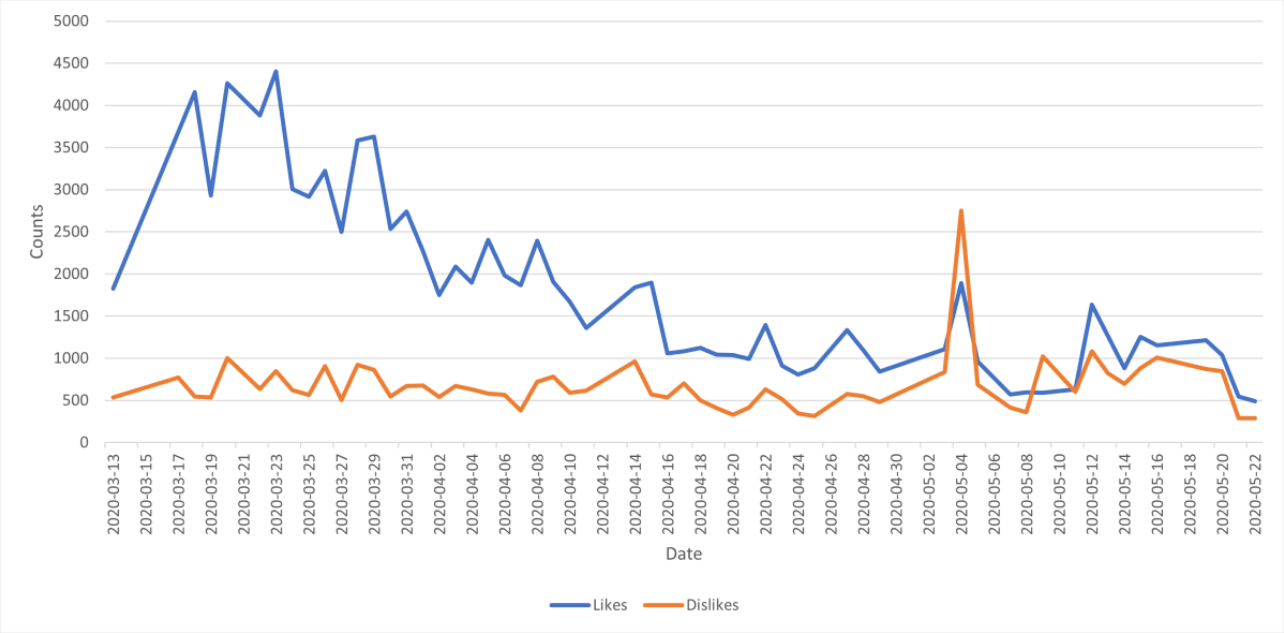
Figure 3. Like counts and dislike counts for the sampled daily briefing videos over time.



Prominent Topics in the Comments

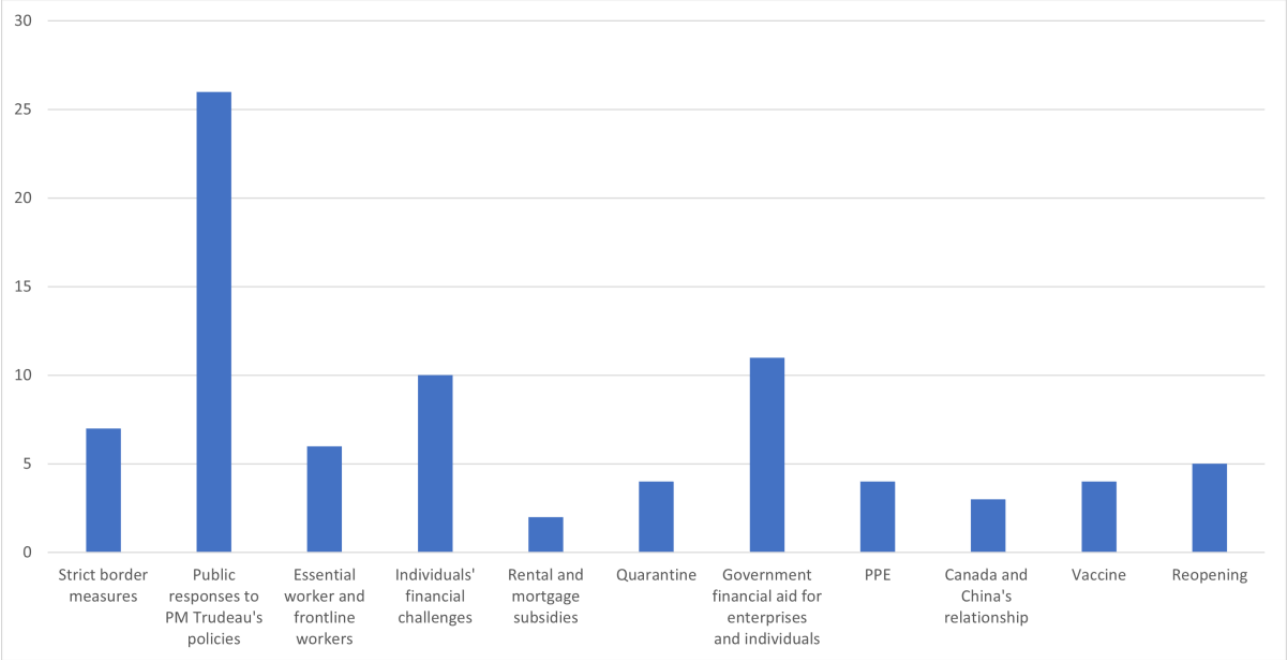
We retrieved and downloaded the associated 46,732 comments for each of the 57 videos as our final data set. We identified 1 to 3 salient topics for each of the documents (#1 to #57) associated with each daily briefing video, resulting in 168 topics. We present the topic modelling results for each of the 57 documents in Multimedia Appendix 2, including the publication dates of the videos, prominent topics in the documents, popular bigrams in the topics, and representative comments on each topic. For example, document #1 included all posted comments under Prime Minister Trudeau's daily briefing on March 13, 2020. We identified two prominent topics in document 1: border measures and comment on the government. Popular bigrams were "close the," "dam border," "international travel," and "prime minister." A representative YouTube comment is "CLOSE THE BORDER!!!! Wake up Trudeau… close the god dam border Now. Stop all flights from Italy and Europe NOW."

Prominent Themes

Multimedia Appendix 3 shows the salient themes with their descriptions, topics (bigrams), and representative comments. We identified 11 themes from the 168 most prominent topics, including strict border measures, public response to Prime Minister Trudeau's policies, essential work and frontline workers, individuals' financial challenges, rental and mortgage subsidies, quarantine, government financial aid for enterprises and individuals, personal protective equipment, Canada and China's relationship, vaccines, and reopening. For example, public response to Prime Minister Trudeau's policies was a prominent theme, exemplified by the topic (uni)bigrams of government, Prime Minister, Justin Trudeau, Canada, officials, liberal, government and right wing. An example comment is "Respect and listen to the Prime Minister, he is trying his best with the Government to keep everyone in our Country safe from Covid19."

Figure 4 shows the number of occurrences of the prominent themes between March 13 and May 22, 2020. For example, the theme of public responses to Prime Minister Trudeau's policies was the most popular, followed by government financial aid for enterprises and individuals and individuals' financial challenges.

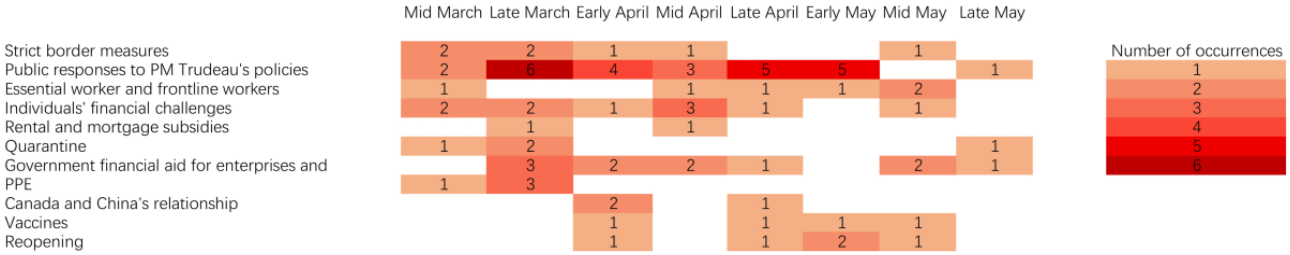
Figure 4. Occurrences of each theme from March 13 to May 22, 2020. PM: Prime Minister; PPE: personal protective equipment.



Themes Over Time

In addition to counting the number of occurrences, we also tracked the prominent themes over time, as shown in Figure 5. We divided each month into three periods: early month (day 1 to day 10), mid-month (day 11 to day 20), and late month (day 21 and after). Public concerns were ongoing for the themes of public responses to Prime Minister Trudeau's policies and individuals' financial challenges, as comments related to these themes appeared multiple times from March to May. For example, the theme of public responses to Prime Minister Trudeau's policies had been continuously discussed by the public since March (except for in mid-May). The theme of strict border measures mainly occurred from mid-March to mid-April. However, it was discussed again in mid-May. The themes of vaccines and reopening were mainly discussed from late April.

Figure 5. Prominence of each theme from March 13 to May 22, 2020. Early, day 1-10; mid-month, day 11-20; late, day 21 and after. PM: Prime Minister; PPE: personal protective equipment.



Popular Comments

We selected the 50 comments with the highest numbers of likes and the 50 comments with the highest numbers of replies. We present 19 comments that ranked in the top 50 most liked and replied in Table 2. The table shows the contents of these 19 comments along with their published dates, categorized themes, numbers of replies, and numbers of likes. For example, a single comment posted on March 28 received 488 likes and 104 replies from other YouTube users. This comment reflected the theme of strict border measures. Among the 19 selected popular comments, we found that five comments were about the theme of quarantine, and three comments reflected the theme of open government. The theme of quarantine was related to quarantine-related measures, as the public expressed a desire for more strict quarantine measures when they commented on and responded to Prime Minister Trudeau's daily briefings. The theme of open government was related to the public's request for a more open government and public interaction dynamics.

Table 2. Most popular comments, origins (daily briefing dates), assigned themes, and numbers of replies and likes.

Comment	Date of origin (2020)	Theme	Replies, n	Likes, n
"Why are we still not checking people at the airports?"	March 28	Strict border measures	104	488
"They should be pausing all mortgages and rent payments, the CRA can't give you money by the 1st"	March 22	Rental and mortgage subsidies	99	525
"I really hope when this is defeated that our society doesn't go more Orwellian"	May 04	Good wishes	88	230
"MR TRUDEAU: All you need to do is issue a moratorium stating that all Canadians with a rental lease or a mortgage is immediately suspended for 3 to 6 months. After which their existing monthly payments will restart and continue as usual. This will put at least 30% more money in every person's account fairly. These funds can be used to pay cred it cards, car loans, food etc. It is a brilliant idea already being implemented in the USA by a number of Banks and institutions. This is simple and would help all Canadians. Obviously no penalty would by involved and this would be a Government approved legal postponement of all rents and mortgages for the period stated."	March 24	Individuals' financial challenges	78	246
"Its time to come together and support each other and question everything."	May 04	Good wishes	68	802
"I don't care about staying home. I'm a homebody anyways. I care about being poor and ending up completely homeless after the whole Covid19 crisis ends. My landlord already wants me to move out by August, and no one knows if it will have died down by then or if I'll have a job by then so I can safely move."	March 29	Individuals' financial challenges	67	165
"Meanwhile, Canadian Tire, Lowes, Home Depot, Costco all the checkout attendants facing hundreds of customers per day and not one of them was wearing a mask and that was yesterday March 21st"	March 22	Quarantine	67	356
"Comments are allowed? Interesting"	March 26	Open government	66	335
"The scariest YouTube title ever"	April 09	Emotion	63	340
"I just want to know if these people are secretly getting haircuts. The rest of us will look like sheep dogs if this continues."	March 26	Emotion	54	178
"I wish you didnt do the voice over, he is already doing it bilingually. we dont need to hear it two times in English besides the translation is badly done."	April 14	Not related	54	615
"Anybody coming into Canada from other countries should have mandatory isolation for 14 days."	March 28	Quarantine	53	222
"I dont understand why people still went on cruises even tho they were specifically told not to a longgggggg time ago"	March 28	Emotion	51	269
"Lets have open questions from the public."	April 09	Open government	40	203
"Close the border dont exempt American citizens. Close it down."	March 17	Quarantine	38	304
"We should not rely on the US, like we are the 51st state!"	March 05	Emotion	34	180
"Dont have a social gettering of more than 10 people. Thats the guideline in South Korea. I think 50 is too much^^"	March 17	Quarantine	33	415
"Dr Tam waiting for 'evidence' of human to human transmission is disgraceful especially considering entire cities in China had already been locked down and the Three early German cases traced back to a Chinese business woman had already been reported. The precautionary principle should have been followed and Canadians deserve answers. We deserve better and Dr. Tam let us all down"	April 14	Quarantine	32	162
"Never in my life have I heard so many answers that dont answer a question. Ever. Lol"	April 14	Open government	32	317

Discussion

Principal Results

This study is the first to investigate and track public opinions and reactions to Canadian Prime Minister Trudeau's daily COVID-19 briefings. This study uses a machine learning approach and longitudinally examines public discourse about Prime Minister Trudeau's daily briefings over time. The results reveal several prominent themes over time, including strict border measures, public responses to Prime Minister Trudeau's policies, individuals' financial challenges, government financial aid for enterprises and individuals, and essential work and frontline workers. In addition, the themes of vaccines and reopening were highly discussed from late April. The study demonstrates that YouTube comments are a useful source of public opinions and priorities during global health emergencies.

Theme 1: Strict Border Measures

This theme refers to comments that discuss topics such as border entry policy, international travel, and border screening measures. The majority of the comments in this theme requested that the government implement stricter border measures to prevent transmission from carriers who have or do not have COVID-19 symptoms, exemplified by the comment "CLOSE THE BORDER... Stop all flights from Italy and Europe NOW." Public discourse on this topic started in mid-March and remained a hot topic until mid-April. The results correspond with a policy announced by the Canadian government on March 18, 2020, that implemented a ban on all foreign nationals entering Canada, including restrictions on all nonessential travel at the Canada–United States border. Discussions of border measures were not prominent in late April and early May but reappeared in mid-May, consistent with the border closure agreement between Canada and the United States, which was valid until May 21.

Our results suggest that the "border policy issue" has continuously been a concern for Canadians, who support strict border measures to prevent the spread of COVID-19 in Canada. Previous studies demonstrated that air transportation has the potential to spread influenza, such as A/H1N1 [22], and enhanced precautions should be taken for travelers to countries with increasing cases of respiratory diseases, such as Middle East respiratory syndrome [23]. Brown and colleagues [24] showed that airport exit and entry screening at international borders facilitated the rapid detection of illness and the implementation of appropriate public health control measures to prevent the spread of Ebola virus. Our results suggest that future research can provide empirical evidence for the public and policy makers regarding the effectiveness of border measures to prevent the spread of COVID-19, as this has been a primary public concern over time.

Theme 2: Public Responses to Prime Minister Trudeau's Policies

Public responses to Prime Minister Trudeau's policies refer to public opinion comments on the Canadian government, parties, or the Prime Minister himself. The majority of comments include opinions regarding the government's performance and policies during the COVID-19 pandemic. One representative comment is "Respect and listen the Prime Minister, he is trying his best with the Government to keep everyone in our Country safe from Covid19 with emergency funds for those that need it." Compared to other themes, this theme is more popular, and it continuously received public attention from mid-March to late May. The popularity of this theme is due to the positive interaction dynamic between the general public and the government of Canada, which encourages people to communicate with government organizations on social networks. This interaction can be traced back to 2011, when Canada acknowledged the need to use social media to interact with the public for the first time [25]. Social media users in Canada are primarily interested in communicating with the government and obtaining customized information [26]. One study [27] showed that social media engages the public to foster participatory dialogues and discussions of policy development and implementation. In addition, we found criticisms related to the government's COVID-19–relevant policies, such as:

> *Government Health Officials WHAT? They are months behind! Recommended NO MASKS only because they did not prepare, and they hadn't enough masks.*

Previous studies have examined mixed sentiments toward governments' policies in emergencies. During the 2009 H1N1 influenza pandemic, more than half the US population felt positive emotions toward the government's policy responses, while a certain number of people did not [28].

Theme 3: Individuals' Financial Challenges

Financial challenges refer to comments that include people's discussion, concerns, or policy proposals related to financial loss during the pandemic, such as "having no income for essential living costs due to lost jobs." One representative comment is:

> *I'm more worried about the financial issue than the health one right now. We are doing everything we can health-wise in this family, but my son is now out of work, and we know hubby will be soon.*

Our results show that the public has been frequently and continuously discussing finance-related topics since Prime Minister Trudeau's first daily briefing. The assessment of the impact of the COVID-19 pandemic on the labor market in Canada shows that the pandemic drove a 32% reduction in aggregate weekly hours worked from February to April 2020, along with a 15% reduction in employment [29]. As indicated by Statistics Canada, the average net savings for all Canadian households was CAD $852 (US $671) in 2018 [30], which suggests that people may be unable to afford essential living costs if they do not receive a basic income.

We found a positive correlation between the government's policies supporting individuals and public attention to financial challenges. CERB was launched on April 6, 2020; nearly 3.5 million Canadians applied for this benefit in the first week, and this number increased to 7.12 million on April 24, 2020 [31]. More than 7 million people received CAD $2000 (US $1575) from the Canadian government in April, which explains the temporary decrease in the public attention toward financial challenges in early May.

Theme 4: Government Financial Aid for Enterprises and Individuals

Discussion about enterprises and individual financial aid plans was prominent from March to May 2020. This theme includes discussions of government financial aid plans and programs supporting either enterprises or individuals, such as CERB, CESB, the Canada Emergency Wage Subsidy, and the Canada Emergency Business Account. This theme is different from theme 3, individuals' financial challenges, which focuses on individuals' concerns and discussions of their financial obstacles during the outbreak. In late March, the theme of government financial aid became prominent when the government administration firstly announced a number of economic stimulation programs, exemplified by this comment: "If your

business/source of income was interrupted due to COVID-19, whether you lost your business or not, you could still try to apply, as you would be in true need of help at this point." Our results confirm those of previous research on emergency individual financial aid during the pandemic and the importance of financial aid programs for businesses [32,33]. The longitudinal discussions on financial aid plans suggest that financial aid during the COVID-19 pandemic is critical for the public, and further research is suggested to assess the need for financial aid programs and evaluate their implementation.

Theme 5: Essential Work and Frontline Workers

Essential work and frontline workers was a prominent theme in the comments related to Prime Minister Trudeau's daily briefings, such as the welfare system in Canada, incentive pay for essential work, and protection of frontline workers. One representative comment stated, "The government should be incentivizing those who have to work during a pandemic, even a $500/month incentive." This was an active public discussion topic in mid-March; it lost public attention for 20 days, and then became prominent again in mid-April. Our results are consistent with an earlier study that shows that frontline workers should be supported, and public support of frontline workers has been related to a speech by the Prime Minster of India [34]. Our findings suggest that Prime Minister Trudeau's daily speech advocating for frontline workers also resulted in support and attention from the general public. For example, Prime Minister Trudeau mentioned essential work and frontline workers several times during his daily briefings, especially on April 29 and May 7. Our study suggests that political efforts in acknowledging essential workers has a substantial impact on the general public's awareness. It is worth examining whether public acknowledgment influences people's behaviors, such as strictly following social isolation and quarantine measures.

Theme 6: Vaccines

Public discussion of vaccines is another prominent theme that emerged in April. We classified all relevant topics in this theme, such as the development of vaccines, exemplified by this comment: "It could take years to come up with a vaccine, you've been doing a good job, Trudeau. Don't it up by making statements you can't back up." Previous studies analyzing Tweets related to COVID-19 also found that vaccines were a highly discussed topic [7]. Our findings provide further evidence that vaccines have been a significant public concern among Canadians during the COVID-19 outbreak. However, we also found misinformation regarding vaccines on social media, where some comments supported that vaccines are a type of conspiracy. Our findings suggest that the Canadian government should provide more resources to the public to dispel misinformation regarding vaccines. Proper public education is essential to raise public awareness and to mobilize and engage people in communities in Canada.

Limitations

There are several limitations to this study. First, this paper is not based on random sampling. We purposively collected comments that were posted by YouTube users under Prime Minister Trudeau's briefing videos. They only represent a portion of the public opinions regarding Prime Minister Trudeau's daily briefings during the COVID-19 pandemic, which causes biases. Second, our sample size is relatively small compared to the large amount of data on Twitter. Third, we treated secondary comments (ie, comment to comment) in the same manner as first-level comments for the study aims. Thus, this study has limitations in presenting the structural relationship between first-level and second-level comments. Finally, we retrieved all videos, comments, and associated data on May 25, 2020, three days after the last day of the Prime Minister's daily briefing. It is noted that the evaluations could be different due to the increased number of comments added over time.

Conclusion

This study is the first to analyze and track the public discourse of Canadian Prime Minister Justin Trudeau's daily briefing on COVID-19 on social media. Machine learning analysis was applied to 46,732 English YouTube comments from 57 videos from March 13 to May 22, 2020, and the results suggest that several prominent themes should be noted by public health agencies and policy makers, such as strict border measures, public responses to Prime Minister Trudeau's policies, individuals' financial challenges, and government financial aid for enterprises and individuals. Recommendations for future work include (1) further validating YouTube comments as a source of information on COVID-19 and (2) strategies that can be considered by government and public health agencies to strengthen the real-time feedback loop between those agencies and the public on YouTube. Hearing and reacting to real concerns from the public can enhance trust between the government and the public to prepare for future health emergencies.

Abstract

Background: Since the outbreak of COVID-19, the development of dashboards as dynamic, visual tools for communicating COVID-19 data has surged worldwide. Dashboards can inform decision-making and support behavior change. To do so, they must be actionable. The features that constitute an actionable dashboard in the context of the COVID-19 pandemic have not been rigorously assessed.

Objective: The aim of this study is to explore the characteristics of public web-based COVID-19 dashboards by assessing their purpose and users ("why"), content and data ("what"), and analyses and displays ("how" they communicate COVID-19 data), and ultimately to appraise the common features of highly actionable dashboards.

Methods: We conducted a descriptive assessment and scoring using nominal group technique with an international panel of experts (n=17) on a global sample of COVID-19 dashboards in July 2020. The sequence of steps included multimethod sampling of dashboards; development and piloting of an assessment tool; data extraction and an initial round of actionability scoring; a

workshop based on a preliminary analysis of the results; and reconsideration of actionability scores followed by joint determination of common features of highly actionable dashboards. We used descriptive statistics and thematic analysis to explore the findings by research question.

Results: A total of 158 dashboards from 53 countries were assessed. Dashboards were predominately developed by government authorities (100/158, 63.0%) and were national (93/158, 58.9%) in scope. We found that only 20 of the 158 dashboards (12.7%) stated both their primary purpose and intended audience. Nearly all dashboards reported epidemiological indicators (155/158, 98.1%), followed by health system management indicators (85/158, 53.8%), whereas indicators on social and economic impact and behavioral insights were the least reported (7/158, 4.4% and 2/158, 1.3%, respectively). Approximately a quarter of the dashboards (39/158, 24.7%) did not report their data sources. The dashboards predominately reported time trends and disaggregated data by two geographic levels and by age and sex. The dashboards used an average of 2.2 types of displays (SD 0.86); these were mostly graphs and maps, followed by tables. To support data interpretation, color-coding was common (93/158, 89.4%), although only one-fifth of the dashboards (31/158, 19.6%) included text explaining the quality and meaning of the data. In total, 20/158 dashboards (12.7%) were appraised as highly actionable, and seven common features were identified between them. Actionable COVID-19 dashboards (1) know their audience and information needs; (2) manage the type, volume, and flow of displayed information; (3) report data sources and methods clearly; (4) link time trends to policy decisions; (5) provide data that are "close to home"; (6) break down the population into relevant subgroups; and (7) use storytelling and visual cues.

Conclusions: COVID-19 dashboards are diverse in the why, what, and how by which they communicate insights on the pandemic and support data-driven decision-making. To leverage their full potential, dashboard developers should consider adopting the seven actionability features identified.

Introduction

Since the outbreak of COVID-19, public reporting of pandemic-related indicators such as new cases, death counts, and testing rates has surged. This heightened level of activity attests to the core function of governments to protect the public's health and safety as well as their critical role of providing information to achieve this end [1-4]. The uses and advantages of publicly reporting health information are known. They include enabling international comparisons [5,6]; monitoring and improving the quality of care [1,6,7]; fostering accountability and transparency [8-10]; empowering the public to form an opinion on and build trust in their government's response; and supporting individuals to make informed, risk-minimizing behavior changes [11,12].

Dashboards are a dynamic modality for reporting data visually; they are typically designed as a single screen with the aim of quickly and effectively presenting users with critical information to act upon [13-15]. Unlike static reporting modalities, such as articles or reports, dashboards have the potential to present real-time (or near–real-time) data updates at a glance [15]. In the health sector, dashboards have been relied on for health system performance assessments [15,16], internal management [17,18], and responses to earlier outbreaks [19,20].

In 2020, the urgent worldwide need for COVID-19 data, coupled with the penetration of the internet [21], digitalization of health information systems [22,23], and access to open-source web-based software [24], has enabled unmatched speed, scale, and diversification of actors in the development of dashboards to monitor and report on the COVID-19 pandemic. As a result, public web-based dashboards have been widely adopted as a reporting modality for COVID-19 data. Examples extend well beyond national, regional, and local governments to include dashboards by international organizations (eg, the World Health Organization (WHO) [25]), academia (eg, the Johns Hopkins Coronavirus Resource Center [26,27]), and industry (eg, Deloitte [28]), as well as independent initiatives (eg, nCoV2019.live [29]).

Although COVID-19 dashboards may be widely accessible, their effective *use* to modify the course of the pandemic through the translation of data to information, information to opinions, and opinions to decision-making is determined by their actionability. To be actionable, the information should be both *fit for purpose*—meeting a specific information need—and *fit for use*—placing the right information into the right hands at the right time and in a manner that can be understood [30-32]. In other words, the mere accessibility of COVID-19 dashboards does not guarantee data-informed decision-making [12,33]. Although communication sciences, health promotion, and the emerging field of health care performance intelligence offer insights into the effective delivery of information [14,33-36], the factors that make dashboards actionable in the context of COVID-19 have yet to be rigorously assessed.

In this study, we set out to explore the state of the art of publicly available web-based COVID-19 dashboards and identify the features conducive to their actionability. To do so, we took a "snapshot" of this dynamic landscape and assessed COVID-19 dashboards in July 2020. The resulting overview of the dashboard landscape served both to take stock of their use in this initial period and to accelerate their progress in the phases still to come. With these aims, the study was guided by four key questions: (1) Why and for whom were COVID-19 dashboards developed? (2) What information do they provide?

(3) How is this information analyzed and presented? and (4) What are the common features of highly actionable dashboards?

Methods

Study Design

We conducted an observational descriptive assessment and scoring using nominal group technique (NGT) [37,38] on a global sample of COVID-19 dashboards. Each dashboard was reviewed using a study-specific assessment tool that was piloted and validated among a panel of scorers (n=17) prior to its use [37,38]. NGT was chosen over other consensus methods (eg, Delphi) for scorers to independently appraise a subset of dashboards using the assessment tool and collectively discuss what makes them actionable through a series of workshops [38,39]. All workshops were conducted virtually rather than face-to-face in accordance with pandemic-related public health measures.

Panel of Scorers

A panel of scorers was assembled through an existing international network of health care performance intelligence researchers [40]. The scorers had common expertise and training in health care performance data and the use of these data for management and governance. Collectively, the scorers (8 women, 9 men) were of 15 nationalities and were proficient in more than 20 languages (Bosnian, Catalan, Chinese, Croatian, Danish, Dutch, English, French, German, Indonesian, Italian, Kazakh, Malay, Montenegrin, Norwegian, Portuguese, Romanian, Russian, Serbian, Slovenian, Spanish, Swedish, and Turkish). This enabled the dashboards to be assessed in their original languages rather than through translations, avoiding the use of translation software and its limitations when used with data visualizations.

Inclusion and Exclusion Criteria

We defined a COVID-19 dashboard based on the following criteria: (1) reporting of key performance indicators related to the COVID-19 pandemic; (2) the use of some form of data visualization; (3) dynamic reporting, meaning the data are updated regularly; and (4) public availability in a web-based format. No restrictions were placed on a dashboard's primary level (eg, international, national, regional, or local) or the type of organization responsible for its development (eg, international, governmental, academia, news or media, industry, or private initiative). We excluded dashboards that were available only via mobile apps (eg, Telegram) or that required users to log in (eg, Facebook). Dashboards beyond the language competencies of the panel of scorers were also excluded.

Step One: Dashboard Sampling

Our search strategy for dashboards aimed to be thorough but not exhaustive. This was in line with our aim of exploring the state of the art of public web-based COVID-19 dashboards. An initial list of dashboards was collected through sampling conducted from May 19 to June 30, 2020. Three methods were applied: (1) surveying the authors; (2) surveying other international networks of public health, health services, and system researchers and practitioners (Young Forum Gastein, European Public Health Association, and European Network of Medical Residents in Public Health); and (3) snowballing of sources identified through (1) and (2). The sampling survey was developed using a Google Forms data collection tool and disseminated by email (Multimedia Appendix 1).

The consolidated list of dashboards was screened by one team member with the aims to confirm the inclusion criteria were met; exclude duplicates; and assess the available languages for each dashboard against the panel's competencies. Dashboards were labeled as red (exclude), green (include), or yellow (obtain second opinion). A second team member assessed dashboards labeled yellow, from which a final joint decision on inclusion or exclusion was made.

Step Two: Developing an Assessment Tool

An assessment tool was developed by drawing primarily on two existing theoretical models. From communication sciences, we applied the Lasswell model (1948) [41], which states that for mass communication processes to be understood, each element of "who (says) what (to) whom (in) which channel (with) what effect" has to be presented and understood. These five elements—the communicator, message, medium, audience, and effect—informed the basis of the assessment tool's considerations. We tailored these considerations to the communication of COVID-19 data by drawing on the emerging discipline of performance intelligence in health [36,42]. Specifically, we incorporated key considerations from a definition of actionability and its notions of fitness for purpose and use (Barbazza et al, unpublished data, 2021). The resulting considerations are in line with existing health information instruments (eg, [43,44]), although they were tailored to the aims of the study.

These considerations were clustered to depict COVID-19 dashboards by their general characteristics and a description of why, what, and how data is communicated, followed by an appraisal of their overall actionability (Table 1). Actionability scores were defined on a Likert scale from "not actionable" (score=1) to "extremely actionable" (score=5) and assigned based on the scorer's judgement of the considerations assessed and their expert opinion of the dashboard's fitness for purpose and use. Scores were accompanied by a written statement explaining the rationale behind the response. In line with the study's aim to consolidate key features of highly actionable dashboards, the scoring was merely a means to this end: the panel's individual appraisal of actionability facilitated the clustering of the actionability of the dashboards as low (score=1 or 2) or high (score=4 or 5) for further collective deliberation on their common features.

Table 1. Overview of the assessment tool.

Cluster	Considerations
General characteristics	• Level (scale) of focus • Responsible organization and type • Languages available • Scope of web page information
Why	• Purpose of use of the dashboard • Intended audience (user)
What	• Indicator titles • Data sources • Availability of metadata • Frequency of data updates
How	• Use of time trend for analysis • Geographic level (scale) of analysis • Types of possible breakdowns • Use of visualizations • Degree of interactivity • Use of simplicity techniques
Actionability score	• Overall appraisal of actionability

An Excel-based tool (Microsoft Corporation) was developed to record our findings. Each consideration of the assessment tool was formulated as a question with defined answer options. The tool included the underlying theory for the considerations by referring back to the concepts applied and available evidence [1,2,5,16,30,31,33,45-55] (Multimedia Appendix 2) to remind the panel of the significance of each consideration and aid the assessment and scoring process.

Step Three: Piloting and Calibrating

A prototype of the assessment tool was piloted by two authors on five dashboards. The extracted data were reviewed jointly with two other team members. This resulted in refinements to the phrasing of the questions and answer options. A second iteration of the assessment tool was then piloted with the panel of scorers on a sample of 18 dashboards representing a range of contexts, levels, and organization types. Each dashboard was independently reviewed by two scorers. Prior to piloting, a virtual training session with the panel of scorers was organized, recorded, and disseminated to serve as a resource. Each scorer was given six days (June 17-22, 2020) to review their two assigned pilot dashboards.

The pilot data were reviewed to assess the consistency of responses (ie, scorers of the same dashboard recorded equivalent answers) and meaningfulness of the answers (ie, the answer categories were meaningfully differentiated between dashboards). Where possible, the open-ended answer options of the tool were further specified into categorical values based on recurrent themes in the pilot data set. Definitions were added for key terms based on comments by the scorers. The reviewed pilots and tool amendments were returned to the panel of scorers, and a follow-up meeting was organized to discuss the reviews.

Step Four: Data Extraction and Round One Scoring

Each scorer was assigned between 5 and 12 dashboards to assess. The dashboards were distributed with first order priority given to the language competencies of each scorer. To synchronize the assessment, the scorers were given a 2-week period to complete data extraction. The assessment was limited to each dashboard's main page, and a "one-click-away policy" was applied by which content accessible within one click of the main page was also assessed. To store a record of the dashboard on the date it was reviewed, the main page of each dashboard was archived, generating a permanent and publicly available record of its contents [56].

Step Five: Preliminary Analysis and First Consensus Workshop

The data records from each scorer were consolidated by the lead authors into a master data set for analysis and subsequently underwent a series of data quality checks to detect data entry errors, inconsistences, or missed fields. In all instances where errors were detected, corrections were suggested and discussed jointly; once agreed upon, the changes were entered into the master data set.

The findings were totaled and averaged by research question. Free text fields and comments were analyzed in a deductive and inductive approach: topics explored in the tool (Multimedia Appendix 2) were used to guide the deductive thematic analysis [57], and new themes that emerged were identified using an inductive approach [58]. This included an analysis of indicator titles using an existing classification of types of pandemic-related information [3]. Due to the observed variability in phrasing of indicator titles and calculations, key performance indicators were grouped by themes.

A workshop with the panel of scorers was organized to discuss the preliminary results and distribution of actionability scores. During the workshop, panelists individually shared the rationale for their scoring of dashboards with low (score=1 or 2) and high (score=4 or 5) actionability. The common features of dashboards scored as highly actionable were discussed to further calibrate

the panel's scoring of the actionability. From this discussion, a working list of actionability features was consolidated.

Step Six: Round Two Scoring and Second Consensus Workshop

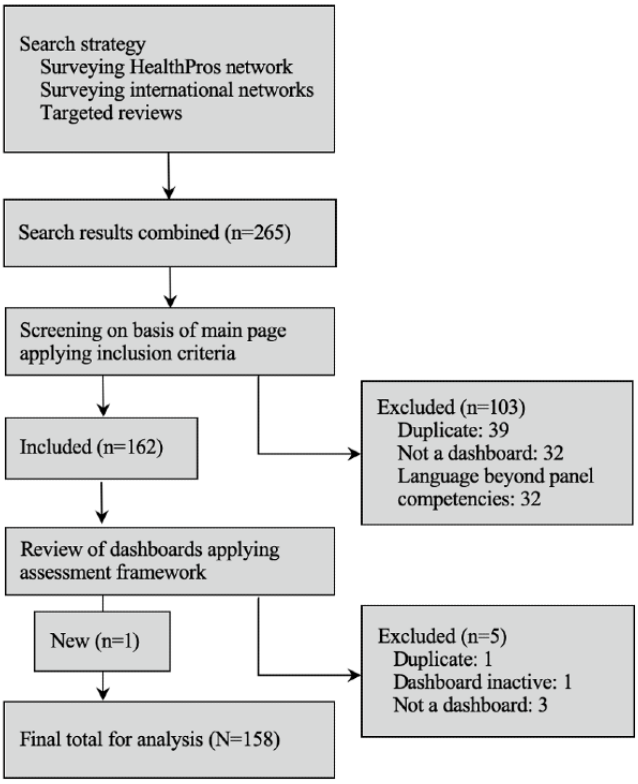
All panelists were returned their original data records and given 1 week to revisit their initial actionability scoring, drawing on the discussion during the workshop. Panelists were given the opportunity to increase each score, lower it, or leave it the same. Following rescoring, the distributions of the scores were recalculated. The data records for the top dashboards (score=5) following this second round were consolidated and provided to the panel, together with the working set of actionability features. A second consensus workshop was convened and, in a similar way to the previous workshop, a round table was conducted for each scorer to share their views. This was followed by a joint discussion to reach agreement on the common features of highly actionable dashboards.

Results

Identified Dashboards

Using our multimethod search strategy, we initially identified 265 COVID-19 dashboards. More than 40 respondents contributed to the sampling survey, including all members of the study team and international public health experts. Following screening of each dashboard's main page, 103 dashboards were excluded. The remaining 162 dashboards were distributed among the panel of scorers for full review. During the assessment process, 5 additional dashboards were excluded and 1 new dashboard was included. A final total of 158 dashboards was included for further analysis (Figure 1).

Figure 1. Flow diagram of COVID-19 dashboard sampling.



Data extraction and the first round of scoring were conducted in a 2.5-week period between July 6 and 23, 2020. The data extract and archived version of each dashboard were referred to throughout the study. Therefore, any updates following this date were not accounted for. The 158 dashboards were assessed in 22 different languages, predominately in English (n=85, 53.8%), followed by Russian (n=11, 7.0%), Spanish (n=9, 5.7%), French (n=9, 5.7%), and Chinese (n=6, 3.8%). A full listing of the dashboards assessed is available in Multimedia Appendix 3.

General Description of the Assessed COVID-19 Dashboards

Table 2 summarizes key characteristics of the 158 dashboards assessed. Our sample included dashboards reporting on 53 countries in all 6 WHO regions [59]. On the date of the review, the severity of the pandemic with regard to total cases and deaths varied widely between location as reported in Multimedia Appendix 3.

More than half of the dashboards (93/158, 58.9%) were developed for use at the national level. Nearly two-thirds of the dashboards (100/158, 63.3%) were developed by government authorities at the national, regional, or municipal level. New initiatives or organizations formed in response to COVID-19 accounted for 10.1% (16/158) of the dashboards assessed [29,60-74].

With regard to language, only one-fifth of the dashboards were available in more than one language with full functionality (32/158, 20.3%). In terms of their scope of information, gauged according to the content of the dashboard as well as information to which users were redirected through affiliate links, almost

all the dashboards were epidemiological in focus (156/158, 98.7%), followed by providing information on infection control measures and health system management (65/158, 41.1%, and 49/158, 31.0%, respectively).

Table 2. Characteristics of the assessed COVID-19 dashboards (N=158) from 53 countries.

Characteristic	Value, n (%)
Region[a]	
Global	20 (12.7)
Europe and Central Asia	63 (39.9)
North and South America	45 (28.5)
Western Pacific	22 (13.9)
Southeast Asia	4 (2.5)
Africa	3 (1.9)
Eastern Mediterranean	1 (0.6)
Level	
International	25 (15.8)
National	93 (58.9)
Regional (provincial, state, county)	33 (20.9)
Municipal (city, district)	7 (4.4)
Type of organization	
International organization	7 (4.4)
Governmental	100 (63.3)
Academia	9 (5.7)
News or media outlet	14 (8.9)
Industry	9 (5.7)
Independent initiative	16 (10.1)
Other	3 (1.9)
Languages available with full functionality[b]	
One language	126 (79.7)
Two languages	22 (13.9)
Three or more languages	10 (6.3)
Additional languages available with reduced functionality[c]	
One or more languages	16 (10.1)
Scope of information[d]	
Epidemiological information	156 (98.7)
Infection control measures	65 (41.1)
Health system management	49 (31.0)
Social and economic implications	31 (19.6)
Population behavioral insights	25 (15.8)
Other	28 (17.7)

[a]Country status and region according to the WHO classification [59].

[b]Full functionality: the webpage is equivalent in the different languages.

[c]Reduced functionality: the webpage is available in additional languages but with less information and fewer functionalities compared to the main languages.

[d]According to the WHO classification [3].

Uses and Users of COVID-19 Dashboards

A quarter of the dashboards (45/158, 28.5%) explicitly stated the intended purpose of their reporting. Of these 45 dashboards, the statements spanned three main themes: (1) high-level reporting to create trust and aid overall compliance (25/45, 56%); (2) sub-national reporting targeting policy interventions, including benchmarking (12/45, 27%); and (3) individual-risk assessment (8/45, 18%).

Only 14.6% (23/158) of the dashboards explicitly stated the intended audience (end users). Target users predominately included the general public (20/23, 87%) and, in a few instances, more specific audiences such as travelers or subject matter experts (6/23, 26%). When examined by the level of reporting, national-level dashboards were less likely to explicitly state the intended audience (9/93, 10%), while international- and municipal-level dashboards were more likely to do so (7/25, 28%, and 2/7, 29%, respectively).

Of the 158 dashboards assessed, 20 (12.7%) reported both the purpose and intended user explicitly. The profiles of these dashboards, in terms of their levels of reporting and the types of organizations that developed them, did not differ from the characteristics of the general sample. For the remainder of the analysis, the sample of dashboards was aggregated rather than subdivided by the intended purpose of the use and audience, due to the limited explicit statements of both.

Content and Data of COVID-19 Dashboards

Key Performance Indicators

Table 3 summarizes the frequency of indicator themes reported by the dashboards. See Multimedia Appendix 4 for illustrative examples of indicator titles. On average, the dashboards reported on 5.3 indicator themes (maximum 15, minimum 1). Almost all the dashboards reported public health and epidemiological indicators (155/158, 98.1%), particularly those that reported on cases and deaths. These account for the only high-frequency indicator themes (indicators present in more than two-thirds of the assessed dashboards). Medium-frequency indicator themes (themes reported in more than one-third but less than two-thirds of dashboards) were related to hospital care (hospitalizations, admissions to infection control units), testing (total tests, testing rates), and spread and death (recovered and active cases).

Only 4.4% of the dashboards (7/158) reported indicators related to social and economic impacts. Indicator themes included employment and hardship relief (eg, [28,75]) and transport, trade, and international travel (eg, [28,75]). Indicators of behavioral insights were also infrequently reported (8/158, 5.1%). Indicator themes included two main types: (1) self-reported adherence related to restrictions (eg, [76,77]) or health and well-being status (eg, [75]) and (2) observed public adherence to restrictions assessed through mobility data or reported breaches of restrictions (eg, [60,78]).

Some use of composite scores to signal overall risk levels or the current status by sector (eg, health, economy) was identified, although this use was infrequent (eg, [28,61,79]).

Table 3. Frequency of indicator themes reported for the 158 dashboards assessed.

Information type and cluster	Indicator themes	Value, n (%)	Frequency[a]
Public health and epidemiological			
Spread and death	Cases (all confirmed cases)	150 (94.9)	High
	Deaths	136 (86.1)	High
	Recovered (healed, cured)	91 (57.6)	Medium
	Active cases	56 (35.4)	Medium
	Mortality rate (case fatality rate)	24 (15.2)	Low
	Reproduction rates (attack rate)	12 (7.6)	Low
	Future projections/risk models	5 (3.2)	Low
	Doubling rate	3 (2.0)	Low
Testing	Testing (total number tested, PCR[b] tests)	80 (50.6)	Medium
	Testing rates (positivity, negative tests)	43 (27.2)	Medium
	Tests–pending results	17 (10.8)	Low
	COVID-19 antibody tests (serology tests)	1 (0.6)	Low
Risk management	Self-quarantine (isolation notices)	18 (11.4)	Low
	Contact tracing	6 (3.8)	Low
Health system management			
Hospital care	Hospitalized (admissions, discharges)	74 (46.8)	Medium
	Admitted to ICU[c] (critical condition)	47 (29.7)	Medium
	On a ventilator	14 (8.8)	Low
Health system capacity	Hospital bed capacity (availability)	12 (7.6)	Low
	ICU bed capacity	10 (6.3)	Low
	Ventilator capacity (available ventilators)	5 (3.2)	Low

[b]PCR: polymerase chain reaction.

[c]ICU: intensive care unit.

[d]N/A: not applicable.

Data Sources and Metadata

One quarter of the dashboards did not explicitly report the source of their data (39/158, 24.7%). National-, regional-, and municipal-level government-run dashboards predominately reported the use of data sourced from official public health authorities. International dashboards predominately reported the use of data sourced from the WHO [25] or the Johns Hopkins Centre for Systems Science and Engineering [26].

Less than half of the dashboards (63/158, 39.9%) specified metadata (data dictionaries, indicator specifications) in the format of notes, footnotes, or linked additional web pages to provide further information on the methodology by which an indicator was calculated. Of the 158 dashboards, 39 (24.7%)

did not report their data sources or metadata details. The majority of dashboards updated their data daily and explicitly stated the update frequency and time of the last update.

Types of Analysis and Presentation of Data on COVID-19 Dashboards

Table 4 summarizes the types of analysis and presentation of data. The dashboards predominately reported indicators over time (138/158, 87.4%), and most of these breakdowns were by day (128/138, 92.8%). Of the dashboards, 40% reported data on two geographic levels (eg, national and regional or regional and municipal). In the case of national-level dashboards (n=93), geographic breakdowns predominately included regional comparisons (73/93, 79%), with some municipal-level (28/93, 30%) and international-level (25/93, 27%) comparisons. Breakdowns by neighborhood (post–code-level) were reported in only a few instances (4/93, 4%).

In addition to geographic breakdowns, more than half of the dashboards (96/158, 60.8%) analyzed data by other breakdowns: on average, three types of breakdowns were included. Of these 96 dashboards, the most common breakdowns included by age (79/96, 82%), sex (71/96, 74%), and mode of transmission (26/96, 27%). Other breakdowns, although less frequently reported, included race, ethnicity, long-term care facilities, health care workers, comorbidities, and socioeconomic status.

As per our inclusion criteria, all dashboards used some form of visualization. On average, two types of visualizations were included per dashboard. These included graphs or charts (134/158, 84.8%), maps (111/158, 70.3%), and tables (95/158, 60.1%). Almost half of the dashboards (76/158, 48.1%) did not include written descriptions to clarify either the quality or meaning of the data, while 31/158 dashboards (19.6%) provided both.

More than half of the dashboards (104/158, 65.8%) used some technique to simplify the data. In these 104 dashboards, color-coding was most often used (n=93, 89.4%), followed by size variation (n=40, 38.5%). The majority of dashboards (126/158, 79.7%) included some element of user interaction. These elements mostly included the possibility to present more information (eg, pop-up windows), change the information (eg, different breakdowns), or change the display (eg, switch from table to map).

Table 4. Summary of analysis and presentation of dashboard information.

Considerations	Value, n (%)
Time trend analysis availability (N=158)	
Time trend analysis available	138 (87.3)
No time trend analysis	20 (12.7)
Use of time trend analysis (n=138)[a,b]	
By day	128 (92.8)
By week	33 (23.9)
By month	19 (13.8)
Geographic levels (scales) of analysis (N=158)[b]	
International (multicountry)	54 (34.2)
National	118 (74.7)
Regional	117 (74.1)
Municipal	54 (34.2)
Neighborhood	13 (8.2)
Other	5 (3.2)
Number of levels (scales) of analysis per dashboard (N=158)	
1 level	34 (21.5)
2 levels	65 (41.1)
3 or more levels	59 (37.3)
Disaggregation availability per dashboard (N=158)	
1 or 2 types of disaggregation	48 (30.4)
3 or 4 types of disaggregation	42 (26.6)
5 or more types of disaggregation	6 (3.8)
No disaggregation options	62 (39.2)
Disaggregation options (n=96)[a,b]	
Age	79 (82.3)
Sex	71 (74.0)
Mode of transmission	26 (27.1)
Long-term care facilities	16 (16.7)
Ethnicity	12 (12.5)
Race	10 (10.4)
Health workers	9 (9.4)
Comorbidities	9 (9.4)
Socio-economic status	2 (2.1)
Other	23 (24.0)
Visualization features (N=158)[b]	
Graphs/charts	134 (84.8)
Maps	111 (70.3)
Tables	95 (60.1)
Video/animations	10 (6.3)
Use of narratives to interpret data (N=158)	
Yes, to clarify the quality of the data only	28 (17.7)

Considerations	Value, n (%)
Yes, to clarify the meaning of the data only	23 (14.6)
Yes, to clarify both the quality and the meaning	31 (19.6)
No	76 (48.1)
Simplification techniques used (n=104)[a,b]	
Use of color-coding	93 (89.4)
Size variation	40 (38.5)
Icons	6 (5.8)
Interactive options (n=126)[a,b]	
More information	115 (91.3)
Change of information	61 (48.4)
Change of display	44 (34.9)

[a]Subset of applicable dashboards (ie, 138 dashboards that *do* use time trends).

[b]Percentages for these considerations do not total to 100%, as multiple considerations could be present per dashboard.

Features of Actionable Dashboards

In the first round of scoring, 21 of the 158 dashboards assessed (13.3%) were scored with the highest actionability score (score=5), and 18 dashboards (11.4%) received the lowest score (score=1), for a mean score of 3.01 (SD 1.20). The second round of scoring resulted in a final total of 20 dashboards that were scored as the most actionable. A quarter of the dashboards (40/158, 25.3%) were scored differently: 24 scored lower, and 16 scored higher. All 17 panelists completed both rounds of scoring. Details on the distribution of scoring by panelist and between rounds are summarized in Multimedia Appendix 5.

The panel workshop following the first round of scoring resulted in a total of 18 features that characterized highly actionable dashboards. After rescoring, these features were further discussed among the panel to consolidate the list in terms of their description and importance as well as its consistency and completeness as a set. A final total of seven key features common to highly actionable dashboards were agreed upon (Table 5). There was consensus among the panelists that some dashboards excelled in certain features over others. These dashboards are noted as illustrative examples.

Table 5. Seven features of highly actionable COVID-19 dashboards.

Number	Feature	Explanation	Examples
1	Know the audience and their information needs	Dashboards with a known audience and explicit aim had focus and continuity in their content, analysis and delivery. Techniques such as guiding key questions or overall composite scores clearly communicated the decision they intended to support. Multilanguage functionality and exact timing of updating signaled an awareness and intent to encourage their regular use by the intended decision maker.	#HowsMyFlattening [60], Covid Act Now [61], State of California [79].
2	Manage the type, volume, and flow of information	The selection of a concise number of indicators brought focus and importance to the information and the possibility to view indicators together at a glance. The use of indicators in moderation, although still spanning varied types of information, was especially effective. The ordering of information, from general to specific or in sections based on theme, made the flow of information intuitive.	Covid Act Now [61] reports on five key indicators. Deloitte [28] and the City of Vancouver [78] included a range of types of information.
3	Make data sources and methods clear	A clear source of data and explanation of an indicator's construction, including potential limitations, was found to be an important component of trust in the dashboard and clarity in its reporting. This information can be provided in short narratives that support users to understand what is in fact being presented.	Denmark [80], France [76], Spain [81], and media pages of the Canadian Broadcasting Corporation [82] and the New York Times [83] paid attention to narrating the calculation of indicators.
4	Link time trends to policy (decisions)	Reporting data over time together with the introduction of key infection control measures facilitated an understanding of their effect (or lack thereof). This was found to be conducive to generating public support for infection control measures.	ABC News [84] and Sledilnik [62] embed policy measures over time. The City of Toronto [85] reports city targets.
5	Provide data "close to home"	To inform individuals of risks in their immediate surroundings, granular geographic breakdowns are needed. Data that are highly aggregated are difficult to understand. Maps (over tables and charts) were most effective to provide geographic information.	The United Kingdom [86] offers post–code-level breakdowns. Germany [87] provided city- and borough-level information for Berlin.
6	Break down the population to relevant subgroups	Providing data with the possibility to explore varied population characteristics made indicators relatable to individual users. It enables understanding of risks and trends based on one's own demographics. It can also facilitate equity-driven decision-making by exposing differences among the population.	Ethnicity and race breakdowns were provided in New Zealand [75] and various US dashboards [79,88-92]. #HowsMyFlattening [60] provided breakdowns on economic status.
7	Use storytelling and visual cues	A concise narrative explaining the significance of a trend supports users to understand the importance of the information. Bare statistics without a narrated analysis leave the burden of interpretation solely to the user. Brief explanations on the meaning of trends used in combination with visual techniques, such as intuitive color schemes and icons, supported ease of interpretation.	Covid Act Now [61] narrates the significance of trends. The State of Colorado [88] uses colored icons to signal the direction of trends.

Discussion

Principal Findings

With this study, we set out to assess the state of the art of public web-based COVID-19 dashboards globally during the initial stage of the pandemic (July 2020) and identify features common to the dashboards that were found to be highly actionable. We assessed 158 dashboards, each operating in a different context. Their differences aside, the dashboards analyzed in this study ultimately share a common aim: to serve as both a communication tool and call for individual and collective action to respond to the COVID-19 pandemic. Despite their contextual differences (or because of them), our results indicate that some dashboards fulfill their function of communicating, informing decision-making, and supporting behavior change better than others. Moreover, while it is also clear there is no single approach to developing a dashboard, our results suggest that introducing certain features may enhance the actionability of a dashboard.

Knowing the audience and their information needs was identified as a key actionability feature, which corresponds with the Lasswell model for effective communication ([1,41]; Barbazza et al, unpublished data, 2021). However, clear reporting of a dashboard's purpose (its "why") and audience (for "whom") was infrequent. This may be explained in part by the fact that the majority of the dashboards were developed by public authorities and hosted on existing web pages. Hence, the target audience (citizens) and the aim (constitutional mandate to protect health) may be considered implicit. However, without clarity on the intended use and user of a dashboard, its development is steered by the *potential* to be useful rather than addressing a specific information need [32,93-95].

"What" a dashboard communicates through its content is not a neutral window into the available data. It is the result of

judgment, discernment, and choice [14]. The average of 5 indicator themes reported per dashboard can be considered to be a manageable volume and is in line with the evidence that "less is more" [33,47]. It is the breadth of types of information presented that is concerningly narrow, with only a handful of dashboards addressing the WHO-recommended four types of information needed for a complete picture of the pandemic [3]. For example, indicators reporting on population behavioral insights gauge the compliance of citizens with infection control measures; thus, they are an important tool for maintaining public trust. However, in our sample, this type of information was rarely reported. This may be due to data infrastructure limitations and the limited availability of these data, especially in the early phases of the pandemic. Similarly, less than half of the dashboards reported on health system management indicators, despite the importance of these indicators in informing the management of both COVID-19 and non–COVID-19 services. Dashboards that did report on these non-epidemiological types of information may serve as inspiration for drawing on innovative data sources and indicators [28,60].

Clarity around data sources and indicator calculations (metadata) are critical for overall quality, credibility, and trustworthiness of reporting [46,48,49]. For transparency on how data were collected and insights into "what lies behind" the reported indicators, providing explicit data sources and calculations should be considered a minimum requirement. Nonetheless, our findings signal that these provisions are not a given. Further efforts are needed internationally and nationally to standardize indicator calculations and set requirements of what constitutes good practice in public reporting of pandemic-related data.

In terms of "how" content is presented, dashboards should be viewed as tools for making clear links between current trends and past policy decisions and individual behavior. Doing so connects change-points and actions, which has been found to contribute to an indicator's use [96,97]. It also serves to leverage the two-way communication potential of dashboards. Dashboards that fail to make the connection between the past and present miss the opportunity to communicate the effects of users' decision-making back to them. Beyond describing the past and present, only a handful of dashboards went further and employed predictive analytics by illustrating different future scenarios of "what could happen." The lack of precision of predictive models and simulations early in the pandemic likely stunted their use. Use of both descriptive and predictive approaches to dashboard design and tighter links between infection control policies and their effects should be further explored into the next phases of the pandemic.

We found frequent use of different display options and interactive techniques among the dashboards assessed. However, the analysis of data by location and by population subgroups was limited overall, which may restrict their utility for individual-level decision-making purposes. The challenge to report data locally and disaggregate the data by relevant breakdowns such as age, sex, socioeconomic status, and ethnic or racial groups may be in large part due to data infrastructure limitations and perceived legal obstacles [98]. Without collecting, registering, and using data about meaningful population subgroups, there is a risk of not being informed about these important (and modifiable) differences [98].

Finally, an actionable dashboard is based on complete, timely, and transparent data that is prepared, contextualized, and presented so that it can be used as information [99]. Our assessment found an overall underuse of known and proven delivery techniques, in particular, the use of explanatory narratives. Plain language text to clarify complicated information has proven to make end users more motivated and confident in using information in their decision-making [1,47,54]. Although commonly used software for the development of dashboards (eg, ArcGIS) has served to optimize their single-screen design, the embedding of narratives into templates may be useful for improving interpretation.

Future research could explore the following points. First, recognizing the highly dynamic nature of COVID-19 dashboards, a follow-up study could provide insights into how dashboards have evolved over time, given improvements in disease prevention, testing, and treatment as well as data infrastructure. Second, exploring across official municipal, regional, and national dashboards in a given context was beyond the scope of this study; however, such an exploration may offer insights into the possibility of tailoring dashboards at different levels to specific purposes and audiences. Third, this study has pursued a theoretically informed expert-based appraisal of actionability. A study from the perspective of the target audience is therefore merited and needed to obtain insights from firsthand use. Finally, the developed assessment tool could be used within a specific country context to analyze actions needed to implement the identified features.

Strengths and Limitations

To our knowledge, this is the most comprehensive summary of COVID-19 dashboards and assessment of their actionability published to date. The search for COVID-19 dashboards was wide-reaching and used multiple methods to amass a global sample. The approach tapped into a unique and highly specialized international network dedicated to health care performance intelligence, allowing for an expert, context-aware, and multicultural team. The multilanguage competencies of the panel made it possible for the dashboards to be reviewed in their original languages for high-quality data extraction. Through detailed data extraction and a structured process of scoring with joint deliberation, we have identified a set of timely and pragmatic features for optimizing dashboards. This is also the first study to our knowledge on the use of dashboards for public reporting from a communication and health care performance intelligence perspective. Importantly, the study was conducted at pace with the ongoing COVID-19 pandemic to ensure the potential for findings to inform the continued development of dashboards in combination with other communication tools.

We acknowledge the following potential limitations. First, the sample of dashboards is ultimately a subset of publicly available web-based COVID-19 reporting. The sample is also skewed to locations in the European and Pan-American regions, which account for two-thirds of the dashboards reviewed. This can be attributed in part to factors including the thorough but not exhaustive sampling strategy applied; the exclusion of

dashboards beyond the 22 language competencies of the panel (ie, Arabic and Hindi); and the focus on web-based dashboards to the exclusion of those exclusively on mobile apps (common to Asian countries). As an exploratory study, reasonable diversity of locations, in combination with different levels (scales) of focus and types of organizations, took precedent and was achieved. Nonetheless, the findings may not be generalizable to all contexts. Second, despite our best efforts to obtain a snapshot of COVID-19 dashboards in a common 2-week period, the severity and specific phase of the pandemic inevitably varied greatly on the date of the review as described. Our approach to assess rather than evaluate the impact of COVID-19 dashboards mitigates the significance of these differences on our findings. Third, the appraised actionability of the dashboards ultimately does not confirm their use in practice, and evaluating this was beyond the scope of this study.

Conclusion

This study has taken stock of the vast landscape of public web-based COVID-19 dashboards; this is a testament to the advancements in health information systems and digitalization of our societies, coupled with the responsibility and imperative to publicly report health information. As could be expected, the 158 dashboards in our sample, spanning a total of 53 countries, are diverse. They have different contexts and levels of focus, purposes, and audiences. They draw from various data sources, offer different content and use a range of ways—albeit at times limited—to break down data and to visualize, simplify, and interact with information. Their actionability also differs, signaling that their fitness for use by decision makers is not a guarantee. The number of dashboards appraised as highly actionable in the period of July 2020 when the dashboards in this study were assessed signals that work is still needed to optimize the use of dashboards. There is no one-size-fits-all template or model to accomplish this. Dashboards must be purpose-driven and context-specific. We urge those working on COVID-19 dashboards to consider the seven features identified in our study and adopt them as called for. By doing so, they stand to fully leverage the potential advantages of public reporting and its use for decision-making and behavior change needed to address the current pandemic.

Acknowledgments

We acknowledge the contributions of and are grateful to the following: Femke Jansen (Management Center Innsbruck); Omid Fekri (WHO Regional Office for Europe); Mekha Mathew (University of Oxford); and respondents to the initial dashboard sampling survey. This work was carried out by the Marie Skłodowska-Curie Innovative Training Network (HealthPros—Healthcare Performance Intelligence Professionals), which has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement Nr. 765141.

Authors' Contributions

DI and EB contributed equally as first authors. DI, EB, SA, NK, and DK were involved in the design of the study. DI and EB coordinated the sampling of the dashboards, defined the inclusion and exclusion criteria, and performed the initial screening. DI and EB developed the dashboard assessment tool, which was piloted and validated by all authors. The panel of scorers (DI, EB, VB, OBF, KJG, TS, PK, NL, SL, BMT, JM, MP, AR, SW, CW, YY, and ZY) participated in data extraction, two rounds of scoring, and two consensus workshops. DI and EB coordinated the data extraction and organized and moderated the consensus workshops. DI and EB cleaned and analyzed the data and drafted the manuscript, with the supervision of SA, NK, and DK. All authors contributed to the interpretation of the results, provided critical comments, and edited, revised, and approved the manuscript in its final form for submission.

Abstract

Background: Since the onset of the COVID-19 pandemic, several health care programs intended to provide telemedicine services have been introduced in Libya. Many physicians have used these services to provide care and advice to their patients remotely.

Objective: This study aimed to provide an overview of physicians' awareness, knowledge, attitude, and skill in using telehealth services in Libya.

Methods: In this cross-sectional study, we administered a web-based survey to health care workers in Libya in May 2020. The questionnaire collected information on physicians' general demographic characteristics, ability to use a computer, and telemedicine awareness, knowledge, attitude, and skills.

Results: Among 673 health care workers who responded to the survey, 377 (56%) and 248 (36.8%) reported high awareness and high computer skill scores, respectively, for telemedicine. Furthermore, 582 (86.5%) and 566 (82.6%) health care workers reported high knowledge and high attitude scores, respectively. We observed no significant differences in awareness, knowledge, attitude, and skill scores among physicians employed at public, private, or both types of hospitals. We observed significant differences in the mean awareness (P<.001), attitude (P=.001), and computer skill scores (P<.001) , where the score distribution of the groups based on the ability to use computers was not similar. Knowledge scores did not significantly differ among the three groups (P=.37). Respondents with professional computer skills had significantly higher awareness (χ^2_3=14.5; P<.001) and attitude (χ^2_3=13.5; P=.001) scores than those without professional computer skills. We observed significant differences in the mean computer skill scores of the groups (χ^2_3=199.6; P<.001).

Conclusions: The consequences of the COVID-19 pandemic are expected to persist for a long time. Hence, policy programs such as telemedicine services, which aim to address the obstacles to medical treatment owing to physical distancing measures, will likely continue for a long time. Therefore, there is a need to train and support health care workers and initiate government programs that provide adequate and supportive health care services to patients in transitional countries.

KEYWORDS

attitude; awareness; coronavirus; COVID-19; knowledge; pandemic; skills; telemedicine

Introduction

SARS-CoV-2 was identified as the cause of severe viral pneumonia in Wuhan, Hubei Province, China, in December 2019. The World Health Organization declared COVID-19, the disease caused by this virus, a pandemic in March 2020 [1-4]. As of July 22, 2020, more than 15,000,000 COVID-19 cases and more than 617,000 COVID-19–related deaths have been recorded in 213 countries and territories [5].

Preventive measures have been implemented to reduce the potential exposure of individuals to the virus and to decrease the burden of COVID-19 transmission. These measures include hand washing, avoiding touching the face and eyes, cleaning and disinfecting surfaces and objects, wearing protective equipment including masks, and most importantly, social distancing by staying at home, avoiding close physical contact with others, and maintaining adequate interpersonal distance [6-8].

The COVID-19 pandemic has affected traditional in-person health care services. New strategies and approaches, including telemedicine and telehealth services, must be implemented to facilitate video consultations and the use of mobile apps, with the goals of delivering medical advice, diagnosis, and treatment to reduce the risk of infection [9,10]. Telemedicine and telehealth services are especially important for individuals without COVID-19 seeking medical treatment during the pandemic, especially those with chronic or acute illnesses. Several countries had begun increasing the use of telemedicine services even prior to the COVID-19 pandemic [11-16]. Telemedicine was effective during previous outbreaks including those of the Ebola virus, Zika virus, and the severe acute respiratory syndrome coronavirus [17,18].

Telemedicine is defined as the use of web-based resources and electronic information along with advanced digital network technology to promote long-distance professional health services, disseminate medical safety reports, deliver health-related education to the public, and carry out public health monitoring [19,20].

Since the onset of the COVID-19 pandemic, several health care service programs aiming to provide telemedicine services have been introduced in Libya. Even with their recent introduction, many physicians have used these services to provide care and advice to patients remotely. There is a need to assess the awareness, knowledge, attitude, and skills of physicians who use telemedicine services. The skilled use of telemedicine by physicians benefits patients, who can receive a wide range of health care services without the need to visit the clinic. Telemedicine services can reduce the risk of infection among populations by facilitating social distancing and decreasing the burden on the hospitals that provide care to individuals with COVID-19 [21-23].

This study aimed to provide an overview of physicians' awareness, knowledge, attitude, and skills of telemedicine—a technology that has been recently introduced in transitional countries. Furthermore, we investigated the effects of COVID-19 on this technology to determine whether it is adequately applicable during the ongoing COVID-19 pandemic.

Methods

Study Design

In this cross-sectional study, we administered a web-based survey to health care workers in Libya in May 2020 via text messages and email. Responses were anonymous without any identifying data. This study focused on health care workers who were officially registered with Libyan hospitals during the COVID-19 pandemic and were involved in patient care. The first section of the survey collected baseline demographic information and characteristics of the health care workers, including age, gender, years of experience, employment status, department of work, and computer skills, and there were several general questions related to telemedicine experience. The second section contained a survey instrument that was previously developed by Zayapragassarazan et al [24], which contains four detailed subsections.

Awareness Subsection

This subsection consisted of 12 items on telemedicine, which were used to assess awareness. Each item was assessed with a 3-point scale with scores of 0-2 (0=don't know, 1=heard of it, 2=know about it). The overall score could range from a minimum of 0 to a maximum of 24.

Knowledge Subsection

This subsection consisted of 11 items that assessed the physician's level of telemedicine knowledge. Each item was assessed with a 2-point scale with scores of 0 and 1 (0=yes, 1=no). The overall score could range from a minimum of 0 to a maximum of 11.

Attitude Subsection

This subsection consisted of 11 items used to determine the attitude of the respondents toward telemedicine. Each item was assessed with a 5-point Likert scale with scores ranging 0-4 (0=strongly disagree, 1=disagree, 2=undecided, 3=agree, 4=strongly agree). The overall score could range from a minimum of 0 to a maximum of 44.

Computer Skills Subsection

This subsection consisted of 13 items used to determine the physician's level of information technology and computer skills. Each item was assessed with a 4-point scale with scores of 0-3 (0=unskilled, 1=learner, 2=mediocre, 3=expert). The overall score could range from a minimum of 0 to a maximum of 39.

Assessment of the Effect of COVID-19 on Telemedicine

The third section included several questions on the effects of the spread of COVID-19 on telemedicine, the role of telemedicine in reducing in-person consultations, the time spent on practicing telemedicine, the usability of telemedicine based

on local internet settings, and the role of telemedicine in helping physicians avoid or decrease the risk of infection potentially resulting from internal conflicts in Libya.

Raw scores of each subsection of the awareness-knowledge-attitude-skill questionnaire were converted to percentages and compared with other group variables. We considered scores of ≤49% as low, 50%-70% as average, and ≥71% as high. The survey was conducted in accordance with the Checklist for Reporting Results of Internet E-Surveys [25].

Statistical Analysis

Descriptive statistics related to the general demographic characteristics of the physicians were calculated. Frequency and percentage values were used to describe these variables. Mean (SD) values were used to describe continuous data. None of the major continuous outcomes, including survey scores, were normally distributed. Therefore, we analyzed them using the Mann-Whitney *U* test to determine whether there were significant differences between the two groups and the score of each section. We performed the Kruskal-Wallis *H* test to compare groups with ≥3 independent variables. The chi-square test was used to determine potential associations between the categorical groups. Statistical analysis was performed using SPSS software (version 25.0, IBM Corp). A *P* value of ≤.05 was considered significant.

Ethical Consideration

The study procedures comply with the ethical standards of the relevant national and institutional committee on human experimentation, with the Helsinki Declaration of 1975, as revised in 2008. Ethical approval (approval# 109.3-2020) for this study was obtained from the Bioethics Committee at the Biotechnology Research Centre (Tripoli, Libya). The survey was conducted anonymously, and all participants provided written informed consent before participating in the study.

Results

Telemedicine Awareness, Knowledge, Attitude, and Skills of Health Care Workers

From among 800 health care workers who received the survey, 673 responded (response rate=84.1%). Among them, 299 (44.4%) were male and 374 (55.6%) were female. The participant cohort comprised 288 (42.8%) specialists or senior physicians and 385 (57.2%) physicians in training. Table 1 summarizes the baseline demographic characteristics of the study participants.

Most participants (n=631, 93.8%) had an average or high level of computer and internet skills. Most participants (n=525, 78%) had participated in training programs on telemedicine during the COVID-19 pandemic. Most participants (n=639, 94.9%) expressed their willingness to participate in such training courses.

The questionnaires assessed the physicians' awareness, knowledge, attitude, and skills of telemedicine. The assessment scales had a high level of internal consistency (Cronbach α=.823 for awareness, Cronbach α=.735 for knowledge, Cronbach α=.910 for attitude, and Cronbach α=.950 for skills).

Interestingly, 399 (59.3%) participants perceived telemedicine as a helpful tool for elderly patients, and 486 (72.2%) speculated that telemedicine could be used by physicians to obtain patients' electrocardiography and x-ray reports for medical consultation. Some participants (n=178, 26.4%) speculated that telemedicine technologies can facilitate direct consultations. Only 28 (4.2%) participants speculated that laboratory findings could be shared with patients through telemedicine technologies, and only 81 (12%) participants speculated that follow-up and treatment response evaluation could be performed using telemedicine technology.

Many participants (n=580, 86.2%) did not agree that patients should have access to information regarding their medical condition. However, 573 (85.1%) participants believed that telemedicine could help bridge the gap between primary and secondary care by fostering communication among physicians, consultants, and nurses. Interestingly, 254 (37.7%) participants had little or no experience using emails and sending files.

Data on physicians' awareness, knowledge, attitude, and skills of telemedicine are summarized in Table 2. In total, 377 (56%) participants had high awareness scores, 582 (86.5%) had high knowledge scores, 556 (82.6%) had high attitude scores, and 248 (36.8%) had high scores for computer skills of telemedicine technology for all specialties. Overall, 132 (19.6%) participants were not familiar with telemedicine technology, and 28 (4.2%) had low telemedicine knowledge. In addition, 16 (2.4%) participants had low attitude scores.

Table 2. Different levels of awareness, knowledge, attitude, and skills among health care workers in Libya (N=673).

Degree	Awareness	Knowledge	Attitude	Skills
Low (≤49%), n (%)	132 (19.6)	28 (4.2)	16 (2.4)	226 (33.6)
Average (50%-70%), n (%)	164 (24.4)	63 (9.4)	101 (15.0)	199 (29.6)
High (≥71%), n (%)	377 (56.0)	582 (86.5)	556 (82.6)	248 (36.8)

Table 3 compares awareness and knowledge scores, and Table 4 compares the attitude and skill scores among the study participants. The Mann-Whitney *U* test was performed to investigate significant differences in the awareness, knowledge, attitude, and computer skill scores between males and females. Females had significantly higher mean awareness (*P*=.02) and computer skill scores (*P*<.001) than males. However, we observed no significant differences in the mean knowledge (*P*=.55) and attitude (*P*=.99) scores between males and females.

Table 3. Differences in the awareness and knowledge scores of the study participants based on baseline demographic characteristics (N=673).

Variables	Total, n (%)	Awareness scores (range 0-100)			Knowledge scores (range 0-100)		
		Mean (SD)	*U*[a] or *H*[b] value	*P* value	Mean (SD)	*U* or *H* value	*P* value

[a]Mann-Whitney *U* test for pairwise comparison of independent variables.

[b]Kruskal-Wallis *H* test for multiple-group comparison of independent variables.

[c]*P*<.05.

[d]*P*<.001.

We performed the Kruskal-Wallis *H* test to investigate differences in the awareness, knowledge, attitude, and skill scores of other categorical groups, including those based on employment status, ability to use computers, and departments of work. We observed no significant differences in the awareness (*P*=.25), knowledge (*P*=.34), attitude (*P*=.38), and computer skill (*P*=.12) scores among health care workers employed at public, private, or both types of hospitals. We observed significant differences in the mean awareness (*P*<.001), attitude (*P*=.001), and computer skill (*P*<.001) scores, where the score distribution based on the ability to use computers was not similar among these groups. We observed no significant differences in the knowledge scores of the three groups based on employment status (*P*=.34). Participants with professional computer skills had significantly higher awareness (χ^2_3=14.5; *P*<.001) and attitude (χ^2_3=13.5; *P*=.001) scores than those without professional computer skills. Furthermore, we observed significant differences in the mean computer skill scores among different groups (χ^2_3=199.6; *P*<.001). Overall, those who were more capable of using computers displayed significantly higher computer skill scores than those who were lesser capable of using computers.

We observed significant differences in attitude scores (χ^2_8=16.7; *P*=.02) and computer skills (χ^2_8=22.9; *P*=.002) among health care workers in different departments. In particular, those working in the departments of gynecology and obstetrics, family medicine, and psychiatry had significantly higher attitude scores (*P*=.02), while those in the department of psychiatry and those in surgical specialties had significantly higher computer skill scores (*P*=.002) than those of their counterparts in other departments. However, awareness (*P*=.25) and knowledge (*P*=.15) scores did not significantly differ among health care workers in different departments.

Effects of COVID-19 on Telemedicine

Among the study participants, 638 (94.8%) thought that telemedicine technology could be used to limit the spread of COVID-19. Additionally, 630 (93.6%) participants thought that telemedicine could help reduce hospital visits to avoid COVID-19 transmission. However, only 283 (42.1%) participants thought that telemedicine could replace traditional

medical visits during the COVID-19 pandemic. In addition, 616 (91.5%) participants thought that the telemedicine system could facilitate patient communication and cooperation with physicians during the COVID-19 pandemic. Furthermore, 622 (92.4%) participants thought that the use of telemedicine and remote health care systems saved a lot of time that was otherwise lost in hospitals and clinics and that these remote services could more rapidly provide medical advice. However, only 437 (64.9%) participants thought that internet services in Libya met the demand for uninterrupted telemedicine services. Moreover, 121 (18%) participants thought that telemedicine could help physicians avoid the issues of conflict and civil war in Libya and decrease the risk of infection arising from these internal conflicts. Interestingly, 575 (85.4%) participants thought that telemedicine could potentially prevent physicians who worked in unsafe environments from sensing insecurity during the civil war. Additionally, 606 (90%) participants thought that telemedicine could help physicians avoid the risk of contracting and transmitting COVID-19. However, only 385 (57.2%) participants thought that the telemedicine service technologies would help improve the financial status of physicians.

Discussion

Principal Findings

Telemedicine has been introduced recently in transitional countries, including Libya, to provide remote health care services, especially to patients with chronic diseases. In this study, 377 (56%), 582 (86.5%), and 566 (82.6%) physicians responding to our survey had high awareness, knowledge, and attitude levels for telemedicine, respectively; however, only 248 (36.8%) participants had adequate or high computer skills.

The COVID-19 pandemic has placed greater emphasis on telemedicine technology as a means of providing adequate care to patients without increasing the risk of SARS-CoV-2 transmission to patients during in-hospital clinic visits. Additionally, telemedicine benefits health care workers because it decreases the risk of infection among them, reduces stress in the hospital, provides an adequate tool for treatment and follow-up evaluation of their patients, and provides a suitable approach for providing mental health services.

This study provides an overview of physicians' awareness, knowledge, attitude, and skill levels of telemedicine in a transitional country that is afflicted with a civil war, a financial crisis, and a devastating health care system during the COVID-19 pandemic [26-28].

Only 179 (26.6%) participants had professional computer skills, while 452 (67.2%) and 42 (6.2%) participants had average and beginner computer skill levels, respectively. Thus, overall, the computer and information technology skills of the physicians were inadequate. Such skills are crucial for the productive use of telemedicine services. Therefore, we recommend software and computer skill training programs for physicians who are newly introduced to telemedicine technology in transitional countries. Nonetheless, the approach may be difficult even with these skills. Among all our participants, 236 (35.1%) indicated that the internet services in Libya were not sufficient to meet patient needs through telemedicine technology owing to electricity and internet interruptions in Libya after the civil war [29]. This remains yet another challenge for telemedicine service providers, requiring immediate attention from internet providers and telephone companies [30]. Many patients have complained about the unavailability of these services owing to their high demand during the COVID-19 pandemic.

Most study participants (n=556, 82.6%) had higher attitude scores. This is important because attitude represents how telemedicine was perceived by health care workers [31]. The attitude of health care workers is an important factor in understanding and accepting telemedicine technologies. For such acceptance, the program developer needs to train health care workers and make the telemedicine programs usable for them [32].

Knowledge and attitude are important for the acceptance of telemedicine by health care workers. In this study, 582 (86.5%) participants had high knowledge scores; this value is higher than that reported previously in Germany (where approximately 63% of individuals had some telemedicine knowledge) [33]. Another study conducted in Lagos [34] reported that only 60.9% of participants had telemedicine knowledge. Furthermore, another study conducted in Pakistan [35] reported an average level of telemedicine knowledge among health care workers. Further initiatives and commitments are required to expand the use of telemedicine and increase its efficiency, especially among health care professionals in a postconflict setting. There is a need for greater understanding of telemedicine among health care practitioners, particularly those who are new telemedicine users. Hence, it is important to address the financial and physical access–related obstacles to telemedicine [36].

There are several constraints in the implementation of telemedicine in transitional countries, especially in emergency settings, notwithstanding the implementation of strategies to reduce the risk of exposure to the virus during the COVID-19 pandemic. Certain technical issues and the need to train health care workers to provide adequate telemedicine services need to be addressed. The COVID-19 pandemic has put a strain on hospital health care workers and has posed challenges to politicians, managers, and practitioners with regard to the limits of the broader health care infrastructure and assumptions that have restricted its potential for swift and innovative reforms [30,37,38].

Limitations

Our study was limited to Libya; hence, our findings may not be generalizable to the populations of other countries. Furthermore, the cross-sectional design of our study does not allow for drawing concrete conclusions establishing causation between variables. In addition, our study does not provide details regarding the types of telemedicine technologies and how they can be implemented, along with patients' attitude toward telemedicine. Further studies on telemedicine are required to provide qualitative measures of health care services to patients, to assess the access to health care services in other transitional countries, and to determine whether these telemedicine adaptations benefit patients, especially those with chronic illnesses and psychiatric morbidities [39-41]. Additionally, there

is a need to determine the cost benefit of these services and whether modifications are required in these services.

Conclusions

The consequences of the COVID-19 pandemic are expected to be long lasting. Hence, policy programs, such as telemedicine services, which aim to address obstacles to medical treatment owing to physical distancing measures, are also required to be provided over a long term [42]. Therefore, there is a need to train and support health care workers and initiate government programs that provide adequate and supportive health care services to patients in transitional countries and to respond to issues regarding the access to these services, including internet access and advertisements, and social programs that help patients understand how to use these services.

Abstract

Background: During the COVID-19 pandemic, there has been a rapid increase in the amount of information about the disease and SARS-CoV-2 on the internet. If the language used in video messages is not clear or understandable to deaf and hard of hearing (DHH) people with a high school degree or less, this can cause confusion and result in information gaps among DHH people during a health emergency.

Objective: The aim of this study is to investigate the relationship between DHH people's perception of the effectiveness of physical distancing and contagiousness of an asymptomatic person.

Methods: This is a cross-sectional survey study on DHH people's perceptions about COVID-19 (N=475). Items pertaining to COVID-19 knowledge were administered to US deaf adults from April 17, 2020, to May 1, 2020, via a bilingual American Sign Language/English online survey platform.

Results: The sample consisted of 475 DHH adults aged 18-88 years old, with 74% (n=352) identifying as White and 54% (n=256) as female. About 88% (n=418) of the sample felt they knew most things or a lot about physical distancing. This figure dropped to 72% (n=342) for the question about the effectiveness of physical distancing in reducing the spread of COVID-19 and 70% (n=333) for the question about the contagiousness of an infected person without symptoms. Education and a knowledge of the effectiveness of physical distancing significantly predicted knowledge about the contagiousness of an asymptomatic individual. Race, gender, and age did not emerge as significant predictors.

Conclusions: This results of this study point to the strong connection between education and coronavirus-related knowledge. Education-related disparities can be remedied by making information fully accessible and easily understood during emergencies and pandemics.

Introduction

Health disparities have been experienced by deaf and hard of hearing (DHH) people in general, as well as during the COVID-19 pandemic. DHH people often do not have equitable access to health information, especially during emergencies [1-3], which further contributes to low perceived quality-of-life outcomes and associated health disparities [4]. For DHH people who speak American Sign Language (ASL), equitable access to health information requires an interpreter to translate between spoken English and ASL, as well as captioning, particularly for information given during live broadcasts about an emergency. To date, not all COVID-19–related video media have included sign language interpreters. However, most DHH ASL speakers, particularly DHH people with a high school degree or less, depend on information presented in ASL in videos as their go-to source for health information, with Facebook being the most often used source [5]. Previous studies have shown that DHH people with a high school degree or less have lower human papillomavirus knowledge, genetic testing awareness, and HIV screening uptake, all of which can be remedied with greater accessibility of pertinent information in ASL [6-8].

While the American public tends to rely on social media to keep up with news [9], social media can also be used as an informal source of information about others' experiences with the health care system or as a means to gain knowledge about specific health information shared by individuals. However, when health information is reproduced and shared informally without oversight by experts, misinformation can occur, including sharing of misinformation related to the ineffectiveness of certain social behaviors in reducing the spread of infections (eg, presenting inaccurate evidence against the use of masks). People who demonstrate low electronic health (eHealth) literacy often fall victim to misinformation as they are not able to verify the accuracy of health information. They may also dismiss information about the severity of certain diseases that was shared by reliable sources on the internet [10-13]. Although the prevalence of misinformation about health on social media is harmful, it can be difficult to correct this misinformation [14]. Consequently, DHH people who have low eHealth literacy and rely on social media to learn information about COVID-19 may be at risk for believing misinformation regarding health and health risks.

During the COVID-19 pandemic, there has been a rapid increase in the amount of information about COVID-19 on the internet, resulting in an "infodemic." This infodemic makes the identification of accurate COVID-19 information from reliable sources difficult [15-17]. DHH people who do not have the requisite background and training in emergency preparedness may select certain information to translate into ASL and share these ASL videos on social media for other DHH people to watch. If the content relayed in these videos is inaccurate or the language used is not clear or understandable to DHH people with a high school degree or less, it can cause confusion and result in information gaps among DHH people during a health emergency. These information gaps can cause harm in medically underserved DHH groups (eg, low education, low income, and low literacy) that are already at risk for disparate outcomes [18]. Accurate critical health information may also not be adequately disseminated to DHH people whose primary language is ASL. These concerns suggest a need to gather a baseline of DHH people's awareness of and risk perceptions related to the current pandemic. Specific research aims for this study include investigating the following: (1) the relationships between DHH people's awareness of physical distancing and perception of the effectiveness of physical distancing in reducing the spread of COVID-19, and (2) the relationship between DHH people's perceived effectiveness of physical distancing and perceived contagiousness of an asymptomatic person.

Methods

A COVID-19 knowledge and risk perception survey in ASL was created by a team of experts in DHH health, translation, and survey development [19,20]. The web link to participate in this survey was disseminated via social media as well as through direct email invitations to those who previously took surveys through the Center for Deaf Health Equity at Gallaudet University.

Data Collection Procedure

Following Institutional Review Board approval by Gallaudet University (RB-FY20-80), research staff recruited DHH individuals throughout the United States, both on social media and through email invitations to past survey participants. Participation in this study required access to a computer and the internet to complete an online bilingual ASL/English survey about knowledge of physical distancing and asymptomatic individuals' contagiousness. As a result, the findings are limited to DHH people with access to computer technology and internet/Wi-Fi connectivity. Only those who self-reported using ASL as their primary language were included because this group was identified as a medically underserved group [21-23]; exclusion criteria included those aged <18 years and those who lost their hearing ability due to aging. After the participant viewed the study information in ASL and English, they were directed to a page where they could choose to provide consent or decline to participate. Following consent, the online survey presented in both ASL and English took approximately 10 minutes to complete. No names or identifying information were included in the survey and a unique identifier was used to avoid storing personal information in the survey data set.

Participant Sources

Participants for this study were drawn from two sources: anonymous participation through a survey link shared via Facebook and a recruitment database pool that was sent an invitation email to take the online survey. The COVID-19 knowledge and risk perception survey included questions about physical distancing awareness, knowledge of physical distancing effectiveness, and knowledge of the contagiousness of an infected person without symptoms. The survey was administered to US Deaf adults from April 17, 2020, to May 1, 2020. Prior to survey administration, all items were translated into ASL with coaching from a Deaf researcher with expertise in translating survey items; the final translations were captured on film.

Survey Items

For the purposes of this study, awareness of physical distancing and perceived effectiveness of physical distancing were assessed with the following questions: "How much do you know about physical distancing?" and "How effective do you think physical distancing is for the prevention of the spread of the coronavirus (in other words: to what extent does your physical distancing behavior contribute to other people not getting sick)?" The response options for the former question were "never knew," "little," "some," "most," and "know a lot," while the response options for the latter question were "not at all effective," "little effective," "somewhat effective," "mostly effective," and "very effective." Participants' perception of the ability of an infected person without symptoms to spread COVID-19 was assessed with the following question: "Based on what you know, how contagious is someone who has been infected with the coronavirus but who shows no symptoms (no coughing; no fever)?" For this question, the response options were "not at all contagious," "little contagious," "somewhat contagious," "contagious," and "very contagious."

Statistical Analyses

Weighted descriptive statistics, such as cross-tabulation and percentage procedures, were used to summarize the sample. As a logistic regression model required binary response variables, responses to the perceived effectiveness of physical distancing and perceived contagiousness of an infected person without symptoms questions were recoded into binary low and high groups. Response options of "not at all effective," "little effective," and "somewhat effective" were recoded into the low group, while "mostly effective" and "very effective" were recoded into the high group. Response options of "not at all contagious," "little contagious," and "somewhat contagious" were recoded into the low group, while "contagious" and "very contagious" were recoded into the high group. A backward elimination variable selection procedure was performed on a logistic regression model, using age, gender, race, education, and baseline physical distancing awareness to predict the odds of having an accurate perception of the effectiveness of physical distancing in reducing the spread of COVID-19 (reference group). The criteria for retaining predictors was a P value <.05. Finally, all variables including physical distancing awareness and knowledge of physical distancing effectiveness were entered as explanatory sets to assess their relationships with knowledge of the contagiousness of an infected person without symptoms (high knowledge of the level of contagiousness was the reference). For observational, cross-sectional studies, a minimum sample size of 400 is recommended for analyses with six predictor variables in the final model [24]. SPSS (Version 25.0; IBM Corp) was used for all analyses.

Results

The weighted sample of those that answered all questions for this study consisted of 475 adults aged 18-88 years old, with 74% (n=352) identifying as White and 54% (n=256) as female (Table 1). When asked about their preferred language on a daily basis (response options: ASL, English, both ASL and English), half of the sample (50%) preferred ASL only. About 88% (n=418) of the sample felt they knew most things about or a lot about physical distancing. This figure dropped to 72% (n=342) for the question about the effectiveness of physical distancing in reducing the spread of COVID-19 and 70% (n=333) for the question about the contagiousness of an infected person without symptoms. Bivariate correlation analysis indicated positive associations among physical distancing awareness, knowledge of physical distancing effectiveness, and knowledge of contagiousness variables (r=0.24-0.38; P<.001).

Table 1. Weighted sample characteristics and logistic regression of perceived contagiousness in asymptomatic individuals.

Sample characteristics	Participants, n (%)	Adjusted odds ratio (95% CI)	*P* value
Age group (years)			.31
18-34	113 (23.8)	1.00	N/A[a]
35-49	154 (32.4)	0.65 (0.29-1.43)	N/A
50-64	126 (26.5)	0.45 (0.20-1.01)	N/A
65-74	58 (12.3)	0.78 (0.29-2.12)	N/A
≥75	24 (5.0)	1.17 (0.23-5.97)	N/A
Gender identity			.22
Male	203 (42.8)	1.00	N/A
Female	256 (53.8)	1.63 (0.92-2.87)	N/A
Nonbinary	16 (3.4)	2.06 (0.24-17.94)	N/A
Race/ethnicity			.74
White	352 (74.2)	1.00	N/A
Black	21 (4.4)	0.61 (0.21-1.79)	N/A
Latinx	67 (14.2)	0.92 (0.34-2.49)	N/A
Asian/Other	35 (7.3)	1.26 (0.53-3.02)	N/A
Education			.001
High school degree	176 (37.0)	1.00	N/A
Some college	175 (36.8)	1.85 (0.80-4.30)	N/A
College degree	124 (26.2)	4.67 (2.22-9.80)	N/A
Physical distancing awareness	N/A	1.66 (0.64-4.32)	.30
Physical distancing effectiveness	N/A	3.13 (1.78-5.50)	.001

[a]N/A: not applicable.

In the first model, a backward elimination variable selection procedure was used to identify the significant predictors for perceiving physical distancing as effective in reducing the spread of COVID-19. In this model, physical distancing awareness and education emerged as significant predictors of perceiving physical distancing as effective (adjusted odds ratio for physical distancing awareness=5.00, 95% CI 2.09-11.95; adjusted odds ratio for education=1.89, 95% CI 1.13-3.16). Race, gender, and age did not predict perceptions of the effectiveness of physical distancing. In the second model, both physical distancing awareness and perception of the effectiveness of physical distancing were entered as a set in the first block. All demographics were entered as a set in the second block. As shown in Table 1, with adjustments for correlates, the results showed that only perception of the effectiveness of physical distancing and education were significant in their relationships with perceived contagiousness of asymptomatic individuals. Compared to DHH respondents who had 12 years of education or lower, DHH respondents with a college degree were nearly five times more likely to report that asymptomatic individuals are contagious (adjusted odds ratio=4.67, 95% CI 2.22-9.80). Again, age, gender, and race did not predict knowledge of contagiousness of an infected person without symptoms.

Discussion

Principal Findings

A majority of this US DHH study sample had heard of physical distancing, but not all believed that physical distancing was effective in reducing the spread of COVID-19 or that an asymptomatic individual was contagious. Above and beyond sociodemographic variables and physical distancing awareness, DHH people who had a college degree were almost twice as likely to believe that physical distancing was effective at reducing the spread of COVID-19 compared to DHH people who did not have a college degree. Although both education and physical distancing awareness strongly predicted perceptions of the effectiveness of physical distancing, this study did not find evidence for the contribution of age, gender, and race to the development of appropriate perception of physical distancing effectiveness. This finding is consistent with research studies that reported a connection between more years of education and a greater level of health-related awareness or screening uptake [6-8]. Our study also showed that DHH people who have a college degree, as well as knowledge of the effectiveness of physical distancing, were much more likely to believe that an infected person without symptoms is contagious compared to DHH people who did not have a college degree and

demonstrated low knowledge of the effectiveness of physical distancing.

The lower knowledge of physical distancing and COVID-19 among DHH people who do not have a college degree may be in part explained by inadequate, inaccessible, or misleading information presented in ASL on social media. According to the 2020 World Health Organization situation report on the novel coronavirus, the COVID-19 outbreak has been accompanied by a global infodemic on social media. As a result, some social media sources may be of low quality, which can potentially lead to the sharing of unreliable information by people in the community. At the same time, social media has been cited as an essential tool for health information seeking among DHH people who do not have a college degree [5] and it can reliably be used to promote rational social health behavior during emergencies and pandemics. Thus, for all social media postings, ASL videos about health during a pandemic must actively cite and include trusted sources for further information. Given the strong connection between education and eHealth literacy [25], as well as the importance of the readability of online health content to accommodate people with a low level of education [26], our community has a responsibility to ensure that social media health videos are fully accessible in ASL and understood by all, including those who have only a high school degree. Clinicians have a responsibility to incorporate patient-centered care and communication in their practice to ensure that patients who are DHH understand what they need to do to take care of their health. Next, we provide recommendations on the development of videos to help increase ASL comprehension for DHH people with a high school education or less.

DHH people with limited access to written English due to language delay or deprivation and DHH immigrants whose first language is not English often have limited ASL fluency [27]. To best accommodate the language needs of these underserved subgroups, ASL videos should be screened for readability for DHH with a high school education or less. This may include avoiding relying on fingerspelling to describe concepts, and instead using visual descriptions and illustrations to make the information easier to understand. Specific concepts might need more elaboration, such as how germs are spread and how masks help prevent the spread of germs. Increasing the use of visual descriptions and elaborating on complex concepts would be key components in providing clear and well-conceived emergency messages. Videos in ASL that include visual descriptions and elaboration of concepts are likely to support comprehension, be effectively transmitted, and ultimately help ensure public health safety by reducing the spread of COVID-19.

According to the National Association of the Deaf Position Statement on Accessible Emergency Management for Deaf and Hard of Hearing People [28], the best practices to disseminate awareness training to DHH citizens during the pandemic are the following: (1) ensuring that the materials are accessible in a language that they understand, (2) including medical and public health experts who use ASL in interactive panels, (3) providing training to qualified sign language interpreters, and (4) ensuring that all news and notification systems are accessible by any form of telecommunication technology.

Conclusion

The results of this study point to the strong connection between education and COVID-19–related knowledge. Therefore, the information that DHH organizations and public health agencies disseminate during emergencies and pandemics must be clear, contain adequate and reliable information, and be timely in concordance with other information being disseminated. For online streaming of time-sensitive news, such as state and local government updates, live captioning in addition to sign language interpreting would provide DHH people with full access to information. ASL videos that are created for social media or the internet must include features that support ease of understanding, which fosters improved knowledge and more accurate perceptions. Information in ASL disseminated through other sources (such as television and the news) must also be clear and accessible to the whole DHH community.

Abstract

Background: Lockdowns and shelter-in-place orders during COVID-19 have accelerated the adoption of remote and virtual care (RVC) models, potentially including telehealth, telemedicine, and internet-based electronic physician visits (e-visits) for remote consultation, diagnosis, and care, deterring small health care businesses including clinics, physician offices, and pharmacies from aligning resources and operations to new RVC realities. Current perceptions of small health care businesses toward remote care, particularly perceptions of whether RVC adoption will synergistically improve business sustainability, would highlight the pros and cons of rapidly adopting RVC technology among policy makers.

Objective: This study aimed to assess the perceptions of small health care businesses regarding the impact of RVC on their business sustainability during COVID-19, gauge their perceptions of their current levels of adoption of and satisfaction with RVC models and analyze how well that aligns with their perceptions of the current business scenario (SCBS), and determine whether these perceptions influence their view of their midterm sustainability (SUST).

Methods: We randomly sampled small clinics, physician offices, and pharmacies across Colorado and sought assistance from a consulting firm to collect survey data in July 2020. Focal estimated study effects were compared across the three groups of small businesses to draw several insights.

Results: In total, 270 respondents, including 82 clinics, 99 small physician offices, and 89 pharmacies, across Colorado were included. SRVC and SCBS had direct, significant, and positive effects on SUST. However, we investigated the effect of the interaction between SRVC and SCBS to determine whether RVC adoption aligns with their perceptions of the current business scenario and whether this interaction impacts their perception of business sustainability. Effects differed among the three groups. The interaction term SRVC×SCBS was significant and positive for clinics (P=.02), significant and negative for physician offices (P=.05), and not significant for pharmacies (P=.76). These variations indicate that while clinics positively perceived RVC alignment with the current business scenario, the opposite held true for small physician offices.

Conclusions: As COVID-19 continues to spread worldwide and RVC adoption progresses rapidly, it is critical to understand the impact of RVC on small health care businesses and their perceptions of long-term survival. Small physician practices cannot harness RVC developments and, in contrast with clinics, consider it incompatible with business survival during and after COVID-19. If small health care firms cannot compete with RVC (or synergistically integrate RVC platforms into their current business practices) and eventually become nonoperational, the resulting damage to traditional health care services may be severe, particularly for critical care delivery and other important services that RVC cannot effectively replace. Our results have implications for public policy decisions such as incentive-aligned models, policy-initiated incentives, and payer-based strategies for improved alignment between RVC and existing models.

Introduction

This study assessed the perceptions of small health care business owners toward remote and virtual care (RVC) services, which include telemedicine, telehealth, electronic physician visits, and internet-mediated communications and have become increasingly prevalent during COVID-19 with lockdowns, shelter-in-place orders, and other social distancing measures [1-4], effectively restricting patient access to in-person care. Consequently, in-person care–based small businesses have been severely impacted.

Hospitals and health systems are currently attempting to modify their care delivery methods in response to COVID-19. They have used various measures, such as discontinuing all elective procedures, converting ambulatory surgery suites to intensive care units, and moving a large portion of their supply offline to generate capacity in the event that the volume of patients with COVID-19 exceeds the projected volume. However, while hospitals and health systems have received financial incentives from the Federal Emergency Management Agency during COVID-19, no such incentives have been provided to the more than half a million small health care businesses, clinics, physician offices, blood banks, laboratories, and pharmacies, which form the traditional core of the health care ecosystem in the United States [5,6]. Consequently, many of these traditional small businesses have been experiencing considerable financial distress.

Over the past two decades, the health care industry had experienced a significant influx of entrepreneurs intending to capitalize on the country's expanding health care expenditures, which amount for almost 20% of the gross domestic product, with an average of 5.5% growth projected through 2026 [7]. These entrepreneurs have often found themselves in a position of "doing good" as they provided much-needed services for the aging, ill, and disabled population at convenient locations. With the recent increase in the need for drug and substance abuse services and recent advancements in medical and technological treatments, they have entered a valuable niche in the health care market. Considering this trend in the health care industry, a plethora of businesses have been operating in the United States under the umbrella term of "clinics" to cater to the differing needs of care of the population. These clinics have been providing affordable care in areas such as physical and occupational therapy, diabetes care, kidney care, drug treatment, and rehabilitation centers, alternate medicine, hearing aid clinics, imaging centers, and nutrition or dietician services [8,9].

Similarly, small physician offices (ie, those with <5 physicians) constituted a significant component of the US health care system, garnering 54.5% of the total of 883.7 million visits to physician offices in 2016 [10]. Press reports reveal that small physician offices are under distress during COVID-19, and that "that won't pay the light bill or the rent" [11], even though they note that these businesses are ready to respond to the challenge and provide care during the pandemic if they can receive incentives to stay operational.

Independent pharmacies in the United States have also been recently struggling, with their market share declining by approximately 10% in the last decade, although they still account for 35% of all retail pharmacies and a US $77.6 billion market share in 2017 [12]. Recent efforts to enhance price transparency have alleviated the "gag clauses," which have served as a primary contributor to high out-of-pocket expenditures for drugs for patients [13,14] and have also resulted in a commensurate reduction in profit margins for some of those pharmacies. Stricter regulatory control has decreased the availability of over-the-counter medication now rather than a decade ago. Furthermore, physicians affiliated with health systems often electronically prescribe medication to be obtained from large pharmacy chains affiliated with the health care system, which have proliferated wider than before and are reportedly diverting large chunks of revenue from small, independently owned pharmacies [15].

Considering the lockdowns and shelter-in-place directives during the pandemic, consumers not only have greater access to web-based physician consultations but also have patronized online pharmacies [16]. Consequently, traditional pharmacies are losing their market share, leading to severe financial strain on them [17]. Indeed, more than half of the independent pharmacy owners are experiencing a negative revenue influx [18], with fewer individuals visiting stores [19]. Unlike large pharmaceutical companies, small pharmacies have also struggled to embrace the emerging RVC models and be sustainable, and this remains a concern [20].

This leads to the question of why these small businesses do not adopt RVC. We offer several conjectures to answer this question. First, RVC might be perceived as a temporary phenomenon, which could decline post COVID-19 because an online consultation cannot effectively replace an in-person consultation in many circumstances. Second, there may be a genuine fear that resource limitations may inhibit the ability of these small businesses to adopt RVC, and this may deter their sustained survival. Costs associated with digital infrastructure investment, platforms, connections, training, test runs, and scheduling services may be perceived as prohibitive. Third, whether organizations and insurance companies can reimburse RVC models remains a concern. Finally, assessment of the costs and benefits of adopting an RVC model can be difficult. The potentially expensive and arduous process of adopting an RVC model remains a major task, and there is no clarity on whether all patients and organizations would eventually transition to these models. Maintaining a brick-and-mortar store along with the RVC may be costly and overwhelming to these small business entities.

Small businesses can certainly benefit from integrating RVC processes into their existing business operations. Consumers, both on the demand and supply sides of care, are familiar with

the use of cell phones, video chat platforms, text messaging, and cloud-based communication; hence, they can adopt a digital care platform without adequate training. Further, RVC models help overcome physical barriers, thereby increasing the reach of small businesses (and competition) to a much larger geographic area. Data collected by RVC systems may help identify how small firms may gain more business, connect patients with specialists in just-in-time mode, and improve branding.

This study aims to address these issues through a perceptual survey of small physician-owned businesses, clinics, and pharmacies. We sought to determine whether the owners of these businesses view RVC as a threat, whether they consider themselves capable of integrating the many opportunities accompanying RVC with their existing business model, and whether they fear midterm survival in the wake of RVC.

To answer these questions, we propose three conjectures based on our expectation that clinics, as opposed to small physician-owned businesses and pharmacies, will be better able to realize and leverage the value proposition of RVC because many clinics are affiliated with larger organizations that already have established digital platforms. Some of these may be retail or franchise establishments, perhaps connected to a larger health care system or hospital, which renders them more likely to be able to leverage the organization's existing RVC or other digital platforms to their benefit to a larger extent than independent physician-owned businesses or pharmacies. Our conjectures are the following:

1. Small clinic owners will perceive value in aligning opportunities accompanying RVC models with their current business practices.
2. Small physician offices will not perceive value in aligning opportunities accompanying RVC models with their current business practices.
3. Small and independent pharmacy owners will not perceive value in aligning opportunities accompanying RVC models with their current business practices.

Methods

Recruitment

We conducted a focus group study with 8 health care experts via Zoom; they comprised 4 entrepreneurs familiar with the health care environment in Colorado, 2 physicians, and 2 executive health faculty members. The discussion centered around the impact of RVC on the sustainability of small physician offices, clinics, and pharmacies during COVID-19. The experts generally supported the notion that RVC adoption is posing a challenge to small health care businesses. As conjectured, the experts believed that clinics, by their scale and scope, would likely not only benefit from but also be able to rapidly integrate RVC into their business practices, more so than physicians and pharmacies. Furthermore, the experts believed that physician offices are most likely to directly compete with, and hence be threatened by, RVC. Clinics often provide in-person consultations; therefore, the focus group speculated that RVC was not a major direct threat to their sustainability as it was for physician offices. Furthermore, the experts speculated that small local pharmacies would be negatively impacted during COVID-19 and that consumers would increasingly tend to visit online pharmacies, thereby avoiding waiting in line at physical locations that may increase the risk of infection. To investigate whether these opinions were reflective of health care businesses in Colorado, our study was aimed at empirically validating these presumptions, using a scientifically collected sample of small health care businesses in Colorado.

Data Collection

Considering the time sensitivity of this study, we solicited a professional consulting firm for data collection. The consulting firm sampled 445 small health care businesses in Colorado (135 clinics, 141 physician offices, and 169 pharmacies) through an opt-in approach during June-July 2020. Of these, 282 firms responded to the survey. In total, 12 observations were excluded owing to missing responses, resulting in a final sample size 270 businesses consisting of 82 clinics, 99 physician offices, and 89 pharmacies. The identities of the respondents were not disclosed.

The survey instrument used to collect the data is presented in Table 1. Questions regarding the current sustainability of the business in the subsequent 1-3 years were asked to the survey participants. Furthermore, satisfaction with the current state of the business and current remote care practices, if any, adopted by the business were measured. The survey was brief and succinct, taking only 5 minutes to complete, addressing only critical research questions and eliciting realistic responses.

The survey instrument, consisting of only 11 questions, was piloted with a sample of 22 respondents, leading to minor adjustments to a few items. Responses were coded, validated, and analyzed using STATA (version 14.2, StataCorp).

Table 1. Survey questionnaire and coding scheme.

Variable	Description	Questionnaire items	References
Dependent variables			
Sustainability of the physician office, clinic, or pharmacy (SUST)	Business owner's perception of practice or business survival in the near future.	At an overall level, to what extent do you feel your clinic/practice/pharmacy is sustainable, considering the current COVID-19 scenario, in a span of the next 1-3 years?	Scale: 1 (least confident) to 5 (very confident)
Independent variables			
Satisfaction with the current business scenario (SBCS)	Business owner's satisfaction with the current practice and/or business scenario during COVID-19.	Questions: to what extent are you currently [during COVID-19 situation] satisfied with: (1) the overall clinic/practice/pharmacy relevant business scenario, situated across your city/town/county, (2) the current method of practice or business operations, and (3) the quality of day-to-day business transactions?	Scale: 1 (very dissatisfied) to 5 (very satisfied); Cronbach α=.79
Satisfaction with remote and virtual care models (including telemedicine, telehealth, and e-visits) (SRVC)	Business owner's satisfaction with the current (during COVID-19) remote care (telemedicine, telehealth, remote consulting, and e-visit provisions) provided by your clinic/practice/pharmacy.	Questions: to what extent are you currently (during COVID-19 situation) satisfied with the provisions and operations in your organization relevant to: (1) remote care, (2) telehealth and telemedicine, and (3) remote consulting and e-visits?	Scale: 1 (very dissatisfied) to 5 (very satisfied); Cronbach α=.82
Control variables			
Age (AGE)	Age of the owner	My age is_____.	N/A[a]
Gender (GEN)	Gender of the owner	I am: (a) male and (b) female	N/A
Income (INC)	Net income of the owner from the business	My annual income from the clinic/practice/pharmacy relevant business: (1) less than US $50,000, (2) US $50,000-US $100,000, (3) US $100,000-US $200,000, (4) US $200,000-US $300,000, (5) US $300,000-US $500,000, (6) US $500,000-US $750,000, (7) US $750,000-US $1,000,000, and (8) higher than US $1,000,000.	N/A
Education (EDU)	Education of the owner	My education is: 1=illiterate, 2=up to middle school, 3=up to high school, 5=some college, 6=undergraduate level, and 7=graduate and above.	N/A

[a]N/A: not applicable.

Sample Descriptors and Demographics

Table 2 shows the descriptive statistics and pairwise correlations among the key variables. Most of the owners (mean 3.09, SD 0.6) believe that their business is on the verge of being sustainable, notwithstanding certain concerns. Owner satisfaction with the current business scenario was moderate to high (mean 3.16, SD 0.67). In contrast, owner satisfaction with remote care was low (mean 2.87, SD 0.76), probably owing to the unpreparedness and uncertainties associated with the delivery and rendering of remote care channels and options.

Of the 270 respondent business owners and chief executives, 229 (85%) identified as male. Respondent ages varied from 25-60 years, with 122 (45%) participants aged 25-35 years, 31 (12%) participants aged 35-45 years, 115 (43%) participants aged 45-55 years, and only 2 (0.01%) participants aged 55-60 years.

Further, 26 (10%) participants reported that they earned less than US $50,000 annually, 34 (13%) earned between US $50,000-US $100,000, 90 (33%) earned between US $100,000-US $200,000, 16 (6%) earned between US $300,000-US $500,000, 13 (5%) earned between US $500,000-US $750,000, 10 (4%) earned between US $750,000-US $1,000,000, and 19 (7%) earned more than US $1,000,000.

In addition, 1 (0.4%) participant reported having no education, 1 (0.4%) participant had 4 years of schooling, 4 (1.5%) participants had middle school education, 18 (7%) participants had high school education, 34 (13%) participants had some college education, 112 (42%) participants had an undergraduate degree, and 100 (37%) participants had graduate-level or higher education.

Table 2. Summary statistics and pairwise correlations among variables (N=270).

#	Variable	Mean (SD)	Minimum	Maximum	1	2	3	4	5	6	7
1	SUST[a]	3.09 (0.60)	1	4	1.00						
2	SCBS[b]	3.16 (0.67)	1	4	0.52	1.00					
3	SRVC[c]	2.87 (0.76)	1	4	0.48	0.31	1.00				
4	Age	37.45 (8.37)	25	60	0.02	0.07	0.06	1.00			
5	Gender	0.85 (0.36)	0	1	0.08	0.03	0.05	0.03	1.00		
6	INC[d]	4.67 (1.82)	2	8	–0.13	–0.14	–0.03	0.03	0.00	1.00	
7	EDU[e]	6.03 (1.02)	1	7	–0.14	–0.10	–0.05	–0.14	0.07	0.17	1.00

[a]SUST: sustainability of the physician office, clinic, or pharmacy.

[b]SCBS: satisfaction with the current business scenario.

[c]SRVC: satisfaction with remote and virtual care models (including telemedicine telehealth and e-visits).

[d]INC: income.

[e]EDU: education.

Study Variables

We used a dependent variable reflecting the owner's perception of the business sustainability of physician offices, clinics, or pharmacies in the near future (SUST). This variable was measured using a single-item question. On average, SUST had a mean score of 3.09 (SD 0.6) of 5, indicating that most businesses are somewhat confident in remaining sustainable (Table 2).

Two independent variables were of interest in this study. First, the independent variable of satisfaction with the current business scenario (SCBS) measured the owner's satisfaction with the current practice or the business scenario during COVID-19. This variable was operationalized with three questions on the business scenario across the city/town/county, the current ways of practice or business operations, and the quality of day-to-day business transactions during the pandemic. The internal consistency of the items was high, as reflected by their Cronbach α of .79 and a variable response of 3.16 (SD 0.67) (Table 2).

Second, the satisfaction with RVC (SRVC) models indicated the owner's or chief executive's satisfaction with current remote care (telemedicine, telehealth, remote consulting, and e-visit provisions) provided by their clinics, practice offices, or pharmacies. This variable was operationalized with using three questions on the provisions and aligned operations in the clinic, physician office, or pharmacy relevant to remote care, telehealth, and telemedicine, and remote consulting during COVID-19 (Table 1). The items had high internal consistency with a Cronbach α of .82 and a variable response of 2.87 (SD 0.76) (Table 2).

We were particularly interested in exploring how owners perceived the importance of remote care to remain competitive and mitigate concerns relevant to their current business scenario during COVID-19. To explore this, we established an interaction variable multiplying SCBS and SRVC (SCBS×SRVC), which was used in the models to reflect the net effect of satisfaction with the current business and existing remote care provisions on perceptions of business sustainability.

In addition to these key variables of interest, a limited set of control variables such as age, gender, income, and education were included to account for potential counterfactual explanations relevant to our models.

Econometric Analysis

The empirical model used herein analyzed the impact of owners' perceptions of their current business scenario and their ensuing use of remote care systems on the perceived sustainability of their small businesses. We used an ordinary least square estimation as follows:

$$Y[SUST]_i = \beta_0 + \beta_1\ SCBS_i + \beta_2\ SRVC_i + \beta_3\ SCBS_i \times SRVC_i + Controls_i + \varepsilon_I \quad (1)$$

where *Y* is the dependent variable; β_0, β_1, β_2, and β_3 are the parameter coefficients; and ε is the disturbance associated with each observation. We estimated this model for all businesses in our sample and then separately for the subsamples of clinics, physician offices, and pharmacies.

Results

Table 3 presents the estimation results obtained using equation (1) and summarizes the estimates for the entire sample and individually for clinics, physician offices, and pharmacies.

We found that both SCBS and SRVC variables have significant, positive direct effects on SUST, which indicates that the effort invested in the current situation and in adopting remote care systems influenced the sustainability of the businesses as perceived by the owners. However, this study aimed to investigate whether remote care provision was perceived as adequate in the current business scenarios to influence business sustainability. Accordingly, the coefficients of the interaction variable SCBS×SRVC were further analyzed.

Table 3. Estimation results (N=270).

[a]SUST: sustainability of the physician office, clinic, or pharmacy.

[b]SCBS: satisfaction with the current business scenario.

[c]SRVC: satisfaction with remote and virtual care models (including telemedicine telehealth and e-visits).

[d]N/A: not applicable.

First, we found that for clinics, the estimation coefficient was positive and significant (β=.274; *P*=.02). This finding indicated a positive interaction between the current business scenario and the adoption of remote care platforms, reflecting higher perceived business sustainability. Second, for physician offices, the opposite trend was observed, in that the estimation coefficient was negative and significant (β=–.182; *P*=.05). This finding indicates a negative interaction between their satisfaction with RVC and their satisfaction with their current business scenario, reflecting lower future sustainability of their businesses. Third, for pharmacies, the estimation coefficient was not significant (β=.026; *P*=.76). This finding indicates that pharmacy owners did not perceive the interaction between their satisfaction of remote care platforms and the current business scenario to be associated with the sustainability of their businesses. Finally, the estimation coefficient of SCBS×SRVC of the complete sample was not significant (*P*=.83), probably owing to an aggregation of positive and negative interactions across the subsamples.

Discussion

Practice and Policy Implications of the Findings

RVC adoption (ie, telemedicine, telehealth, e-visits, and similar internet-enabled treatment options) has grown significantly during COVID-19. RVC fulfills a widespread patient-centric need for access to services of the US health care sector, which is likely to be a high-growth sector in the near future. The growth of RVC has impacted traditional small health care businesses that have traditionally relied on in-person care and serve a local geographic area. Our study was aimed at measuring the perceptions of RVC of these small business owners and determining whether they believe that RVC would threaten their survival or sustainability or, in contrast, if they perceived RVC as a growth opportunity.

Our study assessed the perceptions of three categories of health care providers: physician offices, clinics, and pharmacies. We found that clinic owners were most likely to believe that their adoption of the RVC model interacted positively with their perceptions of the current business scenario, which, in turn, led to a more positive perception of their business sustainability over the subsequent 1-3 years. In other words, their satisfaction with the RVC model was synergistic with their satisfaction with

current business practices, and this was associated with a more optimistic opinion of the firm's midterm business survival. These findings may be certainly moderated by the type of clinic in question. A majority of clinics, such as physical therapy businesses, imaging services, or diabetes care centers that depend on in-person visits, may not perceive RVC as a direct threat. For them, adoption of a digital platform, particularly to enhance efficiency, customer service, and information provision, may complement their services and extend their reach to a younger, more digitally savvy audience.

However, this was not the case with physician offices. The interaction between their satisfaction with the current business scenario and RVC was negative, resulting in a lower perception of their firm's midterm sustainability. In other words, these business owners speculated that RVC, when combined with the existing business scenario, was negatively associated with their likely midterm survival. While the interaction between their perception of the current business scenario and RVC was negative for pharmacies as well, the coefficient was nonsignificant, suggesting that pharmacies did not consider their satisfaction with RVC and the current business scenario to impact their business's midterm sustainability.

Overall, clinics perceived RVC and the current business scenario to be positively associated with business sustainability. In contrast, physician offices speculated that RVC adoption along with the current in-person business scenario was negatively associated with their business's midterm survival.

Many of these small businesses do not qualify for financial assistance from the Federal Emergency Management Agency during COVID-19, and this has significantly, albeit temporarily, decelerated business operations during the pandemic and caused them financial distress. Furthermore, their inability to rapidly adopt a satisfactory and synergistic RVC model to atone for the loss of traditional customers further aggravated this problem. The recent policy-level incentive to render RVC models a permanent provision in the US health care system, without considering the opinions and realities of small health care businesses (which are the backbone of the traditional health care delivery system), seems myopic. RVC cannot replace traditional in-person health care provision in all circumstances, and if physician offices and other small health care businesses cannot survive the competition posed by the RVC model, the results could lead to a marked deficit in critical care. Hence, new technologies should be adopted in a nuanced manner, with policy-level support for these small businesses, thus laying the foundation for gradual and progressive RVC adoption [18].

Certain other issues also need careful policy restructuring: (1) linking insurance payments and payor guarantees to encourage small businesses to adopt the RVC model; (2) developing creative, new consumer-centric models in this context; (3) ensuring affordable RVC platforms for small businesses with reliable technological and infrastructural logistics to ensure that remote care is error-free and of the highest quality; and (4) integrating RVC models with traditional brick-and-mortar health care models that have been established in accordance with the high-touch concept. If remote RVC technology can complement and not compete with in-person treatment models, such a system would have a high combined efficiency. For instance, technologies such as remote patient monitoring and vital reading systems can help improve the impact of traditional systems.

A related implication is to prepare current and next-generation patients and care providers to embrace RVC-related changes that have not been and are not a part of the curriculum in medical or business schools. Medical practitioners may not be good business persons and vice versa. Small physician offices have been particularly faced with this conundrum while facing several regulatory and practice-level changes, which were not a part of their curriculum. Advancements in RVC involve artificial intelligence, machine learning, data science, and above all, a set of customer-oriented, internet-based patient communication and payment or profit models, which need both medical and business skills. The future curriculum should foster the acquisition of business knowledge and skills.

Conclusions

The rapid spread of COVID-19 has yielded unprecedented challenges. Simultaneously, it has helped to rapidly accelerate the adoption of RVC models. RVC serves as a starting point for several innovations that would potentially modify the existing care models and, when used carefully, may lead to a synergistic mixed model of in-person and internet-based care provision. However, our results show that RVC adoption may have progressed too rapidly, with small businesses struggling to integrate RVC technologies with their existing in-person platforms. Physician offices, in particular, are experiencing incompatibility between their current business models and RVC technologies and are concerned about the potential impact of RVC adoption on their midterm survival. If a significant proportion of brick-and-mortar physician offices become nonoperational, the collective impact of such a closure on the US health care system could be catastrophic. Hence, careful consideration of the adoption of RVC models (potentially including business education, government incentives, and support for small businesses) is vital to the sustained adoption and functionality of RVC models. While it is clear that the future of health care depends on these transformative models, the complexity lies in managing these models with appropriate support, training, reimbursement, and incentive models for small businesses, while meeting the expectations and demands of patient-centric health care delivery.

Abstract

Background: In April 2020, two independent clinical trials to assess SARS-CoV-2 prophylaxis strategies among health care workers were initiated at our hospital: MeCOVID (melatonin vs placebo) and EPICOS (tenofovir disoproxil/emtricitabine vs hydroxychloroquine vs combination therapy vs placebo).

Objective: This study aimed to evaluate the reasons why health care workers chose to participate in the MeCOVID and EPICOS trials, as well as why they chose one over the other.

Methods: Both trials were offered to health care workers through an internal news bulletin. After an initial screening visit, all subjects were asked to respond to a web-based survey.

Results: In the first month, 206 health care workers were screened and 160 were randomized. The survey participation was high at 73.3%. Health care workers cited "to contribute to scientific knowledge" (n=80, 53.0%), followed by "to avoid SARS-CoV-2 infection" (n=33, 21.9%) and "the interest to be tested for SARS-CoV-2" (n=28, 18.5%), as their primary reasons to participate in the trials. We observed significant differences in the expected personal benefits across physicians and nurses (P=.01). The vast majority of volunteers (n=202, 98.0%) selected the MeCOVID trial, their primary reason being their concern regarding adverse reactions to treatments in the EPICOS trial (n=102, 69.4%).

Conclusions: Health care workers' reasons to participate in prophylaxis trials in an acute pandemic context appear to be driven largely by their desire to contribute to science and to gain health benefits. Safety outweighed efficacy when choosing between the two clinical trials.

KEYWORDS

clinical trials; COVID-19; health care worker; motivation; personnel; pre-exposure; professional practice; prophylaxis; SARS-CoV-2; volunteers, web-based survey; workplace safety

Introduction

Therapeutic and phase I clinical studies have primarily focused on motivations for participating in clinical trials. However, limited information is available regarding subjects' motivators to participate in prophylaxis trials in an acute pandemic context, with particular reference to COVID-19, especially in Western countries. In this setting, when several trials compete in recruiting participants from the same center, the participants' reasons for choosing one trial over the other can be very relevant.

Currently, no pre-exposure prophylaxis therapy has been approved for COVID-19, but numerous clinical trials have been initiated in Europe and the United States, most of them assessing the potential of hydroxychloroquine as a prophylactic agent (eg, EudraCT-2020-001565-37, EudraCT-2020-001536-98, NCT04352946, NCT04354870, and NCT04328467) [1-5].

As of April 21, 2020, two independent clinical trials to assess COVID-19 prophylaxis strategies among health care workers have been initiated at the Clinical Trials Unit, La Paz University Hospital (Madrid, Spain): the MeCOVID trial (melatonin vs placebo; EudraCT-2020-001530-35) and the EPICOS trial (a four-arm clinical trial comparing the efficacy of tenofovir disoproxil/emtricitabine, hydroxychloroquine, combination therapy, and placebo; EudraCT-2020-001385-11).

This study aimed to evaluate the motivations among health care workers at our hospital to participate in COVID-19 prophylaxis trials and the reasons to select one of the two trials currently underway at our hospital.

Methods

A choice between the two clinical trials was offered to our hospital personnel through the internal news bulletin. All potential participants received the information regarding both clinical trials and had the opportunity to have any questions answered before choosing between the two studies. Their choices were not influenced by the team of investigators.

Participants were screened to their chosen trial. In both clinical trials, they underwent COVID-19 screening using a serologic rapid test (Orient Gene, Orient Gene Biotech; or Wondfo, Guangzhou Wondfo Biotech). All screened subjects were asked to complete a web-based survey after their screening visit.

The questionnaire consisted of 9 questions on participant demographics, professional designation and work site, knowledge of COVID-19, motivation to participate, reasons to choose one trial over the other, and treatment expectations (Multimedia Appendix 1).

The survey was administered as a Google form. An invitation email containing a link to the questionnaire was distributed among all screened volunteers. No reminder emails were sent to nonresponders. Participants' responses were anonymized and maintained confidential in accordance with Google's privacy policy.

Descriptive statistics including variables with percentage values were determined. We performed the Shapiro–Wilk test to determine whether age was normally distributed in our study population; accordingly, we rejected our null hypothesis in the test for normality ($P<.001$) and found that age was normally distributed.

Statistical analyses were performed using R software (version 3.6.3, The R Foundation). We analyzed differences between age and position using the Mann–Whitney *U* test and between sex and position using the chi-square test. Furthermore, we performed the Fisher exact test to analyze differences in the responses of physicians and nurses.

Results

In the first month of recruitment, 206 health care workers were screened and 160 were randomized (MeCOVID: n=156, 97.5% and EPICOS: n=4, 2.5%). Volunteers selected the trial in which they wanted to participate, the vast majority (n=202, 98.0%) having selected the MeCOVID trial. Table 1 shows the distribution of survey outcomes in the sampling frame. Furthermore, Table 2 shows the main data and the survey findings stratified by designation (physicians vs nurses vs others).

Table 1. Distribution of outcomes in the sampling frame (N=206).

Questionnaire response status among health care workers	Participants, n (%)
Returned the questionnaire	151 (73.3)
Complete	142 (68.9)
Partial or break-off with sufficient information[a]	9 (4.4)
Did not return the questionnaire (nonresponders)	55 (26.7)
Logged in to survey but did not complete any items[b]	16 (7.8)
Returned responses[c]	29 (14.1)
Invitation returned undelivered[d]	10 (4.8)

[a]Registered for the survey and responded to almost all questions (maximum of 2 questions not answered).

[b]Registered for the survey but returned no responses.

[c]Remaining sample (participants remaining after excluding those who returned the questionnaires, those who logged in to survey but did not complete any items, and those for whom the invitation was returned undelivered.

[d]Email invitation was returned undelivered. Email delivery failed owing to the use of an incorrect, outdated, or out-of-space email address.

Table 2. Main survey findings stratified by participant designation (N=151).

Survey findings	Participant designation			*P* value[a]
	Physicians (n=64)	Nurses[b] (n=79)	Others[c] (n=8)	
Responder characteristics

[a]*P* values refer to differences between the responses of physicians and nurses. “Others” have been excluded from the analysis owing to their small sample size.

[b]“Nurses” includes nurse practitioners (n=54) and nursing assistants (n=25).

[c]“Others” includes laboratory technicians (n=2) and ancillary personnel (n=6).

In total, 56 (37.1%) participants reported having expert knowledge of COVID-19, of whom 39 (69.6%) were physicians, 16 (28.6%) were nurses, and 1 (1.8%) had another designation. The main motivation for many to participate in the trials was “to contribute to scientific knowledge” (n=80, 53.0%), followed by “to avoid SARS-CoV-2 infection” (n=33, 21.9%) and “the interest to be tested for SARS-CoV-2 by a serologic rapid test” (n=28, 18.5%) (Multimedia Appendix 2).

Regarding the expected personal benefits, we observed significant differences (*P*=.01) in the responses of physicians and nurses: the main expected benefit among physicians (n=18, 54.6%) was to gain access to SARS-CoV-2 rapid tests, while that among nurses (n=20, 62.5%) was to prevent SARS-CoV-2 infection (Multimedia Appendix 3).

Among the 147 subjects in the MeCOVID trial, the main motivation to participate was "the fear to present any toxicity related to EPICOS treatments" (n=102, 69.4%), while that among participants in the EPICOS trial was "the belief that hydroxychloroquine and tenofovir/emtricitabine might be more effective than melatonin to prevent SARS-CoV-2 infection" (n=2, 50%).

Again, we observed significant differences in the responses of physicians and nurses with respect to their reasons for selecting the MeCOVID trial. In total, 53 (85.5%) physicians and 49 (63.6%) nurses reported choosing the MeCOVID trial owing to adverse reactions to drugs used in the EPICOS trial. Conversely, 17 (22.1%) nurses and only 2 (3.2%) physicians preferred the MeCOVID trial to the EPICOS trial owing to the higher efficacy of melatonin, and 17 (22.1%) nurses and only 6 (9.7%) physicians reported the use of melatonin as a sleep aid (P<.001).

We had expected most participants (n=84, 57.1%) to favor the MeCOVID trial primarily because melatonin would be efficacious and safe, with 44 (29.9%) participants believing that although melatonin would not be efficacious, it would at least not lead to adverse reactions. Most participants (n=3, 75.0%) favoring the EPICOS trial expected the treatment to not only be efficacious but also to lead to some adverse reactions.

Discussion

Principal Findings

Prevention of SARS-CoV-2 transmission among health care workers is key to managing COVID-19 outbreaks. Although the precise number of COVID-19–infected health care workers is lacking, and studies have reported this infection rate to be 20% in Spain, approximately 10% in Italy and the United States, 6% in the Netherlands, and 3.8% in China [6]. Drug prophylaxis is one of the measures proposed to prevent SARS-CoV-2 infection among health care workers, and it is a priority to obtain strong evidence for this intervention.

This study evaluated the motivations among health care workers at our hospital to participate in 1 of 2 COVID-19 prophylaxis trials—MeCOVID and EPICOS—and their reasons to choose one trial over the other, given the different characteristics of these trials. Survey participation was high (n=151, 73.3%), with a response rate of approximately 70%. In our opinion, the reason for this is the use of a web-based survey, which was easy to respond to (taking only approximately 5 minutes to complete).

Empirical studies have reported that altruism and self-interest are the two primary motivations for participants to enroll in unpaid clinical trials. This holds good in various clinical situations, including participation in prophylaxis and vaccines trials, and in trials conducted at different geographical locations [7-10].

To our knowledge, this study is the first of its kind to be conducted in an acute pandemic context. Herein, the motivations of health care workers, who are aware of the severity and complications of COVID-19, to participate in the trials were similar to those reported in other clinical situations; that is, to contribute to science (n=80, 53%) and to gain personal benefits (n=71, 47.0%), and no significant differences were observed in the responses of physicians and nurses. However, the expected personal benefits were significantly different between physicians and nurses, with physicians being more interested in gaining access to SARS-CoV-2 rapid tests and nurses expecting to prevent SARS-CoV-2 infection. Such a combination of motivators has also been reported among subjects participating in HIV prophylaxis trials and Ebola vaccine trials [11-14].

A major reason for participants to choose one trial over the other in this study was the fear of adverse reactions to drugs used in the EPICOS trial; hence, two-thirds of the volunteers opted to participate in the MeCOVID trial. Our volunteers seemed to participate in the MeCOVID trial because they perceived it as less risky (they opted for this trial despite one-third volunteers not expecting any treatment efficacy). Furthermore, the reasons to participate in the MeCOVID trial were significantly different between physicians and nurses, with physicians being more concerned about adverse drug reactions.

Strengths and Limitations

Although our study has a large sample and a high survey participation rate, it has some limitations of note. There are some biases in our study: a selection bias owing to the single-center study design and a low participation rate in the EPICOS trial (n=4, 2.5%). However, one of our study objectives was to evaluate motivations of health care workers to participate in COVID-19 prophylaxis trials independent of the trial selected. A large number of physicians and nurses participated in our survey, which enabled us to compare the responses between them. Another study limitation is that we could not precisely measure the reception of the survey via email. To be conservative and to estimate the survey participation rate, we have included the number of emailed individuals in the denominator.

Conclusions

Our results show that health care workers' motivations to participate in prophylaxis trials in an acute pandemic context appear to be driven mostly by their desire to contribute to science and obtain some health benefits. When the opportunity to participate in various trials is offered, safety markedly outweighed efficacy among the participants. Most participants opted to participate in one study over the other for safety reasons, having selected the trial they perceived as less risky, even if they consider it less efficacious.

Authors' Contributions

AMB, AJC, JRA, and IGG conceptualized the study. IGG, JF, and ER designed the study. AMB, AJC, and IGG analyzed the data. LDG, ARM, LMS, JMV, ESM, and JJG performed the investigation. IGG curated the data. AMB and IGG drafted the

manuscript. AJC and JRA reviewed and edited the manuscript. All authors have read and approved the published version of the manuscript.

Abstract

Background: Sending emergency messages via mobile phone text messaging can be a promising communication tool to rapidly disseminate information and promote preventive behavior among the public during epidemic outbreaks. The battle to overcome COVID-19 is not yet over; thus, it is essential that the public practices preventive measures to prevent the spread of COVID-19.

Objective: This study aimed to investigate the effectiveness of reading and obtaining information via emergency alert SMS text messages and their effects on the individual's practice of preventive behaviors during the early stages of the COVID-19 outbreak in South Korea.

Methods: A cross-sectional web-based survey comprising 990 participants was conducted over 3 days (March 25-27, 2020). A multivariable logistic regression analysis revealed the sociodemographic factors that might influence the behavior of reading emergency alert text messages. A hierarchical linear regression model estimated the associations between reading emergency alert text messages for each precautionary behavior practiced against COVID-19. Additionally, the indirect effects of reading the text messages on each precautionary behavior via psychological factors (ie, perceived risk and response efficacy) were calculated. All data were weighted according to the 2019 Korea census data.

Results: Overall, 49.2% (487/990) of the participants reported that they always read emergency alert text messages and visited the linked website to obtain more information. Factors such as female sex (odds ratio [OR] 1.68, 95% CI 1.28-2.21) and older age (30-39 years: OR 2.02, 95% CI 1.25-3.28; 40-49 years: OR 2.84, 95% CI 1.80-4.47; 50-59 years: OR 3.19, 95% CI 2.01-5.06; 60 years and above: OR 3.12, 95% CI 2.00-4.86 versus 18-29 years) were identified to be associated with a higher frequency of reading the text messages. Participants who always read the text messages practiced wearing facial masks (β=.074, P=.01) more frequently than those who did not. In terms of social distancing, participants who reported they always read the text messages avoided crowded places (β=.078, P=.01) and canceled or postponed social gatherings (β=.103, P<.001) more frequently than those who did not read the text messages. Furthermore, reading text messages directly and indirectly affected practicing precautionary behaviors, as the mediation effect of response efficacy between reading text messages and practicing preventive behaviors was significant.

Conclusions: Our findings suggest that emergency alert text messages sent to individuals' mobile phones are timely and effective strategies for encouraging preventive behavior in public. Sending emergency alert text messages to provide the public with accurate and reliable information could be positively considered by the health authorities, which might reduce the negative impact of infodemics.

Introduction

In recent years, mobile technology and text messages have emerged as a promising communication tool to rapidly disseminate information during several emergencies [1-3]. There is a widespread use of and access to smartphone and mobile devices, with mobile phone technology penetration at nearly 100% worldwide. South Korea has among the highest ownership percentages (94%) [4]. Their improved geolocation capacity and access to broadband and satellite communication infrastructure have enabled emergency alert SMS text messages to be sent to end users directly [5]. One of the attractive features of mobile text communication for emergency communication is the ability to target text messages to all phones in a specific location very quickly [6,7], making such communication highly efficient. Moreover, unlike some other media sources, readers can read, reread, and analyze the information provided via text messages [8]. A previous study in the United Kingdom suggests that a system that sends emergency messages via mobile phone text messaging would be generally well accepted by the public and likely to improve uptake of protective behaviors when combined with other approaches [9].

After the outbreak of Middle East Respiratory Syndrome (MERS) in 2015, South Korea passed the Framework Act on the Management of Disasters and Safety. This Act established disaster and safety management systems for state and local governments and prescribed matters necessary for disaster management to protect citizens' lives, bodies, and properties. The Act included new regulations for emergency management and response to improve safety, such as requiring owners or managers of telecommunication facilities' preferential capacity to forecast, alert, notify, or undertake other emergency measures concerning a disaster when necessary. The central and local governments of South Korea have sent emergency alert text messages to the public during the COVID-19 outbreak. In general, emergency alert text messages include two types of content. In the first type, the central government sends persuasive messages, encouraging individuals to take preventive measures. In the second type, local governments also recommend precautionary behaviors but mostly send risk information such as the number of confirmed cases in the residence area, contact tracing of confirmed cases, and closure of certain places. Examples of text messages sent to the public in March 2020 are shown in Table 1.

Table 1. Examples of emergency alert text messages sent to the public during the COVID-19 pandemic.

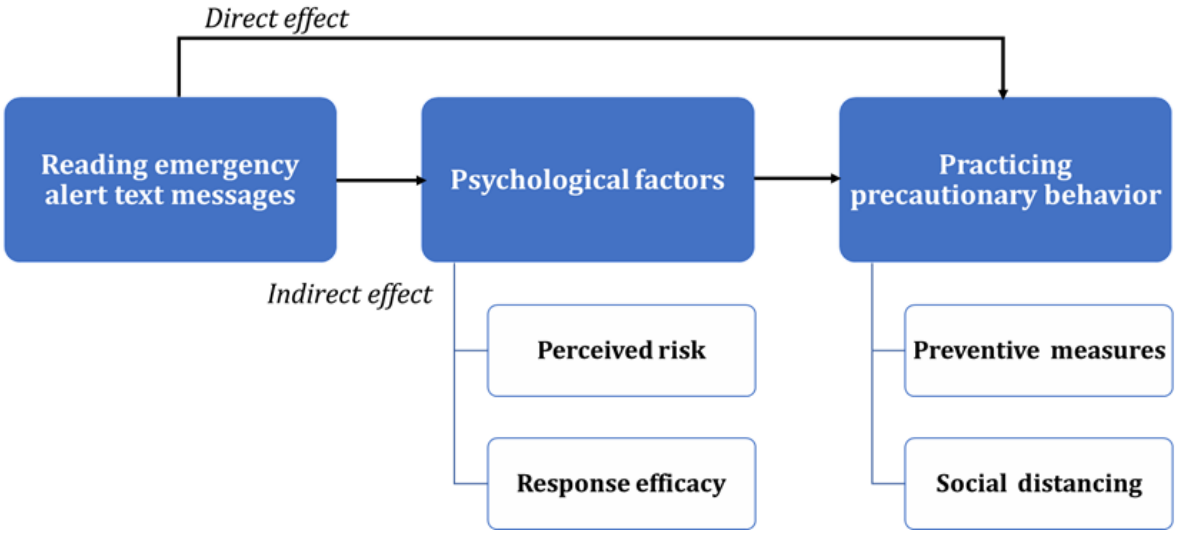
The battle to overcome COVID-19 is not yet over. Therefore, nonpharmaceutical interventions such as wearing facial masks and practicing social distancing are critical. Efforts to sustain and elevate these practices by the public are among the most important goals of public health authorities. Effective public health risk communication about the outbreak and guidance on how to respond can alleviate the negative impacts of the public health emergency and save lives [12]. There can be negative consequences if the public does not practice preventive behaviors quickly enough [13]. Thus, public health education and public health policies should be implemented so that "social learning," which may be described as the collective effects of communication efforts, can take place since the public is one of the most critical stakeholders in combatting the outbreak [13,14].

Successful emergency communication is determined by how quickly or reliably a message can be disseminated and how people respond to the information they receive [15,16]. Emergency alert messages have no benefit unless the readers read the message and follow the provided guidelines. Therefore, understanding why people accept or resist responding to warning and alert messages is essential. Some researchers have proposed decision models that could harmoniously explain recipient behaviors in response to emergency alerts [17-20]. These models include protective action decision-making [18], protection motivation theory [20], person-relative-to-event theory [21], and the theory of planned behavior [17]. According to the protection motivation theory, threat appraisal depends on individual perceptions of disease severity (ie, evaluating the state of the environment and observing what happens to others) and the individual's susceptibility. A coping appraisal is driven

by the efficacy belief, which comprises perceived response efficacy (ie, the belief that the recommended behavior will protect) and self-efficacy (ie, the ability to perform the recommended behavior). We examined two psychological concepts by adopting the protection motivation theory to explore preventive behaviors among individuals—perceived risk and response efficacy.

In this study, we investigated the effectiveness of reading and obtaining information from emergency alert text messages and their effects on the individual's preventive behaviors during the COVID-19 outbreak in South Korea. First, we examined the extent to which people read the text messages and identified sociodemographic factors that contribute to this behavior. Second, we determined whether the individuals responded to these messages by investigating the direct effect of reading text messages on practicing preventive behaviors. Finally, we examined whether the effect of reading text messages on practicing precautionary behaviors was mediated via psychological factors by investigating indirect effects through perceived risk of COVID-19 infection and response efficacy of each behavior. The framework of this study was constructed as shown in Figure 1. To our knowledge, most previous studies evaluating the effect of emergency alert text messages depended on behavioral intentions, mainly in hypothetical emergencies [9,22-24]. These previous studies are limited because behavioral intent in hypothetical situations may not accurately predict behavioral responses in actual situations [25,26].

Figure 1. Framework used in this study.



Methods

Study Design and Sampling

A cross-sectional web-based survey design was adopted to (1) evaluate preventive behaviors of the public and (2) assess whether they read emergency alert text messages during the COVID-19 pandemic, by using an anonymous questionnaire. The survey was conducted via a web-based platform developed by a research company called Korea Research. The company recruited respondents by sending survey invitations containing general information about the survey, such as its aim and consent statement via email or text messages, to registered survey panel members who met the inclusion criteria. The inclusion criteria were as follows: (1) aged 18 years or older, (2) a resident of South Korea, and (3) a Korean speaker.

The recruiting company sampled respondents using a proportional quota sampling process based on age, sex, and geographic region. The respondents were asked to provide electronic informed consent on the first page of the survey. Korea Research is responsible for protecting the confidentiality of the anonymous survey respondents. Over 1000 participants completed the surveys, of which 990 were included in the analysis after excluding incomplete responses. The participation rate was 62.5%, which is assumed to be acceptable for web-based surveys [27-29]. The present study protocol was reviewed and approved by the Institutional Review Board at Seoul National University (IRB No. 2003/002-005), Seoul, South Korea. All participants, upon enrollment, provided their informed consent. The data collection took place over 3 days (March 25-27, 2020), about 2 months after the Korea Centers for Disease Control and Prevention confirmed the first case of COVID-19 during the early stage of the pandemic and just before 10,000 confirmed cases had been reported (ie, on April 3, 2020).

Measurements

Dependent Variables

Outcome variables were precautionary behaviors related to the threat of COVID-19. They were classified into one of two categories: (1) preventive measures (eg, wearing facial masks and practicing hand hygiene) and (2) social distancing behaviors (eg, avoiding crowded places and postponing or canceling social events). Participants self-reported the frequency of the actions they undertook during the previous week by using a 4-point Likert-type scale (1=never, 2=sometimes, 3=often, and 4=always).

Independent Variables

Whether the participants read COVID-19 emergency alert text messages was assessed by the following question: “Do you read the COVID-19 emergency alert text messages received?”

Participants responded by choosing one of four options: “I never read the messages” (score=1); “I rarely read the messages” (score=2); “I read the messages occasionally and visit the linked website if necessary” (score=3); or “I always read the message and visit the linked site to get more information” (score=4). Participants who reported they never or rarely read these text messages were also asked why. They were then grouped into binary groups to reduce the likelihood of low content validity due to the survey item; these groups included two behaviors: reading the message and visiting the linked website. The binary groups consisted of (1) participants who always read the text messages and visited the linked website to get more information (score=4) and (2) those who do not (score=1 for “always” and score=0 for “otherwise”).

Among the psychological factors, perceived risk of COVID-19 infection comprised (1) perceived susceptibility, signifying an individual's beliefs about their possibility of infection, and (2) perceived severity, signifying the seriousness of infection [30]. Participants were asked, “What do you think is the possibility of you contracting COVID-19 infection?” and “What do you think will be the severity if you are infected with COVID-19?” Responses were rated on a 5-point Likert-type scale, with responses ranging from “very low” (score=1), “neither low nor high” (score=3), to “very high” (score=5). To promote response efficacy, participants answered the question, “To what extent do you think the precautionary behavior is an effective way to reduce the risk of COVID-19 infection?” for each behavior examined in this study [31]. Their responses were rated on a 4-point Likert-type scale, ranging from “not at all” (score=1) to “extremely” (score=4).

Sociodemographic factors included sex (score=1 for male, score=2 for female), age, and the presence of children younger than elementary school age at home (score=1 for more than 1 child, score=0 for no children). We also assessed the participants’ education level (score=1 for middle school or below, score=2 for high school graduate, score=3 for college and above) and monthly household income reported in their local currency (ie, KRW: score=1 for below KRW 2 million [US $1800], score=2 for KRW 2-3.99 million [US $1800-3600], score=3 for KRW 4-5.99 million [US $3600-5400], and score=4 for KRW 6 million [US $5400] or above). We collected information about the participants’ occupation and whether they were employed, as well as the presence of underlying disease. We also asked the participants to report any diagnoses for the underlying diseases (eg, hypertension, dyslipidemia, diabetes, chronic cardiac disease, asthma, and cancer). We then grouped the participants based on with or without a diagnosis for one or more underlying diseases.

Covariates

Other measures associated with the exposure to COVID-19–related alert text messages in other information channels served as covariates in the hierarchical linear regression analysis. Media exposure was measured by the following question: “In the past week, how often did you use media every day to learn about the news?” with answers ranging from “never” (score=1) to “quite often” (score=4). Additionally, we measured the variable of obtaining COVID-19–related information. Participants rated the following questions on a 4-point Likert scale: “Did you actively search for information about COVID-19 during the last week?” with responses ranging from “never” (score=1) to “very often” (score=4).

Statistical Analysis

All data were weighted by age, sex, and geographic region distributions in South Korea, according to the Korean Statistical Information Service (2019) [32]. The sampling weights were provided by Korea Research, the company that conducted the survey, by using a random iterative method weighting process, in which each participant was assigned a single weight value. Sampling weights were incorporated into all analyses, and corresponding analytic methods were used. Sampling weights were based on all cases from the present study. Statistical analyses were conducted using R version 4.0.2 software (R Foundation for Statistical Computing). All quantitative variables are reported as absolute numbers with proportions (%) and mean values with SD.

The two groups for reading text messages included (1) those who always read and visited the linked website for more information and (2) those who did not. We measured group differences according to participants’ sociodemographic characteristics, psychological factors, and preventive behaviors, which were analyzed by a chi-square test or *t* test, as appropriate (Table 2). A multivariable logistic regression revealed which sociodemographic factors (eg, sex, age, educational level, monthly household income, employment status, presence of young children in the household, and presence of underlying disease) might influence emergency alert text message reading behavior.

Table 2. Characteristics of survey participants.

Variables	Participants (N=990)	Weighted[a] values (N=990)	Participants who read text messages		*P* value[b,c]
			Always (n=487)	Otherwise (n=503)	
Sociodemographic factors					
Sex, n (%)					
Male	475 (47.9)	491 (49.6)	209 (42.8)	282 (56.1)	<.001[b]

Hierarchical linear regressions were computed to estimate the role of reading emergency alert text messages toward each precautionary behavior practiced against COVID-19 by sequentially adding predictors into 3 blocks within each model. To control for the effects of covariates on the dependent variables, sociodemographic factors (ie, sex, age, education level, income level, occupation status, presence of children, and underlying disease), media exposure, and obtaining information were entered into block 1 as potential confounding factors affecting each type of precautionary behavior. Psychological factors such as perceived susceptibility, perceived severity, and response efficacy of each behavior were entered into block 2 of each model. Because we were primarily interested in the effects of reading emergency alert text messages beyond these covariates, predictor variables were subsequently entered into block 3 of each model. To determine whether reading text messages resulted in any significant increment in the amount of variance explained in practicing each precautionary behavior, *F* test statistics were evaluated to determine statistically significant R^2 changes in the explained variance (%) at each step of the analysis. Standardized β coefficients were examined for each variable, and variance inflation factor estimates for each hierarchical model were computed to ensure that tolerance estimates were below 0.10 and variance inflation factor estimates were less than 10.

Additionally, the indirect effects of reading the text messages on each precautionary behavior via psychological factors (ie, perceived risk and response efficacy) were calculated using PROCESS macro model 6 with 5000 bootstrap samples for SPSS (version 25; IBM Corp) [33]. The bias-corrected 95% CI values for each mediational path were obtained.

Results

Characteristics of Survey Participants

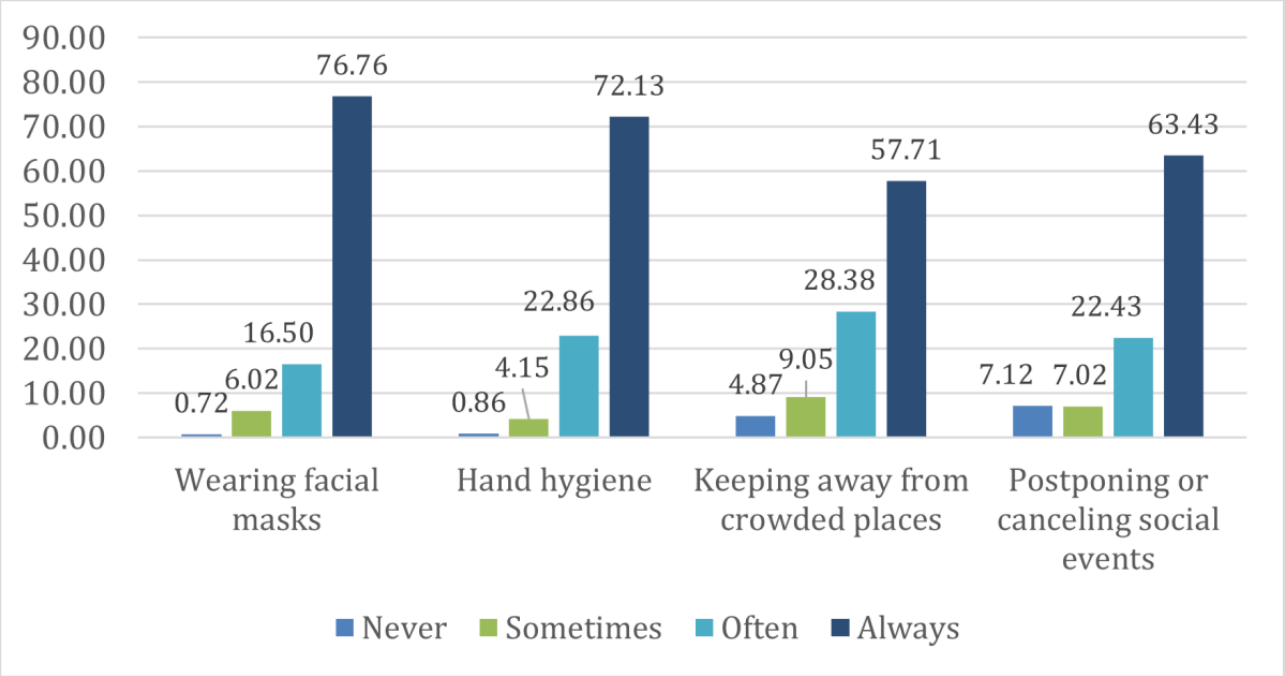
Among the 990 participants, 491 (49.6%) were men and 499 (50.4%) were women, with a mean age of 46.45 (SD 15.05) years. Most participants had received at least some college education (486/990, 49.1%), followed by those with a high school education (475/990, 48%). The most common monthly household income was approximately KRW 2-3.99 million (US $1800-3600), followed by more than KRW 6 million (US $5400) and KRW 4-5.99 million (US $3600-5400). With regard to their occupation status, 60.9% (602/990) of the participants were working, and 39.1% (387/990) were out of labor. Moreover, 9.7% (96/990) of the participants had young children at home, and 40.4% (399/990) of the participants reported having more than one underlying disease (Table 2).

Psychological Factors and Precautionary Behaviors Related to COVID-19

Participants' perceived risk of contracting COVID-19 infection was measured by a 5-point Likert scale, and the average perceived susceptibility was higher than "low" (score=2; mean 2.62, SD 0.84). Only 1.7% of the participants reported a perceived chance of infection as "very high" (score=5), and 8.7% of them reported it as "high" (score=4). The majority of participants (490/990, 49.5%) reported that their chance of infection was "neither high nor low." The average perceived severity score was higher than the perceived susceptibility score, which was close to "high" (score=4; mean 3.68, SD 0.93). However, 42.3% of the participants reported perceived severity as "high" (score=4), and 18.7% of them reported it to be "very high" (score=5). With regard to response efficacy, which was measured on a 4-point Likert scale for the four precautionary behaviors, the response efficacy of practicing hand hygiene was the highest (mean 3.77, SD 0.49), followed by that of canceling or postponing social events (mean 3.70, SD 0.57), wearing facial masks (mean 3.69, SD 0.54), and avoiding crowded places (mean 3.66, SD 0.58), as shown in Table 2.

The most frequently practiced precautionary behavior was wearing a facial mask when outside, for which 76.8% (760/990) reported they "always" practiced the behavior. For hand hygiene, such as washing hands frequently and using hand sanitizers, 72.1% (714/990) reported they "always" practiced the behavior. With regard to social distancing behaviors, postponing or canceling social events was the most practiced behavior (628/990, 63.4% reporting "always"), followed by avoiding crowded places (571/990, 57.7% reporting "always"), as shown in Figure 2.

Figure 2. Frequency of practicing precautionary behaviors in the past week (N=990).



Reading Emergency Alert Text Messages

For reading COVID-19–related emergency alert text messages, 49.2% (487/990) of the participants reported they *always* read the message and visited the linked website to obtain more information. Additionally, 40.3% (399/990) of the participants reported they read the message occasionally and visited the linked website if necessary, 8.4% (83/990) reported they rarely read the message, and 1.9% (21/990) reported they never read the message. Among those who reported they rarely or never read the emergency alert text messages (n=104), most reported not reading the messages because they were “sent too often” (73/104, 70.2%), followed by those who reported “did not want to know the information“ (12/104, 11.5%) or “did not need the information” (9/104, 8.6%).

A multivariable logistic analysis was performed to examine the factors that influence reading emergency alert text messages. Reading text messages was positively associated with female sex (odds ratio [OR] 1.68, 95% CI 1.28-2.21; $P<.001$) and older age (30-39 years: OR 2.02, 95% CI 1.25-3.28; $P<.001$; 40-49 years: OR 2.84, 95% CI 1.80-4.47; $P<.001$; 50-59 years: OR 3.19, 95% CI 2.01-5.06; $P<.001$; ≥60 years: OR 3.12, 95% CI 2.00-4.86; $P<.001$ versus 18-29 years). Men in their 20s comprised the primary sample group that ignored the emergency alert text messages (Table 3).

Factors Influencing Practicing Preventive Behaviors

Hierarchical linear regression models were used to test the association of factors influencing practicing preventive behaviors, including perceived risk and response efficacy, and reading emergency alert text messages (Table 4). For wearing facial masks, sociodemographic factors, media exposure, and information seeking (step 1) accounted for 7.4% of the variance and psychological factors (step 2) explained an additional 17.9% of the variance. Adding reading text messages as predictor variable (step 3) explained an additional 0.5% variance for the behavior wearing facial masks (F_{975}=26.05, P<.001). After adjusting for potentially confounding factors, reading text messages were found to be positively associated with wearing facial masks (β=.074, P=.012). Overall, the effect of response efficacy of practicing this behavior was found to be significant and the strongest (β=.431, P<.001). The positive effect of female sex (β=.108, P<.001) and younger age (β=−.064, P=.048) were also found to be significant.

[b]Not applicable.

For hand hygiene, sociodemographic factors, media exposure, and information seeking (step 1) accounted for 7.4% of the variance and psychological factors (step 2) explained an additional 17.8% of the variance. Reading text messages (step 3) did not account for significant additional variance in practicing hand hygiene ($\Delta R^{2=}$0.002, P=.09; F_{975}=25.618, P<.001). Response efficacy (β=.429, P<.001) was found to be significantly associated among the psychological factors. Furthermore, the coefficient of always reading text messages was not significant to practicing hand hygiene.

In terms of the social distancing behavior of keeping away from crowded places, sociodemographic factors, media exposure, and information seeking (step 1) accounted for 5.6% of the variance. Adding psychological factors (step 2) explained an additional 8.9% of the variance. Reading text messages (step 3) explained an additional 0.5% of the variance(F_{975}=13.253, P<.001). Among psychological factors, only response efficacy was found to be associated with the behavior of avoiding crowded places (β=.299, P<.001). Reading emergency alert text messages had a significantly positive effect, and participants who reported they always read text messages were more likely to practice avoiding crowded places (β=.078, P=.01).

For the social distancing behavior of cancelling or postponing social gatherings, sociodemographic factors, media exposure, and information seeking (step 1) accounted for 3.7% of the variance, and psychological factors (step 2) explained an additional 9.6% of the variance. Adding reading text messages as predictor variable (step 3) explained an additional 0.9% of the variance in wearing facial masks (F_{975}=12.425, P<.001). After adjusting for potentially confounding factors, reading text messages was found to be positively associated with canceling or postponing social gatherings (β=.103, P=.001). The effect of response efficacy of practicing this behavior was significant and the strongest (β=.306, P<.001), as shown in Table 5.

Mediation Effect of Psychological Factors Between Reading Text Messages and Practicing Preventive Behaviors

We examined the direct and indirect effects of reading text messages that were mediated via psychological factors such as perceived risk and response efficacy of practicing behaviors. When it comes to the recommended behavior, the direct and indirect effects of reading text messages on wearing masks was significant. For hand hygiene, only the indirect effect, mediated via response efficacy of the behaviors, was significant. Concerning social distancing, the direct and indirect effects of reading text messages mediated by the response efficacy of the behavior were also significant (Table 6). Therefore, this result confirms the significant effect of reading text messages on practicing precautionary behavior.

Table 6. Direct and indirect effects of reading emergency alert text messages on practicing preventive behaviors based on perceptions (eg, perceived susceptibility, severity, and response efficacy). Unstandardized point estimates represent the indirect effect of the independent variable on the dependent variable through the mediator.

Discussion

Principal Findings

In this study, the effects of reading emergency alert text messages on practicing preventive behaviors during the COVID-19 outbreak in South Korea were examined. Reading text messages was found to be related to all precautionary behaviors tested, including wearing facial masks, practicing hand hygiene, avoiding crowded places, and avoiding social gatherings. Reading text messages directly or indirectly affected practicing precautionary behaviors, as the mediation effect of response efficacy between reading text messages and practicing those behaviors was significant. Sociodemographic factors (eg, male participants in their 20s) were related to a lower likelihood of reading emergency alert text messages.

Several findings provide valuable insights to the public health management authorities to prevent and protect the population's health during an emerging infectious disease outbreak. First, our study results indicate that health risk communication via emergency alert text messages is efficient and effective for engaging the public in practicing preventive behaviors during public health emergencies. Participants who always read and visited the linked website practiced precautionary behaviors 1.48-1.80 times more frequently than other participants. This effect was significant, even when media use was included in the logistic model as a covariate. Early release of official guidelines and timely provision of information led by governments to guide the public on responding to emergencies is essential during public health emergencies [34,35]. Therefore, mobile phones, especially text messages, can be an effective means of communication to elicit the rapid response required by public health authorities.

The phenomenon of “infodemics,” defined as the rapid spread and amplification of vast amounts of valid and invalid information on the internet or through other media, is a tremendous and ongoing challenge on the COVID-19 pandemic [36,37]. Since the beginning of the COVID-19 pandemic, both the production and consumption of information have increased rapidly and significantly [9,12]. According to a study conducted in Korea, more than two-thirds of the participants reported exposure to COVID-19 misinformation between January and April 2020 [38]. Communication via emergency alert text messages can be an effective strategy for public health authorities to provide accurate and reliable information, confront misinformation or disinformation, and reduce the negative impact of such infodemics. Additionally, digital inequality, also known as the digital divide, is a significant concern among national and international scholars and policy makers, as internet access such as material, skills, and usage is not evenly distributed among the general population [39,40]. People can receive text messages on their mobile phones without using a smartphone or connecting to the internet. Therefore, text messages can be a communication tool to alleviate digital inequalities.

Second, some people rarely or never read text messages. The present study identified a subpopulation that does not pay attention to the text messages sent by the public health authorities. People often ignore the emergency warning and alert messages as initial responses are often marked by skepticism, disbelief, and denial [41-43]. Explanations for the lack of response include repeated, long-term exposure to a warning that may contribute to message fatigue and a loss of ability to capture and maintain the attention needed to elicit a response at later times [25,44-46]. Kuligowski and Dootson [35] proposed a 6-step process to process information and respond. These steps include (1) receiving the information, (2) paying attention to the message, (3) aiming to understand the information provided, (4) believing the threat presented by the message, (5) personalizing the presented risk to themselves or others, and finally, (6) deciding to take protective action and to respond based on the information received in the message

[19,35,47]. Their study indicates that a high level of attention to the provided information is essential for the recipient to move to the next step. Hence, convincing the public that reading emergency alert text messages can help guide them to better respond to public health emergencies is important.

Considering the COVID-19 emergency has lasted about a year and seems likely to continue for some time, more people will likely not pay attention to text messages in the future. Therefore, further research is needed to identify the reasons for not paying attention to text messages and investigate how to maintain interest. The content, length, frequency, and timing of the alert should be reviewed to maximize the effectiveness of emergency alert text messages. Moreover, people with limited literacy might resist to read or be attentive toward these text messages. Using a symbol and number-coded system that is easy to remember and interpret by the public, even among those with limited literacy, can be considered to address this challenge [48]. As communication can help reduce health inequalities derived from health communication [49], efforts to reduce vulnerability should also be implemented.

This study also identified a subpopulation that read alert text messages less frequently than others. Men in their 20s were the least likely to read the text messages they received. Infrequent reading of text messages by participants in their 20s might be because they are more proficient in using mobile technology and prefer obtaining information via online digital resources. However, their digital health literacy—the ability to evaluate health resources and apply gathered information to health-related decisions—was relatively low [38,50]. Therefore, young people have less opportunity to obtain official information from public health authorities and are more likely to be exposed to misinformation distributed online. This disparity can make them more vulnerable to the COVID-19 infodemic. Additionally, current practice in emergency alert text messages sends the same message, regardless of the recipient's demographic characteristics. To enhance the efficacy of text messages, tailored messages for each population and subgroups can be considered.

Finally, reading text messages in this study was mediated through heightened response efficacy of practicing behaviors rather than perceived risk. Moreover, response efficacy is one factor that has the strongest positive effect on practicing preventive behaviors [13,51,52]. Public health authorities and policymakers can consider making efforts to improve messages sent via texting to strengthen response efficacy on practicing preventive behaviors. For instance, investigating the unmet needs of health risk information and providing for them can be helpful. In other words, receiver-centered messages should be provided. We propose that future studies analyze the messages sent by texting to design more effective messages.

Implications

A set of implications for interventions, communication strategies, and future research can be drawn from the findings of this study. Governments, health agencies, and researchers should take advantage of mobile text messages by producing and sharing evidence-based and correct information, as well as recommending precautionary behaviors to the public. Public health authorities should pay careful attention to what messages are provided to the public. Based on the findings of this study, we believe that persuasive messages that target to improve response efficacy on recommended behaviors would be most useful.

Second, for effective text message communication, the public needs a moderate or higher trust level in the government and health authorities [48]. Successful risk communication and efficacy of policy recommendations depend not only on how quickly or reliably a message can be disseminated but also on the individuals' beliefs and subsequent response [6,15,16,53,54]. The first step in this process is the firm belief of whether the recommended action will mitigate the threat or manage the fearful situation [54].

Third, health authorities' efforts to provide transparent and credible information should be encouraged and sustained. South Korea has prior experience in managing outbreaks of infectious diseases such as the MERS outbreak in 2015, which resulted in significant damage to the Korean population, widespread distrust, and societal levels of high stress. Nevertheless, the MERS pandemic has provided many important lessons, especially the importance of information disclosure to the public [13]. In case of the MERS outbreak, the Korean health authorities' decision to disclose specific information, such as hospitals that were exposed to MERS-CoV, contributed to further prevention of the spread of infection during the outbreak [55].

Limitations

The present study has several limitations. First, variables in this study were assessed using a single-item questionnaire. Single items are less time-consuming, minimize participant burden, and prove beneficial to surveys that need to be done quickly to provide timely information. Single-item measures are argued to have comparable or equal predictive validity compared to multiple-item measures in some study areas [56]. However, this approach can be problematic because of the unknown biases in meaning and interpretation, and the internal consistency, as well as reliability statistics, cannot be tested. Therefore, additional studies using multi-item questionnaires should be performed.

Second, the participants did not all receive the same text messages. As shown in Table 1, the central governments' messages were the same for all of the population, and the contents were mostly about public health policy updates, persuading practice of precautionary behaviors. The messages sent from local governments usually covered more residence-specific risk information, such as reports of confirmed cases in the area, contact tracing of confirmed cases, and closure of certain places. This study was not designed to test the effect of specific messages, like previous experimental studies [57-59]. There is still a chance that differences in how people are primed might influence their preventive behaviors. Nevertheless, this study has the advantage of being conducted on many people in real-life situations. This study's results should be interpreted focusing on the effect of using emergency alert text messages as one of the information sources, rather than focusing on the effect of the content of the messages received.

Third, we did not explore self-efficacy in this study. Self-efficacy refers to the individual's level of confidence in preventing the risk and is an essential coping appraisal component [54,60]. Thus, further study to examine the influence of self-efficacy is suggested. Lastly, the participants ' characteristics, such as health literacy, government trust, or perceived credibility on the text messages, were not explored in this study. These variables may contribute to both whether and how messages were read and whether precautionary behaviors were practiced. The effects of these variables should also be examined in further study.

Conclusions

New information technologies, communication devices, apps, and social media for health risk communication are continually emerging. However, sometimes *oldies are goodies*, which this study implicates. The present study provides evidence that emergency alert text messages sent to an individual's mobile phone are efficient and an effective communication strategy for the sustainability of preventive behaviors among the public. Government and public health authorities should use text messages to provide the population with accurate and reliable information. This approach can reduce the negative impact of an infodemic by confronting misinformation or disinformation. At the same time, efforts to ensure people keep reading text messages should be implemented. This study provides critical and timely insights into how governments and public health authorities build appropriate health risk communications that do not overlook and lower their priorities for those in urgent need.

Acknowledgments

This work was supported by the National Research Foundation of Korea (BK21 Center for Integrative Response to Health Disasters, Graduate School of Public Health, Seoul National University); National Research Foundation of Korea Grant funded by the Korean Government (No. 21B20151213037); and Rainbow Communication and Consulting.

Authors' Contributions

LMJ and YMS conceptualized the study. LMJ was responsible for the methodology and conducted a formal analysis. YMS was responsible for data acquisition. LMJ wrote the initial draft of the manuscript, and YMS assisted with writing, review, and editing of the manuscript. Both authors have read and approved the final manuscript.

Abstract

Background: To control the COVID-19 pandemic, people should adopt protective behaviors at home (self-isolation, social distancing, putting shopping and packages aside, wearing face coverings, cleaning and disinfecting, and handwashing). There is currently limited support to help individuals conduct these behaviors.

Objective: This study aims to report current household infection control behaviors in the United Kingdom and examine how they might be improved.

Methods: This was a pragmatic cross-sectional observational study of anonymous participant data from Germ Defence between May 6-24, 2020. Germ Defence is an open-access fully automated website providing behavioral advice for infection control within households. A total of 28,285 users sought advice from four website pathways based on household status (advice to protect themselves generally, to protect others if the user was showing symptoms, to protect themselves if household members were showing symptoms, and to protect a household member who is at high risk). Users reported current infection control behaviors within the home and intentions to change these behaviors.

Results: Current behaviors varied across all infection control measures but were between *sometimes* (face covering: mean 1.61, SD 1.19; social distancing: mean 2.40, SD 1.22; isolating: mean 2.78, SD 1.29; putting packages and shopping aside: mean 2.75, SD 1.55) and *quite often* (cleaning and disinfecting: mean 3.17, SD 1.18), except for handwashing (*very often*: mean 4.00, SD 1.03). Behaviors were similar regardless of the website pathway used. After using Germ Defence, users recorded intentions to improve infection control behavior across all website pathways and for all behaviors (overall average infection control score mean difference 0.30, 95% CI 0.29-0.31).

Conclusions: Self-reported infection control behaviors other than handwashing are lower than is optimal for infection prevention, although handwashing is much higher. Advice using behavior change techniques in Germ Defence led to intentions to improve

these behaviors. Promoting Germ Defence within national and local public health and primary care guidance could reduce COVID-19 transmission.

Introduction

The impacts of COVID-19 must primarily be tackled through changes in behavior undertaken by individuals and societies until a vaccine becomes available. In many countries (including the United Kingdom), people with COVID-19 infection are instructed to remain at home, together with cohabiting family or other household members, to prevent transmission between households. This increases the risk of within-household virus transmission. For example, in several environments where interhousehold movement is well controlled (eg, Taiwan, Ningbo, and Shenzen [1-3]), the virus continues to proliferate within close contacts.

To interrupt these transmission pathways, individuals must adopt *personal protective behaviors* [4]. Such targeted behaviors include handwashing, disinfection of surfaces, thorough cleaning and waste disposal, social distancing within the home (where possible), and wearing situationally appropriate personal protective equipment. A recent cohort study in Beijing, China demonstrated that performing these behaviors could dramatically reduce the likelihood of household transmission, but the highest risk of transmission was prior to symptom onset (typically before such behaviors are performed) [5]. Therefore, protective behaviors should be implemented before any household members develop symptoms. There is substantial individual variation in these behaviors, which are complex, environmentally and culturally dependent, and influenced by individual attitudes and beliefs [6]. Changing such complex behaviors effectively and rapidly within the context of COVID-19 requires an approach based on behavior change theory, evidence, and extensive participatory input [7].

Specific guidance for the public on protective behaviors has been developed in many countries and is widely recommended by politicians, the media, and public health and primary care networks [8]. However, few behavioral interventions have been used to support the public in these behaviors within their homes. A systematic review by our group has found evidence of only one digital intervention to date (Germ Defence [9,10]) that demonstrably improved health outcomes in respiratory tract infections within households. Germ Defence is a mobile-friendly website that provides targeted, tailored advice about how and why users should use infection control behaviors, aiming to supplement public health guidance with evidence- and theory-based behavior change techniques [11], optimized using extensive user feedback. In a large randomized controlled trial of 20,066 people (the PRIMIT [Primary Care Randomised Trial of an Internet Intervention to Modify Influenza-Like Illness and Respiratory Infection Transmission] trial) during the previous H1N1 (swine flu) pandemic [12], those randomized to use Germ Defence had reduced frequency and severity of respiratory tract infections, and reduced transmission to household members. Germ Defence is a freely available resource, and the intellectual property is held by the University of Southampton.

Germ Defence was rapidly adapted for the COVID-19 pandemic by a team of medical, public health and behavior change experts, and public contributors. It was then disseminated through multiple pathways (primarily but not exclusively in the United Kingdom), including public health and primary care networks (eg, by texting the website link to patients via general practitioner practices), national and local press, television coverage, and social media.

In this study, we aim to:

1. Examine current infection control behaviors in UK households
2. Compare current infection control behaviors with intentions to change behavior after using Germ Defence to control infection transmission

Methods

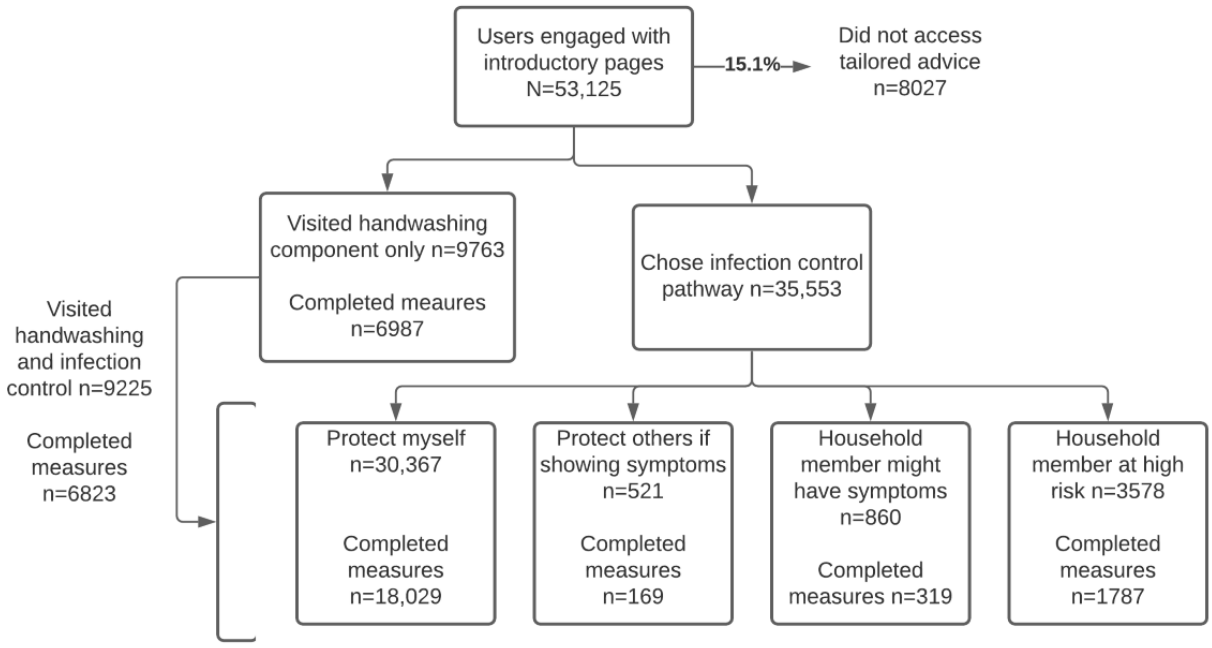
Design

This was a cross-sectional observational study of anonymous participant data from an active behavioral intervention. Consent was assumed from website use and acknowledged in the website privacy policy. All data was collected in line with General Data Protection Regulation EU Law. The study received ethical approval from the University of Bath (PREC reference 20-088). All time stamped data files used in analysis (and analysis scripts) are available at [13].

Participants and Data

The data analyzed were collected from users of the Germ Defence website between May 6 and May 24, 2020. Usage was driven by media coverage, and users were encouraged to share the intervention on social media and by email. During this period, 70,566 website hits were recorded, with 53,125 users completing the introductory content (first 3 pages) and 28,285 people completing the core module, which included measures of current and intended behavior. Website use and engagement data was collected using Google Analytics embedded in the site (see Figure 1 for full CONSORT [Consolidated Standards of Reporting Trials] use diagram).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram of Germ Defence website use and group categorization.



Data collection was kept to a minimum to reduce dropout. Behavioral measures were recorded through self-report questions within the website for current and intended behavior (see Table 1).

Table 1. Online self-report measures recorded during Germ Defence intervention

Behavior	Self-report item[a]
Reducing illness infection control	
Social distancing	When you were/are with them, how often were you/do you plan to be more than 2 meters/6 feet away from the people you live with?
Cleaning/disinfecting	How often did you/do you plan to clean things that might have viruses on them?
Putting shopping/packages aside	How often did you/do you plan to put something aside for at least 1 day that might have viruses on it?
Self-isolating	How often did you/do you plan to spend time in a room on your own?
Wearing face coverings	How often did you/do you plan to wear a face covering and glasses (and safely remove and clean them) when you are in the same room as other people?
Handwashing behavior	
Before snacking	How often did you/do you plan to wash your hands before you ate/eat with your fingers (eg, snack, fruit, or sweets)?
After coming home	How often did you/do you plan to wash your hands when you came/come into a house (eg, after work, shopping, travelling)?
After coughing	How often did you/do you plan to wash your hands after blowing your nose or sneezing/coughing on your hands?
After coming into contact with possible carrier	How often did you/do you plan to wash your hands after you had been/being close to someone who may have a virus (within 6 feet)?
After touching something	How often did you/do you plan to wash your hands after touching something that lots of other people have touched (eg, doors, money, or handrails)?
Website helpfulness (recorded on a scale of 1-10)	
Helpfulness score	How strongly do you agree or disagree that Germ Defence was helpful to you?

[a]Measures were all scored on a Likert scale with answers of 1 (almost never), 2 (sometimes), 3 (quite often), 4 (very often), and 5 (almost always). Users could also answer *not applicable* (eg, if they lived alone and therefore did not need to socially isolate within their household).

Intervention

Germ Defence content was developed using theoretical modeling and qualitative research [14] in line with the person-based approach [15], drawing principally on the theory of planned behavior [16], Leventhal's common sense model of illness [17], and protection motivation theory [18]. The intervention content, design, and structure were optimized iteratively using in-depth qualitative think-aloud interviews with public contributors (authors JB and CR) and members of the public to ensure the intervention was accessible, credible, and motivating for as many people as possible [15].

Based on process evaluations of the original randomized controlled trial [12] and a previous public dissemination [19], Germ Defence has been updated and streamlined for use during the COVID-19 outbreak, including broadening the infection control behaviors that were recommended. The intervention is a single session designed to be easily accessible with no sign-up or password required. Full details of the intervention structure and development are reported elsewhere [3,16,18,19] and archived copies are available at [20] (see Germ Defence v3). Intervention content was "frozen" during the reported data collection period. A structured outline of content is available in Textbox 1.

Textbox 1. A detailed outline of Germ Defence content and structure (note: the website and all associated content can be accessed for free).

Introductory content (3 pages)

- Introductory pages seek to increase users' perceived risk by emphasizing the personal and social health consequences of contracting COVID-19. These are followed by messages to increase skills and confidence to reduce exposure to the virus.

Website pathway selection (2 pages)

- To allow users to choose the advice they consider most personally relevant, the intervention is structured so that users initially select between two components of interest: handwashing and reducing Illness. The reducing illness component is tailored such that a user selects one of four streams of content (each lasting 11 pages) that is relevant to the user's situation: (1) to protect themselves generally, (2) to protect others if the user was showing symptoms, (3) to protect themselves if household member(s) showed symptoms, or (4) to protect a household member who is at high risk. The advice is tailored in this way to encourage users to adopt behaviors appropriate to the perceived level and pattern of risk in their household. For example, users in the protect themselves generally group would vary from very low to very high risk. It was not possible to provide specific tailored advice for every household combination of risks and resources (eg, based on the need and potential for household members to self-isolate within the home); therefore, Germ Defence aimed to educate users to adopt behaviors that were appropriate and feasible for their own circumstances.

Tailored infection control behavior advice (7 pages)

- Clear and detailed advice is then provided for self-isolating, social distancing, disinfecting/cleaning, wearing face coverings, and putting items aside that may have viruses on them such as shopping/packages. Advice is provided to the extent that users feel is appropriate for the perceived risk. These pages also contain ideas and information on how to structure the home and engage in behaviors safely. The handwashing component provides advice focused on handwashing that is relevant to all groups over 5 pages.

Goal-setting advice (3 pages)

- Both the handwashing and reducing illness components contain goal-setting sections where users indicate their behavior over the past week, view a motivational message, and then plan their behavior for the future. Users who do not select any improvement are encouraged to review their plan. After completing either the handwashing or reducing illness components, users are asked how helpful they found the website.

Additional information

- Users are then able to revisit the first two components, choose from two additional components with more detailed information about the same behaviors (eg, how to social distance with young children, how to stop touching your face), or view details about the website.

Statistical Analysis

We included data from all users who accessed the website during the study period.

For analysis, users were grouped according to the tailored website pathway they selected within the *reducing illness* component (*protect myself generally* vs *protect others if I am showing symptoms* vs *protect myself if a household member has symptoms* vs *protect a household member at high risk*). Users could also view the handwashing component, which was relevant to all groups. If they did not view *reducing illness*, they were not included in group comparisons, but handwashing responses were still recorded. Users could complete more than one type of tailored pathway, but we only analyzed responses for the pathway that was selected first.

To understand current infection control behaviors (aim 1), behavioral measures were analyzed individually and collapsed together to form an *average infection control behavior* score. When users completed a plan more than once (eg, if they received website feedback that their initial plan could be further improved), the *final* plan was used. If users did not think a behavior was relevant to them (eg, they lived alone so did not need to socially isolate or could not socially isolate from young children), they could answer *not applicable*. This was coded as missing data and not included in analysis. Linear regression compared between-group scores for behavior.

To compare current behaviors with intended behavior after using Germ Defence (aim 2), linear regression models comparing between-group scores for intentions controlled for current behavior were used. Paired *t* test comparisons examined the

difference between current behavior and intended behavior within groups.

Results

Use of the Germ Defence Website

We considered data from 53,125 users who completed at least the initial introductory website pages. Users accessed Germ Defence from 129 countries (a full CONSORT diagram of use is presented in Figure 1). The majority (n=44,446, 83.7%) of users were from the United Kingdom (England: n=40,164, 75.6%; Scotland: n=2204, 4.2%; Wales: n=1459, 2.8%; Northern Ireland: n=566, 1.1%; other: n=73, 0.1%). The mean use time was 8 minutes 28 seconds, and the mean number of pages viewed was 19.9. Of the recorded sessions, 54.1% (n=28,740) lasted longer than 1 minute. Over half (n=28,687, 54%) of the users accessed Germ Defence using a mobile device, 31% (n=16,469) accessed with a tablet, and 15% (n=7968) with a desktop or laptop computer. Only 10.6% (n=5631) of users were *return users* visiting for a second time. Aggregated use statistics for users outside the United Kingdom are provided in Multimedia Appendix 1. Detailed use for each website component is presented in Figure 1. The overall mean helpfulness of the website was rated as 7.77 (SD 2.31) out of 10.

Infection Control Behaviors and Intended Behaviors in Users of Germ Defence

All groups (protect themselves generally, protect others if the user was showing symptoms, protect themselves if household members were showing symptoms, and protect a household member who is high risk) reported using most current infection behaviors sometimes or quite often within the home. Overall, users reported they would wear a face covering almost never or sometimes (mean 1.61, SD 1.19) and would socially distance sometimes or quite often (mean 2.40, SD 1.22). Users reported socially isolating in their own room sometimes or quite often (mean 2.78, SD 1.29) and putting packages and shopping aside sometimes or quite often (mean 2.75, SD 1.55). Users reported cleaning and disinfecting quite often or very often (mean 3.17, SD 1.18).

Frequency of the five infection control behaviors from the *reducing illness* pathway within each group is reported in Table 2 (with handwashing reported in a separate table), as well as mean differences and 95% CIs of group comparisons (each group vs the *protect themselves generally* group). The frequency of behaviors did not vary appreciably between groups; numerically, the *protect themselves generally* group were least likely to socially distance (mean 2.39, SD 1.22). People in the *protect others if user showing symptoms* group were least likely to clean and disinfect (mean 2.95, SD 1.26) and put aside shopping and packages (mean 2.39, SD 1.48) but most likely to wear a face covering (mean 1.91, SD 1.36). People in the *protect themselves if household members showing symptoms* group were most likely to maintain social distance (mean 2.57, SD 1.23), and users in the *protect household members at high risk* group were least likely to stay in their own room (mean 2.64, SD 1.16) and least likely to wear a face covering (mean 1.42, SD 0.99).

Table 2 shows some small differences in how often participants planned to perform behaviors in the future (corrected for levels of current behavior) between groups. Compared to people in the protect themselves generally group, people showing symptoms planned to clean and disinfect, and put aside shopping less frequently, but they planned to self-isolate more frequently. People in the protect themselves from household member with symptoms group planned to socially distance and self-isolate more frequently than those in the protect themselves generally group. People looking to protect a high-risk household member planned to conduct all of the behaviors slightly more frequently than the protect themselves generally group.

Paired *t* test comparisons examined differences between current and planned behaviors after using the Germ Defence website. Mean difference scores for each group and 95% CIs are reported in Table 3. The difference between intended and current behavior was largest for cleaning and disinfecting (mean difference 0.38, 95% CI 0.37-0.39) and putting aside shopping and packages (mean difference 0.49, 95% CI 0.47-0.50), and was lowest for self-isolating (mean difference 0.15, 95% CI 0.14-0.16). Overall, infection control behaviors increased (mean difference 0.30, 95% CI 0.29-0.31).

Handwashing behavior is reported in Table 4. Mean current handwashing behavior was higher than other infection control behaviors (mean 4.04, SD 0.84) with reported intended behavior consistently higher (mean increase 0.41, 95% CI 0.40-0.42).

Table 2. Current and intended infection control behaviors.

Behaviors	Protect themselves generally (n=18,029)[a], mean (SD)	Protect others if user showing symptoms (n=169)			Protect themselves if household member showing symptoms (n=319)			Protect a household member at high risk (n=1787)

Discussion

Summary of Findings

Germ Defence was accessed by a large number of users across 129 countries, primarily from the United Kingdom. This demonstrates public interest in adopting appropriate infection control behaviors in the home during the COVID-19 pandemic. After using Germ Defence, all groups reported intentions to increase the frequency of their infection control behaviors, including handwashing.

Except for handwashing, self-reported infection control behaviors in the home were only reported *sometimes or quite often* regardless of whether people were seeking to protect themselves, concerned about demonstrating COVID-19 symptoms, had a household member showing symptoms, or were seeking to protect a high-risk household member. The frequency of wearing face coverings was consistently the lowest of the behaviors, while cleaning and disinfecting was the most frequently reported of the behaviors outside of handwashing. All of these infection control behaviors were reported to be performed much less frequently than handwashing.

As would be expected, certain behaviors and intentions varied according to the circumstances of groups; for example, people seeking to protect others when showing symptoms reported higher current frequencies of wearing face coverings, while people seeking to protect a high-risk household member reported the intention to socially distance within the home more frequently.

Comparison With Existing Literature

This study provides the first up-to-date analysis of infection control behaviors and intentions across the United Kingdom in a large sample during the COVID-19 pandemic. Within-household transmission will be increasingly important as infection control measures become established in external, public environments [6,21]. Therefore, understanding current

infection control behaviors within homes (and how to improve them) is vital to continue controlling the pandemic.

Self-reported infection control behaviors other than handwashing are lower than is optimal for infection prevention, even in Germ Defence users who were likely more motivated and willing to engage in protective behaviors than the general population (as they were seeking additional information) [22]. Increasing engagement in these behaviors is important as societal restrictions are released and perceived risk reduces [23].

Germ Defence users reported intentions to increase the frequency of infection control behaviors over their current rates. Although such intentions potentially misrepresent the observed behavioral change after an intervention (the *intention-behavior gap* [24]), our evidence suggests that Germ Defence may overcome this. Analysis of comparable data from the PRIMIT trial handwashing intervention showed slightly smaller behavior and intention differences (Cohen d=0.45). This change was sufficient to cause reduced infection transmission and severity within households after 16 weeks [12]. Comparable data during the current pandemic (reducing illness behaviors: Cohen d=0.53; handwashing: Cohen d=0.50) shows a slightly larger effect across a broader range of behaviors that may have a larger impact on infection rates.

Study Limitations

As a cross-sectional observation of an active intervention, Germ Defence lacks longitudinal follow-up. Care must be taken when interpreting findings within the rapidly changing context of the COVID-19 pandemic. Our method of categorization using website pathways may not be accurate for some users or might overlook individual differences within categories.

Our data may not be a representative sample from the wider UK population for several reasons. First, users of Germ Defence are likely to be more motivated and report higher frequencies of infection control behaviors. Second, although analytic data indicates that the large majority of the intervention's users were from the United Kingdom, we could not identify non-UK users within behavioral data. Finally, self-reported infection control behaviors may not be accurate reflections of actual behaviors occurring within households.

However, none of these limitations affect our main findings; indeed, people are prone to overreport protective behaviors, further highlighting the need for improvement.

Implications for Practice and Research

A concerted effort to improve household infection control behaviors across the UK population is likely to be an efficient use of health resources, both to reduce current rates of infection and to prevent the likelihood and severity of future outbreaks. Handwashing behaviors are already relatively high—perhaps due to existing familiarity with the behavior supported by a focus in public health advice on increasing handwashing in earlier stages of the pandemic. Therefore recommending digital interventions such as Germ Defence to target other infection control behaviors within the home may help control the current pandemic.

Given the current rates of infection control behaviors within the home even within a motivated sample, it is vital to address barriers to engaging in them. For example, people living in crowded, working households are more likely to come into contact with the virus [5] and may find it difficult to self-isolate. Similarly, cultural differences, financial challenges, or caring responsibilities may cause barriers to social distancing [6]. Research should explore how to support these behaviors for as many households as possible. Indeed, digital interventions such as Germ Defence can use tailored content to target behaviors that are relevant for specific user groups.

Conclusion

Our findings show substantial room for improvement in protective behaviors across the United Kingdom—even in our motivated, self-selected sample—as societal restrictions are eased. People are not sufficiently self-isolating within the home to prevent household transmission, even when a household member or the individual themselves are demonstrating COVID-19 symptoms. Promoting evidence-based behavior change interventions might improve these behaviors, reducing transmission within households and the incidence and severity of infections.

Germ Defence is a scalable, evidence-based, acceptable, and free public health intervention with negligible safety risk, which could be included in public heath guidance and promoted via primary care networks at minimal cost for wide population coverage.

Acknowledgments

We thank all who have supported and disseminated Germ Defence, including the University of Bath (Andy Dunne) and the National Institute for Health Research (NIHR) Bristol Health Protection Research Unit (Helen Bolton and Clare Thomas). We thank all who have assisted in the translation of Germ Defence into other languages [9]. We also thank the many citizen scientists and public contributors who assisted in the development of the Germ Defence intervention.

The study was funded by the United Kingdom Research and Innovation (UKRI)/Medical Research Council Rapid Response Call: UKRI CV220-009.

The Germ Defence intervention was hosted by the Lifeguide Team, supported by the NIHR Biomedical Research Centre, University of Southampton. LY is a NIHR Senior Investigator and theme lead for University of Southampton Biomedical Research Centre. LY and RA are affiliated to the NIHR Health Research Health Protection Research Unit in Behavioural Science and Evaluation of Interventions at the University of Bristol in partnership with Public Health England. MW is an NIHR Academic Clinical

Lecturer, under grant CL-2016-26-005. The views expressed are those of the authors and not necessarily those of the National Health Service, the NIHR, the Department of Health, or Public Health England. Abstract

Background: During a pandemic, it is important for clinicians to stratify patients and decide who receives limited medical resources. Machine learning models have been proposed to accurately predict COVID-19 disease severity. Previous studies have typically tested only one machine learning algorithm and limited performance evaluation to area under the curve analysis. To obtain the best results possible, it may be important to test different machine learning algorithms to find the best prediction model.

Objective: In this study, we aimed to use automated machine learning (autoML) to train various machine learning algorithms. We selected the model that best predicted patients' chances of surviving a SARS-CoV-2 infection. In addition, we identified which variables (ie, vital signs, biomarkers, comorbidities, etc) were the most influential in generating an accurate model.

Methods: Data were retrospectively collected from all patients who tested positive for COVID-19 at our institution between March 1 and July 3, 2020. We collected 48 variables from each patient within 36 hours before or after the index time (ie, real-time polymerase chain reaction positivity). Patients were followed for 30 days or until death. Patients' data were used to build 20 machine learning models with various algorithms via autoML. The performance of machine learning models was measured by analyzing the area under the precision-recall curve (AUPCR). Subsequently, we established model interpretability via Shapley additive explanation and partial dependence plots to identify and rank variables that drove model predictions. Afterward, we conducted dimensionality reduction to extract the 10 most influential variables. AutoML models were retrained by only using these 10 variables, and the output models were evaluated against the model that used 48 variables.

Results: Data from 4313 patients were used to develop the models. The best model that was generated by using autoML and 48 variables was the stacked ensemble model (AUPRC=0.807). The two best independent models were the gradient boost machine and extreme gradient boost models, which had an AUPRC of 0.803 and 0.793, respectively. The deep learning model (AUPRC=0.73) was substantially inferior to the other models. The 10 most influential variables for generating high-performing models were systolic and diastolic blood pressure, age, pulse oximetry level, blood urea nitrogen level, lactate dehydrogenase level, D-dimer level, troponin level, respiratory rate, and Charlson comorbidity score. After the autoML models were retrained with these 10 variables, the stacked ensemble model still had the best performance (AUPRC=0.791).

Conclusions: We used autoML to develop high-performing models that predicted the survival of patients with COVID-19. In addition, we identified important variables that correlated with mortality. This is proof of concept that autoML is an efficient, effective, and informative method for generating machine learning–based clinical decision support tools.

Introduction

Many regions worldwide are still fighting the first wave of the COVID-19 pandemic, while other areas that have reopened are experiencing a resurgence of cases [1]. During such an emergent situation, it is important for clinicians to effectively and efficiently triage patients. In recent months, studies have proposed several machine learning models that can accurately predict COVID-19 disease severity. Many of these studies have been successful in generating a high-performing model [2-4]. However, until now, these models have only been trained on one kind of machine learning algorithm, and many researchers have limited the evaluation of their models' performance to area under the curve (AUC) analysis. Studies have either not reported areas under the precision-recall curve (AUPRCs) or have only reported low AUPRCs. Furthermore, these studies have been difficult to replicate due to hyperparameter tuning. The automation of machine learning end-to-end processes has allowed for the development of simple, fast, and easy-to-replicate models that often outperform manually designed models. This study was designed to (1) optimize the performance of predictive models by using automated machine learning (autoML) to generate various machine learning models and automate hyperparameter optimization; and (2) choose the best performing machine learning model based on AUPRCs.

Artificial intelligence (ie, machine learning) models have often been criticized for being black-box models. We tried to stare into this so-called "black box," identify the variables that drive model performance, and understand the extent of these variables' effects on model performance. The interpretability of models is crucial in medical environments; for results to be widely accepted, they must be explainable to medical providers. To assess the correctness of a model, clinicians must be able to use their intuition. Therefore, a model's response must be understandable to clinicians and comparable to biologically plausible expectations.

In this study, we aimed to generate multiple machine learning models, assess their performance, and select the highest-performing model. After ranking variables by importance, we chose the top 10 most influential variables and retrained the autoML models to generate new models that only used these 10 variables. This was done to create high-performing models with low dimensionality. In addition, we sought to provide interpretable black-box model results to clinicians and patients. Finally, the COVID-19 mortality calculator, which is based on this study, was developed and freely available online as a web application [5].This study provides proof of concept that autoML is an efficient, effective, and informative method for building machine learning–based clinical decision support tools.

Methods

Variable Selection and Collection

After conducting a literature review, we selected 48 variables for generating high-performing machine learning models. These variables included demographics such as gender; race; age; comorbidities; physical signs/symptoms; and laboratory test results, such as ferritin, interleukin-6, tumor necrosis factor-α, D-dimer, C-reactive protein, and lactic dehydrogenase (LDH) levels [2-4, 6-12].

Data collection and analysis were approved by the Albert Einstein College of Medicine Institutional Review Board. The data were collected by using Clinical Looking Glass (CLG), which is an interactive software application that was developed at the Montefiore Medical Center. This application is used to evaluate health care quality, effectiveness, and efficiency. CLG integrates clinical and administrative data sets, thereby allowing clinicians to build temporally sophisticated cohorts and assess outcomes [13-16].

We queried the CLG database for patients who were aged >18 years, tested positive for COVID-19 (ie, confirmed with a nasopharyngeal specimen and real-time polymerase chain reaction) within 24 hours before or after admission, and were admitted to our institution from March 1 to July 3, 2020. The index time was when a patient tested positive for COVID-19 based on their real-time polymerase chain reaction results. We investigated a total of 48 variables and used the earliest values that were available within 36 hours before or after the index time. The outcome of interest was mortality from any cause within 30 days after the index time.

Model Development and Evaluation

We used the open-source H2O.ai autoML package for the R language [17-19]. The package can be downloaded to a local device. This allowed us to avoid uploading patient data to a third-party cloud service. The H2O.ai autoML package trains and cross-validates common machine learning algorithms, such as gradient boosting machine (GBM), extreme gradient boosting (XGBoost), general linear models (GLMs), random forest (RF), and deep learning (DL). In addition, the package trains two types of stacked ensemble models—one based on all previously trained models and another based on the best model of each model family. Additional information on how each model was built and which hyperparameters were tuned via autoML can be found in documentation that is provided by H2O.ai [18,19].

We used the 10-fold cross-validation method to train the autoML model on a randomly selected data set that included 80% of the original data. We then used the trained autoML model to generate 20 models and rank them in order of performance (ie, AUPRC). These 20 models were based on the remaining 20% of the original data set.

The AUPRC is a measure of a model's predictive performance, which is based on the relationship between the positive predictive value (PPV) for the outcome (ie, death; y-axis) and the model's sensitivity for detecting patients who actually die (ie, x-axis). For reproducibility, we did not use the DL method and trained each model separately. For convenience, we named the best model that was generated with 48 variables MODEL-48. After creating Shapley additive explanation (SHAP) and partial dependence (PD) plots to evaluate MODEL-48, we selected the 10 most influential variables. We used these 10 variables to repeat model training, model ranking, and the selection of the best performing autoML-generated model. For convenience, we named the best model that was generated with these 10 variables MODEL-10.

To further evaluate MODEL-48 and MODEL-10, we generated a binary classifier (ie, dead or alive within 30 days). We chose a threshold probability that maximized the F2 score of each model. Unlike the F1 score, which gives equal weight to precision (ie, PPV) and sensitivity (ie, recall), the F2 score gives more weight to sensitivity and penalizes a model for generating more false negatives than false positives. As our goal was to identify patients who were at a high risk of death (ie, patients who need more attention and further intervention), our model's metric of success was based on enhancing its sensitivity for detecting patients who were at risk of death. However, this came with the drawback of overcalling death as a predicted outcome. Sensitivity, specificity, PPVs, and negative predicative values (NPVs) were calculated for each binary classifier. The F-score calculation formula was as follows:

In this formula, to calculate the F2 score, β must equal 2.

Opening the Black Box: Intuitive Understanding of Model Variable Utility

Once a model determined the most important variable in its internal black box, we used SHAP and PD plots to develop our understanding of the black box. A SHAP plot displays variables in a top-to-bottom format; the most important variable is displayed at the top and the least important variable is displayed at the bottom. Variable importance is determined by the model in question. In this study, SHAP values (ie, x-axis) were indicative of the relative contribution of each patient's variable values (eg, a systolic blood pressure of 50 mmHg) to the overall prediction of a patient's mortality. SHAP values of >0 on the x-axis were indicative of variables that contribute to a greater chance of mortality, and SHAP values of <0 were indicative of variables that contribute to a lower chance of mortality. In our SHAP plots, each patient was represented by a dot on a horizontal line (ie, a line for each variable). Each dot's color reflected patients' variable values, which were scaled to a normal, color-coded distribution (ie, red indicates large values and blue indicates small values) [20].

A PD plot is a graphical depiction of a variable's marginal effect on the predicted outcome (ie, mortality). The effect of a variable was measured with mean response values. In this study, mortality had a response value of 1, which indicates a 100% chance of dying. A PD plot can show whether the relationship between a target and a feature is linear, monotonic, or complex [21].

Choosing the Top 10 Most Important Variables: Dimensionality Reduction

Dimensionality reduction is an important process in machine learning model development. Sometimes, the variables in a model correlate with each other, making them redundant variables (ie, blood urea nitrogen [BUN] level, creatinine level, and estimated glomerular filtration rate are all indicators of renal function). If we could generate a model with a low number of unique variables, we would be able to shorten computation times in real clinical settings. In addition, dimension reduction allows models to overcome data sparsity by using variables that have more data points. Furthermore, by identifying the top 10 most important variables, clinicians can focus on ordering medical tests instead of obtaining data on 48 variables, and machine learning developers can have fewer concerns about handling missing values.

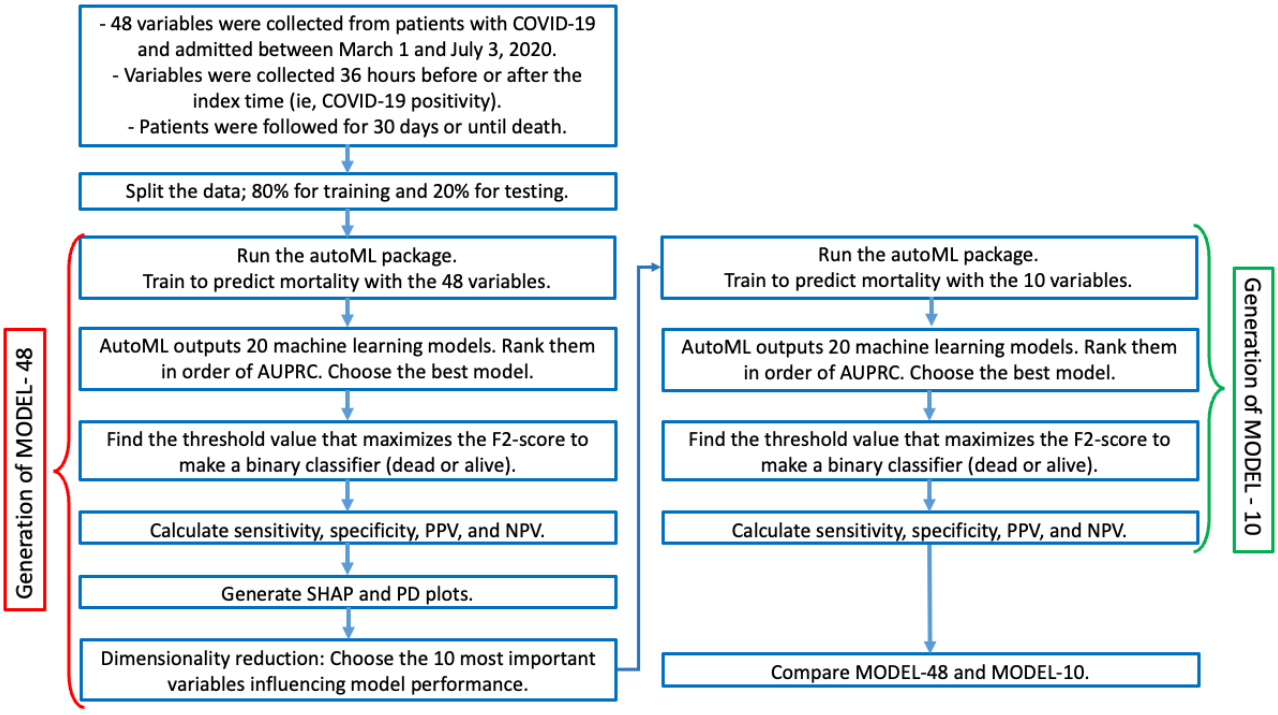
In this study, after evaluating SHAP and PD plots, we chose the 10 most influential variables for generating MODEL-10 (ie, a model that requires only 10 input variables to predict mortality). We first ranked each variable's influence according to the SHAP values in the highest-performing models. Afterward, we chose variables that were influential in these models. Subsequently, if the rank of a variable was not the same in each model, we chose variables based on clinical insights. Clinically speaking, we wanted at least one unique variable for each biological process (ie, cardiac processes, renal processes, coagulation processes, etc). If there was more than a single variable for describing the same clinical domain or biological process (ie, troponin and probrain natriuretic peptide levels), we chose the variable with the fewest number of missing data points (ie, variables that are commonly ordered by clinicians).

Handling Missing Values

Different autoML models have different methods for handling missing values. For example, in a tree-based model (ie, GBM, XGBoost, RF models), missing values are interpreted as data that contain information (ie, data that are missing for a reason) instead of data that are missing at random. During tree building, split decisions are made at every node. Each decision is based on the option that minimizes the loss of model functionality and treats missing values as a separate category. This category is then used as the basis for another split decision. Alternatively, GLMs and DL models use the mean imputation method to handle missing values. Further explanations for how each model imputes missing values can be found in documentation that is provided by H2O.ai [18].

The workflow of our study design is depicted in Figure 1.

Figure 1. Flowchart summary of our methodology. AutoML: automated machine learning; AUPRC: area under the precision-recall curve; NPV: negative predictive value; PD: partial dependence; PPV: positive predictive value; SHAP: Shapley additive explanation.



Data Access, Responsibility, and Analysis

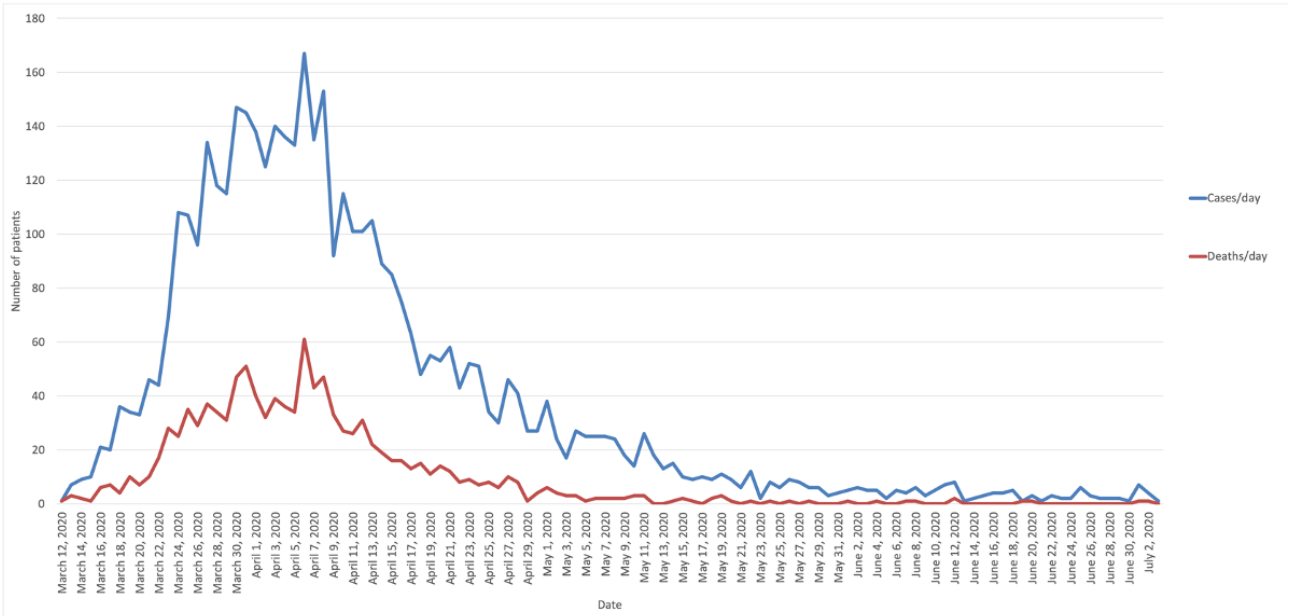
KI had full access to all the data in this study. KI takes responsibility for the integrity of the data and the accuracy of the data analysis.

Results

Study Population

Between March 1 and July 3, 2020, 4313 adult patients tested positive for COVID-19 and were admitted to a Montefiore Health System hospital within 24 hours of their first COVID-19–positive test. Of these 4313 patients, 1087 (25.2%) died within 30 days of infection (Figure 2).

Figure 2. A graph that shows the number of patients who were admitted to the hospital due to SARS-CoV-2 infection (ie, blue line; number of cases per day) and the number of patients who died (ie, red line; number of deaths per day). Data were collected from March 1 to July 3, 2020 at the Montefiore Medical Center.



A summary of case data, patients' survival rates, and patients' demographic characteristics is shown in Table 1. The training set consisted of 3468 patients, and the test set consisted of 845 patients. Summaries of the variables for the entire cohort, the training data set, and the testing data sets are provided in Tables S1, S2, and S3 in Multimedia Appendix 1.

Table 1. Summary of patients' demographic characteristics.

Characteristics	Value
Age (years), mean (SD)	63.97 (16.77)
Gender, n (%)

MODEL-48 Generation and Performance

The output of the 20 machine learning models that were trained via autoML is depicted in Table 2. The best performing model was the stacked ensemble of all machine learning models (AUPRC=0.806). This was MODEL-48. The best performing independent models were the GBM and XGBoost models, which had an AUPRC of 0.803 and 0.793, respectively. The distributed RF model (AUPRC=0.783) came in 14th place and the GLM (AUPRC=0.738) came in last place. The DL model was generated separately from the autoML models for reproducibility purposes. The AUPRC of the DL model plateaued at 0.736.

Table 2. Output of the automated machine learning models that used 48 variables. Model ranks are ordered according to AUPRCs[a].

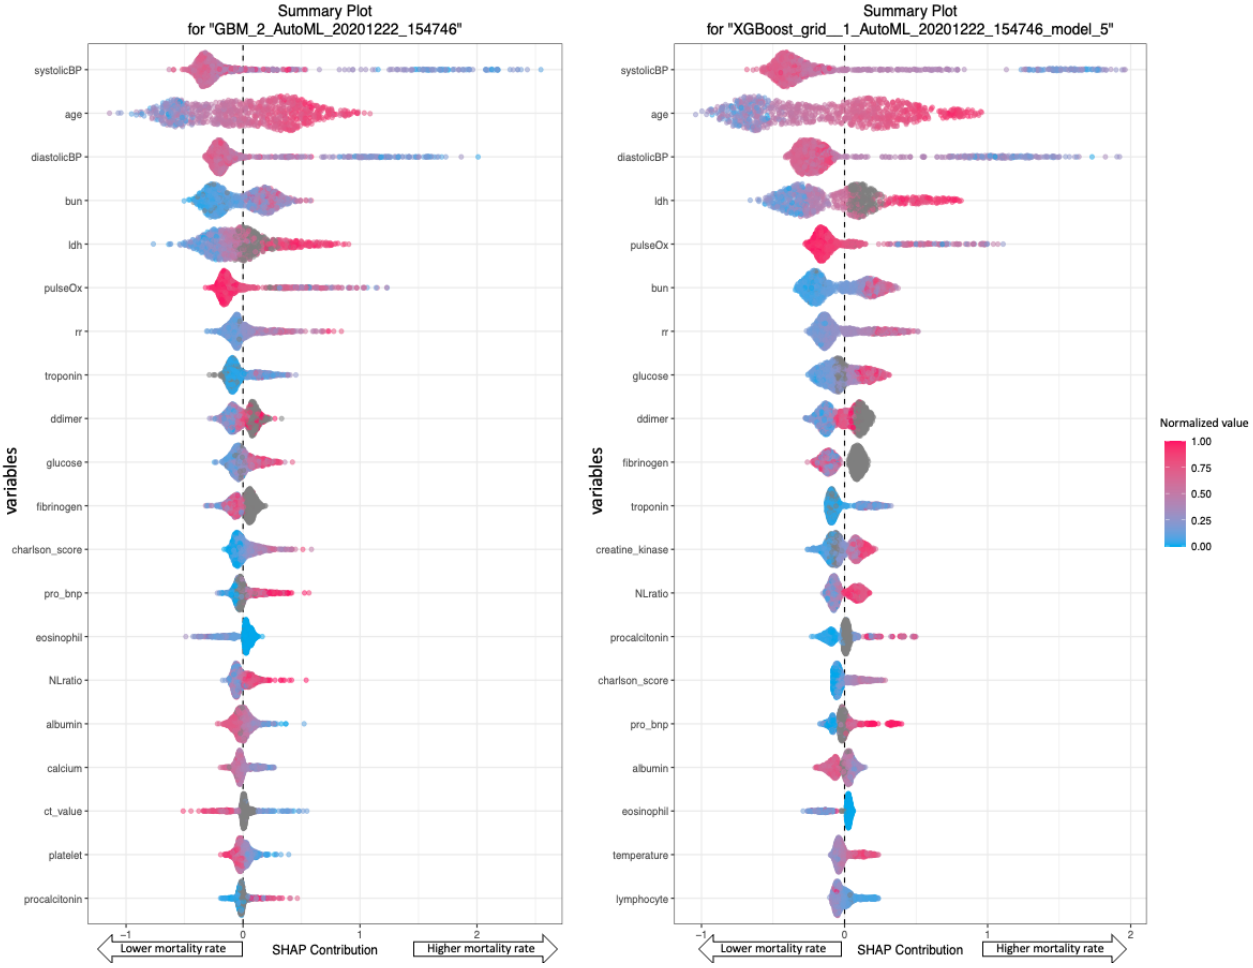
[a]AUPRC: area under the precision-recall curve.

Variable Importance

Figure 3 shows the SHAP plots for the GBM and XGBoost models. In these plots, variables were ranked in descending order of importance. Each patient was represented by one dot on each variable line. The horizontal location of each dot indicated whether the effect of a variable was associated with a higher or lower chance of death [22]. Variable-specific SHAP values of >0 indicated an increased risk of death. For example, the GBM and XGBoost models determined that systolic blood pressure was the most important variable, followed by age and diastolic blood pressure.

Figure 3. SHAP summary plots of the GBM and XGBoost models. According to the GBM and XGBoost models, higher systolic blood pressure levels (ie, red dots) were associated with a lower probability of death (ie, the left side of the vertical dotted line), and older age (ie, red dots) was associated with higher probability of death (ie, the right side of the vertical dotted line). BUN: blood urea nitrogen; charlson_score: charlson comorbidity index; ct_value: cycle threshold value; diastolicBP: diastolic blood pressure; GBM: gradient boosting machine; LDH: lactate dehydrogenase; NLratio: neutrophil-lymphocyte ratio; pro_bnp: pro-brain natriuretic peptide; pulseOx: pulse oximetry; rr: respiratory rate; SHAP: Shapley additive explanation; systolicBP: systolic blood pressure; XGBoost: extreme gradient boosting.



PD plots show the marginal effect that one variable can have on the predicted outcome of a machine learning model. PD plots for the most influential variables are depicted in Multimedia Appendix 2. Each line in a PD plot depicts the best performing model in each machine learning algorithm family. For example, in Figure 4, all models determined that percent mortality increased with age (ie, starting at around 50 years of age). Similarly, all models determined that percent mortality increased with glucose level. However, this was only true for glucose levels of <300 mg/dL (Figure 4).

The importance of each variable in every model is represented on a heatmap in Figure 5.

Figure 4. Partial dependence plots for age and glucose level. Partial dependence plots for the other variables are shown in Multimedia Appendix 2. Each line represents a different machine learning algorithm. DRF: distributed random forest; GBM: gradient boosting machine; GLM: generalized linear model; XGBoost, extreme gradient boosting; XRT: extremely randomized trees.

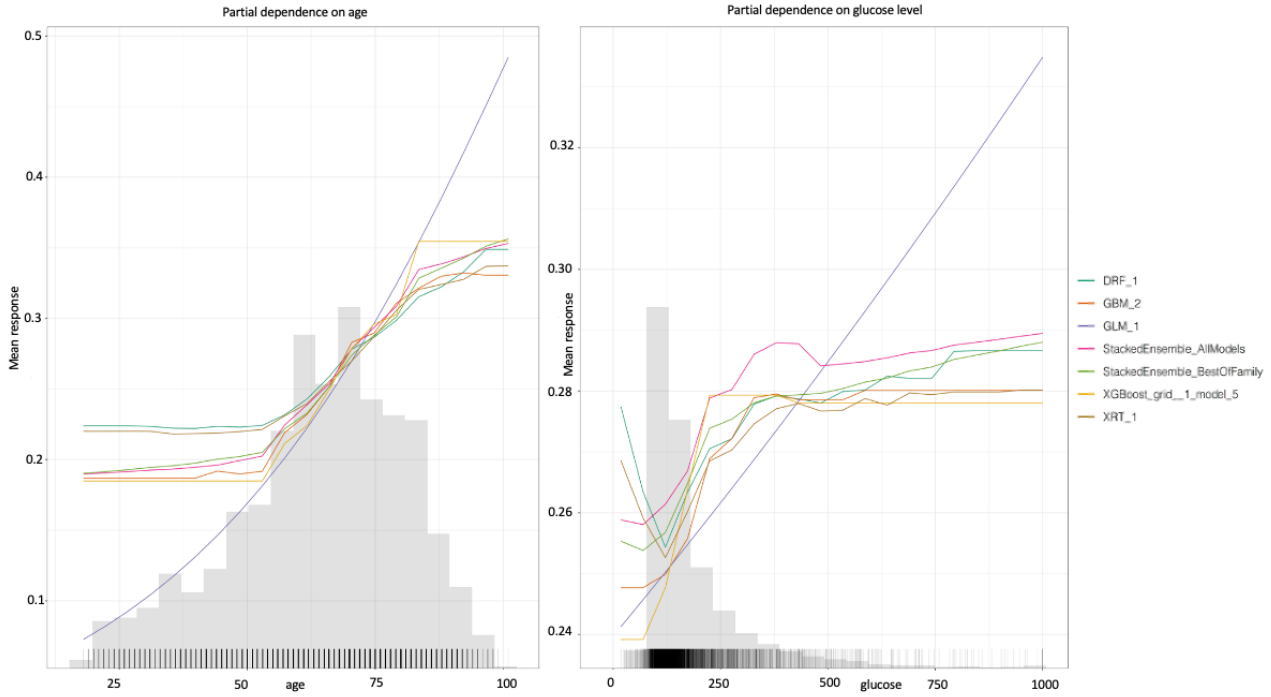


Figure 5. A heatmap that represents the importance of each variable in every machine learning model. DRF: distributed random forest; GBM: gradient boosting machine; GLM: generalized linear model; XGBoost: extreme gradient boosting; XRT: extremely randomized trees.

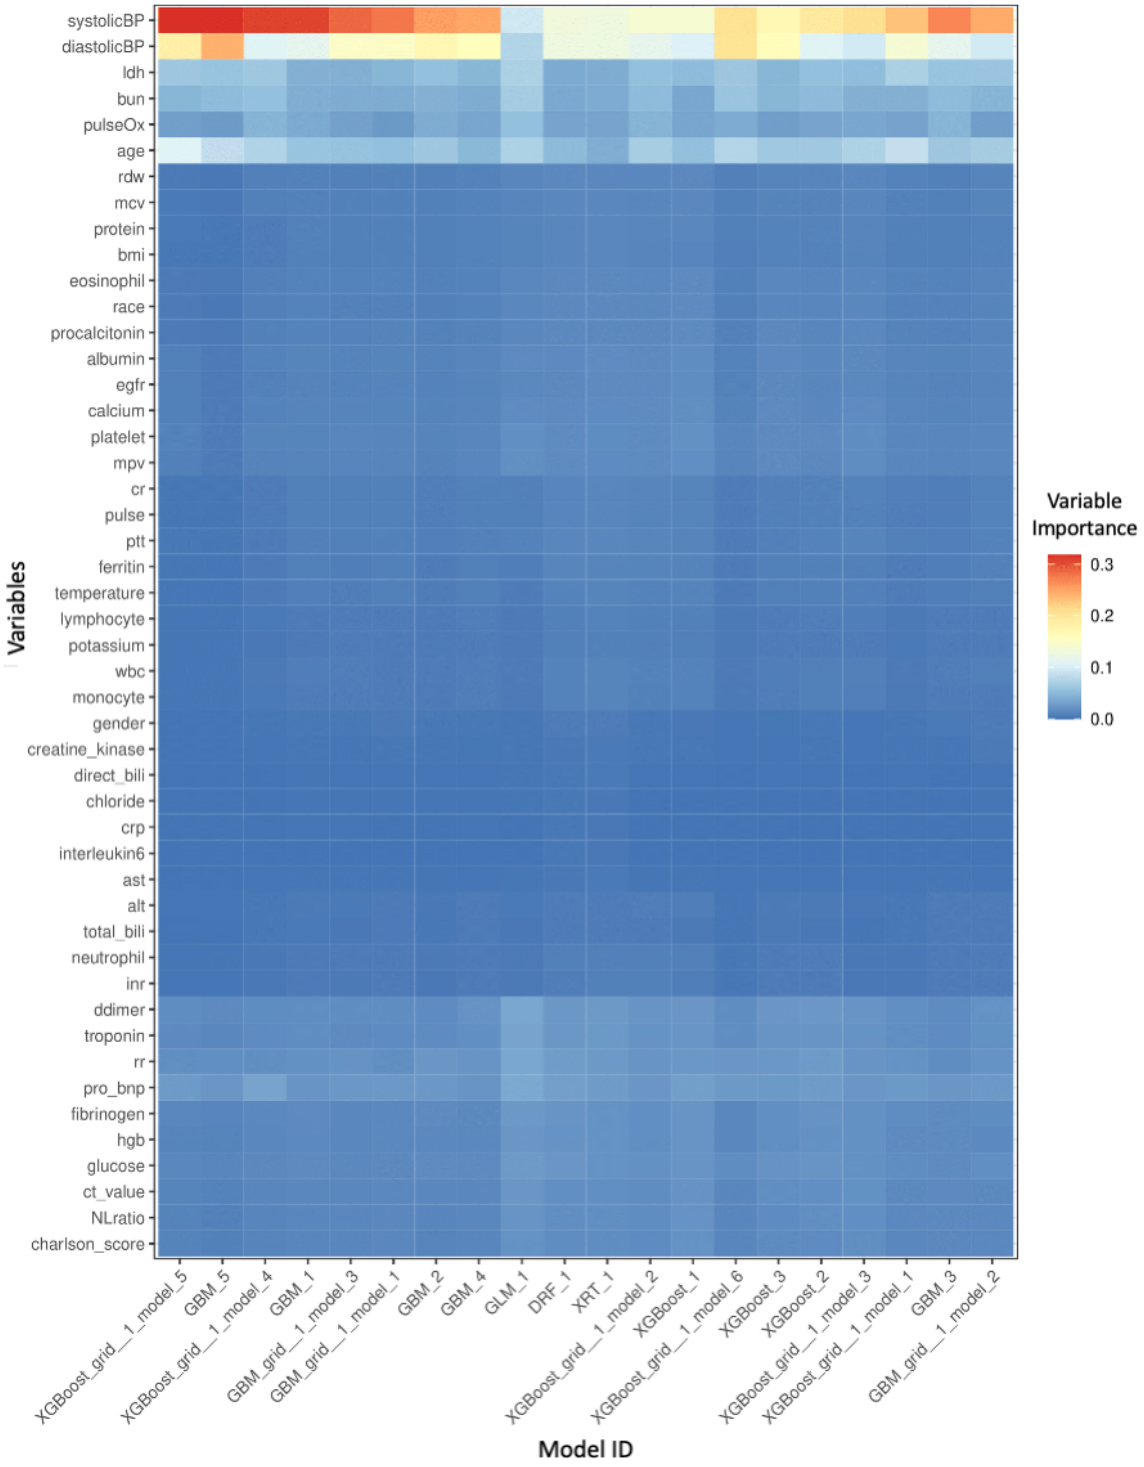

Selection of the Top 10 Variables: Dimensionality Reduction

The SHAP plots for the GBM and XGBoost models (ie, the two highest-performing models) showed that systolic and diastolic blood pressure, age, LDH level, pulse oximetry level, respiratory rate, BUN level, and troponin level were top 10 variables in both models. BUN and troponin levels are indicators of renal and cardiac function, respectively. With regard to our marker for coagulation, we chose D-dimer level over fibrinogen level because it ranked higher and had more data points. Furthermore, we used Charlson comorbidity scores to represent comorbidities. Glucose level was also a highly ranked variable. This was likely due to the increased risk of mortality in patients with diabetes. However, since the Charlson comorbidity score also accounts for diabetes, we believed that the Charlson comorbidity score

was a more comprehensive predictive variable than glucose level. To confirm whether our choice to use Charlson comorbidity score over glucose level was justified, we trained an autoML model on Charlson comorbidity score data (ie, without glucose level data). We then compared it to a model that was trained on glucose level data (ie, without Charlson comorbidity score data). The former model (AUPRC=0.79) performed better than the latter model (AUPRC=0.78), thereby validating our choice.

According to our variable selection process, the top predictive variables were systolic and diastolic blood pressure, age, LDH level, pulse oximetry level, respiratory rate, BUN level, troponin level, D-dimer level, and Charlson comorbidity score. We believed that these variables provided a good representation of biological processes that are affected by SARS-CoV-2 infection. In addition, these variables are easy to obtain in clinical settings. They also reduce the incidence of missing values.

MODEL-10 Generation and Performance

We used the top 10 influential variables to generate 20 more machine learning models and rank them in order of AUPRC (Table 3). The best performing model was the stacked ensemble of each machine learning algorithm family (AUPRC=0.791). This was MODEL-10. The best performing independent model was the XGBoost model, which had an AUPRC of 0.790.

Table 3. Output of the automated machine learning models that used 10 variables. Model ranks are ordered according to AUPRCs[a].

Rank	Model ID	AUPRC	Area under the curve
1	StackedEnsemble_BestOfFamily_AutoML_20201219_142406	0.791	0.903
2	XGBoost_grid__1_AutoML_20201219_142406_model_6	0.790	0.894

[a]AUPRC: area under the precision-recall curve.

Performance of MODEL-48 and MODEL-10 as Binary Classifiers

The maximum F2 score of MODEL-48 was 0.793, and the probability threshold was 0.110. The binary classifier for this threshold had a sensitivity, specificity, PPV, and NPV of 0.919, 0.735, 0.513, and 0.968, respectively (Figure 6). The maximum F2 score of MODEL-10 was 0.779, and the probability threshold was 0.202. The binary classifier for this threshold had a sensitivity, specificity, PPV, and NPV of 0.838, 0.836, 0.609, and 0.944, respectively (Figure 7).

Figure 6. Binary classifier of MODEL-48. The model had an optimized F2-score threshold. This classifier had a sensitivity of 0.92, a specificity of 0.74, a positive predictive value of 0.51, and a negative predictive value of 0.97.

Predicted outcome of MODEL-48	True Outcome	
	Dead, n	Alive, n
Dead, n	181	172
Alive, n	16	476

Figure 7. Binary classifier of MODEL-10. The model had an optimized F2-score threshold. This classifier had a sensitivity of 0.84, a specificity of 0.84, a positive predictive value of 0.61, and a negative predictive value of 0.94.

Predicted outcome of MODEL-10	True Outcome	
	Dead, n	Alive, n
Dead, n	165	106
Alive, n	32	542

Discussion

Principal Findings

We were able to use autoML and clinical values (ie, those that were collected early during a patient's admission to a hospital) to successfully generate multiple machine learning models, assess their performance, and select the highest-performing models for predicting patients' chances of surviving a SARS-CoV-2 infection. In addition, our study demonstrates that machine learning models that only use 10 clinical variables can predict survival. These models also had high sensitivity values, specificity values, and NPVs. Therefore, autoML is an efficient, informative, and easily reproducible method. The clinical implementation of autoML-based models may require further investigation. However, we demonstrate that autoML is a comprehensive approach for building machine learning–based clinical decision support tools.

Our results show that the best models were GBM and XGBoost models. They both had high performance, as determined by their AUPRCs and AUCs. The RF model, DL model, and GLM performed substantially worse compared to the GBM and XGBoost models. The DL model may have performed better if we had a larger data set, but our DL model required much longer training times than the other models. Tree-based machine learning algorithms (eg, GBM, XGBoost, and RF) are more efficient, and possibly more effective, than neural network algorithms in terms of analyzing tabular data. We used the AUPRC as our metric of model utility because it accounts for the two critical clinical performance metrics that were of specific interest to us—the positive predictive value and sensitivity. We wanted to identify patients who were likely to die so that we could take action and treat as many patients as possible. Alternatively, the AUC accounts for model sensitivity and specificity and ignores the effects of mortality prevalence on model performance. The prevalence of mortality sets the context in which the model must perform; without this information, the model is irrelevant.

Machine learning models can be used to enhance electronic medical record systems and calculate the values of variables that are collected from patients. Based on the performance of MODEL-10, our dimensionality reduction process was successful; 10 variables were enough to generate high-performing models. This shows that not all parameters are necessary for performing calculations and making predictions. Clinicians and hospitals should begin the patient assessment process by prioritizing the ordering of medical tests (ie, tests for the 10 variables). Dimensionality reduction not only reduced the number of variables we needed to consider, but also minimized the number of missing values in the data set and reduced the risk of imputation bias. This may be the reason why the performance of MODEL-10 was similar to that of MODEL-48. These 10 variables may also help researchers with conducting studies on unique cohorts and reproducing our results.

The purpose of autoML is not limited to predicting the survival of patients with COVID-19. AutoML can be used to generate models that are based on other types of clinical data and predict other outcomes (eg, models for predicting which patients require a ventilator). We hope that our study helps other researchers with applying our autoML approach, accelerating the implementation of artificial intelligence models into medical systems, and delivering better medical care.

Clinical Insights From the Black Box

The trade-off between predictive power and interpretability is a common issue when working with black-box models, especially in medical environments where results have to be explained to medical providers and patients. Interpretability is crucial for questioning, understanding, and trusting artificial intelligence and machine learning systems. According to our variable importance heatmap (Figure 5), many models

determined that age, pulse oximetry level, and systolic and diastolic blood pressure were important variables for predicting the outcome. Biomarkers such as BUN level, LDH level, estimated glomerular filtration rate, and probrain natriuretic peptide level were also influential variables. These findings show that our model results are in line with the clinical findings of other researchers [23-27].

Our SHAP and PD plots provided insight into the black box. The SHAP plots allowed us to determine the importance of variables and provided information on how the variables influenced models' predictions. Alternatively, PD plots provide numerical information on a variable's effects. For example, the SHAP plots for the GBM and XGBoost models showed that high glucose levels were associated with an increased probability of mortality (ie, high SHAP value). Additionally, the PD plots showed that increases in glucose level were proportional to increases in patients' chances of death. However, this was only true for glucose levels of <300 mg/dL. These results may support the idea that people with diabetes are at an increased risk of mortality. Therefore, SHAP and PD plots can be used to confirm clinical findings and show clinical thresholds.

Other variables that were less influential are also worthy of examination. For example, the SHAP plots (Figure 3) for the GBM model showed that low albumin levels were weakly associated with an increased chance of death. Such findings may provide insight into the disease mechanism of COVID-19. In addition, models that only use 10 variables can be implemented by institutions that might not be able to collect all 48 variables that were tested in this study. If high-performing models can be generated with only 10 variables, clinicians and hospitals can focus on collecting these variables when conducting patient assessments. Such models also minimize the problem of data sparsity and the risk of imputing missing data points. In addition, the use of such models will help clinicians with manually entering values (eg, inputting values on a mobile device).

Limitations and Future Work

We recognize that there were limitations to our study. Our cohort was limited to patients with severe conditions that required them to be admitted to a hospital. Therefore, our findings may not be generalizable to all patients with COVID-19. For example, we were surprised to learn that our machine learning models did not identify race as an important predictor of death, given the fact that at a population level, the relative risk of mortality among Black patients is higher than that of White patients [28]. However, one population study analyzed the relative risk of mortality among Black patients and White patients with COVID-19 who were admitted to our institution (ie, Montefiore Medical Center). This study found that there were no considerable differences in mortality rates between the two groups once patients were admitted to our hospital [28]. During a pandemic, hospital beds are scarce. Therefore, only patients who exhibit severe symptoms are allowed to be admitted to emergency rooms. Fortunately, our colleagues from our institution conducted a conventional logistic regression analysis, which resulted in the same finding; hospitalized White and Black patients with illnesses of equal severity and relevant predictor's for disease progression at admission had similar mortality rates [28]. The results from our machine learning models are in line with those of the logistic regression analysis.

In our study, systolic and diastolic blood pressure were the most important variables. However, these variables may simply indicate that patients with severe illnesses and hypotension are at an imminent risk of death. Temporal features were not considered in our analysis. For example, we did not determine whether hypotension at admission was an important variable for patients who survive during the first 24 hours of admission. Further, we did not determine whether a variable's importance diminishes in populations that survive after the first 48 or 72 hours of admission. In a future study, we would like to test whether our models are robust enough to predict death during different times of admission. For example, we would test our models' performance for predicting the death of patients within the first week of admission and the fourth week after admission.

The handling of missing values is a challenging problem in machine learning model development. Fibrinogen, procalcitonin, and cycle threshold values were missing for many people in our cohort (Table S1 in Multimedia Appendix 1). We understand that missing values are not indicative of a variable's clinical importance. For example, changes in practice patterns alter the meaning of missing data. After the first few weeks of the COVID-19 pandemic, our institution implemented a best practice protocol that required clinicians to measure patients' D-dimer levels upon admission and recommend anticoagulation treatment to patients with elevated D-dimer levels. Clearly, the presence of D-dimers during the early period of the pandemic had a different meaning from that of the presence of D-dimers during the later period of the pandemic. Similarly, missing D-dimer level values were considered random events during the later period of the pandemic and purposeful events during the early period of the pandemic [29]. Therefore, missing data from the early period of the pandemic have a different meaning compared to that of missing data from the later period. However, our imputation methods did not account for temporal changes in the meaning of missing data. This is an important challenge that must be considered in future machine learning software development studies.

With regard to the generalization of our model, future studies need to be conducted to assess whether our models are useful at other institutions during the second wave of COVID-19. As patient demographics can differ from institution to institution, hospitals may need to customize their models in accordance with their patient populations. Models should also be designed to integrate new data and adjust to the ever-changing environment. We are continually working on reinforcement learning methods for updating our model in real time.

Conclusion

We used autoML to generate high-performing machine learning models that predicted the mortality of patients with COVID-19. We also identified important variables that were strongly associated with patients' survival. Our study provides proof of concept that autoML is an efficient, effective, and informative method for training machine learning models and gaining insight into disease processes. AutoML models may help clinicians

with triaging patients during the COVID-19 pandemic. Our COVID-19 mortality calculator, which is based on this study, is freely available online as a web-based computer application [5].

Abstract

Background: Health behavior is influenced by culture and social context. However, there are limited data evaluating the scope of these influences on COVID-19 response.

Objective: This study aimed to compare handwashing and social distancing practices in different countries and evaluate practice predictors using the health belief model (HBM).

Methods: From April 11 to May 1, 2020, we conducted an online, cross-sectional survey disseminated internationally via social media. Participants were adults aged 18 years or older from four different countries: the United States, Mexico, Hong Kong (China), and Taiwan. Primary outcomes were self-reported handwashing and social distancing practices during COVID-19. Predictors included constructs of the HBM: perceived susceptibility, perceived severity, perceived benefits, perceived barriers, self-efficacy, and cues to action. Associations of these constructs with behavioral outcomes were assessed by multivariable logistic regression.

Results: We analyzed a total of 71,851 participants, with 3070 from the United States, 3946 from Mexico, 1201 from Hong Kong (China), and 63,634 from Taiwan. Of these countries, respondents from the United States adhered to the most social distancing practices (χ^2_3=2169.7, *P*<.001), while respondents from Taiwan performed the most handwashing (χ^2_3=309.8, *P*<.001). Multivariable logistic regression analyses indicated that self-efficacy was a positive predictor for handwashing (odds ratio [OR]$_{\text{United States}}$ 1.58, 95% CI 1.21-2.07; OR$_{\text{Mexico}}$ 1.5, 95% CI 1.21-1.96; OR$_{\text{Hong Kong}}$ 2.48, 95% CI 1.80-3.44; OR$_{\text{Taiwan}}$ 2.30, 95% CI 2.21-2.39) and social distancing practices (OR$_{\text{United States}}$ 1.77, 95% CI 1.24-2.49; OR$_{\text{Mexico}}$ 1.77, 95% CI 1.40-2.25; OR$_{\text{Hong Kong}}$ 3.25, 95% CI 2.32-4.62; OR$_{\text{Taiwan}}$ 2.58, 95% CI 2.47-2.68) in all countries. Handwashing was positively associated with perceived susceptibility in Mexico, Hong Kong, and Taiwan, while social distancing was positively associated with perceived severity in the United States, Mexico, and Taiwan.

Conclusions: Social media recruitment strategies can be used to reach a large audience during a pandemic. Self-efficacy was the strongest predictor for handwashing and social distancing. Policies that address relevant health beliefs can facilitate adoption of necessary actions for preventing COVID-19. Our findings may be explained by the timing of government policies, the number of cases reported in each country, individual beliefs, and cultural context.

KEYWORDS

COVID-19 pandemic; health belief model; behavior change; preventative health behaviors; handwashing; social distancing; international; online survey; social media; cross-sectional study

Introduction

The severity and rapid transmission of COVID-19 has forced most regions to implement community mitigation strategies. These strategies have ranged from government guidelines on personal protective measures and social distancing to strict lockdown orders that closed schools and businesses [1]. Nationwide school closures in 194 countries in early April 2020 demonstrated the extent of these interventions [2]. These measures have reduced transmission or delayed the peak of infection of past pandemics to varying degrees, which were estimated to have prevented at least 60 million COVID-19 cases [3,4].

Although these interventions reduce the stress on health care systems, they also incur high economic and societal costs, making adherence more difficult for those under financial strain [3,5]. Recent studies have begun to assess adherence to COVID-19 guidelines, evaluating demographic characteristics and the impact of guideline duration [6-8]. Some have suggested that concepts from social and behavioral sciences can provide insight into adherence to guidelines, but current data evaluating these hypotheses in multiple countries and in the context of COVID-19 using relevant behavior change theories, such as the health belief model (HBM), are limited [9]. Given the rapid spread of COVID-19 and the scale of guidelines worldwide, a cross-cultural assessment of preventative health behaviors is essential to identifying which approaches improve adherence. This study aims to compare handwashing and social distancing behaviors across four different countries using the HBM.

Methods

Participant Recruitment

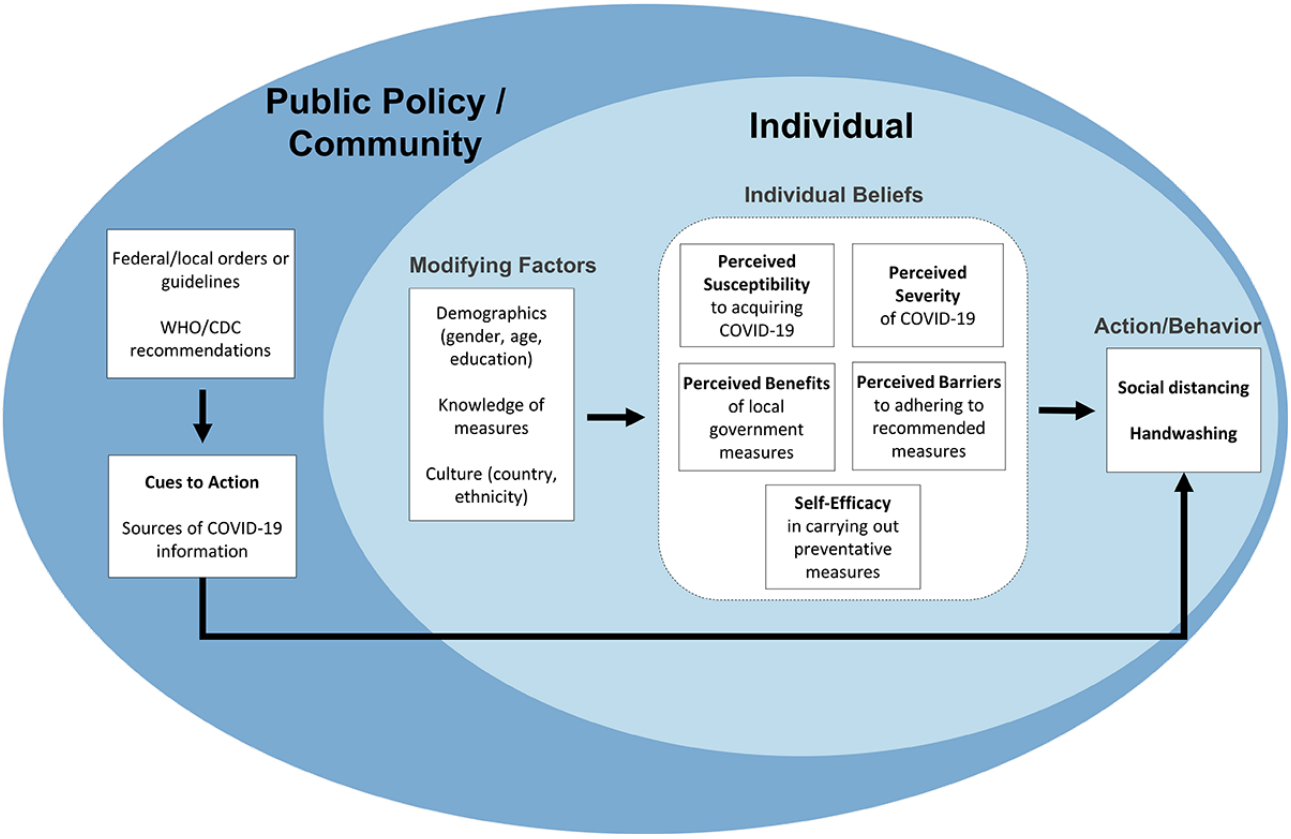
From April 11 to May 1, 2020, we conducted a confidential, cross-sectional, international open survey through the following social media platforms: Facebook, Instagram, Line, and Twitter. The survey was announced and advertised through Stanford Health Policy's social media accounts. Facebook boosted posts were used to target social media users who were 18 years of age or older. We focused our analysis on countries and regions with at least 1000 survey responses: the United States, Mexico, Hong Kong (China), and Taiwan. Facebook is the most popular social media platform among adults in all four countries, whereas Instagram, Twitter, and Line have relatively high penetration in specific groups and countries [10-13]. Though the limitations of using convenience sampling and social media are well-known, this method is cost-effective, time-efficient, and most feasible for reaching a large international audience in a fast-spreading pandemic [14]. The alternative of administering telephone surveys is associated with extremely low response rates (6% in 2018) and limitations on item complexity and survey length [15,16].

The survey was developed on Qualtrics (Qualtrics Inc), an online survey distribution tool, and administered in English, Spanish, and Mandarin. Translations were provided by native speakers fluent in the respective languages, who tested the survey before it was fielded. Prior to survey completion, participants were provided with information about the study and were asked to acknowledge consent to the study. All items were optional except for country of residence. Through Qualtrics, cookies were used to assign a unique user identifier to each client computer to prevent participants from completing the survey more than once. Only completed surveys were analyzed. Given that no incentives were offered to participants and that the survey was voluntary, we did not assess whether surveys were completed in an atypical amount of time. The study was reviewed and approved by Stanford University's Institutional Review Board.

Conceptual Model and Survey Items

We used the HBM, a widely used framework for explaining health behaviors and guiding related interventions, to create survey items to assess health beliefs among respondents in the four countries [17]. The HBM accounts for both individual- and community-level factors of health motivation, making it an ideal option for addressing health behavior problems that evoke health concerns during the COVID-19 pandemic. Figure 1 shows the key constructs in the HBM that determine behavior, including individual beliefs (ie, perceived susceptibility, severity, benefits, and barriers as well as self-efficacy), which may be influenced by sociodemographic factors or knowledge, and cues to action, which may be influenced by public policy.

Figure 1. Conceptual framework of the study adapted from the health belief model to assess individual health beliefs, modifying factors, and the effects of public policy on social distancing and handwashing behaviors during the COVID-19 pandemic. CDC: Centers for Disease Control and Prevention; WHO: World Health Organization.



Survey items (see Multimedia Appendix 1) were developed based on prior expertise, survey knowledge, and group discussion. We asked participants the following questions for each HBM construct:

1. Perceived susceptibility. What do you think your risk is of getting infected with COVID-19?
2. Perceived severity. How afraid are you of the COVID-19 pandemic?
3. Perceived benefits. How do you feel about the government measures of COVID-19 in your area?
4. Perceived barriers. Have any barriers prevented you from adhering to measures in your area?
5. Self-efficacy. How confident are you that you are able to and willing to carry out these measures?
6. Cues to action. What are your sources of information regarding COVID-19?

Perceived susceptibility, perceived severity, and self-efficacy items were assessed using a 5-point Likert scale. During analysis, response scales were eventually collapsed into three categories, such as *not likely/slightly likely*, *moderately likely*, and *likely/very likely*. Perceived benefit items were assessed using three categories: *unnecessarily restrictive/moderately restrictive*, *essential/appropriate*, and *not enough*. Perceived barriers and cues to action were both assessed on a binary *yes/no* scale.

To account for modifying factors that influenced individual beliefs, we assessed for age (ie, 18-24, 25-34, 35-44, 45-59, and 60+ years), gender (ie, male, female, and other), highest educational attainment (ie, high school or less and college and above), country of residence (ie, United States, Mexico, Hong Kong, and Taiwan), race or ethnicity (eg, Asian, Hispanic/Latino, and White or European), change in income due to COVID-19 (ie, yes or no), and awareness of government measures or guidelines (ie, some/not aware and most/all).

Handwashing behaviors were assessed by asking respondents whether they washed their hands or used hand sanitizer in the following seven situations: (1) after coming home from being outside; (2) after grocery shopping; (3) after interacting with nonhousehold members; (4) while being in public; (5) before or after using their vehicle; (6) after blowing their nose, coughing, or sneezing into their hand; and (7) before eating. Responses for all situations were summed up to a score of 7. Social distancing behaviors were evaluated by assessing whether respondents did the following: (1) avoided nonessential gatherings, (2) kept at least the recommended distance from nonhousehold members (eg, 6 feet, 1.5 meters, 2 meters, etc), or (3) avoided close contact with individuals at higher risk for severe illness from COVID-19. Responses were summed up to a score of 3. Total adherence to either handwashing or social distancing responses was assessed by a binary variable, with individuals performing all of the practices as one group (yes = 1) and those who performed fewer than all practices as the other group (no = 0); this was done for each of the two behaviors.

Statistical Analysis

We conducted poststratification weighting for each country by age and gender—and race or ethnicity for the United

States—using each country's most recent census data [18-21]. Weights were calculated by dividing each stratified proportion of the country's population by each stratified proportion of the study's country sample, followed by renormalizing for each country to ensure that weighted sample size equaled the unweighted sample size [22]. Weighted frequencies and percentages were calculated for categorical variables and compared using chi-square tests. To assess which country performed more handwashing and social distancing practices, countries were analyzed together in multivariate analyses, with each country coded as a key independent dichotomous variable, adjusting for gender, age, education, and reduced income.

Countries were also analyzed separately with multivariable logistic regressions to examine the association of HBM constructs with two main outcomes: handwashing and social distancing practices. HBM covariates included perceived susceptibility, severity, benefits, and barriers; self-efficacy; and cues to action. All models were adjusted for gender, age, education, and reduced income. To ensure our handwashing variable appropriately captured COVID-19-related handwashing behaviors, we also ran a sensitivity analysis that assessed the association between handwashing time (ie, >20 seconds vs ≤20 seconds) and HBM constructs, because this handwashing duration was a specific COVID-19 recommendation in all four countries [23-26]. For all models, odds ratios (ORs) and 95% CIs were calculated. All statistical analyses were performed using R statistical software, version 3.6.3 (The R Foundation), and *P* values were 2-sided with an α of .05.

Results

Participant Characteristics

A total of 71,851 individuals were included in our analysis: 3070 from the United States (4.3%), 3946 from Mexico (5.5%), 1201 from Hong Kong (1.7%), and 63,634 from Taiwan (88.6%). Of these, 71,728 (99.8%) completed at least 80% of the survey (14 of 17 questions). Missing data for each item were less than 5% and, thus, were not imputed. After weighting, the gender and age distributions were representative of each country according to their most recent census data (see Multimedia Appendices 2 and 3). Overall, Mexico had a younger population compared to other countries, and most respondents in all four countries had a college degree or higher. A total of 2099 out of 3931 respondents (53.4%) from Mexico, 337 out of 1189 (28.3%) from Hong Kong, 779 out of 3062 (25.4%) from the United States, and 10,725 out of 63,399 (16.9%) from Taiwan reported reduced income due to COVID-19. A total of 68,614 out of 71,633 respondents (95.8%) in all countries were aware of government measures and/or guidelines (see Table 1).

Table 1. Weighted demographic characteristics of survey respondents by country.

Characteristic	Value (N=71,851), n (%)[a]				*P* value[b]
	United States (n=3070)	Mexico (n=3946)	Hong Kong (n=1201)	Taiwan (n=63,634)

Awareness of governmental measures and/or guidelines					<.001
Some/not aware	20 (0.7)	123 (3.1)	26 (2.2)	2850 (4.5)	—
All/most	3034 (99.3)	3818 (96.9)	1167 (97.8)	60,595 (95.5)	—

[a]Weighted values were calculated by dividing the actual proportion of the country's population by the proportion from the study's sample, then renormalized for each country to ensure weighted and unweighted sample sizes were equal. Due to rounding and missing data (<5% for each item), the sum of frequencies and percentages for the sample weighted columns may not equal the country's total sample size.

[b]*P* values were calculated using 2-sided chi-square tests.

[c]Not available.

[d]Responses of *other* gender include individuals who chose nonbinary/third gender, prefer not to say, or other (<3% of total responses).

[e]Responses of *other* race or ethnicity include individuals who are African, Black, African American, American Indian or Alaskan Native, Middle Eastern, Native Hawaiian or other Pacific Islander, or other. Categories were collapsed due to low numbers (<2% of total responses).

Handwashing and Social Distancing Behaviors

Bivariate chi-square analyses showed that respondents from Taiwan practiced the most handwashing behaviors (χ^2_3=309.8, *P*<.001) relative to other countries, while those from the United States practiced the most social distancing (χ^2_3=2169.7, *P*<.001). Of the 71,608 respondents who provided a response to their handwashing practices, 39.6% (1215/3066) from the United States, 48.8% (1927/3938) from Mexico, 45% (538/1195) from Hong Kong, and 54.1% (34,328/63,409) from Taiwan reported handwashing in all seven situations (see Figure 2). Of the 71,851 respondents who provided a response to their social distancing practices, 88.0% (2702/3070) from the United States, 64.3% (2539/3946) from Mexico, 44.7% (537/1201) from Hong Kong, and 48.3% (30,737/63,634) from Taiwan reported performing all three social distancing practices (see Figure 3). We found similar patterns of association in the sensitivity multivariate analysis (see Multimedia Appendix 4). Respondents from the United States (OR 0.50, 95% CI 0.46-0.54), Mexico (OR 0.87, 95% CI 0.81-0.93), and Hong Kong (OR 0.67, 95% CI 0.59-0.75) were less likely to perform handwashing compared to those from Taiwan (reference value). Respondents from the United States (OR 7.73, 95% CI 6.93-8.66) and Mexico (OR 2.17, 95% CI 2.02-2.33) were more likely to practice social distancing compared to those from Taiwan. In contrast, respondents from Hong Kong were less likely to practice social

distancing compared to those from Taiwan, although the association was only slightly significant (OR 0.88, 95% CI 0.87-0.99).

Figure 2. Distribution of handwashing practices by country. Respondents were asked whether they washed their hands or used hand sanitizer in any of the following seven situations: (1) after coming home from being outside; (2) after grocery shopping; (3) after interacting with nonhousehold members; (4) while being in public; (5) before or after using their vehicle; (6) after blowing their nose, coughing, or sneezing into their hand; and (7) before eating.

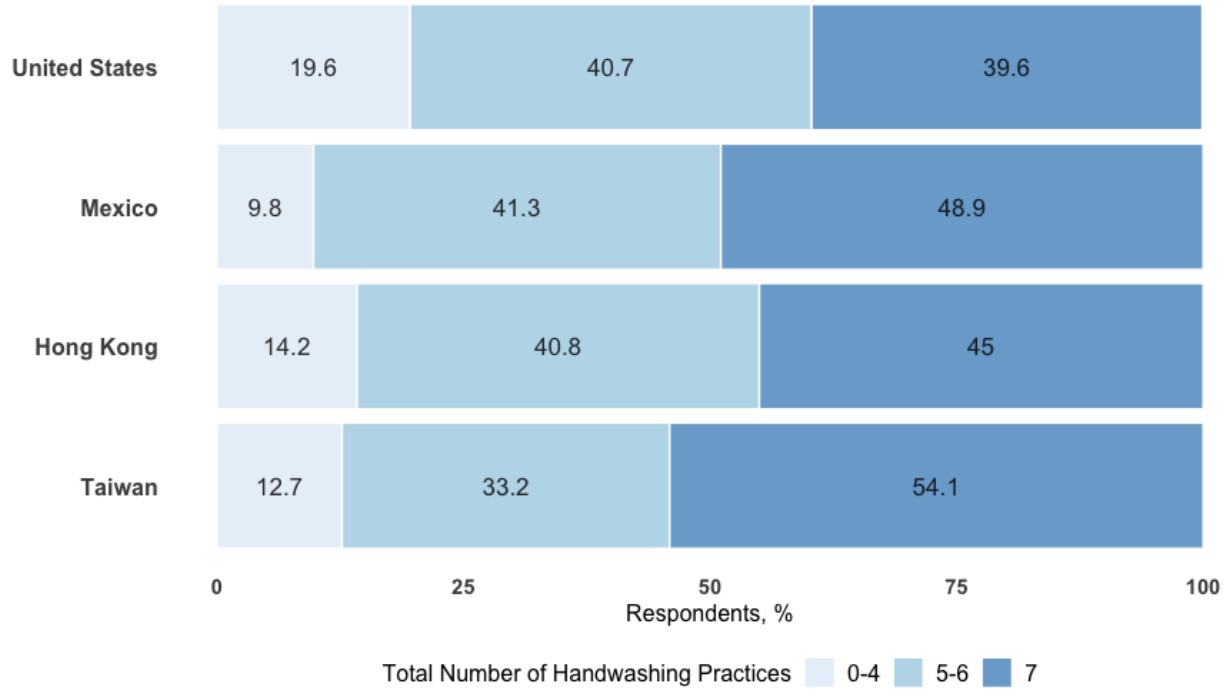

Figure 3. Distribution of social distancing practices by country. Respondents were asked whether they did the following: (1) avoided nonessential gatherings, (2) kept at least the recommended healthy distance from nonhousehold members (eg, 6 feet, 1.5 meters, and 2 meters), or (3) avoided close contact with individuals at higher risk for severe illness from COVID-19.

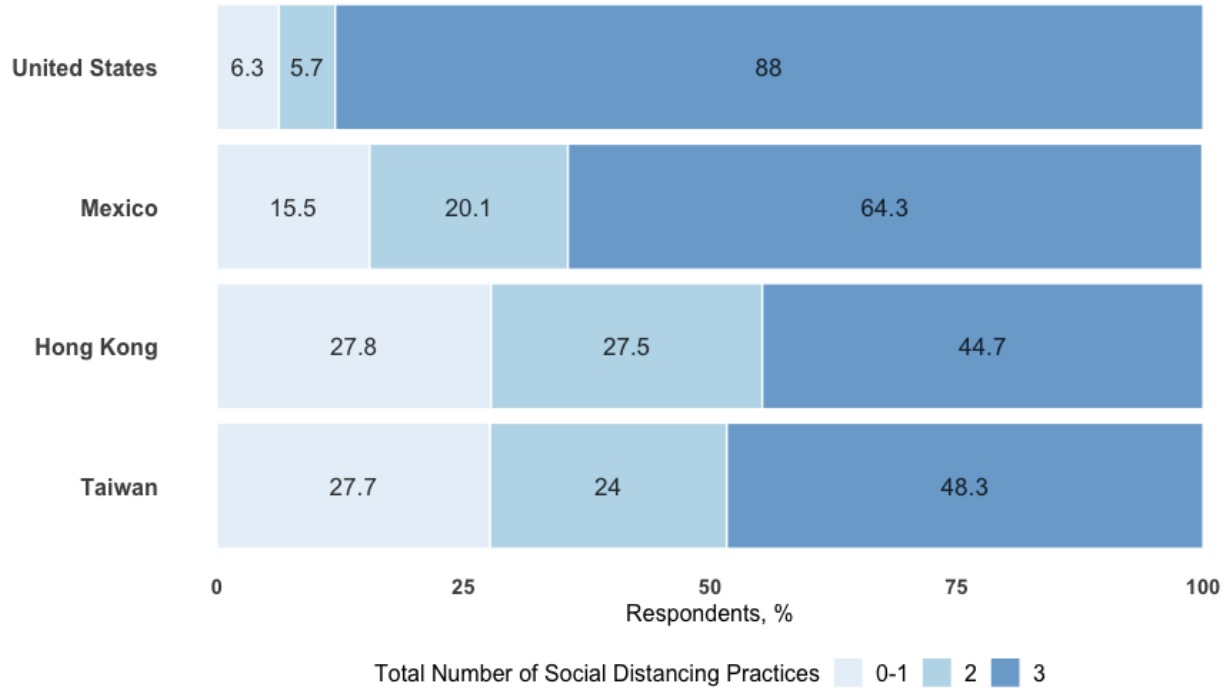

Health Belief Model Constructs

Table 2 compares the distribution of responses to health belief questions by country, which were assessed using chi-square tests and were all statistically different across each country (P<.001). For perceived susceptibility, the percentage of respondents who felt they were likely (ie, moderately likely to very likely) to be infected with COVID-19 was higher in the United States (1683/3068, 54.9%) and Mexico (2688/3941, 68.2%) compared to those from Hong Kong (557/1192, 46.7%) and Taiwan (19,080/63,425, 30.1%). For perceived severity, a higher percentage of individuals from Taiwan (28,082/63,470, 44.2%) were not afraid (ie, slightly afraid or not afraid) of the COVID-19 pandemic compared to those from the United States (876/3064, 28.6%), Mexico (1154/3940, 29.3%), and Hong Kong (289/1195, 24.2%). For perceived benefits, most individuals in the United States (2062/3016, 68.4%) and Taiwan (53,573/62,625, 85.5%) believed that the government measures in place were appropriate or essential, while most individuals in Mexico (2256/3871, 58.3%) and Hong Kong (745/1172, 63.6%) believed that their measures were not enough. For self-efficacy, a majority of individuals in all countries were confident or very confident in their ability to carry out preventative measures: 88.5% (2712/3066) in the United States, 91.4% (3599/3940) in Mexico, 79.3% (946/1193) in Hong Kong, and 75.8% (48,144/63,481) in Taiwan.

Regarding perceived barriers to social distancing, Mexico (2547/3946, 64.5%) had the highest proportion of individuals who perceived difficulty in obtaining face masks, followed by 60.5% (1856/3070) of individuals in the United States, 52.7% (633/1201) in Hong Kong, and 12.2% (7736/63,634) in Taiwan. Having an essential job (eg, grocery store worker), as perceived by the individual or determined by local governments, was a common perceived barrier in all countries. Other common barriers included family obligations in Mexico as well as transportation needs in Hong Kong and Taiwan. For handwashing barriers, respondents from the United States (1536/3070, 50.0%) and Mexico (2056/3946, 52.1%) perceived more difficulty in obtaining hand sanitizer compared to those in Taiwan (2708/63,634, 4.3%) and Hong Kong (104/1201, 8.7%). Only a small proportion of individuals in all countries (<5% each) reported having difficulty obtaining hand soap.

For cues to action, respondents selected up to three sources of information for COVID-19. News (eg, TV news, newspaper, and radio) and social media were the most frequently reported sources of information in every country, with Hong Kong reporting the highest percentage (news: 1002/1201, 83.4%; social media: 846/1201, 70.4%) and Mexico the lowest (news: 1965/3946, 49.8%; social media: 1337/3946, 33.9%). More respondents selected federal, or central, government rather than regional government as a top information source in Taiwan (14,730/63,634, 23.1% vs 1387/63,634, 2.2%) and Mexico (1155/3946, 29.3% vs 567/3946, 14.4%), while more respondents selected regional rather than federal government in the United States (1129/3070, 36.8% vs 312/3070, 10.2%). Both choices were comparably low in Hong Kong (<5% each).

Table 2. Weighted responses to health belief model (HBM) constructs by country.

HBM construct, survey question, and responses	Value (N=71,851), n (%)[a]				*P* value[b]
	United States (n=3070)	Mexico (n=3946)	Hong Kong (n=1201)	Taiwan (n=63,634)	
Perceived susceptibility to infection: What do you think is your risk of getting infected with COVID-19?					<.001
Not likely/slightly likely	1385 (45.1)	1253 (31.8)	635 (53.3)	44,345 (69.9)	—[c]

[a]Weighted values were calculated by dividing the actual proportion of the country's population by the proportion from the study's sample, then renormalized for each country to ensure weighted and unweighted sample sizes were equal. Due to rounding and missing data (<5% for each item), the sum of frequencies and percentages for the sample weighted columns may not equal the country's total sample size.

[b]*P* values were calculated using 2-sided chi-square tests.

[c]Not available.

[d]The top four media resources selected by respondents, when asked to pick their top three from the list, are shown.

Association of HBM Constructs With Handwashing and Social Distancing Behaviors

In multivariable analyses, individuals with higher self-efficacy were more likely to perform more handwashing practices compared to those with lower self-efficacy ($OR_{United\ States}$ 1.58, 95% CI 1.21-2.07; OR_{Mexico} 1.54, 95% CI 1.21-1.96; $OR_{Hong\ Kong}$ 2.48, 95% CI 1.80-3.44; OR_{Taiwan} 2.30, 95% CI 2.21-2.39) (see Table 3). The significance of other HBM constructs varied by country. Performing more handwashing practices was positively and significantly associated with perceived severity in the United States ($OR_{severity}$ 1.33, 95% CI 1.09-1.61), perceived susceptibility in Mexico ($OR_{susceptibility}$ 1.23, 95% CI 1.06-1.42) and Hong Kong ($OR_{susceptibility}$ 1.44, 95% CI 1.11-1.87), and perceived susceptibility and perceived severity in Taiwan ($OR_{susceptibility}$ 1.08, 95% CI 1.04-1.12; $OR_{severity}$ 1.24, 95% CI 1.20-1.29). In the United States, Mexico, and Taiwan, those who perceived government measures for COVID-19 as restrictive were significantly less likely to handwash compared to those who perceived measures as appropriate or essential ($OR_{United\ States}$ 0.41, 95% CI 0.30-0.55; OR_{Mexico} 0.65, 95% CI 0.50-0.86; OR_{Taiwan} 0.82, 95% CI 0.76-0.89). In the United States, non-White respondents were more likely to handwash compared to White or European respondents ($OR_{Hispanic/Latino\ or\ other}$ 3.22, 95% CI 2.69-3.86; OR_{Asian} 2.76, 95% CI 1.89-4.04). Similar patterns of association for covariates persisted even when we used handwashing time (>20 seconds), another important COVID-19 handwashing behavior, as the binary outcome in the sensitivity analysis (see Multimedia Appendix 5).

Similar to handwashing, individuals with higher self-efficacy were also more likely to practice social distancing compared to those with lower self-efficacy ($OR_{United\ States}$ 1.77, 95% CI 1.24-2.49; OR_{Mexico} 1.77, 95% CI 1.40-2.25; $OR_{Hong\ Kong}$ 3.25, 95% CI 2.32-4.62; OR_{Taiwan} 2.58, 95% CI 2.47-2.68) (see Table 4). Social distancing was also positively associated with perceived severity in the United States ($OR_{severity}$ 1.62, 95% CI 1.24-2.12), Mexico ($OR_{severity}$ 1.29, 95% CI 1.11-1.50), and Taiwan ($OR_{severity}$ 1.17, 95% CI 1.13-1.21). Similarly, in the United States, Mexico, and Taiwan, those who perceived government measures for COVID-19 as restrictive were significantly less likely to practice social distancing compared to those who perceived measures as appropriate or essential ($OR_{United\ States}$ 0.52, 95% CI 0.36-0.76; OR_{Mexico} 0.65, 95% CI 0.49-0.85; OR_{Taiwan} 0.82, 95% CI 0.76-0.88). In the United States, family obligations and transportation needs were associated with fewer social distancing practices (OR_{family} 0.25, 95% CI 0.17-0.36; $OR_{transportation}$ 0.25, 95% CI 0.11-0.57). In Hong Kong, those who had difficulty obtaining masks were more likely to socially distance (OR_{masks} 1.61, 95% CI 1.23-2.10), but those who had an essential job or transportation needs were less likely to socially distance ($OR_{essential\ job}$ 0.66, 95% CI 0.48-0.89; $OR_{transportation}$ 0.67, 95% CI 0.52-0.87). Similarly in Taiwan, those who had an essential job or transportation needs were less likely to socially distance ($OR_{essential\ job}$ 0.71, 95% CI 0.68-0.74; $OR_{transportation}$ 0.85, 95% CI 0.82-0.89).

Discussion

Principal Findings

In this international study to examine COVID-19-related health behaviors using the HBM, we showed that respondents from the United States practiced the most social distancing, while those from Taiwan practiced the most handwashing. Despite these differences in health behaviors, self-efficacy was a significant predictor in all four countries. Our findings may be explained by the strictness and timing of government policies, the number of confirmed infection cases in each country, individual beliefs, and cultural context.

In the context of government interventions, Taiwan's early border control, case identification, isolation of suspected cases, and resource allocation led to recommendations for social distancing, though not strictly enforced [27]. Similarly, Hong Kong's early identification and strict quarantine of suspected cases resulted in regulations that prohibited large public gatherings but otherwise maintained regular activities [28,29]. On the other hand, 43 US states issued lockdown orders between mid-March and early April 2020, each lasting until the end of April at the minimum [30]. Mexico issued similar orders on March 26, 2020,with the strictest measures lasting until the end of May 2020 [31]. These varying degrees of strictness and timing of government interventions among the four countries may have attributed to increased social distancing in the United States and Mexico compared to Hong Kong and Taiwan.

Furthermore, at the start of our study period on April 11, 2020, the World Health Organization Situation Report recorded 1.6 million confirmed COVID-19 cases, with more than 99,000 deaths in over 200 countries and territories [32]. This included 461,275 confirmed cases in the United States, 3441 in Mexico, 1001 in Hong Kong, and 382 in Taiwan [26,32,33]. By the end of our study period on May 1, 2020, the numbers of cases and deaths had doubled worldwide [32]. The United States and Mexico saw a 124% and 417% increase in the number of confirmed COVID-19 cases, respectively, while Taiwan and Hong Kong reported only a 6.8% and 3.9% increase, respectively [26,32,33]. The rapid increase in confirmed cases in the United States and Mexico compared to Hong Kong and Taiwan likely also played a role in understanding handwashing and social distancing behaviors.

Among the HBM constructs, our study found that self-efficacy was the strongest positive predictor for both handwashing and social distancing in all countries. These findings were largely consistent with previous studies that examined preventative

behaviors for cancers using the HBM [34,35]. Although a review of HBM studies suggested that the construct of perceived barriers was the best individual predictor across different types of studies and behaviors, self-efficacy can be seen as an important factor in overcoming the barriers to taking actions [17]. Perceived barriers were not significantly associated with hand hygiene, possibly because difficulties accessing water, soap, and hand sanitizer were less common among our survey respondents. For instance, Mexico is an upper-middle-income country and in some regions and communities these items might not be readily available; however, the population we reached through social media may be comparable to the populations we assessed from the other high-income countries [36]. For social distancing behaviors, having transportation needs was consistently associated with practicing less social distancing. This is especially relevant in Hong Kong and Taiwan, where public transportation is heavily utilized with their population densities of 6690 and 652 persons per square kilometer, respectively [37,38]. In their most densely populated districts, these numbers are even higher at 57,250 and 27,418 persons per square kilometer, respectively [37,39]. It is also important to note that we treated each perceived barrier as a unique covariate in the model to assess the most relevant barriers to social distancing, which may differ from other studies. Moreover, given that our respondents were mostly well-educated social media users, the true proportion of individuals with perceived barriers in our study was likely underestimated.

Previous studies have also suggested perceived susceptibility to be a good predictor for preventative behaviors [17]. In our study, perceived susceptibility was, overall, a significant positive predictor for practicing more handwashing. Perceived severity was also a strong predictor for both handwashing and social distancing in the United States and Taiwan, which may have been influenced by the worldwide news coverage and the strictness of government interventions. The associations found between perceived benefits and health behaviors may be tied to the timing of policies in each country and overall trust in the government. Cues to action, measured as types of media publicity, were not significant for predicting behavioral change in our model.

Modifiable factors that influence individual beliefs, such as culture and prior knowledge, are important to consider. In Hong Kong and Taiwan, wide adoption of preventative behaviors after the 2003 SARS outbreak may have better prepared residents for COVID-19, which may explain their greater sense of self-efficacy in handwashing and social distancing compared to other countries. Many residents were already taking regular individual actions, practicing good hand hygiene for infection control or wearing masks to counter air pollution when the pandemic hit. In fact, the study team received several emails from respondents in Taiwan and Hong Kong, noting that they had practiced handwashing prior to the pandemic because they were taught to do so as children. For this study, we were unable to statistically account for social factors and prior knowledge in our analyses, but future studies should consider including them into models to assess the influence of social and cultural factors on preventative health behaviors.

Using Social Media for Recruitment During COVID-19

Our study may also provide insight into the effect of using social media recruitment strategies to reach a large audience. Given the rapidly evolving information, beliefs, and policies surrounding COVID-19, internet sampling allowed us to (1) capture real-time data simultaneously in different countries in a short time span, (2) reach a large number of participants in lockdown, and (3) overcome financial limitations [40]. The combination of boosting and sharing of social media posts allowed us to effectively target specific populations and locations while also reaching a larger audience, as was evident by the number of respondents from Taiwan. Our findings expand on recent COVID-19 studies from the United States and Taiwan that used similar methods to assess other COVID-19 attitudes, behaviors, and knowledge among different populations [41-43].

Limitations

There are limitations to this study. Firstly, we used convenience sampling to recruit participants, which could have introduced potential sample selection bias. For example, we found an underrepresentation of populations with lower educational levels. This may have resulted in an overestimation of adherence rates and underestimation of perceived barriers. However, in multivariate analysis, education was not statistically associated with handwashing or social distancing practices. To best address the imbalances in our sample, we conducted poststratification weighting by age and gender, as well as race or ethnicity for the United States, to improve the generalizability of our results, although we understand that this does not make up for all of the differences [44]. Secondly, we had a disproportionately larger sample size in Taiwan relative to other countries [45]. However, since our main multivariable analyses were country specific, this would not likely affect the estimates found in other countries. Finally, there are weaknesses within the HBM itself. The HBM does not account for a person's nonhealth-related beliefs or determinants that dictate a person's acceptance of a health behavior. Health behaviors can also be learned through modeling as explained by other behavior change theories, such as the social cognitive theory (SCT); for instance, residents in Taiwan and Hong Kong might regularly wear masks and practice hand hygiene from observing those around them [46]. Self-efficacy, the strongest predictor in our study, is also known to play a large role in health behavior in the context of the SCT. However, we did not use SCT in our study because the theory's heavy emphasis on the process of learning disregards an individual's perception about COVID-19 as well as their motivations behind handwashing and social distancing behaviors. The collection of data on health beliefs, which the HBM encompasses, is important for the planning of interventions that can then be targeted to each country's specific needs.

Conclusions

Overall, our findings revealed that certain health belief constructs were independently associated with social distancing and handwashing behaviors. In the context of controlling the continued spread of COVID-19, self-efficacy is a significant predictor that can be easily targeted and modified by public health officials and educators. Policies and communications

that address relevant health beliefs can facilitate adoption of necessary actions for preventing COVID-19.

Abstract

Background: Although commercially available analgesic indices based on biosignal processing have been used to quantify nociception during general anesthesia, their performance is low in conscious patients. Therefore, there is a need to develop a new analgesic index with improved performance to quantify postoperative pain in conscious patients.

Objective: This study aimed to develop a new analgesic index using photoplethysmogram (PPG) spectrograms and a convolutional neural network (CNN) to objectively assess pain in conscious patients.

Methods: PPGs were obtained from a group of surgical patients for 6 minutes both in the absence (preoperatively) and in the presence (postoperatively) of pain. Then, the PPG data of the latter 5 minutes were used for analysis. Based on the PPGs and a CNN, we developed a spectrogram–CNN index for pain assessment. The area under the curve (AUC) of the receiver-operating characteristic curve was measured to evaluate the performance of the 2 indices.

Results: PPGs from 100 patients were used to develop the spectrogram–CNN index. When there was pain, the mean (95% CI) spectrogram–CNN index value increased significantly—baseline: 28.5 (24.2-30.7) versus recovery area: 65.7 (60.5-68.3); $P<.01$. The AUC and balanced accuracy were 0.76 and 71.4%, respectively. The spectrogram–CNN index cutoff value for detecting pain was 48, with a sensitivity of 68.3% and specificity of 73.8%.

Conclusions: Although there were limitations to the study design, we confirmed that the spectrogram–CNN index can efficiently detect postoperative pain in conscious patients. Further studies are required to assess the spectrogram–CNN index's feasibility and prevent overfitting to various populations, including patients under general anesthesia.

KEYWORDS

analgesic index; machine learning; pain assessment; photoplethysmogram; postoperative pain; spectrogram

Introduction

Efficient management of postoperative pain affecting the prognosis of patients is becoming increasingly important [1]. To properly administer analgesics, it is necessary to first objectively assess the patient's degree of pain. In conscious patients, pain can be assessed by asking the patient directly, but unconscious patients or those with difficulty communicating

require an appropriate index to quantify their pain. However, current commercial analgesic indices were developed for the purpose of evaluating nociception in patients under general anesthesia [2,3]; therefore, there is no standard for the quantification of postoperative pain in conscious patients [4]. Thus, developing a new pain index to quantify pain in patients who cannot directly communicate their level of pain may also help in the clinical setting; it will also reduce the need to ask questions each time the patient is conscious when pain must be evaluated frequently.

A photoplethysmogram (PPG) is a biosignal that can be obtained continuously and noninvasively using a pulse oximeter. Because a PPG conveys much information about a patient's condition, many attempts have been made to quantify pain by analyzing PPG signals [3,5-7]. The surgical pleth index (SPI; GE Healthcare), developed for quantifying nociception during general anesthesia, only considers the amplitude and heartbeat interval of a PPG [3]. In addition to these 2 parameters, other pain-related features are present in PPG signals [6,7]. Therefore, the application of a new analytical method has the potential to improve the performance of analgesic indices.

Deep learning architectures, such as a convolution neural network (CNN), can be a good solution to elucidate the hidden features in a PPG because they can identify optimal abstracted features that are beyond human comprehension without any manual procedure [8]. Furthermore, in determining the presence of pain, machine learning has a strong advantage owing to its nonlinear characteristics compared with the SPI, which assesses pain based on simple linear regression [8,9], potentially making it possible to effectively predict nonlinear deviations among individuals or situations [10]. Therefore, a combination of the extended features of PPG and machine learning–based scoring is expected to overcome the limitations of existing pain assessment techniques. However, because a PPG is a 1D signal, whereas CNNs have the advantage of multidimensional data analysis, a dimensional extension of a PPG without loss of time–frequency characteristics is required to apply it optimally in a CNN. A spectrogram, which is a 2D image including the intact time–frequency characteristics of a PPG, can be a good method for applying a CNN to PPGs.

This study aimed to develop a new analgesic index using PPG spectrograms and a CNN to objectively assess pain in conscious patients. In addition, the performance of our newly developed index was compared with that of the SPI.

Methods

Patient Population

The study protocol was approved by the Institutional Review Board of Asan Medical Centre (approval number: 2016-0477) and registered on an international clinical trials registry platform (registration number KCT0002080). Written informed consent was obtained from all patients. All procedures were conducted in accordance with relevant guidelines and regulations. In total, 120 patients (American Society of Anesthesiologists Physical Status 1, 2, or 3) between the ages of 20 and 80, who were scheduled to undergo elective surgery, were included in this observational study. Exclusion criteria were as follows: clinically significant impairment of the cardiovascular, hepatic, or renal function; history of cardiac arrhythmia; use of medication that might affect autonomic function; the presence of presurgical acute or chronic pain (Visual Analog Scale score [VAS] > 0, measured before surgery); clinically significant laboratory findings; and evidence of pregnancy.

Procedure and Data Acquisition

All patients fasted from midnight on the day of surgery without premedication. In the operating theater, patients were monitored for their heart activity using electrocardiography, end-tidal carbon dioxide partial pressure, and noninvasive blood pressure measurement. Neuromuscular transmission was monitored using an M-NMT module at the adductor pollicis muscle (CARESCAPE B850; GE Healthcare). A reusable SPI sensor was placed on the index finger of each patient (on the arm not used for blood pressure measurement). Patients were allowed to acclimatize for at least 5 minutes in the supine position in a quiet operating theater, after which baseline data (without pain) were collected for 6 minutes, of which the latter 5 minutes were used for analysis. General anesthesia was performed by administering propofol and remifentanil by a target effect-site concentration–controlled infusion using the Schnider and Minto models [11,12]. Target effect-site concentrations (*Ces*) of propofol were titrated to maintain the bispectral index (Covidien) at less than 60 during the induction and maintenance of anesthesia. The target *Ces* of remifentanil were adjusted to maintain stable hemodynamics (ie, systolic blood pressure >80 mmHg and heart rate over 45 beats/min). All patients received a bolus dose of oxycodone (0.1 mg/kg) 30 minutes prior to the end of surgery.

Intravenous patient-controlled analgesia with oxycodone began after the administration of the bolus dose of oxycodone. Neuromuscular blockade was reversed with neostigmine and glycopyrrolate at the end of surgery. Tracheal extubation was performed when the train-of-four ratio was greater than 0.9 and bispectral index value was greater than 80. Patients were then transported to the postanesthesia care unit (PACU). When the patients arrived in the PACU, their state of consciousness was assessed with a modified Aldrete score [13]. Electrocardiogram, pulse oximetry, and noninvasive blood pressure were also monitored. Additional PPG and SPI data were obtained for the initial 5 minutes in the PACU. After obtaining the data, patients were assessed for pain using a VAS (0=no pain; 100=the most severe pain). Oxycodone was administered according to postoperative pain intensity. The PPG and SPI values were measured using an S/5 Anesthesia Monitor (Datex-Ohmeda, Inc.) and recorded on a laptop for offline analysis. The PPG data were sampled at 300 Hz, and SPI data were recorded every 10 seconds.

Pain Assessment Model

A spectrogram–CNN model was developed and validated through fivefold cross-validation. The developed model outputs the spectrogram–CNN index as a pain score using a PPG spectrogram as input and CNN as a pain scorer. During model development, patients and test sets were separated to prevent intrasubject interference to avoid data overlaps between the

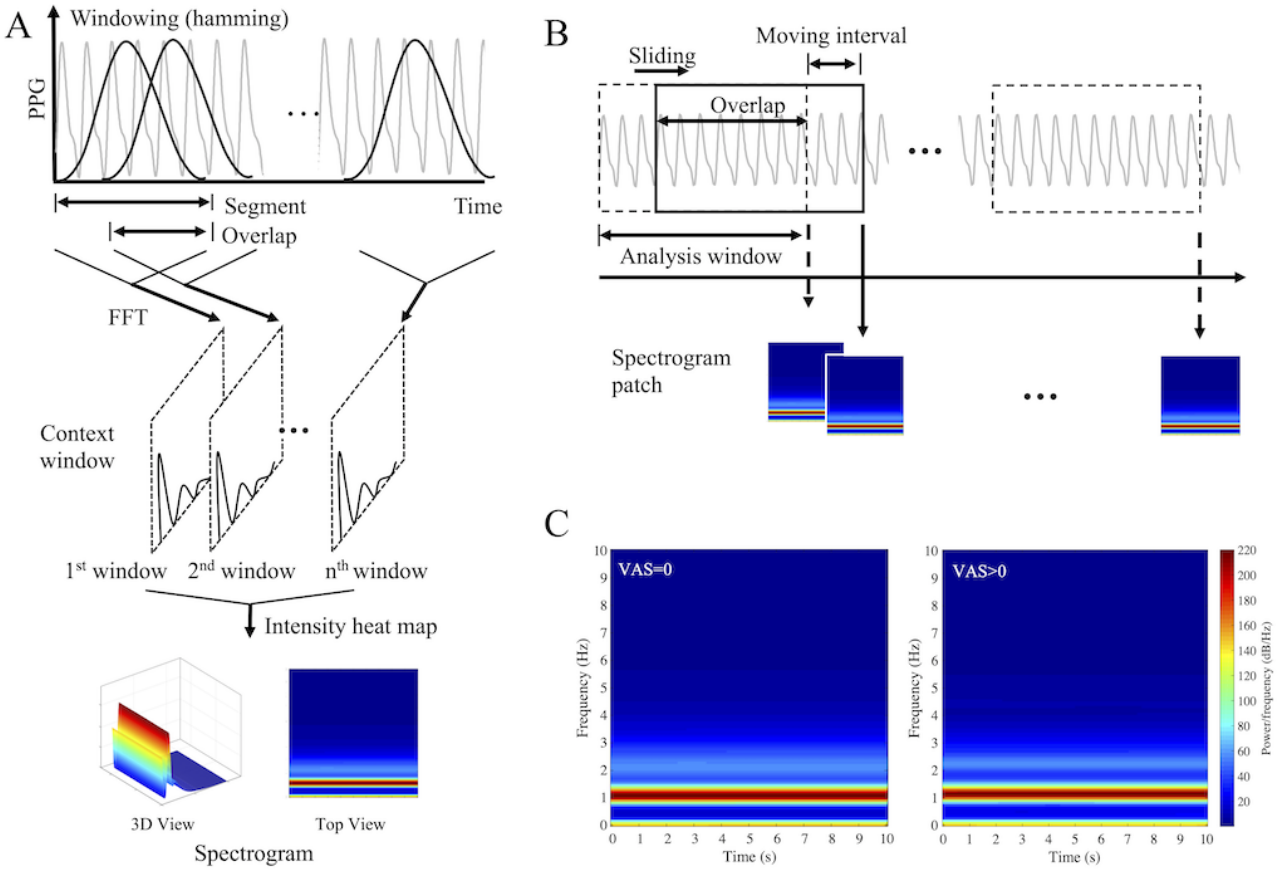
development and test sets of each fold. For model training, 90% of the development set was used as a training set and 10% as a validation set. Finally, for each fold, 20, 73, and 7 patients' data were used as a test set, training set, and validation set, respectively. Pain and nonpain data labels were created based on the VAS, where VAS>0 was defined as pain and VAS=0 was defined as nonpain with labels "1" and "0," respectively. Detailed descriptions of the spectrograms and CNN used in this study are given below.

Spectrogram

Spectrogram creation is a method used for time–frequency analysis of time series signals. A spectrogram reconstructs 2D images while maintaining the information contained in 1D time series data [14]. Spectrograms are useful for visually describing changes in the frequency characteristics of nonstationary signals, such as physiological signals over time [15,16]. Spectrograms can be generated by repeating short-time Fourier transforms that divide a longer time signal into shorter segments of equal length and then computing the Fourier transforms separately on each shorter segment. In this study, 2D spectrogram images generated from 1D PPGs were used as the pain classifier input to reflect the whole waveform and change of waveform, not the specific feature of the PPG waveform. Prior to spectrogram generation, all PPGs were filtered using both a finite impulse response bandpass filter with a 0.5-10-Hz passband and a 30-tap moving average filter. In addition, considering that PPG amplitude is an arbitrary unit, a normalization process was performed to reduce the intersubject and intermeasurement deviations [17]. In the normalization process, *z*-scores were obtained by subtracting the mean of the measured values from each measured value and dividing by the standard deviation. The spectrogram generation process is illustrated in Figure 1.

Spectrogram images were generated by short-time Fourier transforms of 10-second PPGs every 10 seconds without overlap (Figure 1A). At the time, to generate a single spectrogram image, each 10-second PPG was divided into 6.3-second segments with a 6.27-second overlap and transformed to the frequency domain using fast Fourier transform after windowing with a Hamming window (Figure 1B). The frequency range of the spectrogram image was set to 0-10 Hz, and the frequency resolution was set to 0.81 Hz to equalize the number of time frames and frequency bins, that is, to equalize the numbers of horizontal and vertical pixels in the spectrogram image, respectively. Finally, 30 spectrogram patches of size 124 × 124 were generated for each 5-minute PPG. Figure 1C shows the averaged spectrograms without pain (left) and with pain (right). All preprocessing and spectrogram patches were generated using MATLAB (version 2018a; The MathWorks, Inc.).

Figure 1. Process for generation of a single spectrogram (A), process of generating multiple spectrograms over time using a sliding window (B) and the average spectrogram during pain (left) and non-pain (right) conditions (C); FFT: fast Fourier transform; PPG: photoplethysmogram.

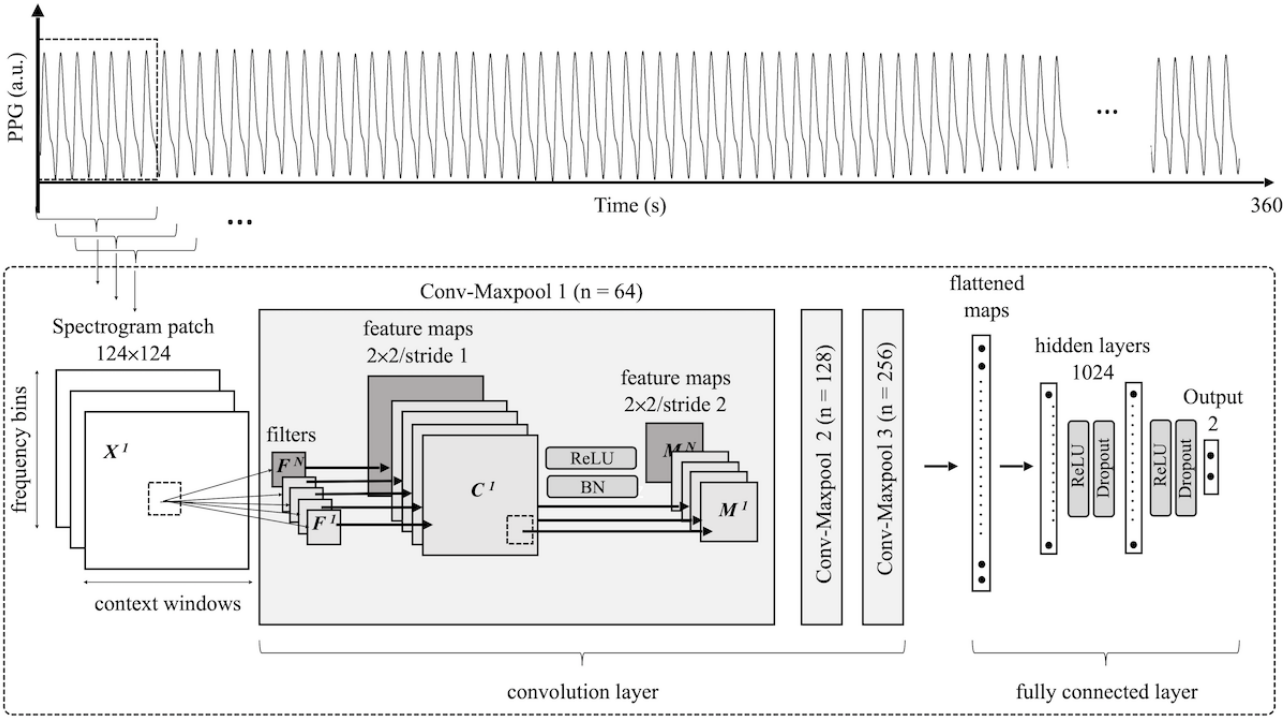


Convolutional Neural Network

CNNs are useful for image analysis because they have the advantage of maintaining the spatial information of 2D or higher inputs. CNNs enable data-driven learning, are highly representative, and effectively combine the spatial information of multidimensional inputs [18]; supervised CNNs extract information more effectively due to class-specific information

[19,20]. The CNN used in this study has a 2D PPG spectrogram input and binary-coded labels: “0” is a pain-free state and “1” is pain state. Figure 2 shows the structure of the CNN developed in this study. First, in the convolution-max pooling layer (Conv-Maxpool), 32, 64, and 128 filters are applied to the spectrogram input to perform a convolution process, and the spatial characteristics are simplified through max pooling. In Conv-Maxpool, the filter size of all convolutional layers is 2 × 2 and the stride is 1. The size of the feature map is reduced by setting the filter size of the max pooling layer to 2 × 2 and stride to 2, equal to the filter size. A batch normalization layer and rectified linear unit (ReLU) activation functions are applied to the Conv-Maxpool to increase learning speed and efficiency. Batch normalization is a structure that improves the speed and stability of neural networks by normalizing interlayer input data [21], and ReLU improves the expressive power of neural networks based on nonlinear features [22,23]. The Conv-Maxpool process is repeated 3 times, resulting in a feature map size of 15 × 15. The fully connected layer consists of 2 hidden layers and 1 output layer, and the ReLU activation function and dropout are also applied to the hidden layer to reduce overfitting [24]. The dropout rate was set to 0.5 in training, but there was no dropout during testing. Cross-entropy is employed as a cost function [25], and adaptive moment estimation (Adam) is used as an optimizer [26]. Finally, the result is output to 2 nodes, representing “pain free” and “pain,” and the values are probabilistically expressed using the SoftMax function [27]. Because the output of SoftMax gives the probability of the input data being a painful condition with a value between 0 and 1, it is converted into a pain index as the “likelihood of pain.” Consequently, the spectrogram–CNN index is calculated by multiplying the probability value output from the pain node by 100. The CNN model was implemented and trained using Python 3.7 (Python Software Foundation) and TensorFlow 2.0 in the Anaconda environment.

Figure 2. Architecture of the convolutional neural network proposed in this study. X: input, F: filter, C: convolution layer, M: max pooling, N: number of filters, BN: batch normalisation, ReLU: rectifier linear unit, Conv-Maxpool: convolution-max pooling.



Statistical Analyses

Receiver-operating characteristic (ROC) curves were computed to compare the sensitivity and specificity of the spectrogram–CNN index and SPI for detecting pain. Cutoff values used for calculation of sensitivity and specificity were computed as “best fit” (highest combined sensitivity and specificity) [28]. The differences between the spectrogram–CNN index and SPI in the ROC curves were calculated using the MedCalc Statistical Software (version 13.3.1; MedCalc Software). Statistical analyses were conducted using IBM SPSS (version 22.0; SPSS Inc.). Data are expressed as mean (SD) for normally distributed continuous variables, median (25%-75%) for non-normally distributed continuous variables, and count SPI for categorical variables. *P* values <.05 were considered to be statistically significant.

Results

In total, 120 patients were enrolled, of whom 20 dropped out because of failure of PPG data storage (n=8), failure of SPI data storage (n=2), abnormal SPI data that could not be included in the analysis (n=9), and failure to measure VAS after surgery (n=1). Thus, 100 patients were included in the final analysis. The characteristics of these patients are summarized in Table 1. All but 1 patient had consciousness values of 2 points (conscious), as assessed by the modified Aldrete score at the time of PACU arrival. One patient scored 1 (arousable on

calling) who later had a value of 2 points upon leaving the PACU.

Individual changes in the spectrogram–CNN index and SPI without and with pain are presented in Figure 3. The 7 patients who had no postoperative pain were excluded from this analysis. In the case of pain, the mean spectrogram–CNN index and SPI values increased significantly (baseline spectrogram–CNN index: 28.5 (SD 22.1) versus PACU spectrogram–CNN index: 65.7 (SD 25.4), $P<.01$ in paired t test; baseline SPI: 42.5 (SD 16.7) versus PACU SPI: 53.5 (SD 17.8), $P<.01$ in paired t test). The area under the curve (AUC) of the ROC and cutoff values for detecting pain in terms of spectrogram–CNN index and SPI are listed in Table 2. The spectrogram–CNN index was statistically superior to the SPI (pairwise comparison of ROC curves: spectrogram–CNN index versus SPI, $P<.01$). Moreover, as shown in Table 2 and Figure 4, the spectrogram–CNN index showed improved performance measures in terms of balanced accuracy, sensitivity, and especially specificity.

Table 1. Characteristics of the study population.

Characteristic	Patients (N=100)
Male/Female	44/56
Age (years), mean (SD)	53.4 (12.5)
Height (cm), mean (SD)	161.8 (8.5)
Weight (kg), mean (SD)	62.2 (12.2)
ASA PS[a] 1/2/3	22/76/2
Type of surgery, n	
Breast	29
Colorectal	19
Hepatobiliary	12
Stomach	30
Thyroid	10
Postoperative pain intensity at PACU[b], n	
No (VAS[c]=0)	7
Mild (0 < VAS ≤ 30)	11
Moderate (30 < VAS ≤ 70)	58
Severe (70 < VAS ≤ 100)	24

[a]ASA PS: American Society of Anesthesiologists Physical Status.

[b]PACU: postanesthesia care unit.

[c]VAS: Visual Analog Scale (0=no pain; 100=the most severe pain).

Figure 3. Individual changes (n=100) in the spectrogram-convolutional neural network index (SCI, A) and the Surgical Pleth Index (SPI, B) and without and with pain. *$P<.05$ vs. baseline. The black circles represent the average of 5 min of the SCI or SPI observed without and with pain. The red circles indicate mean values for all patients. PACU: postanaesthesia care unit.

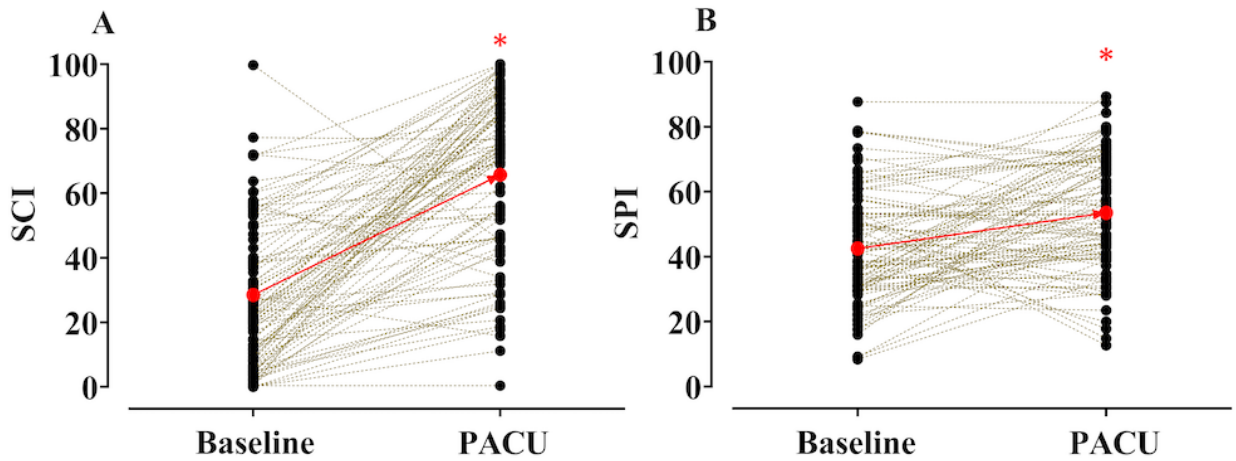


Table 2. Areas under the receiver-operating characteristic curves (AUCs) and cutoff values for assessing pain in the spectrogram-convolutional neural network index and surgical pleth index (SPI) in surgical patients.

Parameter	Spectrogram–CNN[a] index			SPI
	Training set	Validation set	Test set	
AUC (95% CI)	0.992 (0.991-0.993)	0.932 (0.921-0.942)	0.757 (0.746-0.768)	0.659 (0.646-0.671)
P value	<.01	<.01	<.01	<.01

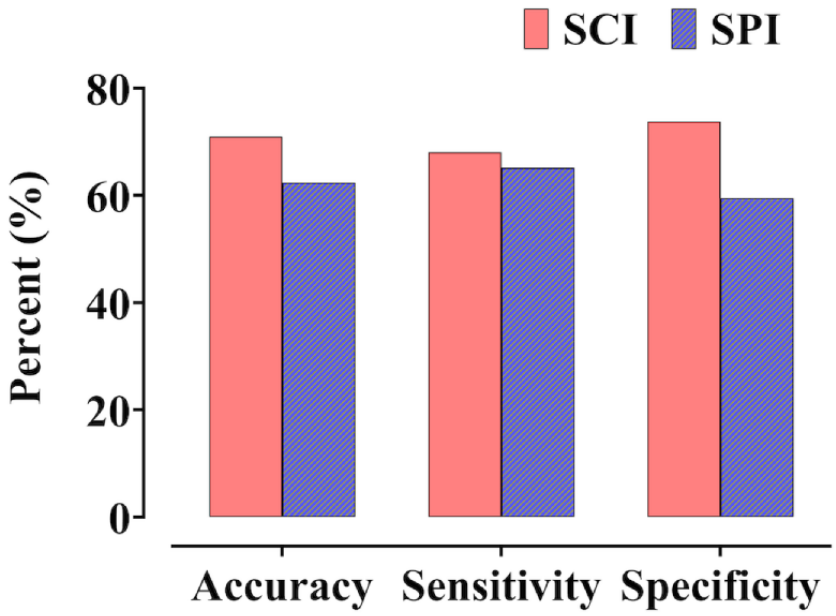
Sensitivity, %, specificity, %	94.6, 96.4	83.1, 88.2	68.1, 73.8	65.2, 59.5
Balanced accuracy, %[c]	95.5	85.7	71.0	62.4

[a]CNN: convolutional neural network.

[b]Cutoff values used for the calculation of sensitivity and specificity were calculated as “best fit” (highest combined sensitivity and specificity).

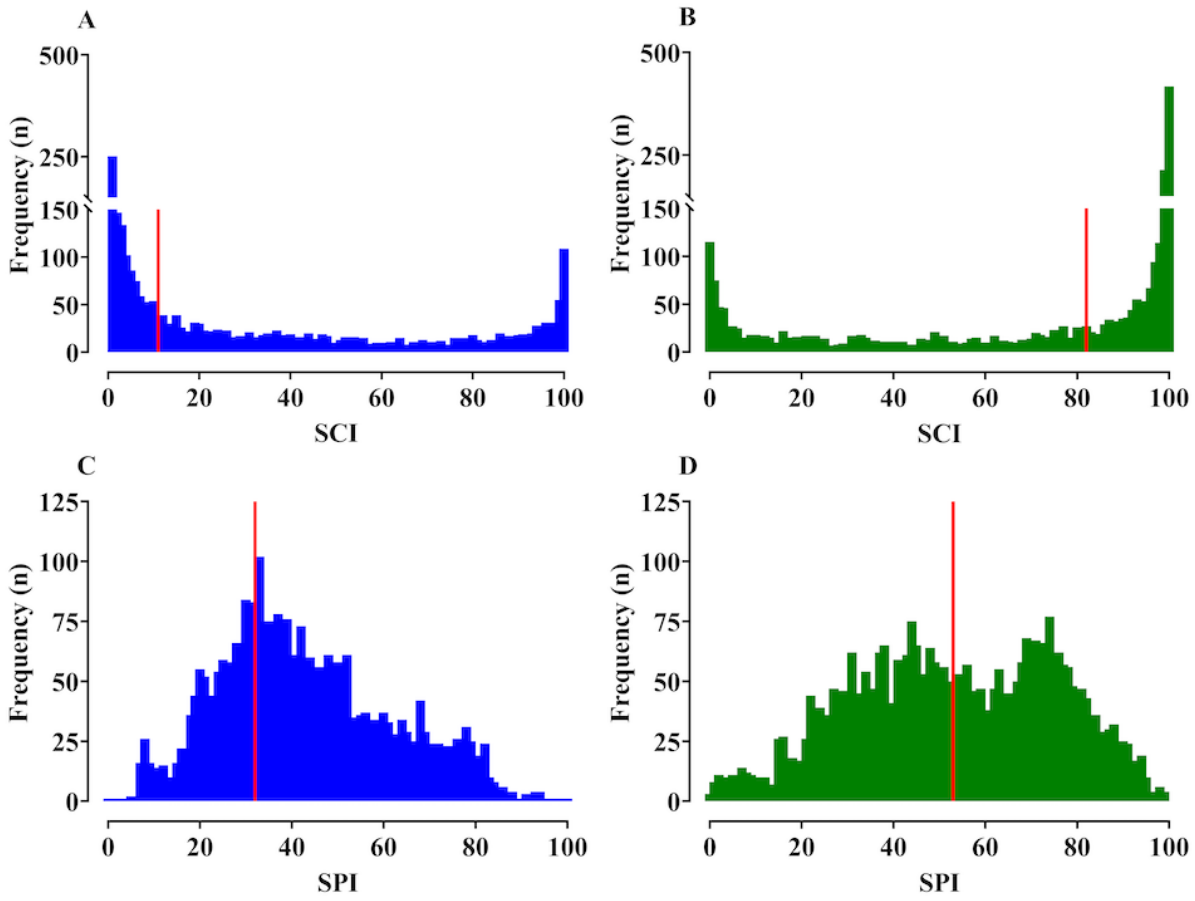
[c]Balanced accuracy is the corrected accuracy of the imbalance of a class set, calculated as (sensitivity + specificity)/2.

Figure 4. Performance measures of spectrogram-convolutional neural network index (SCI, red) and the Surgical Pleth Index (SPI, blue) in terms of accuracy, sensitivity and specificity. Accuracy means balanced accuracy. Cut-off value of SCI was 48.



Neither spectrogram–CNN index (mild: 69.5 [53.2-87.7], moderate: 71.8 [40.5-89.3], severe: 74.6 [62.9-84.7], *P*=.78, Kruskal–Wallis one-way ANOVA on ranks) nor SPI (mild: 53.5 [SD 21.0], moderate: 51.8 [SD 18.0], severe: 57.9 [SD 15.7], *P*=.37; one-way ANOVA) could statistically distinguish between mild, moderate, and severe pain. The frequency distributions of the spectrogram–CNN index and SPI values observed without and with pain during the data collection period are shown in Figure 5. The distribution of SPI values overlapped for with and without pain, suggesting that the SPI shows several false positives/false negatives, whereas the distribution of spectrogram–CNN index values showed a significant difference (*P*<.05) in patients with and without pain, suggesting that the spectrogram–CNN index can distinguish pain more clearly than the SPI.

Figure 5. Frequency distribution of the spectrogram-convolutional neural network index (SCI, A and B) and surgical pleth index (SPI, C and D) values observed without (A and C) and with (B and D) pain. During the data collection period (baseline: 5 min, postanaesthesia care unit: 5 min), the SCI and SPI values were observed every 10 sec. The vertical red lines show the median frequency (A: 11, B: 82, C: 32, D: 53).



Discussion

The spectrogram–CNN index proposed in this study outperformed the commercialized SPI pain index in the postoperative pain assessment of conscious patients. One of the main reasons for its outperformance is the spectrogram input containing the PPG's intact waveform information, making it possible to use hidden pain-related factors that could not be provided only by the peaks. Because existing pain assessment methods, such as the SPI, use only certain features of a PPG that show significant changes in surgical stimuli, numerous pain-related information reflected in the PPG may be overlooked. To overcome these limitations, research has been conducted on new pain-related features derived from sophisticated PPG waveform analysis in addition to the heart rate interval and PPG amplitude reflected in the SPI [5-7]. However, these pain indicators still depend on complex processes, such as peak detection and feature extraction, which require accurate peak extraction algorithms and are vulnerable to signal quality degradation. The proposed PPG spectrogram input does not require any peak detection or feature extraction process, thus avoiding problems such as peak misdetection during preprocessing. In addition, the spectrogram provides information from almost the whole PPG waveform because only the domain in which information is represented is transformed, while the underlying information is retained. This feature of the proposed model is its differentiating factor from SPI, which requires a complicated process of extracting pain features from biosignals, including PPG pulsation start and systolic maximum detection and verification. These preprocessing steps are necessary in existing pain assessment methods, but they are cumbersome and vulnerable, providing only limited features. Therefore, a simplified preprocessing process that still provides plentiful feature information can significantly improve the robustness of pain assessment.

Another key technique proposed in this study is the discrimination of postoperative pain using machine learning. Although machine learning–based pain assessment has already been studied [29-31], it is not suitable for practical clinical situations because it depends on high-dimensional clinical data, such as patient records and electroencephalograms, which are rarely used in postoperative care. However, machine learning from PPGs, which are frequently used in clinical practice during postoperative care, has high practical utility. In this study, we used a spectrogram–CNN combination, which has already been applied to electrocardiograms and electroencephalograms and has shown reasonable performance in predicting seizures and atrial fibrillation [32-35]. The spectrogram converts the data into 2D, and the CNN has the advantage of extracting the spatial features of multidimensional data. The combination of these

techniques thus extends the dimensions of PPG and allows spatiotemporal analysis, maximizing the use of features inherent in the signal. Nonlinear classification may be another important reason for the good performance of the proposed model. While the SPI is derived from a simple linear combination of normalized heartbeat interval and normalized pulse wave amplitude [3,36], the proposed spectrogram–CNN model performs nonlinear classification using the ReLU activation function. In addition, the nonlinearity is increased because the ReLUs are overlapped with each other in a multilayered structure.

In this study, patient data used for model development and validation were separated, and fivefold cross-validation was performed to eliminate interindividual interference and to generalize the model. Therefore, the proposed spectrogram–CNN index is expected to show similar performance in other groups of patients of similar age who did not participate in model development. However, there may be a few new variables to consider. In Table 2, performance measures were approximately 95%, approximately 85%, and approximately 70% for the training, validation, and test sets, respectively. The decision criteria also differed with 50 in the training set, 54 in the validation set, and 48 in the test set, indicating that overfitting occurred. In a random permutation test on balanced accuracy, the average accuracy was 49.5 (SD 0.7), and the range of values was 47.6-51.8. Considering that all balanced accuracies of the training, validation, and test sets were over 71, it is likely that the overfitting in our result stemmed from large intersubject variability rather than the model itself. Overfitting can be interpreted as degradation of the model's versatility, but it can also be interpreted as higher performance, at least in terms of validation accuracy, if sufficient data are used. Therefore, further studies are required to improve the reliability and versatility of this index using a large patient population with diverse body characteristics.

The spectrogram–CNN index may not have been able to distinguish pain intensity because the number of observations was relatively small. A previous study showed that SPI distinguishes postoperative pain intensity [28]; however, the authors of this previous study analyzed 1300 observations, whereas we only used 93. Nonetheless, a more fundamental reason is that the severity of pain was not accounted for when developing the spectrogram–CNN index. If sufficient PPG data were provided when learning to classify pain severity, it would be possible to classify pain intensity.

The database used in this study was shared by 2 research groups. Another group, independent of this study, has already published their results. Their pain classifier, based on a deep belief network using various PPG features, discriminated well between the presence and absence of pain [37]. Compared to the other study that extracted various features, ours used a simple spectrogram containing all PPG information without any complicated feature extraction procedure and is based on a CNN optimized for the spectrogram input. CNNs have lead in the machine learning field because they demonstrated performance improvements in image recognition in 2012 [9]. Moreover, the previous study evaluated pain based on full-length data, whereas ours assessed pain every 10 seconds, the same data display interval as in the SPI. Therefore, it can be applied to real-time pain assessment, which is in contrast to the other study.

There are some limitations to this study. First, the SPI was selected as a comparative index to evaluate the performance of the spectrogram–CNN index, but its suitability is somewhat debated. The SPI is neither developed nor recommended for use in conscious patients. However, when a new analgesic index is developed, it is essential to evaluate its performance, and this is commonly done by comparing it with an existing index using the same data. Although the SPI is not recommended for use in conscious patients, some studies on conscious patients suggest that SPI can discriminate between the presence and absence of pain [28,38]. Between the SPI and another commonly used commercial analgesic index—the Analgesia Nociception Index (PhysioDoloris, MetroDoloris)—the AUC–ROC for detecting postoperative pain in conscious patients was highest for the SPI [38]. Hence, the SPI was chosen as the comparative index for this study. Second, neostigmine and glycopyrrolate, when administered to reverse neuromuscular blockade, can contribute to PPG signals. As this study was observational, only data necessary for the development of a new analgesic index were collected during the normal anesthesia process without intervention. Neostigmine and glycopyrrolate were used in all patients because none of them required sugammadex. Neostigmine is known to be rapidly eliminated from the plasma after administration, with an average half-life of approximately 25 minutes [39]. We collected postoperative PPG data an average of 29.4 minutes after administration of these 2 agents. A previous study reported that baroreflex sensitivity was restored to its baseline value after approximately 82 minutes of glycopyrrolate administration [40]. It is possible that glycopyrrolate has mixed effects on postoperative PPG. However, because sugammadex usage is not common, it may be more beneficial to develop an index to distinguish pain based on data that can be obtained from actual practical conditions. Further studies are required to evaluate the extent of the effect of these 2 drugs on postoperative PPG. Third, it is difficult to determine whether the PPG data collected from the PACU solely reflect pain. In the conscious state, the sympathetic nervous system may be activated for other reasons, such as arousal or anxiety. Anxiety has been associated with reduced heart rate variability and vagal tone [41]. As we did not evaluate patient anxiety, we cannot determine its contribution to the PPG data. Considering the condition of patients who arrived in the PACU immediately after surgery, the PPG data mostly reflected immediate postoperative pain without controlling consciousness.

In conclusion, although there were several limitations to the study design, we confirmed that the newly developed spectrogram–CNN index can effectively detect postoperative pain in conscious patients. Further validation studies are required to assess its feasibility and prevent overfitting to various populations, including patients under general anesthesia.

Abbreviations

AUC: area under the curve
CNN: convolutional neural network
PPG: photoplethysmogram
ReLU: rectified linear unit
SPI: surgical pleth index
VAS: Visual Analog Scale

Edited by G Eysenbach; submitted 27.08.20; peer-reviewed by K Chen, H Demir; comments to author 21.09.20; revised version received 21.09.20; accepted 18.01.21; published 03.02.21.
