Abstract

Background: As the world continues to advance technologically, social media (SM) is becoming an essential part of billions of people's lives worldwide and is affecting almost every industry imaginable. As the world is becoming more digitally oriented, the health care industry is increasingly visualizing SM as an important channel for health care promotion, employment, recruiting new patients, marketing for health care providers (HCPs), building a better brand name, etc. HCPs are bound to ethical principles toward their colleagues, patients, and the public in the digital world as much as in the real world.

Objective: This review aims to shed light on SM use worldwide and to discuss how it has been used as an essential tool in the health care industry from the perspective of HCPs.

Methods: A literature review was conducted between March and April 2020 using MEDLINE, PubMed, Google Scholar, and Web of Science for all English-language medical studies that were published since 2007 and discussed SM use in any form for health care. Studies that were not in English, whose full text was not accessible, or that investigated patients' perspectives were excluded from this part, as were reviews pertaining to ethical and legal considerations in SM use.

Results: The initial search yielded 83 studies. More studies were included from article references, and a total of 158 studies were reviewed. SM uses were best categorized as health promotion, career development or practice promotion, recruitment, professional networking or destressing, medical education, telemedicine, scientific research, influencing health behavior, and public health care issues.

Conclusions: Multidimensional health care, including the pairing of health care with SM and other forms of communication, has been shown to be very successful. Striking the right balance between digital and traditional health care is important.

KEYWORDS

social media; social networking; internet; health care; COVID-19; research activity; medical education; telemedicine; mobile phone

Introduction

Background

A key characteristic of being human is the ability and desire for social networking. Over the ages, humanity has thrived in social communities in which members shared knowledge, opinions, and experiences, empowered by a sense of belonging. As the world continues to advance in terms of technology, social media (SM)—defined as "a group of Internet-based applications (apps) that allow the creation and exchange of user-generated content"—is becoming an essential part of billions of people's lives worldwide and is affecting almost every industry imaginable [1]. The definition of SM (the "read, write web," "Web 2.0," or "social networking") is constantly evolving [2]. The Merriam-Webster Dictionary defines it as "any form of electronic communication through which users create web-based communities to share information, personal messages, ideas, and other content such as photos and videos" [3]. SM is considered one of the most powerful communication tools of the 21st century. There has been a proliferation of SM tools in recent years, creating new opportunities to communicate, connect, create, and share information, without requiring exceptional coding skills to create or retrieve content [4].

Specifically, SM is increasingly becoming an augmenting tool in health care by enabling its users to acquire and share information; connect with others in the field; and communicate with colleagues, patients, or the public regarding health topics. Furthermore, SM supports patient empowerment by expanding the knowledge of the patients and placing them in a position where they can take control of their own health care needs [5]. This review is based on numerous studies and reviews that have investigated the different uses of SM in health care and its limitations and shortcomings. Consequently, this narrative is comprehensive and up to date, including the recent use of SM during the COVID-19 pandemic. The topic is relevant in today's scenario because the use of SM and social networking sites (SNSs) is increasing worldwide, especially in the health care industry. The findings presented in this review have strong implications for health care professionals, educators, and researchers.

Objectives

This review aims to shed light on SM use worldwide and discuss how SM has been an essential tool in the health care industry from the perspective of health care providers (HCPs). The review will be continued in Part II, where the use of SM from the perspective of patients will be discussed.

Methods

Search Strategy and Information Sources

Between March and April 2020, a comprehensive search on 4 databases (MEDLINE, PubMed, Google Scholar, and Web of Science) was conducted for all English-language medical studies that were published since 2007 and discussed SM use in any form for health care. A combination of the following keywords was used to search for titles and abstracts: "social media" (MeSH term) OR "social networking" OR "internet" (MeSH term) OR "WhatsApp" OR "Instagram" OR "Facebook" OR "YouTube" OR "Twitter" OR "LinkedIn" AND "healthcare" OR "health" (MeSH term) OR "medicine" (MeSH term) OR "physician" (MeSH term) OR "nursing" (subheading) OR "dentistry" (MeSH term) OR "telemedicine" (MeSH term), "recruitment" OR "education" (subheading) OR "career" OR "behavior" (MeSH term) OR "research" (MeSH term). Each of the 9 words in the first set was separately searched with each of the 12 words in the second set using "AND."

Screening Process

The articles were entered into an EndNote library, and duplicate publications were removed. Articles published before 2007 were excluded, as the words *social* and *media* at that time did not represent the current definition of SM. Titles and abstracts were assessed for eligibility. Studies that were not in English were excluded, along with those with inaccessible full text after unsuccessful attempts to access them. Irrelevant studies, such as studies that were not related to health care, studies whose primary outcome was not the use of SM in health care, or studies that discussed the negative impact of SM on health, were also excluded. Dissertations were also excluded from the study. The full texts of the studies were then appraised. Several relevant studies investigating SM use from patients' perspectives were found. Reviews on legal and ethical issues pertaining to the use of SM in health care were also obtained, following which, the publications were divided into 4 groups: *HCP*, *patient* or *the public*, *ethics* and *legal considerations*, and *shortcomings*. A decision was made to defer reviewing the last 3 groups and focus on this review on SM use by HCPs.

Categorization

After accessing the complete texts of the articles of interest, their reference lists were searched for additional studies, and the cited studies were also located. Thereafter, the articles were comprehensively reviewed. On the basis of the key findings, articles were initially grouped as follows: *sharing information*, *recruitment*, *education*, and *marketing*. As the review proceeded and more information was obtained, the groups were modified. *Sharing information* was divided into 2 groups: *health promotion*, focusing on HCPs sharing scientific information with the public, and *critical public health care issues*, which focuses on health announcements in crisis, especially COVID-19–related publications that warrant special attention. *Recruitment* was also divided into 2 groups: *recruitment*, which included job employment and residency program enrollment, and *scientific research*, in which studies discussed recruiting research participants and analyzing SM data. *Education* was renamed *professional medical education*, as this name specifies medical education. Studies related to continuous education were added to *marketing*, and the group was renamed *career development* and *practice promotion*. Another group was created—*professional networking* and *destressing*—which included findings from *sharing information* that discussed peer-to-peer communication and those from *education* that did not reflect professional education or career development. Finally, an additional group was created, *telemedicine*, as studies on this subject were abundant.

Results

Summary and Characteristics of Included Studies

The search yielded 5683 titles that were scanned with their abstracts. After exclusion of duplicates and noneligible studies, the initial sample comprised 73 publications. The full-text papers were retrieved. Additional studies from the article references or those emerged from the review but were not identified earlier were also added. This was because of variation in the keywords with respect to spellings (eg, behavior and behaviour), terminology (social networking and social network), and synonyms (eg, recruitment and employment) that were not accounted for in the initial search. A total of 142 articles (63 original studies) and 3 textbook chapters were reviewed (Figure 1).

The studies were conducted in the United States (61), Canada (12), Brazil (2), the United Kingdom (12), Europe (22), the Middle East (9), India (9), Asia (8), and Australia (7). The earliest study was published in 2008, and the latest studies were published in 2020, with most of them being published after 2014 (Figure 2).

Figure 1. Flowchart of the selection procedure.

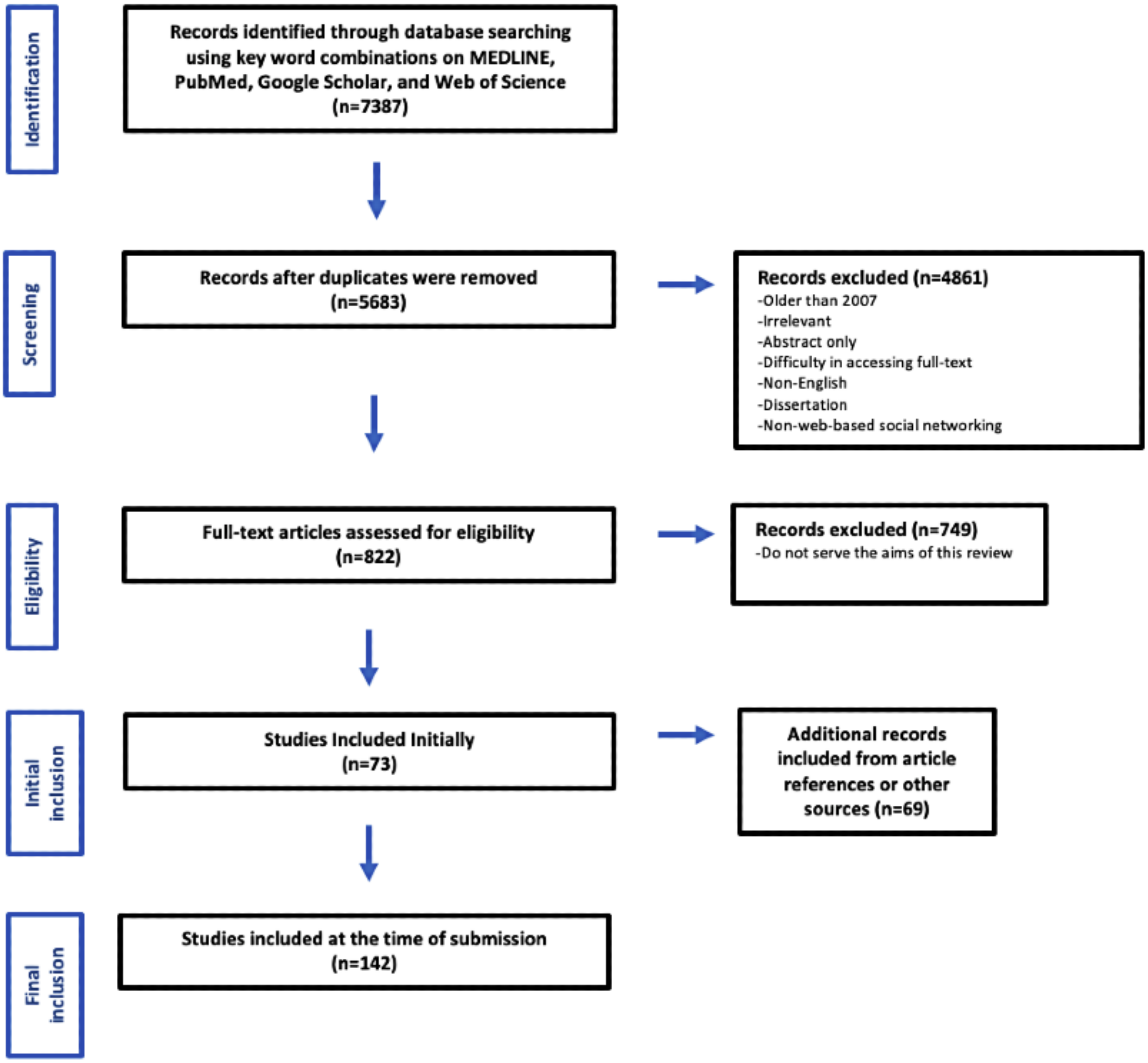

Figure 2. Number of included publications per year.

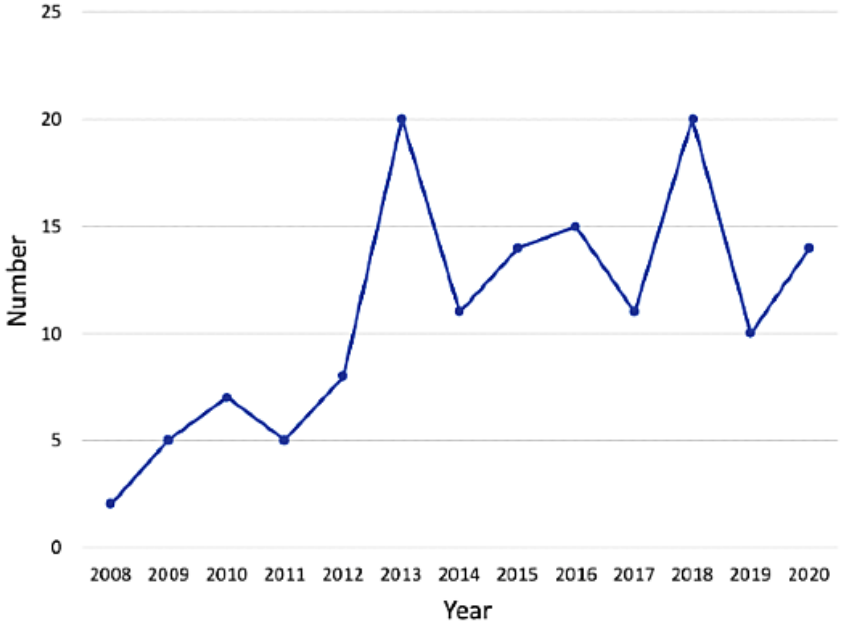

SM Platforms

Most reviews discussed SM in general and did not specify a particular platform; however, some original studies investigated specific platforms. The platforms investigated were WhatsApp/WeChat (15), Facebook (8), Twitter/Weibo (9), YouTube (4), Instagram (1), LinkedIn (1), Podcast (1), and Wikipedia (1).

Medical Specialties

Some reviews discussed SM use in a particular medical specialty, whereas others reviewed studies from diverse or unspecified specialties. Researchers from a variety of medical specialties investigated SM use in their original studies. These specialties were surgery (1), plastic surgery (4), neurosurgery (1), maxillofacial surgery (2), medicine (2), emergency medicine (2), psychiatry (3), orthopedics (3), otolaryngology (1), immunology (2), dermatology (1), radiology (1), urology (2), anesthesia (1), cardiology (1), pediatrics (1), oncology (3), nursing (5), dentistry (11), and pharmacy (1).

Discussion

Principal Findings

This literature review aimed to examine SM use in the modern world and how it has been recently incorporated into health care. Most of the reviewed articles were published in the past decade, suggesting that this review is both relevant and contemporary. It is evident from the published studies that SM has broad applications in modern health care. As discussed in the subsequent sections, HCPs (the term is used in this review as including physicians, dentists, nurses, medical and dental allied personnel, and health care organizations) not only use SM to provide care to their patients but also for personal development and destressing.

SM Use

SM use is one of the most common web-based activities, with an estimated 2.9 billion users worldwide as of 2019, a number that is projected to increase to 3.4 billion by 2023 [6]. With this, digital networking has witnessed a massive growth, and social communities have become boundless. Facebook, Twitter, Instagram, WhatsApp, and Google are relatively new platforms, but they are being used every day by millions of people worldwide. SM platforms are among the most commonly used sources for acquiring and disseminating information [7,8]. They are not only used for socialization, knowledge acquisition, and entertainment, but they have also been linked to significant political events led by young users [2].

Many SM tools have been introduced, and they continue to evolve. They may be categorized as tools for social networking (eg, Facebook and Instagram), professional networking (eg, Doximity and Sermo), media sharing (eg, YouTube and WhatsApp), content production (eg, Twitter), and blogs [9].

In terms of technological knowledge, SM users belong to 1 of the following 2 groups, as classified by Prensky [10]: digital natives and digital immigrants. Digital natives are those born after 1980, who are skilled in using technology, and who rely heavily on technology and social networking. Most digital natives were introduced to technology at an early age. Conversely, digital immigrants are those who acquired technological skills and adopted technology later in their careers [9]. SM use is generally high among digital natives, who explicitly prefer it over traditional media [11]. Some researchers believe that there is no dichotomous divide between internet users and nonusers. Although the terms are commonly used, Prensky's model and its usefulness have been challenged [12]. First, basic digital skills are not difficult to acquire, especially with repetitive use. With practice, a person born in the 1960s can become as digitally fluent as a millennial. Second, the distinction between both generations implies that digital immigrants can never completely acquire digital abilities and

that digital natives are automatically technologically skilled. This approach is neither scientific nor based on any empirical evidence. Third, the model overlooks the fact that age is not the only factor in determining digital skills. Socioeconomic and cultural factors of digital capability must not be ignored. For instance, a millennial who lacks access to technology is not a digital native.

Regarding SM demographics, its use is prevalent across all ages and professions [13]. However, different SM platforms differ in their demographics. The demographics of some of the most commonly used SM platforms worldwide can be further explored. Facebook has 2.7 billion monthly active users. According to a 2020 report, the highest number of Facebook users were aged between 18 to 29 years and 30 to 49 years, with more female than male users and more urban than suburban or rural users [13]. India had the largest number of users, followed by the United States, Indonesia, and Brazil. Regarding Instagram, there are 1 billion users globally. As of August 2020, there were more female than male users, and the United States had the highest number of users [13]. Users aged between 25 and 34 years represented the largest group of users [14]. Twitter had over 330 million users, who were predominantly male [13]. The top 3 countries for Twitter use were the United States, Japan, and India [13]. Approximately 30% of all users were aged between 25 and 34 years [15]. The Chinese Twitter-like SM platform is Weibo, and it had an estimated 480 million users [16]. WhatsApp is a mobile messaging app that is used by 2 billion users in 180 countries and in 60 different languages [17]. WhatsApp is more commonly used by younger people [17]. WhatsApp's direct Chinese competitor is WeChat, and it has about 1.17 billion users [18]. YouTube is commonly used worldwide, particularly in the United States. It is estimated that it has approximately 2 billion users. The users are more commonly male than female, and its use is prevalent in urban, suburban, and rural locations [13]. Finally, there were about 46 million students and recent college graduates on LinkedIn out of 675 million users [19]. Male users constituted 67% of the total users, and the United States had the highest number of users, followed by India, China, and Brazil.

Although most SM platforms share common features such as free registration, public and private communication, and fast content upload and retrieval, each platform is unique and has distinctive uses. It is common for users to have different accounts across multiple platforms, using each platform for different purposes. Facebook is an SNS that can be accessed from any internet-enabled device, such as personal computers and smartphones. Registration on Facebook is free, and users can create a profile that reveals selective information about themselves [20]. Users can post text, photos, and multimedia that become available to any user in their *friend list*. Users generally begin by adding family members and friends to their friend list, which can be expanded to include colleagues, acquaintances, and strangers with or without common interests. Apart from being able to share public comments and *likes*, a few years after Facebook was founded, a messaging feature was added that allows users to send private messages to individuals and groups. Users can use a variety of embedded apps; join and create *groups* and *pages*; play games; and receive updates regarding the activities of their friends, pages, and groups. Although the platform was initially limited to students in certain American universities, Facebook now has users worldwide. Instagram is a newer SM platform owned by Facebook and is designed primarily for free photo and video sharing [21]. By modifying their privacy preferences, Instagram users can opt to have either public accounts or limit their content to users that they accepted as *followers*. The platform also allows viewing, commenting on, and *liking* posts shared by users that they follow as well as private messaging between users. WhatsApp, which was acquired by Facebook in 2014, is a text and voice messaging app that has become incredibly popular owing to its features, flexibility, and compatibility with various phone and computer operating systems [22]. Although a free service, WhatsApp allows exchange of messages and calls on both desktop and mobile devices, in addition to media sharing and group features. WhatsApp's objective was to provide an alternative to SMS. Using WhatsApp, billions of users across the globe can simultaneously and instantly connect with others.

"Twitter is what's happening in the world and what people are talking about right now"—this is how Twitter describes itself [23]. It is a microblogging platform that allows users to post and access short text, image, or video posts called tweets. Although tweets were originally limited to 140 characters, the limit was increased to 280 characters in 2018, along with permitting the sharing of website links and multimedia. Twitter's mission is to provide users with the ability to create and share ideas and information instantly and without barriers. Users follow other personal, official, or organizational accounts. They can either create their own tweets or *retweet* those by others to their followers. YouTube is a web-based video-sharing platform that allows users to upload, view, share, rate, report, comment on videos, and subscribe to other users [24]. Its mission is to provide users with a voice through video sharing, stemming from the belief that the world would be a better place when people listen, share, and build a community through their stories. The name of this platform is straightforward: *You* represents content that is user-generated and not created by the site itself, and *Tube* is an older term for television. Most YouTube content is uploaded by individuals, but some media corporations have established partnerships with YouTube to offer some of their materials on this platform. LinkedIn, acquired by Microsoft in 2016, is a business and employment-oriented SM service that operates as both a website and mobile app. LinkedIn is mainly used for professional networking, allowing employers to post about job openings and seekers to share their curricula vitae [25]. Using the platform, users can build strategic professional relationships rather than expand their friend circle. LinkedIn's vision is to provide professional opportunities to its users, and its mission is to connect professionals worldwide. It originated in the living room of one of its cofounders a year before its launch in 2003. LinkedIn today has a diversified business model that has generated successful recruitments.

SM users have claimed that they have more digital friends and connections than real-world ones, which highlights the transformation of the ways in which people connect with each other and the importance of web-based relationships in today's world [26]. Over time, social networking platforms have targeted

different age cohorts, making SM use widespread among the general population. For example, as of April 2020, men aged between 25 and 34 years constituted the largest demographic group of Facebook users, and those aged 65 years and older were the fastest-growing group [27,28]. Similarly, the largest group of Twitter users were people aged 25 to 34 years, whereas 15% of users were older than 50 years [15].

The public attitude toward SM use has drastically changed over the years as it became more accessible and diverse in its offerings. Consequently, SM has become a universal communication channel, and responses in reality and on the web have increasingly become intertwined and concurrent [29,30]. Furthermore, SM offers lucrative opportunities to disseminate information and thoughts directly to the public, share experiences, build communities, and connect people with common interests, something unthinkable 20 years ago [31].

SM Use in Health Care

The more digitally oriented the world becomes, the more the health care industry visualizes SM as an important channel for health care promotion, employment, recruitment of new clients or patients, marketing for HCPs, and building a captivating brand name. HCPs have realized that SM is not just a platform to post vacation photos and interact with followers. Perhaps the 4 most common areas where SM plays a major role in the health care industry are health promotion, research, marketing and branding for individuals and practices, and recruitment. It has been evident that web-based content can be spread to offline environments, such as classrooms and meeting rooms. Furthermore, SM has undeniably changed patient-practitioner relationships because of patients' better understanding of health information and their more active role in health maintenance [32].

The effect of behavioral and social factors on health outcomes has evolved significantly in recent decades [33]. HCPs continually search for new and more efficient methods to reach larger populations, especially those who were inaccessible via traditional methods. It is incumbent upon them to use every available tool to reach their intended audience. Thus, HCPs and health organizations should capitalize on the opportunities provided by SM and update strategies to reach communities and age cohorts at a relatively low cost [7,34]. In other words, SM brings a new dimension to health care and is changing the nature and speed of health-related interactions between individuals and health organizations. For example, communicating through photos and videos along with text is part of the mobile revolution, and messaging apps are now regarded as a viable medium for sharing knowledge and discussing clinical cases [35]. In summary, using SM could be a key strategy in addressing some of the challenges and limitations often faced by HCPs in traditional health communication through faster and cheaper dissemination, more accessibility, better interaction, and increased patient empowerment [7]. Moreover, information can now be easily brought to audiences with special needs or low literacy [36].

In the fast-paced modern world, time constraints are common in medical practice, and when combined with the demands of individuals with chronic conditions or unplanned emergency situations, it is challenging for HCPs to dedicate extra time to patients. SM can provide efficient and easy-to-use platforms that encourage patient-practitioner interaction and facilitate necessary actions from both ends [37]. In fact, as of April 2018, there were more than 200,000 health apps, including social networks for people living with a specific medical condition; approximately 19% of smartphone users have at least one health app on their phones [38]. Furthermore, in a 2013 survey of more than 4000 physicians, 65% stated that they used SM for professional reasons [39]. SM use has not been limited to HCPs. Patients have also incorporated SM in their daily lives, which encourages HCPs to explore different ways of making their mark in this growing market [31].

Technology is evolving very rapidly [40]. Competition produces better services, and the diversity of options enables users to choose a tool that best matches their individual needs. Although different platforms often have different target demographics, audience overlapping may occur and should be considered by health organizations when devising their SM health promotion strategies. In health care, SM tools can be used for different purposes (health promotion; dissemination of health information; education; professional development; recruitment; communication with the public, colleagues, and patients; and research) and in diverse medical specialties (cardiology, nursing, radiology, dentistry, surgery, pathology, pediatrics, pharmacy, emergency, and critical and palliative care) [41]. As of August 4, 2020, 27,546 results appeared when searching for *social media* on PubMed, demonstrating the growing interest in SM within the health care industry.

Health care systems, especially in times of crisis and outbreaks, require the dissemination of information to practitioners, patients, and the general public rapidly and effectively [34]. Health organizations and officials, by taking upon a more active SM presence, gain access to vast global networks capable of quickly spreading information and promptly mobilizing large numbers of people toward public health goals [2,42]. Never before has the entire world united as it has in recent months in its fight against the disease caused by SARS-CoV-2, more commonly known as COVID-19. Searching *COVID-19* on PubMed on August 4, 2020, yielded 37,576 results, which exposes the abundance of information and data that has become available in 7 months since the beginning on the pandemic [8]. However, the World Health Organization (WHO) has expressed concerns about fighting 2 battles at once: the pandemic and the *infodemic*—the latter refers to a rapid and far-reaching spread of both accurate and inaccurate information about the disease [43].

It is important to mention that the popularity of SM is directly linked to its many advantages. Advantages of using SM in health care include its expressive nature, accessibility from a smartphone, prompt content sharing and response generation, improved and two-sided communication, reduction of consultation time, smoothing of hierarchy, more efficient teamwork, ability to forge connections between people, and ability to reach large masses [44,45]. Furthermore, SM facilitates the access to health information for extended population groups, regardless of geographic location, age, or education, compared with traditional communication methods [41]. However, the

most influential advantage of SM remains its cost-benefit feature: it can reach an increasing number of people without the high cost of traditional means and the information remains available 24 hours a day, 7 days a week.

Similar to most technologies, SM has its disadvantages. In the health care industry, these include increased workload, risk of unprofessional behavior, disparity in the sense of urgency, a demanding sense of needing to stay connected 24 hours a day, difficulty in obtaining discussion records, worries about leading to or identifying patients, privacy breech, change of patient-practitioner relationship from a professional to a personal one, and the risk of reducing the autonomy of junior doctors [45]. Those who choose to use SM should be aware of the potential risks and problems that they could encounter but should not shy away from using SM because it can greatly increase the reach and impact of HCPs' work and improve patients' health [34]. In the following section, the specific uses of SM in health care are discussed in more depth.

SM Use From the Perspective of HCPs

The literature review yielded an abundance of information. The studies were categorized as follows to best present the findings: health promotion, career development or practice promotion, recruitment, professional networking and destressing, professional medical education, telemedicine, scientific research, and critical public health care issues.

Health Promotion

Producing and disseminating information has played a pivotal role in the history of humanity. Over the years, an increasing number of public health organizations, medical institutes, and HCPs are using SM tools to disseminate visually rich public health messages to the general public. The primary goal is to share solid, evidence-based, and up-to-date health information that educates and affects millions of SM users and to dispel common misconceptions and counterbalance inaccurate material rapidly spreading through SM [2,32]. Examples of how SM can increase the accessibility of a massive number of recipients to health care information around the world include concise educational tweets on Twitter, a pediatric dentistry group on Facebook where fellow specialists discuss anonymized cases and share ideas, photos of a salvation mission to an underprivileged community on Instagram, and the results of a clinical study broadcasted via WhatsApp. These are all examples of how SM can not only increase accessibility, but it can do so at a faster rate than any other means, and perhaps in the cheapest way possible.

Access to oral health care services is limited by a lack of universal coverage. SM, which is a method of mass communication, offers an alternative to traditional communication, which extends to reach underprivileged and underserved communities. The WHO and the United States Centers for Disease Control and Prevention (CDC) are among many other public health institutions that use SM to communicate with the public during public health crises and natural disasters [8,29,35]. Physicians also use SM to promote patient health care education on a smaller scale within their networks. Research has shed light on the many tools that have been used for this purpose. For example, HCPs can tweet, record videos, and participate in health-related discussion forums, which provides an opportunity for physicians to share scientific information and broaden their knowledge [46,47]. Furthermore, information from international conferences and findings from the latest research and clinical trials can be presented in mainstream media to be shared with millions of people [48].

Sharing such information not only helps improve knowledge but can also improve attitudes and practices related to health. For example, in dentistry, SM has played a role in helping patients cope with challenges such as dental anxiety and in presenting dental management options in a convenient and nonthreatening manner [42,49]. Evidence now shows that SM-based interventions are linked to healthy practices such as tobacco cessation, increased physical activity, and diversion from risky sexual behaviors [39,50].

In conclusion, there is evidence that SM helps to improve access to health information. When designing SM campaigns and interventions to disseminate health information, it is important to develop messages that may be more likely to resonate with and elicit reactions from individuals [2]. Messages tailored to certain population segments are more effective than generic messages, as tailored messages address the specific needs of their recipients [51]. Furthermore, interactive (two-way) communication is more effective than linear (one way) communication [7]. Importantly, SM must complement rather than replace traditional health promotion. More research is needed to investigate strategies that can increase access to health information for minorities and marginalized communities and for populations deprived of internet access.

Career Development or Practice Promotion

One of the measures of the success of HCPs is their ability to attract and retain patients. This will not only maximize income but will also boost reputation. SM has played an important role in enhancing practice or practitioner ranking on search engines, even more than academic pedigree and experience [52]. As search engines generally direct patients' traffic, a strong presence on the web can be crucial to attract patients to a practice.

HCPs at all stages of their careers can use SM to brand their name. SM aids in developing their name, expanding their network, and learning about career-enhancing opportunities [53]. It can also be used as a marketing strategy to attract patients of various demographics and has been proven to be effective in engaging and obtaining new patients [54]. In a survey conducted in 2013, 12.5% of health care organizations reported attracting new patients through SM [39]. Moreover, a 2012 study of dental practices in the United States revealed that 51% of the practices used SM, of which 91% used it for marketing purposes and 73% used it to increase their presence on the web [55].

With the extended use of SM among patients and HCPs, practitioners must now compete for patients' attention and need to be strategic regarding the content they share and platforms they use [7]. HCPs should advertise their professional trajectories, areas of experience, and treatment outcomes by

focusing on information tailored to the target audience in an educational manner that does not typify commodification or unfair competition. The eagerness to achieve popularity and to attract new customers or compete with colleagues results in some HCPs thinking only with a short-term approach and prioritizing greater financial gains. For example, some orthodontists and plastic surgeons post before-and-after photographs with drastic improvements without explaining that biological variations among patients, differences in response to treatment, and other external factors may affect the course and outcome of the intervention. Without such information, patients tend to have unrealistic expectations and end up being disappointed [56]. Unfortunately, some practitioners tend to digitally modify images to accentuate treatment-led improvements. This misuse of technology could lead to serious reputational damage for the practitioner and the profession in general in addition to unfavorable court decisions [56].

HCPs build their status using SM in diverse ways. They begin by creating a profile page on one or multiple platforms, which allows them to create and upload content. By connecting with colleagues, they can begin to establish a digital social network. Moreover, groups based on common interests further expand their social network and raise the practitioner's name in bigger circles. These processes can create a haven for viral marketing, which can be leveraged to create a name, develop a digital voice, and disseminate health information in a timely and cost-efficient way [7,30,42]. Moreover, for newly qualified practitioners, contributing to discussions on forums and virtual meetings raises their profile among more experienced practitioners who may be geographically distant. This can leverage word-of-mouth referrals and attract fellow researchers to collaborate.

In terms of cost-effectiveness, a 2017 study on the SM return on investment (ROI) showed an upward trend that represented stable growth for Facebook, whereas Instagram demonstrated substantial ROI. It was concluded that SM resources were superior to standard internet-based resources. When all SM platforms were combined into one graph, there was a consistent finding of growth associated with all SM sources over time [57]. As the following quote summarizes, "physicians have to realize that our patients are doing it (SM), so this is where we need to be" [58].

In summary, there is no one-size-fits-all SM platform, and there is no single way to share content that is superior to all others. It is essential for an HCP to emphasize the importance of their specialty; present the strengths in their particular practice; understand the features and user demographics for SM platforms; and, most importantly, know their target audience. For example, a plastic surgeon or orthodontist may find it beneficial to share pre- and posttreatment or procedure photos of anonymized patients, for which Instagram may be the ideal platform. A practice that is community friendly may invest in a Facebook page to keep the audience updated on offers and services. A family medicine office may share announcements regarding the arrival of a flu-vaccine and post photos of staff members vaccinating themselves to motivate people. Twitter may be useful for posting specialty-related educational messages or sharing information on health-related matters to make HCPs more visible. A pediatric dentist may use YouTube to share videos of tricks used in the office to make the experience less threatening for children. More training courses and talks on how to leverage SM to establish a presence and build a name may be beneficial for HCPs who are not SM savvy.

Recruitment

SM is making great strides not only in the modern world of technology but also in the workplace: it is transforming the way people find and engage in work. It seems that the conventional channels for recruiting employees are not as effective as they once were. Instead, we are shifting toward SM not only as a platform for social interaction, photograph exhibition, and creative expression but also as a space for far-reaching, low-cost job searches. Regarding employment, the interest in SM is bidirectional. On the one hand, employers are often keen to know more about a candidate applying for a position than what is stated in their resume´. On the other hand, employees, especially millennials, will first want to know more about the dynamics of a firm and the personalities of their future boss and coworkers before they commit to the job. Recruitment in the medical field requires more than an application. In this section, the recruitment of HCPs for employment or students for residency programs is discussed.

Human capital is of major importance to any organization because humans produce income and are a source of competitive advantage [59]. Recruitment of qualified employees who are fit for the job is not a simple, one-way decision as it used to be. Performing due diligence in hiring a new employee is more essential than ever and is a multidimensional process, including at least one interview, drug screenings, and background checks. More recently, employers have turned to nontraditional methods and to SM to further analyze potential candidates [60]. SM prescreening may have the potential to offer information about the applicant above and beyond what is stated in the resume´ and can be assessed in a more traditional screening [61]. For job seekers, because of the large number of SM users and the relatively low cost of setting up, SM platforms are ideal for finding employment. Furthermore, many organizations are now investing in SM to display their employer brand and, in return, attract qualified applicants [59,62]. Organizations aiming to attract applicants, especially in fields where competition and demand are high, such as in nursing, must make every effort to promote a unique brand image and attract potential candidates [59,63].

There is evidence that recruiters can accurately determine productivity-related traits solely on the basis of personal information about a candidate available on SNSs [64]. Baert [65] found that personal photographs have become more effective as objects of communication than of memory. This research described interesting theoretical mechanisms that underlie better labor market outcomes for more attractive people. For example, it proposed that self-confidence from good looks could drive productivity, leading to emotional stability, and, consequently, labor market success [66]. The study also found a higher impact of face pictures seen on Facebook's profile photo compared with those attached to a resume´ [65].

From a job seeker's point of view, SM makes it possible to apply to hundreds of jobs, even globally, at once. Through SM,

job applicants can increase their presence on the web to grab the attention of employers [60]. In the health care industry, it is advisable for job seekers to be active in various medical societies to expand their connections and to make a positive impression on future employers. Similar to the real world, it is advisable for applicants to attend virtual conferences and discussion boards and to introduce themselves to others at every reasonable opportunity [67]. It is important to note that employers do not use only professional platforms such as LinkedIn for hiring. In fact, they check many SM platforms when screening for prospective employees [60]. It is not a bad idea that employers and applicants conduct periodic searches for their own names to ensure that their SM persona projects a professional image [2].

Several studies have investigated the effects of SM on recruitment in health care. It was found that a hospital's profile on SM can shape employer brand perceptions and attract nurses. In addition, nurses who visited the hospital's Facebook page were more attracted to work there [59]. In another study, over 92% of employers stated that they were planning to use SM for recruiting [68]. Moreover, a study conducted in 2012 found that the recruitment and screening costs were reduced by 50% by using SM and that 65% of employers were evaluating the integrity and character of potential employees based on their SM profiles [60]. As shown in a review by Davison et al [61], a study found that 20% of the organizations surveyed were planning to use SM for applicant screening. Furthermore, LinkedIn was the most commonly used SM platform for screening applicants, whereas the use of Twitter for screening purposes increased from 11% to 31% between 2011 and 2013 [61]. Interestingly, a study found that there were 38% more job interview invitations to candidates with the most beneficial Facebook pictures [65]. In addition, a Microsoft survey revealed that 79% of employers searched for web-based information regarding prospective employees, but only 7% of the candidates were aware of this possibility [69,70].

Regarding residency programs, SM is a mechanism to accentuate the programs' visibility on the web and to screen residency applicants [71]. It is important to note that it is not only credentials and high scores that secure a spot in a specialty program; personality traits and characters are becoming more significant than ever. Program directors (PDs) now want to know applicants on a personal level. As much of this information would be illegal to obtain in a traditional interview, they may search for it on SM [72]. Admission officers and PDs are now capitalizing on the abundance of information and the popularity of SM [72]. They may encounter content that seems unprofessional or exposes negative character traits that are useful in making decisions about applicants. Many residency programs now search Facebook and other personal SM platforms to screen applicants [73]. Even residents are now using SM platforms to obtain information on possible postgraduate opportunities [71].

There is an abundance of research on the use of SM for applicant selection in residency programs. In one study, 17% of PDs screened applicants on SM, 33% gave lower rankings to applicants based on SM findings, and 69% stated that they will continue to use SM for applicant screening [74]. In another survey, most school children who were interested in studying medicine felt that behaviors on SM should be considered for admission to medical schools [75]. Furthermore, a study conducted in 2016 found that 18% of PDs visited the SM profiles of residency applicants, 10% gave a lower rank or completely disqualified an applicant because of negative web-based behavior, and 10% took formal disciplinary action against a resident because of negative web-based behavior, with Facebook being the platform used by most PDs [76,77]. Another survey found that 97% and 90% of PDs agreed that candidates should be held accountable for illegal acts and unprofessional behavior on the web, respectively, whereas 89% of them agreed that information voluntarily published on the web is fair to use in judging character and professionalism. Furthermore, 82.4% of PDs indicated that they would favor the candidate with a sterile Facebook profile if they were choosing between 2 mock candidates [78]. Moreover, student pharmacists demonstrated a general attitude that web-based personas on SM should not be used to judge professional attitudes and abilities [79]. Although most medical school PDs believed that screening applicants on SM does not constitute a violation of the applicants' privacy, the topic remains controversial and views regarding the appropriateness of using SM profiles to judge character and professionalism vary [78,80]. There is general agreement that SM information is open for judgment by others, especially among older PDs [78].

Professionalism is advocated by the American College of Surgeons as a quality that extends beyond the clinic, operating room, and hospital and into the community in the real world and on the web [81]. There are some issues associated with using SM to judge a possible employee's or resident's professionalism and character. First, screening is usually done by a single person without a standardized scoring rubric. Second, content is unstandardized among the different SM platforms, and the information displayed differs across platforms; for instance, it would not be fair to compare someone's Facebook photo album of a Spring Break trip with someone's contribution to a medical discussion on Twitter. Moreover, screening SM content showed poor test-retest reliability, especially as the content could change rapidly. Interrater reliability is potentially affected by the content being rated and the characteristics of the rater. Construct validity also seems to be weak as no specific construct is usually in mind; instead, a rater casually scans profiles to make a judgment on an applicant or screen potential new hires. Finally, there is a problem with generalizability across platforms. It is suggested that personality traits should be judged from platforms with flexible formats (eg, Facebook), whereas professional traits and experiences should be judged from more structured platforms (eg, LinkedIn) [61].

In summary, although e-professionalism is a new topic, it is receiving considerable attention from recruiters and is being taught as a part of medical curricula [76,79,82,83]. It is necessary in this age to educate job or residency candidates about their digital voice and persona management [65]. Job or residency candidates should consider their publicly available web-based information as an extension of their resume´ and should be aware that many employees use SM to investigate applicants. Therefore, candidates should ensure that their public SM profiles include nothing unprofessional about themselves

[65,67]. Finally, the establishment of clear and equitable guidelines for searching candidates on SM is essential to prevent potential bias.

Professional Networking and Destressing

Professional connections represent important channels through which HCPs exchange knowledge, share expertise, refer patients, seek a second opinion, collaborate on research, hire and employ, provide social support, and improve health care outcomes. In the last few years, work-related communication has changed considerably with the advent of electronic communication tools, especially with the aid of instant messaging on smartphones [30,84]. Virtual professional communities can enable members to quickly access evidence-based information and disseminate work, which can lead to increased immediate impact [85,86]. Most SM platforms are found to be easy to implement, effective, quick, and low cost [87]. In a recent systematic review, positive predictors for using SM among HCPs were identified to be younger age, lower rank, and fewer years of experience, and the most commonly used platforms for communicating with colleagues were Facebook, Twitter, LinkedIn, and WhatsApp [88].

Owing to the exceedingly large number of HCPs on SM, platforms that are designed only for medical personnel have been introduced. Digital communication and social interactions occur between people who may or may not be known to each other [44]. In addition to medical issues, discussions usually address diverse subjects such as politics, practice management, career enhancement opportunities, and even dating in a medical environment [2,89]. Sermo, the world's largest virtual doctors' lounge, is a leading social network for physicians that is now available in 30 countries [90]. Doximity is a newer physician-only social networking platform with more than 500,000 members as of 2020 [91]. In addition, there is the Medical Directors Forum, which is an SNS exclusively for medical directors that provides a secure environment for peer-to-peer interaction [92]. Studies on HCPs' preferred SM platform showed that Facebook was used most frequently (86%). Other commonly used platforms were Medscape Physician Connect (52%), Sermo (44%), LinkedIn (42%), YouTube (40%), Blogging (25%), and Twitter (20%) [26]. These statistics have been confirmed in subsequent studies [32]. For health-related reasons, physicians primarily used LinkedIn (70.7%) and Twitter (51.2%) [32]. Another study reported that HCPs spent an average of 11 to 13 hours per week on medical professional networking sites [26].

WhatsApp has been used as an intradepartmental, patient-related communication method because of its instant and more efficient handovers [93]. When physical proximity was a barrier, physicians preferred to use WhatsApp to exchange work-related knowledge over traditional text messages [84]. The American Academy of Pediatric Dentistry has a private group on Facebook with fewer than 3800 members who share clinical cases, clinical experiences, research results, new products, and relevant events [9]. Facebook has many other groups for dentists that are open to the public to view and join [30]. Microblogs such as Twitter allow a dynamic and concise exchange of information that is instantly accessible by an increasingly large number of readers [89]. Furthermore, the dissemination of scientific literature on SM (eg, Twitter) has increased the number of citations and downloads of published articles [94-96]. LinkedIn serves as a professional space for HCPs to demonstrate their expertise and capabilities; 54% of physicians have used it to communicate with colleagues [32,42].

SM also has a positive impact on students. The sense of belonging is crucial for undergraduate training. By being part of a well-respected learning environment, students benefit educationally and socially [97]. Moreover, having guidance and support on a 24/7 basis can ease their transition from university to more independent training centers [30].

In recent months, SM platforms have become helpful in maintaining communication with friends and family and reducing isolation and sense of loneliness, which could have a negative psychological impact [98]. Amid the COVID-19 pandemic, many practices have been affected and many jobs have been lost worldwide [99]. The sense of unity and comradery introduced by SM among users has helped countless individuals overcome hardships, including HCPs. In the first half of 2020, HCPs were deployed into unfamiliar environments because of the COVID-19 pandemic, worked beyond their areas of expertise and over long hours, and had to involuntarily isolate themselves from their families. This crisis has been anxiety inducing and stressful for HCPs, who often resorted to SM to voice their frustrations, experiences, and opinions not only with family and friends but also with the global network of frontline staff enduring similar challenges. The unique virtual siblinghood united the global health care community like never before. A Facebook page was created to facilitate the renting of recreational vehicles for HCPs to self-isolate outside their homes [100]. The public played an important role in paying due respect to HCPs, who were often referred to as heroes, both literally and figuratively. Illustrations portraying their pivotal role were shared on every known SM platform. Videos showing countless people applauding for HCPs at certain hours of the day went viral. Many HCPs engaged in what was labeled as *COVID-19–free zones* to escape, even if momentarily, from the pandemic stress. Clinicians from all specialties in diverse locations joined forces against a single enemy. Their voices echoed louder when they addressed lawmakers demanding improved access to personal protective equipment (PPE), increased testing for COVID-19, reduced reimbursement barriers to telemedicine, and improved mental health care.

To conclude, SM plays an important role in the lives of HCPs at a personal level. Whether SM is used for amusement, *zoning out*, or commiserating, it provides a safe haven for HCPs to put off their metaphoric heroes' capes and find comfort in their humanhood again. Future research should investigate the role of SM in helping HCPs individually and collectively tackle the challenges resulting from the COVID-19 pandemic.

Professional Medical Education

Millennial students of health professions are increasing in numbers each year. They possess qualities consistent with being lifelong learners [71]. As Prensky [10] discussed, traditional education systems are no longer suitable for contemporary students. Millennials and younger generations process

information in a fundamentally different manner from their predecessors. SM offers formal and informal educational opportunities and has the ability to remove physical barriers that could otherwise impede access to educational resources [51]. Not only is SM rich in educational resources but coupling the information with the interactive exchange of ideas and the live discussions has also made it a valuable educational tool. When SM was integrated into teaching, students were motivated by content obtained from SM, and positive behavioral changes were promoted [101]. Moreover, when SM was incorporated into clinical education, students perceived better collaboration with their peers, improved professional and career development, and larger supportive learning communities [102].

Social networks are an underutilized educational resource, not only for trainees but also for experienced clinicians. A large array of educational material is abundant on SM from seniors with advanced experience and from fellow trainees as well, usually at no cost to the user [30]. The differences between experts and novices are slowly diminishing because of novel forms of peer learning and knowledge production facilitated by SM [35]. Most platforms are frequently used to engage learners. YouTube in particular is more commonly used to teach technical skills and has been acknowledged by dentists as a convenient educational platform [30,71,103,104]. YouTube can also be used in classrooms to forge discussion, illustrate a procedure, or reinforce information, which promotes critical thinking and problem-solving skills [70]. A study conducted in Saudi Arabia found that YouTube was the most commonly used SM platform in medical education [105].

Evidence suggests that SM has a place in health care education. Universities use SM to create virtual classrooms and increase access to academic libraries [70]. In the United States, 95% of medical schools have some Facebook presence, and 71% of them have student groups [106]. In a study on nursing students, Twitter was used to view videos of clinical scenarios, and students tweeted their observations for instructor feedback [70]. Internet and SM content have been successfully used to train older caregivers to improve the caregivers' and patients' quality of life [5]. In a unique experience, the University of Rhode Island managed to connect students to geriatric patients on Facebook. It promoted students' empathy and communication skills while helping patients advance their SM skills to battle loneliness [2]. In addition, students in an oral and maxillofacial radiology course perceived using Twitter as a helpful learning tool that enhanced access to faculty [107]. Moreover, medical students and professionals in cardiology reported the use of social networks for education and professional training [103].

Learning may be considered a social activity [106]. The more senses the students stimulate in their learning process, the more likely the information acquired is to be retained. Thus, the greater the engagement and contribution of the students, the better the learning outcomes. SM provides a medium for active collaboration rather than passive learning. In nursing, 92.4% of students perceived a positive learning impact from the podcasting of lecture materials [108]. In another study, students who were more heavily engaged in blog-based discussion of relevant learning material had higher grades than peers who had contributed less to the discussion [109]. Passing an examination was significantly associated with combining discussion on a WhatsApp group with the web-based question bank, and so were their higher grades [110]. Medical students who used Wikipedia had superior short-term knowledge acquisition compared with those who used a digital textbook, which suggested a potential role for Wikipedia in medical education [111]. In addition, medical students who integrated the use of SM in 2 elective courses were satisfied with the new approach [112]. Twitter and Instagram have also been described as helpful tools in radiology education [113]. Participants in a study reported that SM was perceived as helpful and very helpful for improving knowledge, creativity, decision making, critical skills, and problem-solving abilities [114].

In a study by Alsuraihi et al [105], YouTube, Facebook, and Twitter were among the most commonly used resources for learning. Although 95.8% of the students believed that SM was beneficial for learning, 40% thought it might be distracting [105]. In a review by Chan et al [85], it was found that multiple residencies used SM to broaden the horizons of trainees and facilitate engagement in journal clubs using virtual classrooms; a wide range of SM platforms were featured, including Facebook, blogs, Wikipedia, and podcasts. Specifically, dermatologists in a study agreed that WhatsApp discussions enriched their scientific knowledge of clinical cases and promoted learning about relevant references and upcoming meetings [115]. Participants of a 2015 study on surgical teams expressed that WhatsApp helped to flatten the hierarchy among students, residents, and experienced consultants, enabling them all to actively contribute to discussions without inhibition. This comfortable environment is especially helpful for shy and marginalized students [116].

Once students move beyond structured, supervised learning environments, they must recognize their own gaps in knowledge and skills over time and make every effort to fill them, adopting skills for lifelong learning [106]. The increasing mutability of knowledge in the digital age and its exchangeability and accessibility on mobile phones make learning thorough SM platforms a common practice for many medical students [35,117]. However, learning cannot be done through SM alone but is used to augment learning from textbooks, peer-reviewed research publications, and mentors, and just like with other sources of information, critical appraisal to information retrieved from SM must be applied; this is what lays the foundation for a future competent web-based learner [85,106,118]. It is important that students understand that educational material shared through SM cannot be accepted as is without a great degree of skepticism and objective evaluation.

To summarize, today's students are unique in how they learn and acquire skills. Current educational systems must adapt to the needs and qualities of modern students and augment, if not replace, the traditional teaching methods with more digital means. It is essential for educators to put every effort in determining the best means of presenting information to their students and guiding them in their information search and appraisal. Retrospective research can be planned to compare the performances, learning outcomes, and teaching strategies between 2 student cohorts: those that were taught in a traditional manner and those that relied on SM.

Telemedicine

As people are becoming increasingly fluent in using novel technologies, health care has recently changed when, where, and how patients and HCPs communicate [119]. Telemedicine is the use of communication technologies and electronic information to provide health care support to patients or health care workers who are physically distant from HCPs [120]. Many branches of medicine are now adopting electronically mediated care; terms such as teledentistry and telepsychiatry are not uncommon, and publications related to telemedicine have been increasing [121-123]. Among the specialties that use telemedicine are pediatrics, psychiatry, diabetes, dentistry, nursing, palliative care, and allergies [124-130]. HCPs can now overcome their limited clinical time by communicating with their patients remotely. With the aid of novice technology, they provide a more convenient type of care for patients, especially for following up patients with chronic health care needs [131].

As young and highly qualified HCPs prefer staying in urban communities, telemedicine significantly augments clinical care, especially in underprivileged and underserved communities in rural areas [2,82,132,133]. Furthermore, as health care costs continue to increase, organizations are aiming to reduce costs without jeopardizing the quality of care being provided [134]. Recruitment and workforce sustainability are often an issue, and some countries with large, sparsely populated rural areas have grappled with how to overcome medical and dental provider shortages in these rural areas. Telemedicine and teledentistry can be of great use to ensure that new practitioners appointed in rural locations are not secluded and have the advice and support they need to promote their clinical work and psychological well-being [135]. It may also be used to connect HCPs in third-world countries with specialists in more medically advanced regions; for example, surgical procedures may be streamed live, and questions can be asked in real time [69].

Smartphones are fast, portable, and simple to use; mobile apps now seem to be ideal for quick learning or communication between colleagues or HCPs and the public or patients. Mobile apps are among the most commonly used tools for telemedicine [82]. Globally, but particularly in low- and middle-income countries, communication among HCPs is facilitated via WhatsApp, providing faster diagnosis and immediate management of acute findings [136-138]. A systematic review on telehealth concluded that 74% of the studies reported economic benefits of eHealth interventions for different medical conditions [134].

Programs for electronically monitoring intensive care units allowed HCPs to remotely monitor the conditions of up to 100 patients in multiple hospitals [139]. Pandemics and natural disasters pose challenges to effective and prompt health care delivery. Although telemedicine and eHealth might not solve them all, they can aid HCPs in providing the necessary management in scenarios in which the infrastructure is intact. In recent weeks, the distant triage that allowed patients to be efficiently screened for COVID-19 was patient centered and in compliance with self-quarantine; thus, it protected patients, clinicians, and the community from exposure to the virus [139]. For instance, replacing scheduled office visits with telemedicine visits in case HCPs were quarantined, absent, or sick was a productive initiative at Jefferson Health, Philadelphia, Pennsylvania [139]. An interesting model of telemedicine was explained by Baker and Stanley [40], in which patients use an app to navigate to a specific medical site, answer a few triage questions about their medical condition, wait in a virtual queue to be connected by video to an HCP, and discuss their condition or concern.

Sending clinical photographs privately between colleagues for a second opinion or to enrich discussion is not uncommon. A comprehensive review by Boulos et al [35] shares findings from multiple studies on the use of WhatsApp and Instagram in those contexts. One study found excellent inter- and intraobserver agreement in the assessment images of tibial fractures using WhatsApp [140]. There was a report of a life-saving use of WhatsApp in a resource-limited situation in which the life of a critically ill patient was saved by sending clinical monitor images with electrocardiogram changes and receiving feedback from an expert consultant who was 40 km away from the center where the patient was admitted [141]. Moreover, evaluating maxillofacial computed tomography scans using WhatsApp has been reported to be easy and rapid [142]. WhatsApp was also useful for communication between emergency department consultants when they were not onsite [143]. In dentistry, a study showed that 67.32% of dentists used WhatsApp to send clinical images to colleagues seeking second opinions, and 35.29% of them did so on a weekly basis. About 60.29% of the dentists received a prompt response, whereas 38.23% received delayed responses. In addition, about 98.52% of dentists sent radiographs on WhatsApp for a second opinion [144].

In conclusion, it is noteworthy that telemedicine is not *a practice in and of itself* [145]. It is not the most suitable model of care for every patient and is not the preferred approach when physicians cannot meet clinical standards of care. Patients using telemedicine must also have access to traditional emergency care, if needed. Although these innovations have significant potential benefits, the electronic exchange of health information and care may pose risks to patients' privacy, confidentiality, and safety and to quality and continuity of care. Furthermore, the limitations of electronically mediated physical examination may weaken the relationship between patients and HCPs, thereby jeopardizing care [119]. High-quality research is needed to improve the utilization of telemedicine, and more well-designed studies comparing telemedicine with traditional patient care are essential.

Scientific Research

The perceived benefits of using SM in health care include the ability to connect with geographically distant researchers and to build and foster research communities [4]. SM is a potential tool to revolutionize health research, as it has fewer temporal and spatial limitations and can overcome boundaries between research communities and the public [146,147]. SM can aid research in several ways: by recruiting participants, disseminating surveys, connecting with fellow researchers, identifying research opportunities, sharing study findings, and gaining access to published work.

There are conveniences in taking scientific research to the digital world. Publishing study findings on SM provides enhanced dissemination of research and increases the access to valid evidence-based information for patients. Furthermore, because not all studies end in a publication in a traditional journal, their findings can thus be shared via SM to a wider audience and be of substantial value to a broader research community [4]. Another advantage of SM for scientific research became evident during the COVID-19 pandemic, which made it possible to break geographical barriers and arrange collaborative research projects, surveys, and multicenter studies [8]. Sites such as Google Scholar and ResearchGate create communities for researchers to network, collaborate with each other, and promote publications [53,148]. The anonymity of posts, not having to answer questions in the presence of others and acquiring large samples that attenuate the effect of false information or extreme views were viewed as advantages unique to SM surveys and possible factors that improve research accuracy [146]. Content posted on the web may be used as data for research without interacting with the authors of the content, and perhaps without even considering them to be *human subjects* [146]. Moreover, compared with traditional recruitment methods, web-based surveys have the ability to store large numbers of responses, which can be easily accessed for analysis [5].

Recruiting research participants on SM has gained popularity in recent years. In a review by Lafferty and Manca [4], it was found that the most common tools used for recruiting participants were Facebook, Twitter, and a combination of both. Snowballing sampling method involves participants themselves recruiting more participants by contacting people in their networks [149]. A study on 8252 participants found that web-based recruitment was more efficient and had lower costs per recruited participant compared with traditional methods [150].

Disseminating surveys on the web is now a common practice. One study chose SM platforms to send its survey because it was cost effective, time saving, and easily accessible [151]. In another dentist or patient study, the survey for dentists was distributed via a dentist-only Facebook group that had more than 4500 members; for patients, the survey distribution was mainly through Facebook, LinkedIn, and Twitter, and the recipients were asked to share it with their connections [42]. Furthermore, in a study involving health care quality personnel, the survey was distributed through WhatsApp [114]. In a study in Saudi Arabia, the link to the web-based questionnaire was made available through Twitter and Facebook, the 2 most popular SNSs in the country [152]. Over half of university students strongly or somewhat liked using Facebook for research conducted by university researchers [153]. Zaballos et al [154] developed a web-based multiplatform that integrated WhatsApp and emails to assess the quality of life of individuals with hearing loss issues; the tool facilitated data collection in an easy-to-use platform.

A review by Topolovec-Vranic and Natarajan [155] showed that 40% of the studies found SM to be the most effective recruitment method, whereas 50% of them stated that their target population was *hard to reach*. Approximately 43% of the studies reported cost-effectiveness [155]. In addition, SM helped in recruiting a large number of individuals and reached challenging populations such as adolescents and young adults. Another review found that traditional recruitment methods tend to underrepresent users of marijuana, ecstasy, cocaine, or alcohol or people with at-risk sexual behavior; in comparison, Facebook recruitment yielded more representative results [156].

Researchers who plan to recruit participants on SM must consider their target populations' SM use patterns and preferences. For example, a study on sexual health might consider dating sites for recruitment, whereas Facebook may be more suitable for a nonsexual health study [157]. To best tailor recruitment campaigns, the selection of hashtags or keywords that reflect the interests of the target population might be useful [45].

Regarding shortcomings, it is important to note that research participants recruited from web-based environments may not truly represent the population of interest as a whole, suggesting that SM should only augment traditional recruitment methods [4]. A study suggested that people with disabilities may disproportionately be living in conditions with lower standards of living and may not have access to the internet [158]. In another study, subjects recruited from SM were largely middle class, whereas those recruited at a local hospital were more disadvantaged [159]. A review by Whitaker et al [156] showed an overrepresentation of young White women resulting from web-based recruitment.

Other limitations of using SM for research include that researchers have little control over distractions, the research idea may be copied, or participants may share research information with other participants, which puts the scientific integrity of the study at risk [4]. In a review by Denecke et al [5], the most reported ethical concerns for using SM for research recruitment were self-selection—that is, users with an interest in the study area will be recruited preferentially, which will affect the representativeness of the sample—and a skew toward well-educated and higher socioeconomic status cohorts on the web [5].

Ethical and privacy concerns regarding SM for research recruitment must be addressed because tracking, profiling, and targeting of users are common in the digital world [45]. Bender et al [160] proposed privacy-enhanced SM recruitment guidelines, including proactive measures to protect privacy and declaration of potential risks. Vulnerable groups such as children and teenagers, homosexuals in regions where homosexuality is illegal, and individuals with mental illnesses require extra emphasis on respect, confidentiality, and caution in obtaining consent [146].

To summarize, there is growing evidence to suggest that SM is a useful research tool that enables researchers to connect with each other, recruit participants, and share their findings with the public. Moreover, the data obtained from SM can be investigated. Nevertheless, researchers must not overlook the shortcomings of SM that may ultimately debilitate the integrity of the study. Privacy concerns and ethical considerations must also be considered. The development of guidelines for ethical conduct in web-based research should be based on the best available practices and should be comprehensive and

standardized to minimize a study's error margin. Future studies that compare different recruitment methods and varying participant demographics recruited using various methods should be encouraged. Research investigating the cost-effectiveness of SM research and those with large sample sizes that enable the generalizability of findings is also recommended.

Critical Public Health Care Issues

SM can be used by emergency notification systems to mass communicate information to large groups in a fast and low-cost manner. Studies have shown that SM can be a source of data to detect outbreaks, infection distribution, and areas of acute health care needs [29]. It can also help understand the public's knowledge, fears, attitudes, and behaviors during a crisis [161-163]. For example, the Red Cross tracks Twitter posts during natural disasters, such as hurricanes and earthquakes, to assess where the greatest needs lie [50,164]. Perhaps one of the first publications investigating SM use during a pandemic is a study that analyzed tweets posted during the 2009 H1N1 outbreak; this study found that SM can be a useful tool for disseminating information and for the public to share their opinions and experiences [165]. Twitter posts were also helpful in monitoring disease activity during the cholera and influenza outbreaks [166,167]. When interaction and collaboration were essential, as with the influenza A-H1N1 pandemic, SM provided an unmatched opportunity to engage the public and was used by prominent health organizations such as the WHO [7,41]. However, coordination between web-based and real-world response activities is also important [29].

Perhaps there is no more powerful example of SM use during a health crisis than what has happened during the COVID-19 pandemic. The dissemination of information during a pandemic has never been this quick and effective in the past. Information on the virus spread as quickly as the virus itself and dominated conversations on SM. On March 11, 2020, there were more than 20 million mentions of coronavirus-related terms on SM [168]. Since the beginning of the outbreak, SM has been one of the most commonly used communication channels by international health organizations such as the WHO and the CDC to possibly disseminate information to every person on earth with access to SM. Thousands of smaller health authorities may have also used SM to communicate with local communities. Although traditional access to medical guidelines and policies often requires some form of affiliation or membership, it is available to internet users today with a tap on a keyboard or a finger slide on a smartphone. The distribution of PPE, sharing treatment protocols, clinical trial results, and allocation of medical resources have been efficient with the aid of SM [8]. A recent study evaluated the 100 most viewed *coronavirus* videos on YouTube; as of March 5, 2020 (very early in the pandemic), these videos had 165 million views [169]. Another study in China collected data from 250 million Weibo users, a Twitter-like SM platform. Posts mentioning symptoms or diagnoses significantly predicted daily case counts ahead of the statistics announced by officials in Hubei Province, the epicenter of the initial outbreak, and the rest of China [170].

Perhaps the founders of Twitter did not expect it to become a helpful tool in the fight against COVID-19. For example, using Twitter, a cardiologist was able to expedite the delivery of a drug to a COVID-19 patient within just 6 hours of his tweet [171]. The American Heart Association launched a registry on Twitter to aggregate COVID-19 cases to better understand risk factor profiles and treatment algorithms [171]. Hashtags such as #GetUsPPE highlighted the scarcity of PPE, resulting in technology pioneers ramping up their production of PPE [171]. After calls were raised on Twitter and other SM platforms, HCPs flew to other parts of their countries that were in crisis, retired clinicians volunteered to rejoin the work force in several countries, and those who were unable to be present helped colleagues through telemedicine. Another example of SM use during the pandemic is the COVIDBRONCH Initiative—an international network of airway specialists who foster rapid acquisition and dissemination of knowledge regarding airway procedures during the pandemic [172].

Despite its catastrophic impact and the substantial loss of lives, humans will overcome the existential threat brought by COVID-19 and will also likely overcome future pandemics. Over time, humans have survived environmental, biological, and man-made calamities because of their innate adaptability, resilience, innovativeness, and persistence. Today, humans use SM to disseminate information quickly and to a large number of people, thus eliciting an almost immediate response. More research is already taking place and will continue to investigate the key role of SM in the fight against pandemics, not only from a medical perspective but also from social and economic viewpoints.

Conclusions

This review provided an overview of the different uses of SM in health care. It is evident that SM use indicates not a trend but a fundamental shift in how people communicate today. Multidimensional health care, which includes SM and other forms of communication, has been shown to be highly successful. Not only can SM be used to improve direct patient care but it can also be used to increase the public's knowledge, facilitate research, connect HCPs, improve medical education, and combat public health crises. However, striking the right balance between digital and traditional health care is imperative. As SM is a relatively recent phenomenon, further research is needed to determine its long-term effectiveness and to identify the best strategies for maximizing its advantages and limiting risks. This review will be continued in the second part, in which the use of SM from patients' perspectives will be discussed. This discussion will be supplemented with specific barriers, ethical considerations, and disadvantages reported in the extant literature.

Abstract

Background: Although the potential of big data analytics for health care is well recognized, evidence is lacking on its effects on public health.

Objective: The aim of this study was to assess the impact of the use of big data analytics on people's health based on the health indicators and core priorities in the World Health Organization (WHO) General Programme of Work 2019/2023 and the European Programme of Work (EPW), approved and adopted by its Member States, in addition to SARS-CoV-2–related studies. Furthermore, we sought to identify the most relevant challenges and opportunities of these tools with respect to people's health.

Methods: Six databases (MEDLINE, Embase, Cochrane Database of Systematic Reviews via Cochrane Library, Web of Science, Scopus, and Epistemonikos) were searched from the inception date to September 21, 2020. Systematic reviews assessing the effects of big data analytics on health indicators were included. Two authors independently performed screening, selection, data extraction, and quality assessment using the AMSTAR-2 (A Measurement Tool to Assess Systematic Reviews 2) checklist.

Results: The literature search initially yielded 185 records, 35 of which met the inclusion criteria, involving more than 5,000,000 patients. Most of the included studies used patient data collected from electronic health records, hospital information systems, private patient databases, and imaging datasets, and involved the use of big data analytics for noncommunicable diseases. "Probability of dying from any of cardiovascular, cancer, diabetes or chronic renal disease" and "suicide mortality rate" were the most commonly assessed health indicators and core priorities within the WHO General Programme of Work 2019/2023 and the EPW 2020/2025. Big data analytics have shown moderate to high accuracy for the diagnosis and prediction of complications of diabetes mellitus as well as for the diagnosis and classification of mental disorders; prediction of suicide attempts and behaviors; and the diagnosis, treatment, and prediction of important clinical outcomes of several chronic diseases. Confidence in the results was rated as "critically low" for 25 reviews, as "low" for 7 reviews, and as "moderate" for 3 reviews. The most frequently identified challenges were establishment of a well-designed and structured data source, and a secure, transparent, and standardized database for patient data.

Conclusions: Although the overall quality of included studies was limited, big data analytics has shown moderate to high accuracy for the diagnosis of certain diseases, improvement in managing chronic diseases, and support for prompt and real-time analyses of large sets of varied input data to diagnose and predict disease outcomes.

public health; big data; health status; evidence-based medicine; big data analytics; secondary data analysis; machine learning; systematic review; overview; World Health Organization

Introduction

Big data analytics tools handle complex datasets that traditional data processing systems cannot efficiently and economically store, manage, or process. Through the application of artificial intelligence (AI) algorithms and machine learning (ML), big data analytics has potential to revolutionize health care, supporting clinicians, providers, and policymakers for planning or implementing interventions [1], faster disease detection, therapeutic decision support, outcome prediction, and increased personalized medicine, resulting in lower-cost, higher-quality care with better outcomes [1,2].

In 2018, the World Health Organization (WHO) proposed the expedited 13th General Programme of Work (GPW13), which was approved and adopted by its 194 Member States, focusing on measurable impacts on people's health at the state level to transform public health with three core features: enhanced universal health coverage, health emergencies protection, and better health and well-being [3]. Forty-six outcome target indicators emerged from the GPW13, covering a range of health issues [3]. Big data analytics may help to support health policy decision-making, accelerate the achievement of the GPW13 core priorities and targets, and guide the roadmap for the European region based on the European Programme of Work (EPW) 2020/2025 [4,5].

Therefore, the aim of this study was to provide an overview of systematic reviews that assessed the effects of the use of big data analytics on people's health according to the WHO core features defined in the GPW13 and the EPW. We included complex reviews that assessed multiple interventions, different populations, and differing outcomes resulting from big data analytics on people's health, and identified the challenges, opportunities, and best practices for future research.

Methods

Study Design

This study was designed to provide an overview of systematic reviews in accordance with guidelines from the Cochrane Handbook for Systematic Reviews of Interventions, along with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) and the QUOROM (Quality of Reporting of Meta-analyses) guidelines [6-8]. The study protocol is published on PROSPERO (CRD42020214048).

Search Strategy

To identify records assessing the effect of big data analytics on people's health, aligned with the WHO health indicators defined in the GPW13 (Textbox 1), a comprehensive and systematic search was performed using six multidisciplinary databases from their inception to September 21, 2020. The search strategy was designed in collaboration with a senior librarian and is described in detail in Multimedia Appendix 1.

References were imported into reference management software (EndNote X9) and duplicates were removed. Unique records were uploaded onto the Covidence Platform (Veritas Health Innovation) for screening, data extraction, and quality assessment. A manual search of reference lists was performed to supplement the search.

Textbox 1. List of 46 World Health Organization health indicators defined at the Thirteenth General Programme of Work.

- Number of persons affected by disasters (per 100,000 population)
- Domestic general government health expenditure (% of general government expenditure)
- Prevalence of stunting in children under 5 (%)
- Prevalence of wasting in children under 5 (%)
- Prevalence of overweight in children under 5 (%)
- Maternal mortality ratio (per 100,000 live births)
- Proportion of births attended by skilled health personnel (%)
- Under 5 mortality rate (per 1000 live births)
- Neonatal mortality rate (per 1000 live births)
- New HIV infections (per 1000 uninfected population)
- Tuberculosis incidence (per 100,000 population)
- Malaria incidence (per 1000 population at risk)
- Hepatitis B incidence (measured by surface antigen [HBsAg] prevalence among children under 5 years)
- Number of people requiring interventions against neglected tropical diseases (NTDs)
- Probability of dying from any of cardiovascular disease (CVD), cancer, diabetes, chronic renal disease (CRD) (aged 30-70 years) (%)
- Suicide mortality rate (per 100,000 population)
- Coverage of treatment interventions for substance-use disorders (%)
- Total alcohol per capita consumption in adults aged >15 years (liters of pure alcohol)
- Road traffic mortality rate (per 100,000 population)
- Proportion of women (aged 15-49 years) having need for family planning satisfied with modern methods (%)
- Universal Health Coverage (UHC) Service Coverage Index
- Population with household expenditures on health >10% of total household expenditure or income (%)
- Mortality rate attributed to air pollution (per 100,000 population)
- Mortality rate attributed to exposure to unsafe water, sanitation, and hygiene (WASH) services (per 100,000 population)
- Mortality rate from unintentional poisoning (per 100,000 population)
- Prevalence of tobacco use in adults aged ≥15 years (%)
- Proportion of population covered by all vaccines included in national programs (diphtheria-tetanus-pertussis vaccine, measles-containing-vaccine second dose, pneumococcal conjugated vaccine) (%)
- Proportion of health facilities with essential medicines available and affordable on a sustainable basis (%)
- Density of health workers (doctors, nurse and midwives, pharmacists, dentists per 10,000 population)
- International Health Regulations capacity and health emergency preparedness
- Proportion of bloodstream infections due to antimicrobial-resistant organisms (%)
- Proportion of children under 5 years developmentally on track (health, learning, and psychosocial well-being) (%)
- Proportion of women (aged 15-49 years) subjected to violence by current or former intimate partner (%)
- Proportion of women (aged 15-49 years) who make their own decisions regarding sexual relations, contraceptive use, and reproductive health care (%)
- Proportion of population using safely managed drinking-water services (%)
- Proportion of population using safely managed sanitation services and hand-washing facilities (%)
- Proportion of population with primary reliance on clean fuels (%)
- Annual mean concentrations of fine particulate matter (PM2.5) in urban areas ($\mu g/m^3$)
- Proportion of children (aged 1-17 years) experiencing physical or psychological aggression (%)
- Vaccine coverage for epidemic-prone diseases
- Proportion of vulnerable people in fragile settings provided with essential health services (%)

- Prevalence of raised blood pressure in adults aged ≥18 years
- Effective policy/regulation for industrially produced trans-fatty acids
- Prevalence of obesity (%)
- Number of cases of poliomyelitis caused by wild poliovirus
- Patterns of antibiotic consumption at the national level

Study Selection

Peer-reviewed publications categorized as systematic reviews assessing the effects of big data analytics on any of the GPW13 and EPW health indicators and core priorities were included, regardless of language and study design. We only considered studies in which the search was performed in at least two databases, and included a description of the search strategy and the methodology used for study selection and data extraction. We only included studies that evaluated concrete relationships between the use of big data analytics and its effect on people's lives, according to the WHO strategic priorities and indicators. Along with the 46 indicators listed in Textbox 1, we also included studies evaluating the use of big data during the COVID-19 pandemic. To identify gaps, we included reviews focusing on challenges, best practices, and short- and long-term opportunities related to big data technologies. Nonsystematic reviews, primary studies, opinions, short communications, nonscientific articles, conference abstracts, and reviews with big data inappropriately defined were excluded.

Although big data analysis is capable of handling large volumes of data, rather than focusing on the data volume/size, we focused on the process that defines big data analytics, which includes the following phases [9]: (1) data selection, (2) data preprocessing, (3) data transformation, (4) AI/expert systems, and (5) understanding/assessment. The first three phases include subtasks such as: (i) feature selection and extraction, (ii) data cleaning, and (iii) data integration from multiple sources. The included studies covered all phases of the process. Title, abstract, and full-text screening were independently performed by two reviewers using the inclusion criteria. Any disagreements were resolved by a third independent investigator.

Data Extraction

The following data were extracted from the retrieved articles: publication information, journal name and impact factor, study characteristics, big data characteristics, outcomes, lessons and barriers for implementation, and main limitations. Data were individually extracted by team members and cross-checked for accuracy by a second investigator.

Assessment of Methodological Quality of Included Reviews

Two researchers independently assessed the studies using the AMSTAR 2 (A Measurement Tool to Assess Systematic Reviews 2) checklist, which includes the following critical domains, assessed in 16 items: protocol registered prior to review, adequacy of literature search, justification for excluded studies, risk of bias in included studies, appropriateness of meta-analytic methods, consideration of bias risk when interpreting results, and assessing the presence and likely impact of publication bias [10]. Appropriateness to each appraisal feature was rated as yes, no, partial yes, not applicable, or unclear. Any conflict was resolved by a third party. Studies with a review protocol tracking number were analyzed. A final summary score was given to each included record, rated as "critically low," "low," "moderate," or "high" [10].

Data Synthesis

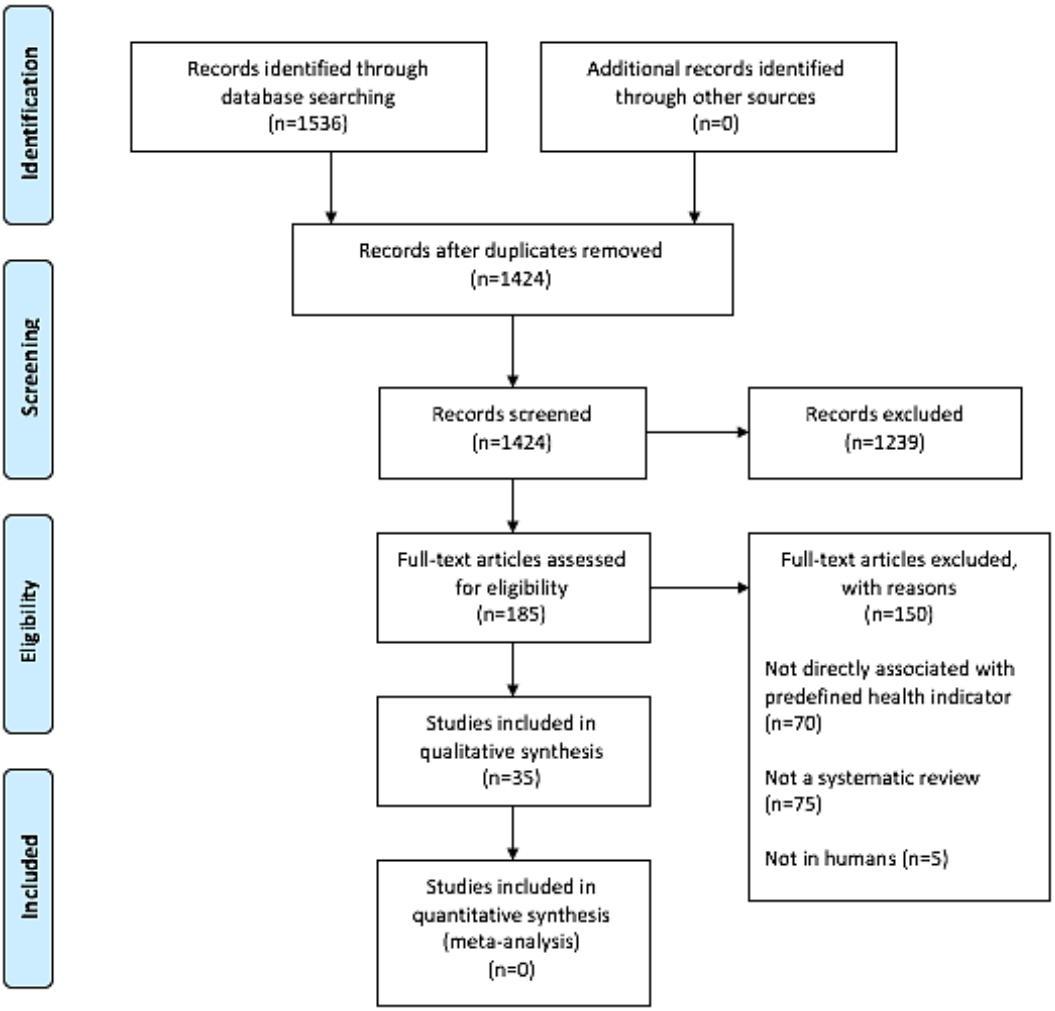
Results are reported in summary tables and through a narrative synthesis, grouping studies assessing the same disease or condition, and identifying challenges and opportunities. We also schematically represent the evidence and gaps from these reviews as an overall synthesis.

Results

Reviews Retrieved

The search retrieved 1536 publications, 112 of which were duplicates. Most of the studies were excluded after title and abstract analysis (n=1237), leaving 185 selected for full-text screening, and 35 [11-45] were ultimately included in the final analysis after applying the eligibility criteria according to the QUOROM guidelines [8] (Figure 1). Reference list screening did not retrieve any additional review. One study under "awaiting classification" could not be retrieved.

Figure 1. Flow chart of the different phases of article retrieval.



Quality of Evidence in Individual Systematic Reviews

Multimedia Appendix 2 shows the detailed results of the quality assessment of the 35 systematic reviews. Overall, most of the reviews (n=25) were rated with "critically low" confidence in the results using the AMSTAR 2 criteria, with 7 rated "low" and 3 rated as "moderate." None of the reviews achieved a "high" rating. Common methodological drawbacks included omission of prospective protocol submission or publication, inappropriate search strategy, lack of independent and dual literature screening and data extraction, absence of explanation for heterogeneity among the studies, unclear or no reasons for study exclusion, and lack of risk of bias assessment.

No standard critical appraisal tools were mentioned. Among the 12 reviews that performed any quality assessment, the Quality Assessment of Diagnostic Accuracy Studies 2 tool was used in four reviews demonstrating an overall low risk of bias [14,16,27,28], whereas other tools assessed the risk of bias in studies not specifically aiming at diagnostic accuracy features. El Idrissi et al [18] used their own quality assessment tool and Luo et al [34] used an adapted version of the Critical Appraisal Skills Programme. Appraisal of the quality of evidence aligned with the Grading of Recommendations Assessment, Development and Evaluation method was reported in only one review [17]. Many reviews did not evaluate bias.

Characteristics of Included Reviews

Summary features and main findings of the 35 systematic reviews are presented in Multimedia Appendix 3 and Multimedia Appendix 4, respectively. The included reviews were published in 34 different journals from 2007 to 2020. Most were published in English in a first-quartile journal with an impact factor ranging from 0.977 to 17.679. They covered over 2501 primary studies, involving at least 5,000,000 individuals. Only three reviews included meta-analyses, and one included a randomized clinical trial; the others were based on cohort studies.

Data Sources and Purposes of Included Studies

Many reviews included data collected from electronic medical records, hospital information systems, or any databank that used individual patient data to create predictive models or evaluate collective patterns [12,13,16-21,24-27,30,33-35,37,38,40,42-45]. Additionally, four reviews included primary studies based on imaging datasets and databanks, assessing different parameters of accuracy [15,29,31,36]. Other reviews focused on genetic databases [28,35], data from assisted reproductive technologies [30], or publicly available data [11,14,22,32]. Four studies lacked precision about the origin of the datasets used in their analysis or did not specifically use patient data in the investigation [23,37,39,41].

The purposes of the reviews varied broadly. Generally, they (1) outlined AI applications in different medical specialties; (2) analyzed features for the detection, prediction, or diagnosis of multiple diseases or conditions; or (3) pinpointed challenges and opportunities.

WHO Indicators and Core Priorities

Most of the studies assessed the effects of big data analytics on noncommunicable diseases [12-15,17,21,22,24,27,31,32,34,36,38,40-44]. Furthermore, three reviews covered mental health, associated with the indicator "suicide mortality rate" [19,25,45]; three studies were related to the indicator "probability of dying from any of cardiovascular, cancer, diabetes, or chronic renal disease" [16,18,20,28,29]; and two studies were related to the indicator "proportion of bloodstream infections due to antimicrobial-resistant organisms" [26,33]. One study described technology use in disaster management and preparedness, covering the "number of persons affected by disasters" indicator [11], and one study was associated with the indicator "maternal mortality ratio" [30]. Overlap made precise classification into WHO health indicators challenging, and four studies could not be categorized because they mainly described challenges or opportunities in big data analytics [23,39] or because they were related to the COVID-19 pandemic [35,37].

Diseases or Conditions Assessed

Diabetes Mellitus

AI tools associated with big data analytics in the care of patients with diabetes mellitus (DM) were assessed in six reviews that included 345 primary studies [15,20,32,38,40]. Three studies reviewed AI in screening and diagnosing type 1 or type 2 DM, providing varied ranges of accuracy, sensitivity, and specificity [20,32,40]. Variables included systolic blood pressure, body mass index, triglyceride levels, and others. Two reviews covered DM control and the clinical management of DM patients [32,40]. One noted that techniques for diabetes self-management varied among the tools evaluated and reported mean values for its robust metrics [18]. The other evaluated the use of data-driven tools for predicting blood glucose dynamics and the impact of ML and data mining [20], describing the input parameters used among data-driven analysis models. However, the authors of these reviews concluded that achieving a methodologically precise predictive model is challenging and must consider multiple parameters.

Various studies assessed the ability of big data analytics to predict individual DM complications such as hypoglycemia, nephropathy, and others [15,32,38]. Supervised ML methods, decision trees, deep neural networks, random forests (RF) learning, and support vector machine (SVM) reportedly had the best outcomes for assessing complications. One review assessed deep learning–based algorithms in screening patients for diabetic retinopathy. Of 11 studies, 8 reported sensitivity and specificity of 80.3% to 100% and 84%% to 99%, respectively; two reported accuracies of 78.7% and 81%; and one reported an area under the receiver operating curve (AUC) of 0.955 [15].

Mental Health

Five reviews reported on AI, data mining, and ML in psychiatry/psychology [12,14,19,25,45], most commonly assessing these techniques in the diagnosis of mental disorders. Two reviews assessed the use of ML algorithms for predicting suicidal behaviors. High levels of risk classification accuracy (typically higher than 90%) were reported in two reviews, either for adult primary care patients or teenagers [19,25]. Although the review authors stated the potential of ML techniques in daily clinical practice, limitations were highlighted, including no external validation and reporting inconsistencies.

The use of ML algorithms for early detection of psychiatric conditions was also reported [12,45]. ML was used to develop prediagnosis algorithms for constructing risk models to signal a patient's predisposition or risk for a psychiatric/psychological health issue, for predicting a diagnosis of newly identified patients, and to differentiate mental conditions with overlapping symptomatology. For studies using structural neuroimaging to classify bipolar diseases and other diagnoses, the accuracy ranged from 52.13% to 100%, whereas studies using serum biomarkers reported an accuracy ranging from 72.5% to 77.5%.

Only one review used social media to generate analyzable data on the prevention, recognition, and support for severe mental illnesses [14]. The study included broad descriptions of ML techniques and data types for detection, diagnosis, prognosis, treatment, support, and resulting public health implications. The authors highlighted the potential for monitoring well-being, and providing an ecologically and cost-efficient evaluation of community mental health through social media and electronic records.

COVID-19

Two reviews reported the application of big data analytics and ML to better understand the current novel coronavirus pandemic [35,37]. One assessed data mining and ML techniques in diagnosing COVID-19 cases. Although the study did not define the best methodology to evaluate and detect potential cases, the authors noted an elevated frequency of decision tree models, naïve Bayes classifiers, and SVM algorithms used during previous pandemics.

Another review focused on SARS-CoV-2 immunization, and proposed that AI could expedite vaccine discovery through studying the virus's capabilities, virulence, and genome using genetic databanks. That study merged discussions of deep learning–based drug screening for predicting the interaction between protein and ligands, and using imaging results linked to AI tools for detecting SARS-CoV-2 infections.

Oncology

Four studies described the utility of ML, computerized clinical decision systems, and deep learning in oncology [24,28,29,31]. Using computerized clinical decision support systems (DSS) significantly improves process outcomes in oncology [24]. A compelling example shows that initial decisions were modified in 31% of cases after consultation of clinical DSS, which consistently resulted in improved patient management. Furthermore, implementing clinical DSS led to an average cost

reduction of US $17,000 for lung cancer patients. A remarkable workload decrease reportedly occurs when these systems are implemented in oncology facilities, leading to improved patient management and adherence to guidelines [24].

One study evaluated ML techniques in a genomic study of head and neck cancers, and found a wide range of accuracy rates (56.7% to 99.4%) based on the use of genomic data in prognostic prediction. Lastly, two studies reported accuracy levels ranging from 68% to 99.6% when using deep learning algorithms in the automatic detection of pulmonary nodules in computerized tomography images.

Cardiovascular and Neurological Conditions

Six studies described the effect of big data analytics in cardiology [13,16,21,42] and neurology [43,44]. One review assessed the use of ML techniques for predicting cardiac arrest [42]. Different variables were used as predictors among individual studies, including electrocardiographic parameters, heart rate variability, echocardiography, and others. Supervised ML techniques were most frequently applied to predict cardiac arrest events, with clear evidence of regression techniques and SVM algorithms. The authors reported a mean AUC of 0.76 for risk score development and efficiency evaluation [42].

Similarly, two studies assessed the use of intelligent systems in diagnosing acute coronary syndrome and heart failure [13,21], demonstrating high accuracy levels using several methods such as SVM, feature selection, and neural networks. These studies also described useful clinical features for creating prediction and diagnostic models, such as patient clinical data, electrocardiogram characteristics, and cardiac biomarkers.

Scores to identify patients at higher risk to develop QT-interval prolongation have been developed, and predictive analytics incorporated into clinical decision support tools have been tested for their ability to alert physicians of individuals who are at risk of or have QT-interval prolongation [16].

Regarding stroke, two systematic reviews evaluated using ML models for predicting outcomes and diagnosing cerebral ischemic events [43,44]. Generally, ML models were most frequently associated with mortality prediction, functional outcomes, neurological deterioration, and quality of life. The diagnosis of ischemic stroke was associated with similar or better comparative accuracy for detecting large vessel occlusion compared with humans, depending on the AI algorithm employed [44]. RF algorithms had 68% sensitivity and over 80% specificity compared with humans. Analyses of convolutional neural network (CNN) algorithms were limited, but systems using CNNs reported performance metrics on average 8% to 10% greater than those of ML employing RF, with up to 85% mean sensitivity for automatic large vessel occlusion detection. However, AI algorithm performance metrics used different standards, precluding objective comparison. Core and perfusion studies from RAPID-computed tomography and magnetic resonance imaging had the highest metrics for AI accuracy, above 80%, with some datasets showing 100% sensitivity to predict favorable perfusion mismatch. The authors noted several errors of AI use in diagnosing stroke [44].

Miscellaneous Conditions

Several studies reported significant improvement in disease diagnosis and event prediction using big data analytics tools, including remarkable enhancement of sepsis prediction using ML techniques [26]. Another review provided moderate evidence that ML models can reach high performance standards in detecting health care–associated infections [33].

One review focused on the diagnostic accuracy of AI systems in analyzing radiographic images for pulmonary tuberculosis, mostly referring to development instead of clinical evaluation [27]. In studies assessing accuracy, the sensitivity ranged from 56% to 97%, specificity ranged from 36% to 95%, and the AUC ranged from 78% to 99%.

One review also assessed multiple sclerosis diagnosis. Among detection methodologies, rule-based and natural language processing methods were deemed to have superior diagnostic performance based of elevated accuracy and positive predictive value [41]. This study indicates that these methods have potential impacts for early recognition of the disease, increasing quality of life, and allowing prompt pharmacological and nonpharmacological intervention.

Asthma exacerbation events and predictive models for early detection were evaluated in one review, which reached a pooled diagnostic ability of 77% (95% CI 73%-80%) [17]. Among the included studies, most models for predicting asthma development had less than 80% accuracy. None of the 42 studies modeled the reincidence of exacerbation events, and overall accuracy performance was considered inadequate. However, the authors encouraged creating models using large datasets to increase prediction accuracy levels. Logistic regression and Cox proportional hazard regression appeared to be the most commonly used methodologies. Gastric tissue disease and the usability of deep learning techniques were evaluated in one study [36]. CNN was the most common model used for gastric problem classification or detection. Additionally, residual neural network and fully convolutional network were considered to be appropriate models for disease generation, classification, and segmentation.

Two reviews analyzed the use of big data analytics and AI in public health [22,30]. One listed the impact of continuous pharmacological exposure of pregnant women, emphasizing that AI could improve popular understanding of drug effects on pregnancy, mainly through: (i) reliable clinical information disclosure, (ii) adequate scientific research design, and (iii) implementation of DSS [30]. Another review assessing the use of big data in disaster preparedness evidenced that most existing methods are qualitative, covering the response phase of the disaster chain of events [11]. The utilized tools included data originating from geographic information systems, social media interfaces, and disaster prediction modeling studies.

Challenges and Opportunities

Two systematic reviews provided narrative evaluations of the challenges of big data analytics in health care [23,39]. Evidence from these two systematic reviews, and those from the other reviews, are summarized in Textbox 2.

Textbox 2. Current challenges to use big data tools for peoples' health, and future perspectives and opportunities.

Current Challenges

1. Data structure: issues with fragmented data and incompatible or heterogeneous data formats

2. Data security: problems with privacy, lack of transparency, integrity, and inherent data structure

3. Data standardization: concerns with limited interoperability, data obtention, mining, and sharing, along with language barriers

4. Inaccuracy: issues with inconsistencies, lack of precision, and data timeliness

5. Limited awareness of big data analytics capabilities among health managers and health care professionals

6. Lack of evidence of big data analytics on the impact on clinical outcomes for peoples' health

7. Lack of skills and training among professionals to collect, process, or extract data

8. Managerial issues: ownership and government dilemma, along with data management, organizational, and financial issues

9. Regulatory, political, and legal concerns

10. Expenses with data storage and transfer

Future Perspectives and Opportunities

1. To improve the decision-making process with real-time analytics

2. To improve patient-centric health care and to enhance personalized medicine

3. To support early detection of diseases and prognostic assessment by predicting epidemics and pandemics, improving disease monitoring, implementing and tracking health behaviors, predicting patients' vulnerabilities

4. To improve data quality, structure, and accessibility by enabling the improvement of rapid acquisition of large volumes and types of data, in a transparent way, and the improvement of data error detection

5. To enable potential health care cost reduction

6. To improve quality of care by improving efficient health outcomes, reducing the waste of resources, increasing productivity and performance, promoting risk reduction, and optimizing process management

7. To provide better forms to manage population health either through early detection of diseases or establishing ways to support health policy makers.

8. To enhance fraud detection

9. To enhance health-threat detection plans by governmental entities

10. To support the creation of new research hypotheses

Discussion

This overview is the first to assess the effects of big data analytics on the prioritized WHO indicators, which offers utility for noncommunicable diseases and the ongoing COVID-19 pandemic. Although the research question focused on the impact of big data analytics on people's health, studies assessing the impact on clinical outcomes are still scarce. Most of the reviews assessed performance values using big data tools and ML techniques, and demonstrated their applications in medical practice. Most of the reviews were associated with the GPW13 indicator "probability of dying from any cardiovascular disease, cancer, diabetes, chronic respiratory disease." This indicator outranks others because of the incidence, prevalence, premature mortality, and economic impact of these diseases [46]. Similarly, many reviews were related to "people requiring interventions against noncommunicable diseases." The included reviews in this study addressed many necessary health-related tasks; however, the quality of evidence was found to be low to moderate, and studies assessing the impact on clinical outcomes are notably scarce.

The low to moderate quality of evidence suggests that big data analytics has moderate to high accuracy for the (1) diagnosis and prediction of complications of DM, (2) diagnosis of mental diseases, (3) prediction of suicidal behaviors, and (4) diagnosis of chronic diseases. Most studies presented performance values, although no study assessed whether big data analytics or ML could improve the early detection of specific diseases.

Clinical research and clinical trials significantly contribute to understanding the patterns and characteristics of diseases, as well as for improving detection of acute or chronic pathologies and to guide the development of novel medical interventions [47]. However, experimental/theoretical investigations, mathematical approaches, and computer-based studies hinge on handling sample size limitations and performing data imputation [48,49]. Computer-driven analysis can easily handle missing data, examine variable mechanisms in complex systems, and employ essential tools for exploratory evaluations using voluminous input data. Big data analytics can execute an operation on/process data within microseconds after generation of the dataset, allowing for real-time follow up [50,51]. These studies and prospective applications could generate innovative knowledge and promote actionable insights; however, adapting, validating, and translating scientific data into practical medical protocols or evaluation studies is necessary.

Many systematic reviews reported simple or inappropriate evaluation measures for the task at hand. The most common metric used to evaluate the performance of a classification predictive model is accuracy, which is calculated as the proportion of correct predictions in the test set divided by the total number of predictions that were made on the test set. This metric is easy to use and to interpret, as a single number summarizes the model capability. However, accuracy values and error rate, which is simply the complement of accuracy, are not adequate for skewed or imbalanced classification tasks (ie, when the distribution of observations in the training dataset across the classes is not equal), because of the bias toward the majority class. When the distribution is slightly skewed, accuracy can still be a useful metric; however, when the distribution is severely skewed, accuracy becomes an unreliable measure of model performance.

For instance, in a binary classification task with a distribution of (95%, 5%) for the classes (eg, healthy vs sick), a "dumb classifier" that simply chooses the class "healthy" for all instances will have 95% of accuracy in this task, although the most important issue in this task would be correctly classifying the "sick" class. Precision (also called the positive predictive value), which captures the fraction of correctly classified instances among the instances predicted for a given class (eg, "sick"); recall or sensitivity, which captures the fraction of instances of a class (eg, "sick") that were correctly classified; and F-measure, the harmonic mean of precision and recall calculated per class of interest, are more robust metrics for several practical situations. The proper choice of an evaluation metric should be carefully determined, as these indices ought to be used by regulatory bodies for screening tests and not for diagnostic reasoning [52]. The most important issue is to choose the appropriate (most robust) performance metric given the particularities of each case.

Another pitfall identified among the included reviews was the lack of reporting the precise experimental protocols used for testing ML algorithms and the specific type of replication performed.

There is no formal tool for assessing quality and risk of bias in big data studies. This is an area that is ripe for development. In Textbox 3, we summarize our recommendations for systematic reviews on the application of big data and ML for people's health based on our experience, the findings of this systematic review, and inspired by Cunha et al [53].

High variability in the results was evident across different ML techniques and approaches among the 35 reviews, even for those assessing the same disease or condition. Indeed, designing big data analysis and ML experiments involves elevated model complexity and commonly requires testing of several modeling algorithms [54]. The diversity of big data tools and ML algorithms requires proper standardization of protocols and comparative approaches. Additionally, the process of tuning the hyperparameters of the algorithms is not uniformly reported. Important characteristics essential for replicability and external validation were not frequently available. Lastly, most of the studies provide little guidance to explain the results. Without knowing *how* and *why* the models achieve their results, applicability and trust of the models in real-world scenarios are severely compromised. Therefore, we urge the testing and assessment of supervised, unsupervised, and semisupervised methodologies, with explanation and interpretation to justify the results. Moreover, we encourage hyperparameter optimization to achieve adjusted improvement of models, enhance model generalizations for untrained data, and avoid overfitting to increase predictive accuracy.

Only two published systematic reviews evaluated the impact of big data analytics on the COVID-19 pandemic. Primary studies on COVID-19 are lacking, which indicates an opportunity to apply big data and ML to this and future epidemics/pandemics [35,37]. As of November 30, 2020, many published protocols were retrieved through a standard search on PROSPERO. The titles of these review protocols showed an intention to evaluate ML tools in diagnosis and prediction, the impact of telemedicine using ML techniques, and the use of AI-based disease surveillance [55].

Although DSS are an important application of big data analytics and may benefit patient care [56-58], only two reviews assessed such systems [16,24]. One focused on predictive analytics for identifying patients at risk of drug-induced QTc interval prolongation, discussing the efficacy of a DSS that has shown evidence of reduced prescriptions for QT interval–prolonging drugs. Similarly, one study exploring the impact of DSS on quality care in oncology showed that implementing these systems might positively impact physician-prescribing behaviors, health care costs, and clinician workload.

This overview of systematic reviews updates the available evidence from multiple primary studies intersecting computer science, engineering, medicine, and public health. We used a comprehensive search strategy (performed by an information specialist) with a predefined published protocol, precise inclusion criteria, rigorous data extraction, and quality assessment of retrieved records. We avoided reporting bias through the dual and blinded examination of systematic reviews and by having one review author standardizing the extracted data.

Textbox 3. Recommendations for systematic reviews on the application of big data and machine learning for people's health.

- *Choose an appropriate evaluation measure for the task and data characteristics, and justify your choice*

Different evaluation measures such as accuracy, area under the receiver operating characteristic curve, precision, recall, and F-measure capture different aspects of the task and are influenced by data characteristics such as skewness (ie, imbalance), sampling bias, etc. Choose your measures wisely and justify your choice based on the aforementioned aspects of the task and the data.

- *Ensure the employment of appropriate experimental protocols/design to guarantee generalization of the results*

Authors should use experimental protocols based on cross-validation or multiple training/validation/test splits of the employed datasets with more than one repetition of the experimental procedure. The objective of this criterion is to analyze whether the study assesses the capacity of generalization of each method compared in the experiments. The use of a single default split of the input dataset with only one training/test split does not fit this requirement. Repetitions are essential to demonstrate the generalization of the investigated methods for multiple training and test sets, and to avoid any suspicion of a "lucky" (single) partition that favors the authors' method.

- *Properly tune, and explicitly report the tuning process and values of the hyperparameters of all compared methods*

The effectiveness of big data solutions and machine-learning methods is highly affected by the choice of the parameters of these methods (ie, parameter tuning). The wrong or improper choice of parameters may make a highly effective method exhibit very poor behavior in a given task. Ideally, the parameters should be chosen for each specific task and dataset using a partition of the training set (ie, validation), which is different from the dataset used to train and to test the model. This procedure is known as cross-validation on the training set or nested cross-validation.

Even if the tuning of all methods is properly executed, this should be explicitly reported in the paper, with the exact values (or range of values) used for each parameter and the best choices used. When the tuning information is missing or absent, it is impossible to determine whether the methods have been implemented appropriately and if they have achieved their maximum potential in a given task. It is also impossible to assess whether the comparison is fair, as some methods may have been used at their maximum capacity and others not.

- *Pay attention to the appropriate statistical tests*

Authors should employ statistical significance tests to contrast the compared strategies in their experimental evaluation. Statistical tests are essential to assess whether the performance of the analyzed methods in the sample (ie, the considered datasets) is likely to reflect, with certain confidence, their actual performance in the whole population. As such, they are key to support any claim of superiority of a particular method over others. Without such tests, the relative performance observed in the sample cannot, by any means, be extrapolated to the population. The choice of the tests should also reflect the characteristics of the data (ie, determining whether the data follow a normal distribution).

- *Make the data and code freely available with proper documentation*

One of the issues that hampers reproducibility of studies, and therefore scientific progress, is the lack of original implementation (with proper documentation) of the methods and techniques, and the unavailability of the original data used to test the methods. Therefore, it is important to make all data, models, code, documentation, and other digital artifacts used in the research available for others to reuse. The artifacts made available must be sufficient to ensure that published results can be accurately reproduced.

- *Report other dimensions of the problem such as model costs (time) and potential for explainability*

Effectiveness of the solutions, as captured by accuracy-oriented measures, is not the only dimension that should be evaluated. Indeed, if the effectiveness of the studied models is similar and sufficient for a given health-related application, other dimensions such as time efficiency (or the costs) to train and deploy (test) the models are essential to evaluate the practical applicability of such solutions. Another dimension that may influence the decision for the practical use of a big data or a machine-learning method in a real practical situation is the ability to understand why the model has produced certain outputs (ie, explainability). Solutions such as those based on neural networks may be highly effective when presented with huge amounts of data, but their training and deployment costs as well as their opaqueness may not make them the best choice for a given health-related application.

However, limitations exist. The inferior quality scores based on the AMSTAR 2 tool might reflect incomplete reporting and lack of adherence to substandardized review methods. There is neither an established bias risk tool specifically for big data or ML studies nor any systematic way of presenting the findings of such studies. Furthermore, most studies provided a narrative description of results, requiring summarization. Nevertheless, all of the reviews were inspected by most authors, and the most relevant data were condensed in the text or in descriptive tables.

Big data analytics provide public health and health care with powerful instruments to gather and analyze large volumes of heterogeneous data. Although research in this field has been growing exponentially in the last decade, the overall quality of evidence is found to be low to moderate. High variability of results was observed across different ML techniques and approaches, even for the same disease or condition. The diversity of big data tools and ML algorithms require proper standardization of protocols and comparative approaches, and the process of tuning the hyperparameters of the algorithms is not uniformly reported. Important characteristics essential for replicability and external validation were not frequently available.

Additionally, the included reviews in this systematic review addressed different health-related tasks; however, studies assessing the impact on clinical outcomes remain scarce. Thus, evidence of applicability in daily medical practice is still needed. Further studies should focus on how big data analytics impact clinical outcomes and on creating proper methodological guidelines for reporting big data/ML studies, as well as using robust performance metrics to assess accuracy.

Acknowledgments

We highly appreciate the efforts provided by our experienced librarian Maria Björklund from Lund University, who kindly prepared the search strategy used in this research. In addition, we thank Anneliese Arno (University College of London and Covidence Platform) for providing guidance in performing this research through Covidence. We also thank Raisa Eda de Resende, Edson Amaro Júnior, and Kaíque Amâncio Alvim for helping the group with data extraction and double-checking the input data.

Authors' Contributions

IJBdN, MM, MG, NAM, and DNO designed the study. HA, IW, and IJBdN performed first- and second-stage screening, and extracted the presented data. MM solved any disagreements. HA, IW, and IBdN carried out the quality assessment. IJBdN, MM, MG, and DNO drafted the manuscript and its final version. DNO and NAM are staff members of the WHO. The authors alone are responsible for the views expressed in this article and they do not necessarily represent the decisions, policy, or views of the WHO.

Conflicts of Interest

None declared.

Abstract

Background: Men who have sex with men (MSM) face disproportionate risks concerning HIV and other sexually transmitted infections, substance use, and mental health. These outcomes constitute an interacting syndemic among MSM; interventions addressing all 3 together could have multiplicative effects. eHealth interventions can be accessed privately, and evidence from general populations suggests these can effectively address all 3 health outcomes. However, it is unclear how useable, accessible, or acceptable eHealth interventions are for MSM and what factors affect this.

Objective: We undertook a systematic review of eHealth interventions addressing sexual risk, substance use, and common mental illnesses among MSM and synthesized evidence from process evaluations.

Methods: We searched 19 databases, 3 trials registers, OpenGrey, and Google, and supplemented this by reference checks and requests to experts. Eligible reports were those that discussed eHealth interventions offering ongoing support to MSM aiming to prevent sexual risk, substance use, anxiety or depression; and assessed how intervention delivery or receipt varied with characteristics of interventions, providers, participants, or context. Reviewers screened citations on titles, abstracts, and then full text. Reviewers assessed quality of eligible studies, and extracted data on intervention, study characteristics, and process evaluation findings. The analysis used thematic synthesis.

Results: A total of 12 reports, addressing 10 studies of 8 interventions, were eligible for process synthesis. Most addressed sexual risk alone or with other outcomes. Studies were assessed as medium and high reliability (reflecting the trustworthiness of overall findings) but tended to lack depth and breadth in terms of the process issues explored. Intervention acceptability was enhanced by ease of use; privacy protection; use of diverse media; opportunities for self-reflection and to gain knowledge and skills; and content that was clear, interactive, tailored, reflective of MSM's experiences, and affirming of sexual-minority identity. Technical issues and interventions that were too long detracted from acceptability. Some evidence suggested that acceptability varied by race or ethnicity and educational level; findings on variation by socioeconomic status were mixed. No studies explored how intervention delivery or receipt varied by provider characteristics.

Conclusions: Findings suggest that eHealth interventions targeting sexual risk, substance use, and mental health are acceptable for MSM across sociodemographic groups. We identified the factors shaping MSM's receipt of such interventions, highlighting the importance of tailored content reflecting MSM's experiences and of language affirming sexual-minority identities. Intervention developers can draw on these findings to increase the usability and acceptability of integrated eHealth interventions to address the syndemic of sexual risk, substance use, and mental ill health among MSM. Evaluators of these interventions can draw on our findings to plan evaluations that explore the factors shaping usability and acceptability.

Introduction

Men who have sex with men (MSM) face disproportionate risks in relation to use of tobacco, alcohol, and legal and illegal drugs (henceforth termed *substance use*), mental ill health, and HIV and other sexually transmitted infections [1-12]. These outcomes constitute a syndemic, whereby they interact [2,13] to increase overall risks of substance use, mental ill health, and sexual risk among MSM across age groups and ethnicities [13-16]. This clustering and interaction of adverse outcomes suggests that interventions which address substance use, mental ill health, and sexual risk together could have multiplicative effects. eHealth interventions, delivered via electronic media and devices, offer a means to access prevention and treatment programs privately and anonymously particularly for MSM, who generally report high use of such media and devices [17]. Systematic reviews for general or mixed populations suggest that eHealth interventions can be effective in reducing alcohol use [18] and addressing common mental health issues [19-25], and emerging evidence indicates potential effects on drug use and sexual risk [26-29]. The few reviews assessing eHealth interventions among MSM suggest they can achieve short-term behavior change for sexually transmitted infections/HIV prevention [28,30], increase HIV testing [28,31], and improve treatment adherence among HIV-positive MSM [31,32]. To our knowledge, no systematic reviews have assessed the effectiveness of eHealth interventions to reduce substance use or improve mental health among MSM.

In addition to their effectiveness, it is important to examine what factors affect the usability and acceptability of eHealth interventions addressing these various outcomes among MSM. This should inform the development of interventions that can feasibly and acceptably address all 3 outcomes together [33]. Designing eHealth interventions to address MSM's needs and affirm sexual-minority identities is likely to be important [34]. Product assessments suggest that eHealth interventions to reduce depression and anxiety among the general population rarely address the needs of gay and lesbian users [34]. However, there have been no systematic reviews to date conducted on the acceptability and usability of eHealth interventions addressing sexual health, substance use, or mental health risks among MSM.

Toward this end, we undertook a systematic review of eHealth interventions addressing these 3 outcomes and targeting this population. We included interventions addressing these outcomes together or separately, and aimed to synthesize evidence of effectiveness, describe intervention theories of change, and synthesize evidence from economic and process evaluations. This paper reports on the synthesis of process evaluations examining what factors related to interventions, providers, participants, or contexts (ie, environmental or structural factors) promote or impede delivery or receipt of these interventions.

Methods

Inclusion Criteria

Reports eligible for inclusion in the overall review reported on eHealth interventions that were delivered by mobile phone apps, the internet, or other electronic communication technology; offered ongoing support to populations consisting entirely or principally of gay, bisexual, and other men (including cisgender and transgender men) who have sex with men; and aimed to prevent HIV/sexually transmitted infections, sexual risk behavior, alcohol, tobacco or drug use, anxiety, or depression. We excluded interventions that offered one-off (rather than ongoing) support or that involved human providers (eg, in a chat room). Reports eligible for the process evaluation synthesis reported on characteristics of interventions, providers, participants, or context affecting delivery or receipt of eligible interventions. We included published and grey literature and set no restrictions by location or language.

Search Strategy and Screening for Eligibility

Terms used in our search strategy covered 2 concepts joined by the Boolean operator "and": MSM and eHealth. We searched 19 databases containing health and social science literature (from October 2018 to November 2018 and updated on April 2020). Our complete search strategy for the original OvidSP MEDLINE database is included in Multimedia Appendix 1 and the search strategies for all databases are available at the London School of Hygiene & Tropical Medicine's Data Repository [35]. We conducted additional searches by searching 3 clinical trials registers, the OpenGrey database, and Google (limited to first 100 results), and by completing reference checks of included reports and requests from experts.

Citations were uploaded to EndNote (Clarivate Analytics), deduplicated, and then uploaded to EPPI-Reviewer (version 4.0, EPPI-Centre) for screening. CB and JF independently screened titles and abstracts in batches of the same 50 references, resolving disagreements by discussion. After reaching an agreement rate of at least 95%, they single-screened all remaining citations. Screening of full texts followed a comparable process.

Data Extraction and Assessment of Quality

For process evaluations, CB and RM used an adapted version of an existing tool [36] to independently extract data reporting empirically on how processes of delivery or receipt varied with characteristics of interventions, providers, participants, or contexts. They also extracted data on basic study details, methods, and intervention descriptions. They then independently assessed the quality of process evaluation reports using standard Critical Appraisal Skills Program and EPPI-Centre tools [37]. These addressed the rigor of sampling, data collection and data analysis; the extent to which study findings were grounded in the data; whether the study privileged the perspectives of participants (eg, by including open-ended questions or otherwise

allowing space for participants to set out their own views); and the breadth and depth of findings (ie, the extent to which the study explored a broad range of process issues or provided in-depth insights into participant perspectives). Drawing on these criteria, each reviewer then assigned weights (high, medium, or low) to rate the reliability or trustworthiness of the findings, and the usefulness of the findings for shedding light on the research question (ie, the extent to which they shed light on how processes of intervention delivery and receipt varied with characteristics of interventions, providers, participants, or contexts). Reliability reflected the trustworthiness of the overall findings (ie, the extent to which the methods employed were rigorous and could minimize bias and error in the findings). CB and RM met to compare their assessments, resolving all differences through discussion.

Data Analysis

Using thematic synthesis methods [38-40], we explored themes concerning the characteristics of interventions, participants, and context acting as potential barriers and facilitators of delivery and receipt, and which themes applied across or only within the domains of sexual health, substance use, and mental health interventions. Synthesis followed a meta-ethnographic approach [41]. We undertook line-by-line coding of reports examining "first-order constructs" (directly quoted qualitative data) and second-order constructs (author interpretations). In the case of findings from quantitative study components, we coded author interpretations, first checking as part of quality assessment whether these aligned with quantitative data presented (ie, the extent to which study findings were grounded in the data, as noted above). Coding developed third-order constructs by drawing connections between these data. We did not exclude studies based on quality assessment, but rather gave less interpretive weight to conclusions that drew only on poorer-quality reports.

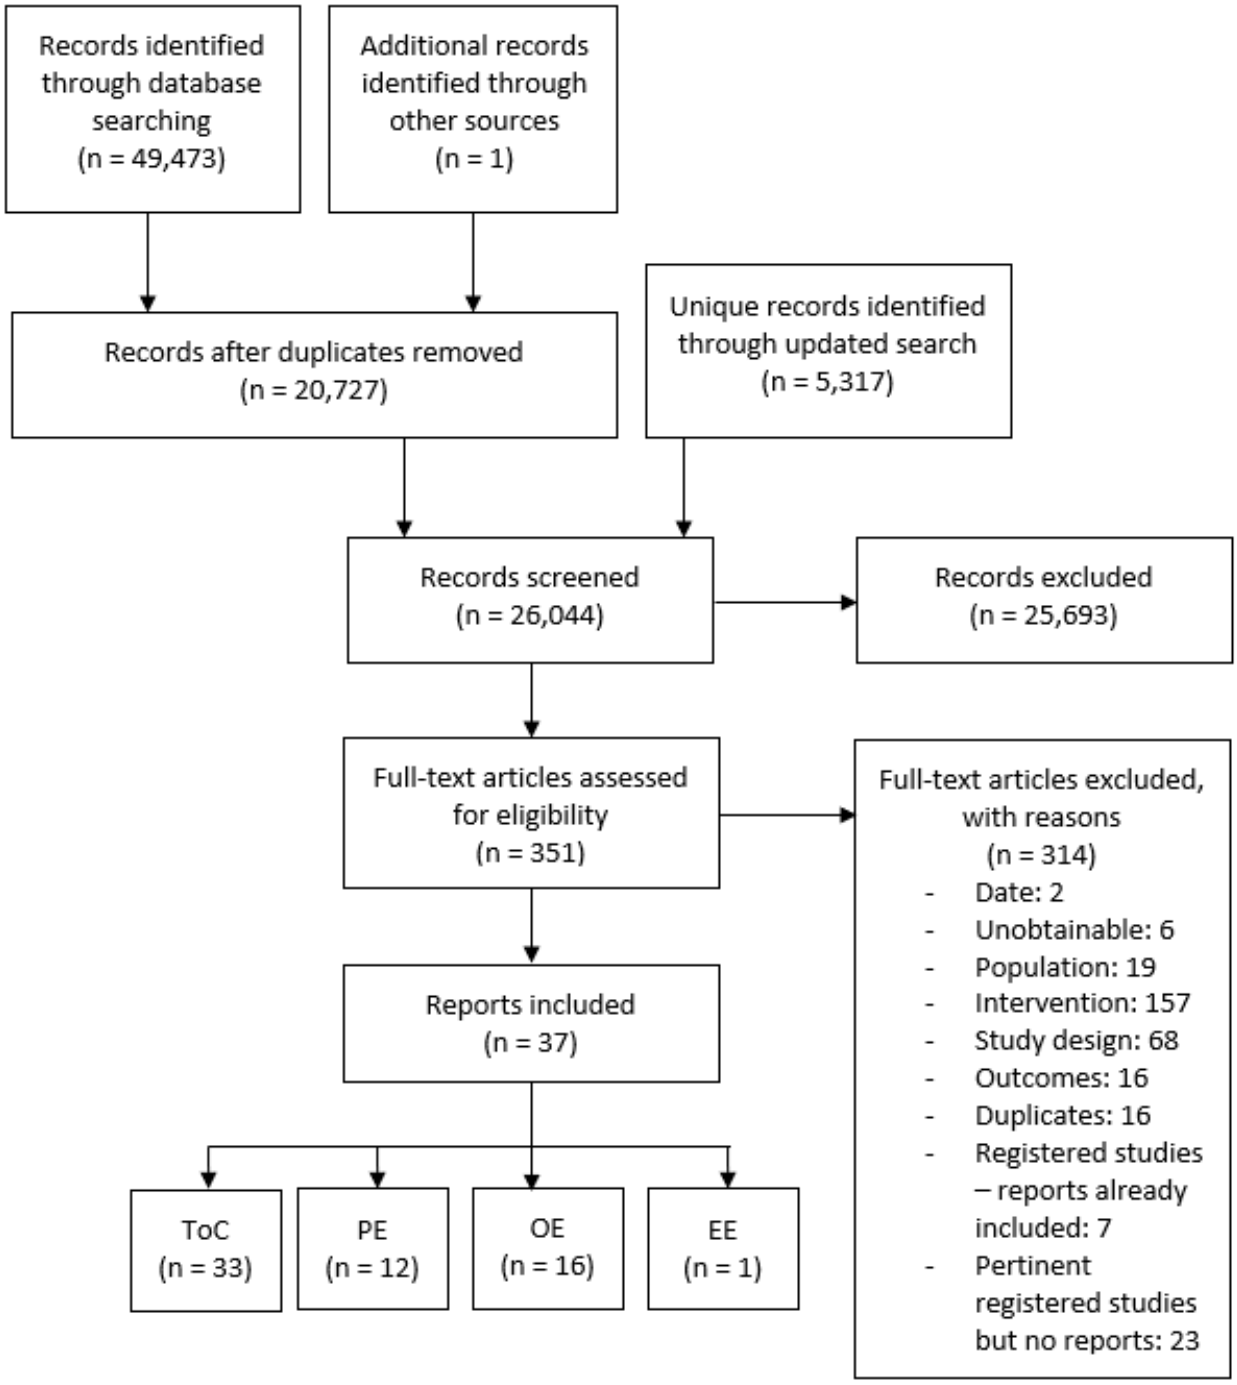
First, CB and RM prepared tables describing the quality of each evaluation, intervention details, study site and population, and pertinent findings. Second, the reviewers independently piloted coding of 2 high-quality studies. Coding began with in vivo codes which closely reflected the words used in the findings sections. The reviewers then grouped and organized codes, applying axial codes that reflected higher-order, cross-cutting themes. They then met to compare and contrast their coding, developing an overall set of codes. Next, they each went on to independently code the remaining reports, drawing on the agreed set of codes and developing new in vivo and axial codes as new themes emerged. At the end of this process, they met to compare their sets of codes. They identified commonalities, differences of emphasis, and contradictions to develop an overall analysis which drew on the strengths of the 2 sets of codes and which resolved any contradictions or inconsistencies.

Results

Results of the Search for Overall Review

Our search retrieved 26,044 unique results, including 1 identified via reference checking (see Figure 1). After title and abstract screening, 6 full texts were unobtainable and 345 reports were screened on full text. Of these, 37 reports were eligible for inclusion in the overall review. These reported on 28 unique studies and 23 unique interventions [42-78]. Reports were published between 2006 and 2020, with most published in 2015 or later.

Figure 1. Searches and screening. EE: economic evaluation; OE: outcome evaluation; PE: process evaluation; ToC: theory of change.



Reports Included in Process Evaluation Synthesis

Twelve reports were eligible for inclusion in the process evaluation synthesis (see Multimedia Appendix 2 for details of each intervention and Multimedia Appendix 3 for study characteristics) [42,49,52,54,59,63,64,67,68,75,76,78]. These reported on 11 studies which assessed 8 unique interventions, and 2 interventions were assessed in 2 different studies [54,59,67,78]. Included process evaluation reports presented findings on how intervention receipt (but not delivery) varied by characteristics of the intervention [42,49,52,59,63,64,67,68,75,76,78] participants [42,49,59,63,64,75,76,78] and context [54,75,78] but not providers. Additionally, 3 interventions addressed sexual health alone [54,68,75,78], 2 addressed mental health alone [42,63,64], 1 addressed sexual health and substance use [49,59,67], and 2 addressed all 3 outcomes of interest for this review [52,76] (see Multimedia Appendix 2). Moreover, 4 interventions targeted sexual minority youth or young adults [49,52,59,63,64,67,68], 2 targeted MSM more generally [42,75], 1 targeted rural MSM [54,78], and 1 targeted people living with HIV [76]. In terms of delivery mode, 5 were delivered via the internet [42,49,52,54,59,67,68,78], 2 via smartphone apps [75,76], and 1 via computer CD-ROM [63,64]. Process evaluations for 7 of the included interventions took place in the United States

[42,49,52,54,59,67,68,75,76,78], and 1 took place in New Zealand [63,64,76].

Quality Assessment

Multimedia Appendix 3 shows the results of our quality assessments. In total, 11 of the 12 included reports were assessed as reporting findings that were grounded in the data presented. Overall quality varied, with most reports assessed as medium or high quality. In terms of the reliability or trustworthiness of their overall findings, 4 reports were assessed as medium quality [42,68,75,76] and 8 as high quality [49,52,54,59,63,64,67,78]. In terms of their overall usefulness for addressing our research questions, 4 were assessed as low quality [52,54,68,78], 3 as medium quality [63,64,67], and 5 as high quality [42,49,59,75,76]. Only 1 report was assessed as high quality in both reliability/trustworthiness and usefulness [49,59], and all were assessed as medium or high quality in at least one of these 2 domains [42,49,52,54,59,63,64,67,68,75,76,78].

Themes Emerging From Synthesis of Process Evaluation Reports

Multimedia Appendix 4 shows the relationship between primary, secondary, and tertiary codes developed through our analysis and synthesis of process data.

Intervention Characteristics Affecting Intervention Receipt

Nearly all process evaluations explored ways in which intervention characteristics affected receipt, although the included reports tended to lack breadth in the areas explored and in-depth exploration of the findings that they did report [42,49,52,59,63,64,67,68,75,76,78]. Nonetheless, several subthemes emerged in our analysis.

Ease of Use

Across health domains, acceptability was enhanced when interventions were easy to use and free of technical problems. Few technical problems were reported. For example, from studies assessed as medium reliability, 10% or fewer Smartphone Self-Monitoring users reported technical difficulties [76] and participants reported that the HealthMindr app was easy to use [75]. However, from studies of medium [42,76] and high [49,54,59,63,67,78] reliability, when participants did encounter technical issues, such as freezing [59] or incompatibility with mobile devices [42,49], this eroded acceptability. In a 2007 study of an intervention targeting rural MSM, features such as sound, animation or graphics could cause the intervention to load too slowly for participants with slower internet speeds, which authors suggested might derail participation [54].

From studies of medium and high reliability, accompanying materials outside of the electronic environment (such as printable materials [42] or a notebook [63,64]) were reported to potentially enhance acceptability, but participants disliked exercises that required using materials they might not have readily at hand [42].

Intervention Content

Clear and Comprehensive Content

From studies of medium reliability across health domains, it was apparent that intervention content which involved clear and comprehensive information facilitated acceptability. For example, Queer Sex Ed participants appreciated that this intervention provided comprehensive information on a range of sexual health and relationship topics rather than focusing narrowly on sexually transmitted infections [68]. In studies of other interventions, acceptability was reportedly enhanced where content was clear and up to date [42], while content participants found confusing detracted from acceptability [76].

Engaging Intervention Content

Fun [68] and enjoyable [42] content increased acceptability, and the use of different types of content arose as a common theme influencing the acceptability. For example, in studies of medium [42] and high [49,59,63,67] reliability, participants tended to give positive feedback on the use of diverse contents [42,49,59] including animations, videos, graphics, and games [67] as well as on the interventions' visual appearances [43,63]. In a high-reliability study of Rainbow SPARX, users were particularly positive about the computer game format and the intervention's "look and feel" [63] as expressed by one user aged 13 years: "I liked, like, how it looked really shiny on my computer, and it looked like a completely different world" [13]. Rainbow SPARX participants also liked particular characters who appeared in the game [63], a theme echoed in a high-reliability study of the Keep it Up! intervention where participants reported liking the scenarios and examples presented [67]. Factors detracting from acceptability included content that participants found boring, repetitive [42,76], too easy [63], too difficult or draining [42], "not soothing" [42], "cheesy" [49,59], or generally unenjoyable [42]; and videos that users judged as too long or that featured low-quality sound and dialogue [49].

Language and Tone

Language and tone emerged as an important aspect of acceptability across interventions addressing all 3 health domains and in studies of medium [42,68,75] and high [49,59,63,64,67] reliability. Participants liked what authors described as a "frank, candid, and sex-positive tone" [59], colloquial language [67], and what one participant described as an "up-beat manner" [67]. For example, Queer Sex Ed users appreciated that the intervention did not rely on "scare tactics" and that its content was easy to understand without making them feel "talked down to" [68]. A Keep it Up! user echoed this sentiment, describing the intervention as "realistic and not condescending or out of touch" [49].

There were also some challenges in getting the language right for MSM-specific interventions. Some users of the Rainbow SPARX and Online Mindfulness-Based Cognitive Therapy interventions suggested that the sexuality-related terminology could be improved [63] and voiced concerns about the intervention's approach to sexual minorities and a feeling of "anti-gay sentiment"[42]. Avellar [42] suggests content might have been overly clinical and miscommunicated the aim of improving overall well-being, although it was not clear whether

participant concerns stemmed primarily from intervention content or from content about participating in a research study.

Interaction and Personalization

Participants in studies of medium [68] and high [49,63,67] reliability valued interactive aspects of interventions spanning all 3 health outcomes. Studies of medium [75,76] and high [59] reliability found that individual-level tailoring based on participant assessments could enhance acceptability. For example, 81% of HealthMindr users found recommendations based on their responses useful or very useful [75] and Smartphone Self-Monitoring users recommended adding what the authors summarized as "more in-depth questions to better reflect their experiences" [76].

Privacy and Intrusiveness

In studies of medium reliability, privacy and intrusiveness emerged as important themes influencing acceptability across 2 interventions, which between them addressed all 3 health outcomes [75,76]. Some Smartphone Self-Monitoring users felt the intervention's use of daily surveys on substance use, sexual behaviors, and medication adherence, and 4-times daily surveys on physical and mental health-related quality of life were too long or too frequent [76]. Users expressed concerns about privacy regarding questions assessing sexual behavior including experiences with individual partners [76]. The vast majority of HealthMindr app users (86%) reported feeling confident in the app's security, including its password features and the fact that the app's name and icon did not suggest it was focused on HIV prevention [75]. At least one participant in the Smartphone Self-Monitoring intervention was uncomfortable with geolocation tagging of phone survey responses, although the authors noted that participants were instructed on how to disable this feature [76].

Pacing and Structuring

The pacing and structuring of content influenced acceptability across health domains. In studies of medium [42] and high [49,64,67] reliability, a modular as opposed to single-session approach could reportedly help users absorb content [67] although they tended to like setting their own pace [64], and one suggested they would have preferred to complete all modules in one sitting [49]. Requiring a full week between sessions of the Online Mindfulness-Based Cognitive Therapy was reported as too long, detracting from acceptability [42].

Users liked when intervention content progressed in a cumulative way [42]. Module order and how far the participant had progressed could also affect acceptability. Findings from a high-reliability study of the 3-module Hope Project (addressing knowledge, motivation, and behavior), which randomized the order in which modules were delivered, suggested that participants were more likely to find the knowledge module interesting when they encountered it last rather than first [78]. Assessing level of interest after each module, this study also found that among those completing all modules, participants were more likely to report finding them very interesting after completing all 3 compared to only the first.

Program length arose as a common theme affecting the acceptability of some modular interventions. Users of the 8-session Online Mindfulness-Based Cognitive Therapy [42], the 7-module Keep it Up! intervention [49,59,67], and 5 five-module Queer Sex Ed intervention [68] suggested that these programs were too long or too time-consuming.

Content Designed To Be Relevant to Participants' Lives and Experiences

Participants valued that interventions were designed for people like them. From studies of high reliability, it was apparent that participants valued when interventions presented realistic scenarios and examples and addressed issues relevant to their own lives [49,59,63,67]. A Keep it Up! user appreciated that the intervention "was geared towards gay men and it understood how we operate and how dating works in the contemporary moment" [49].

Users of the Rainbow SPARX and Queer Sex Ed interventions liked that these programs were "[lesbian, gay, bisexual, and transgender] LGBT–specific" [68], designed for young people [64], and included "'rainbow content" tailored to this group [63]. Some felt there was room to go further [63,68], for example by removing content on female sexual anatomy for MSM users and adding more trans-specific content [68].

Online Mindfulness-Based Cognitive Therapy users had mixed views on how effectively this intervention was tailored for people like them [42]. Some reported appreciating that the program was designed for men who were attracted to men, while others felt the intervention "did not have much value in the context of their lives" [42]. Some Rainbow SPARX users reported that tailoring could be further enhanced by including more sexuality-specific content [63].

Perceived Usefulness of the Intervention

Gaining Knowledge and Skills

In studies of medium [42] and high [49,52,59,63,64,68,78] reliability, participants frequently cited perceived usefulness as positive in terms of the knowledge and skills the interventions aimed to impact. For example, Queer Sex Ed users liked that the intervention aimed to support communication and closeness with their partners, helping, as one participant described, to "open up doors to healthy communication" [68].

Opportunities for Self-Monitoring and Self-Reflection

Findings from the evaluation of the Smartphone Self-Monitoring intervention (targeting sexual health, substance use, and mental health outcomes) suggest that some participants valued its daily, mobile-based self-monitoring in contrast to the comparison group's biweekly, web-based approach. One user described the benefits this way [76]:

> *Helps me keep a "log", like therapy—but can do it every day instead of waiting for a week to see your therapist…Nice to do it throughout the day, multiple times a day, on a daily basis. Life happens daily—not weekly like when you see a therapist.*

Participants in 3 interventions, which between them addressed all 3 health domains, highlighted the opportunities for introspection and self-reflection that the interventions presented

[42,49,59,67,76]. For instance, a Smartphone Self-Monitoring user described the following [76]:

> *I started changing my behavior once I started taking the surveys—I have been thinking about it for a while but the surveys make me concentrate on certain areas of my life that I wasn't focusing on.*

A few also reported that engaging in self-monitoring across multiple domains enhanced their awareness of the relationships between their substance use, sexual behaviors, and other triggers for drug use [76]. A Keep it Up! user described how observing the characters in the intervention helped him to reflect on his own behaviors [67]:

> *I was able to see mistakes that I make in the actions of the characters. I wasn't completely aware of my behavior until I judged a character's behavior and then compared the same behavior to my own.*

Opportunity for Self-Expression

Participants in the Smartphone Self-Monitoring intervention, which addressed all 3 health outcomes, valued the opportunity for self-expression that the intervention offered, as described by this participant: "I feel free to vent to the phone about things that I can't talk to my partner about—I can really express how I feel" [76].

Participant Characteristics Affecting Intervention Engagement and Receipt

Evaluations of 4 interventions (2 targeting sexual health alone [75,78], 1 targeting mental health alone [42], and 1 targeting sexual health and substance use [49]) quantitatively explored the relationship between participant characteristics and intervention engagement.

A medium-reliability study of the HealthMindr mobile phone app found no differences in the time spent on the app by participant location in different cities in the United States, age, ethnicity, or knowledge of local HIV testing [75], while a high-reliability study of the Keep it Up! intervention, targeting young ethnically and racially diverse MSM, found that among Black users, those with graduate degrees spent more time on the intervention than those with high school–level or lower levels of education [49]. A study of medium reliability found no significant variation in retention for a modular mental health intervention by age, socioeconomic status, ethnicity, internalized homonegativity, or experience of homophobic bullying [42]. A study of high reliability found no differences in participants completing 1 versus all 3 modules of the Hope Project (an extension of the WRAPP intervention, targeting rural MSM) by age, ethnicity, marital status, sexual orientation, education, or student status, but did find higher completion among higher-earning participants [78].

Madkins et al [49] conducted a high-reliability, extensive exploration of the relationship between participant characteristics and receipt of the Keep it Up! intervention, which was developed with the engagement of diverse young MSM and designed for young MSM of all racial groups [67]. Researchers found several differences in the acceptability of the Keep it Up! intervention by race/ethnicity, education level, age, and city in the United States [49]. Black, Latino, and other non-White users reported higher acceptability in a range of domains than did White users, and Latino users rated content more highly compared to other non-White users. In the overall sample, users with high school–level education or lower rated the intervention more highly than those with higher education. Exploring the interaction of race/ethnicity and education level, the study found that higher levels of education were associated with lower acceptability among White users, while no such differences were found among Black, Latino, or other non-White users. Older users and those in Atlanta compared to New York tended to rate modules more highly.

Exploring intervention receipt qualitatively, a high-reliability study found that for Rainbow SPARX, a computer game intervention for sexual minority youth aged 13-19 years, some older users reported that some aspects were too easy and the program "babied" them [63]. Acknowledging the challenge of designing a program appropriate for a range of young people, one participant aged 19 years made the following remark [63]:

> *I thought some things were a little easy…Like overall it wasn't difficult to figure out what you needed to do. Those little puzzles were quite easy to do. I guess it would be hard to make them more difficult though because you would have to be careful that everyone could actually get it."*

Qualitative research with participants of Rainbow SPARX and Smartphone Self-Monitoring found that these interventions could play a role in complementing the external mental health support participants were receiving [64,76].

Contextual Factors Affecting Intervention Engagement

Few studies explored how the context for using the intervention was associated with the experience of its use. Those that did focused on internet speed in the high-reliability 2007 [54] and 2010 [78] studies of 2 iterations of the WRAPP sexual health intervention, which targeted rural MSM in the United States. Bowen, et al [54] found that users with dial-up compared to high-speed connections were more likely to report taking too long to load program graphics, while Williams et al [78] found no differences in participants completing 1 versus all 3 modules by type of internet connection.

Discussion

Summary of Findings

One-third of reports included in the overall review included process evaluation data. All but one process evaluation took place in the United States. Most interventions targeted a single health domain of interest for this review (sexual health, substance use, or mental health), with the majority focused on sexual health. However, 2 aimed to address aspects of all 3 [52,76]. Some interventions employed personal tailoring, an approach that has been associated with effective eHealth behavior change interventions [79,80].

Process evaluations rarely explored how intervention receipt varied between contexts. We found no eligible reports examining what factors affected intervention delivery as opposed to receipt.

This seems to reflect the emerging state of process evaluations in eHealth literature, with other reviews of eHealth interventions reporting a similar pattern [81-84]. There was some suggestion that slower internet speed could reduce acceptability of a multimedia intervention among rural MSM in the United States, who are less likely than nonrural residents to have high-speed internet at home [85].

In terms of intervention characteristics, as with use of eHealth interventions among general populations [83], participants appreciated when interventions were easy to use and free of technical problems, while incompatibility with mobile platforms detracted from acceptability and could impede participation. Privacy also emerged as an important aspect of acceptability, suggesting that detailed partner-level questions on sexual behavior could feel intrusive and that features protecting app access and obscuring the purpose of apps (for sensitive health domains) promote acceptability. The importance of privacy is also supported by existing evidence on behavior change interventions for MSM [86] and general populations [83].

Participants liked content that was interactive and aesthetically pleasing, and they enjoyed the use of diverse media such as animations, videos, and graphics. However, among rural MSM these media could also reduce loading times for users with slower internet connectivity. Although modular approaches could support users to absorb program content cumulatively, interventions that were too long detracted from acceptability, with some users preferring that less or no time be required between sessions. The ideal number and length of modules is likely dependent on a variety of participant, intervention, and contextual factors.

Individual tailoring based on participant characteristics and risk profiles increased acceptability, highlighting this as a particularly promising approach and aligning with other studies of eHealth behavioral interventions [79,84,87]. Participants valued when interventions presented scenarios and other content that reflected their experiences as MSM, an approach that stands in contrast to most existing eHealth interventions targeting mental health and HIV prevention [34,88]. Where interventions targeted sexual minority groups more broadly, some suggested further tailoring based on the sexual and gender identities of its users. The language and tone of intervention content emerged as an important factor shaping acceptability for MSM, who appreciated the use of colloquial, direct, “up-beat” [67], and sex-positive language. Our findings also highlight the importance of paying careful attention to language and framing to ensure that these affirm sexual-minority identities. That these concerns arose in interventions designed explicitly for sexual minority users, including one adapted for sexual minority young people using participatory approaches [63], suggests this is an important area to explore during the pilot phase of intervention development.

As with studies of eHealth interventions for general populations [81,83], perceived usefulness was key to acceptability. Participants liked gaining new knowledge and skills from eHealth interventions and developing an awareness of the relationship between sexual behaviors and substance use.

Although reviews of eHealth interventions for general populations report higher use and engagement among participants with higher levels of education [81,83,84], our findings suggest that in the context of generally high use of electronic devices among MSM [17], the targeting of intervention content might be a more important determinant of the relationship between education level and receipt of eHealth interventions than their electronic mode of delivery [49]. Similarly, our findings on the higher acceptability of the Keep it Up! intervention among Black, Latino, and other non-White users compared to White users suggest that eHealth interventions can be developed to enhance inclusive acceptability among racially and ethnically diverse users [49]. There was otherwise little evidence of engagement varying by sociodemographic factors, although findings on socioeconomic status were mixed [42,78]. Qualitative data suggest eHealth interventions can play a role in complementing external mental health support among MSM [63,76] and that interventions targeting all adolescents might struggle to pitch content appropriately for those across this age range [63].

Limitations

Our process evaluation synthesis was limited by the size and quality of eligible reports. Most were assessed as medium- or high-quality in terms of their reliability and usefulness. However, studies often lacked depth and breadth of analysis, and only around half were judged to privilege MSM’s perspectives.

The vast majority of interventions targeted MSM only and all were evaluated principally among MSM, although 3 were assessed among samples that included cisgender women [63,64,68,76]. Author narratives and quantitative data did not always disaggregate MSM from other participants, presenting the possibility that specific findings from these 3 studies might reflect data from other groups. The process evaluation of Smartphone Self-Monitoring was the sole study contributing to findings on intervention benefits of self-monitoring and self-expression [76]. Although the intervention targeted people of all genders and sexual identities living with HIV, more than 80% of study participants identified as male and more than 80% identified as gay or bisexual [76]. In 2 studies, just under half of participants identified as female [63,64,68], but all themes informed by these studies also drew on other studies. The make-up of participants in these 3 studies is therefore unlikely to affect the validity of the themes to which they contributed. Studies of relevant interventions among broader sexual and gender minority populations might add further insight but could not be included, as we could not be certain which findings reflected experiences of or relevant to MSM.

Implications for Research and Practice

eHealth interventions offer an avenue for MSM to access behavior change interventions privately, anonymously, and at times they find convenient. This synthesis identified several factors shaping MSM’s receipt of eHealth interventions addressing substance use, mental ill health, and sexual risk. Its findings suggest such interventions are acceptable for MSM across sociodemographic groups, although evidence in this area is limited and mixed. Different content for younger and older

adolescents might be warranted. Variation in engagement and acceptability by participant characteristics should be explored in future research, and new interventions should be rigorously piloted to refine aspects affecting usability and acceptability [30,81].

Our review has identified several intervention characteristics affecting acceptability that existing research suggests are applicable to eHealth interventions for MSM and non-MSM populations alike. These include aspects of usability, length, aesthetics, multimedia use, and tailoring to participants' personal and risk characteristics [79,81,83,84,86,87]. Other factors should be considered carefully in designing interventions for MSM, including ensuring that language and tone are affirming of sexual minority identity and that content reflects the reality and experiences of MSM. These findings can inform the development of integrated eHealth interventions to address the syndemic of substance use, mental ill health, and sexual risk among MSM and guide research questions for pilot and process evaluation studies. Going forward, process evaluations should explore a broader range of individual, intervention, and contextual factors that might affect implementation, and they should collect more in-depth—ideally qualitative—data privileging the perspectives of intended beneficiaries. Outcome evaluations of such eHealth interventions should conduct linked process evaluations wherever possible, which would shed further light on factors affecting how they are delivered and received [89].

Our findings regarding the value that participants place on interventions that address the reality of their lives and the interrelationships between the different domains of health suggest that eHealth interventions simultaneously addressing sexual health, substance use, and mental health might be particularly acceptable. Our review of theories of change [90] suggests that interventions addressing these different outcomes may aim to exert impacts via common mechanisms of action, further adding to the potential for eHealth interventions targeting multiple outcomes together. Our next analyses will assess the potential effectiveness of eHealth interventions on these outcomes.

Acknowledgments

This work was funded by the National Institute for Health Research Public Health Research Programme (NIHR PHR; PHR 17/44/48). This report presents independent research commissioned by NIHR PHR. The views and opinions expressed by authors in this publication are those of the authors and do not necessarily reflect those of the National Health Service, the NIHR, the Medical Research Council, the Central Commissioning Facility, The NIHR Evaluation, Trials and Studies Coordinating Centre, the PHR Programme, or the Department of Health. The funder had no role in study design, in the collection, analysis or interpretation of data, or in writing this manuscript.

Authors' Contributions

CB conceptualized and led the design of the study. AM, GJMT, JF, PW, RM, and TCM contributed to the development of the study's methods. RM and CB developed the intervention typology and quality-assessed and synthesized process evaluation studies. RM led the drafting of the manuscript, with significant input from AM, CB, GJMT, JF, PW, and TCW.

Abstract

Background: Hyperglycemia in pregnancy occurs worldwide and is closely associated with health issues in women and their offspring, such as pregnancy and birth complications, respectively, as well as comorbidities, such as metabolic and cardiovascular diseases. To optimize the management of diabetic pregnancies, sustainable strategies are urgently needed. Investigation of constantly evolving technologies for diabetes that help to manage pregnancy and health is required.

Objective: We aimed to conduct a systematic review to assess the clinical effectiveness of technologies for diabetes in pregnancy.

Methods: Relevant databases including MEDLINE (PubMed), Cochrane Library, Embase, CINAHL, and Web of Science Core Collection were searched in September 2020 for clinical studies (2008-2020). Findings were organized by type of diabetes, type of technology, and outcomes (glycemic control, pregnancy- and birth-related outcomes, and neonatal outcomes). Study quality was assessed using Effective Public Health Practice Project criteria.

Results: We identified 15 randomized controlled trials, 3 randomized crossover trials, 2 cohort studies, and 2 controlled clinical trials. Overall, 9 studies focused on type 1 diabetes, 0 studies focused on gestational diabetes, and 3 studies focused on both type 1 diabetes and type 2 diabetes. We found that 9 studies were strong quality, 11 were moderate quality, and 2 were weak quality. Technologies for diabetes seemed to have particularly positive effects on glycemic control in all types of diabetes, shown by some strong and moderate quality studies. Positive trends in pregnancy-related, birth-related, and neonatal outcomes were observed.

Conclusions: Technologies have the potential to effectively improve the management of diabetes during pregnancy. Further research on the clinical effectiveness of these technologies is needed, especially in pregnant women with type 2 diabetes.

Introduction

Hyperglycemia in pregnancy occurs worldwide and is closely associated with short- and long-term health issues, such as pregnancy complications in women and birth complications in offspring, and comorbidities, such as type 2 diabetes, as well as metabolic and cardiovascular diseases [1]. Approximately 20.4 million live births (16%) suffered from some form of hyperglycemia in pregnancy in 2019, worldwide [1]—84% were defined as gestational diabetes, 7.9% were diagnosed prior to pregnancy, and 8.5% were type 1 or type 2 diabetes first observed in pregnancy [1].

In 2019, 1,566,993.4 live births in North America and the Caribbean; 2,001,816.8 live births in Europe; and 6,594,159.4 live births in southeast Asia were affected by hyperglycemia in pregnancy [1]. Interestingly, the prevalence of gestational diabetes is rising quickly and was estimated to be 20.8% in North America and the Caribbean, 16.3% in Europe, and 27.0% in southeast Asia in 2019 [1]. The number of unreported cases is assumed to be high.

Hyperglycemia in pregnancy is associated with adverse pregnancy- and birth-related outcomes for mothers and offspring, such as increased risk of preeclampsia, cesarean deliveries, macrosomia, and shoulder dystocia [2-6], but hyperglycemia in pregnancy is also associated with adverse long-term consequences in mothers and children, such as subsequent increased risk of type 2 diabetes, obesity, metabolic syndrome, cardiovascular diseases, or even depression [2,4,5,7,8]. Based on the hypotheses of perinatal programming (fetal programming, developmental programming, transgenerational programming), intrauterine exposure to hyperglycemia is clearly associated with obesity, glucose, intolerance, type 2 diabetes, insulin resistance, metabolic syndrome, high blood pressure, and cardiovascular diseases in postnatal life of the offspring [5,9,10].

Sustainable strategies are urgently needed to effectively improve the management of diabetes in pregnancy with seamlessly integrated technological support for hyperglycemia in pregnancy. Technologies for diabetes, including hardware, devices, and software, are constantly evolving and can help to manage the condition, improving lives and health [11]. *Care 4.0* is a new paradigm to develop digital health and care services by focusing on trusted integrated networks of organizations, people, and technologies [12].

Recently, we demonstrated first insights in clinical effectiveness and successful approaches of mobile health (mHealth) apps as well as telemetric implementations to improve diabetic management in pregnancy [13,14]. Diabetes-specific mHealth apps and telemetric approaches improved clinical outcomes in the management of gestational diabetes effectively.

As a matter of course, there are many more technologies that have proven to be effective in diabetes management in general, for example, continuous glucose monitoring systems [15,16], continuous subcutaneous insulin infusions [17,18], and sensor augmented insulin pumps or closed-loop systems [19,20].

A previous review [21] examined the capability of diabetes technologies in the treatment of diabetic pregnancies; however, to further optimize management of diabetes in pregnancy, up-to-date analyses of technology for diabetes in pregnancies are needed. Therefore, we conducted a systematic review to assess the clinical effectiveness of different technologies for diabetes in pregnancies by analyzing glycemic control, pregnancy- and birth related outcomes, and neonatal outcomes.

Methods

Data Sources and Searches

A systematic review was carried out using PRISMA guidelines [22]. MEDLINE (PubMed), Cochrane Library, Embase, CINAHL, and Web of Science Core Collection were systematically searched for studies published from January 2008 until September 2020 (Multimedia Appendix 1). The following keywords were used as title and abstract search terms and selected from Medical Subject Headings and Embase subject headings databases: “diabetes mellitus,” “pregnancy,” “gestational diabetes mellitus,” “mobile application,” “insulin pump,” “continuous glucose monitoring,” “CGM,” “flash glucose monitoring,” “FGM,” “insulin infusion system” (Multimedia Appendix 2). Using a priori criteria for eligibility, 2 reviewers screened and selected the studies independently. We screened titles and abstracts, assessed full texts, and manually searched reference lists and Google Scholar.

Eligibility Criteria

We included peer-reviewed studies, published in German and English, that investigated the clinical effectiveness of diabetes technologies in pregnancies affected by hyperglycemia, including pre- and postconception. Studies with pregnant woman with a diagnosis of gestational diabetes or with preexisting type 1 diabetes or type 2 diabetes and that clearly reported the type of diabetes investigated were included. We included studies examining gestational diabetes patients only, type 1 diabetes only, type 2 diabetes only, and studies with mixed pregestational diabetes (type 1 diabetes and type 2 diabetes) groups. We included prospective controlled trials (clinical and observational trials). The following types of technologies were included: continuous glucose monitoring systems, continuous subcutaneous insulin infusions, sensor augmented insulin pumps, closed-loop systems, and mHealth apps. We involved studies examining glycemic control, pregnancy- and birth-related, and neonatal outcomes. Poster, comments, letter, study protocols, notes, and proceedings papers were excluded.

Data Extraction and Synthesis

We extracted the most common glycemic control (eg, hemoglobin A_{1c} [HbA_{1c}], fasting blood glucose, hyper- or hypoglycemia, insulin dose), pregnancy- and birth-related (eg, preterm birth, gestational weight gain), and neonatal (eg, birthweight, macrosomia) outcomes as well as author, year, study design, type of diabetes, type of technology, sample size, and main results. Findings were organized by type of diabetes, type of technology, and outcomes.

Quality Assessment

We applied Effective Public Health Practice Project (EPHPP), a validated tool that is suitable for intervention studies such as randomized controlled trials and controlled clinical trials. EPHPP is composed of criteria regarding selection bias, study design, confounders, blinding, data collection methods, withdrawals, and dropout. Study quality is rated as strong (SQ), moderate (MQ), or weak (WQ) [23].

Results

Study Selection and Characteristics

The search yielded 974 records, of which 754 remained after removing duplicates (3 records were identified through reference lists and Google Scholar). Of those, 693 were excluded based on titles and abstracts with our inclusion and exclusion criteria, and the full texts of 61 remaining publications were screened. Finally, 22 studies were included in this systematic review: 15 randomized controlled trials, 3 randomized crossover trials, 2 cohort studies, and 2 controlled clinical trials. Overall, 9 studies focused on type 1 diabetes, 10 studies focused on gestational diabetes, and 3 studies focused on type 1 diabetes and type 2 diabetes (mixed populations). We rated 9 studies as strong

quality, 11 studies as moderate quality, and 2 studies as weak quality (Multimedia Appendix 3). Table 1 gives an overview of the technologies, outcomes, and number of study participants..

Table 1. Overview of the technologies, outcomes, and study participants.

Population, technology, and outcome	Studies, n	Intervention group, n	Control group, n
Type 1 diabetes			
Continuous glucose monitoring systems

[a]HbA_{1c}: hemoglobin A_{1c}.

[b]*Preterm delivery* was defined as <37 weeks.

[c]*Patient compliance* was defined as ratio between actual and instructed blood glucose measurements×100.

Type 1 Diabetes: Overview

Of 9 publications analyzing 379 women in intervention (IG) and 763 in control groups (CG), 3 studies examined continuous glucose monitoring system, 4 studies examined continuous subcutaneous insulin infusion, and 2 studies examined closed-loop systems.

Type 1 Diabetes: Continuous Glucose Monitoring Systems

In general, 3 randomized controlled trials [24-26], analyzing 199 women in intervention groups and 236 women in control groups, were identified.

Glycemic Control Outcomes

HbA_{1c} values declined in all interventions. Feig et al [25] (MQ) observed significantly lower HbA_{1c} values in the intervention group than the control group (mean difference −0.19%; 95% CI −0.34 to −0.03; *P*=.0207). Cordua et al [24] (SQ) found positive but nonsignificant effects (IG: 6.0% vs CG: 6.2%; *P*=.23), and Petrovski et al [26] (SQ) reported significantly improved HbA_{1c} values (*P*<.05) in both groups (real-time continuous glucose monitoring system and intermittent continuous glucose monitoring system).

Petrovski et al [26] (SQ) found significantly less severe events of maternal hypoglycemia (real-time continuous glucose monitoring system group: *P*<.05), whereas Feig et al [25] (MQ) found time spent hypoglycemic was comparable in both groups (3% vs 4%; *P*=.10).

The intervention groups tended to have better target insulin dose or requirement values than those of the control groups (*P*=.14 [25], MQ; *P*=.08 [24], SQ). Petrovski et al [23] (SQ) did not find significant differences between constant and intermittent continuous glucose monitoring system (*P*>.05).

Pregnancy- and Birth-Related Outcomes

Cesarean delivery rates were clearly lower in the intervention groups (MQ, *P*=.18 [25]; SQ, *P*<.05 [23]). Cordua et al [24] (SQ) found significantly more vaginal deliveries in the intervention groups (IG: 74%; CG: 54%; *P*=.08).

All studies found slightly fewer preterm births in the interventions groups (Feig et al [25] <37 weeks: *P*=.57; <34 weeks: *P*=.19; Petrovski et al [23]: *P*>.05, Cordua et al [24]: *P*=.84).

Maternal gestational weight gains were lower in the continuous glucose monitoring system group (Feig et al [25] +8.9 kg vs +9.7 kg, *P*=.09) and the intermittent continuous glucose monitoring system group (Petrovski et al [26] +12.9 kg vs 13.4 kg, *P*>.05).

Neonatal Outcomes

Feig et al [25] (MQ) displayed a slightly lower mean birthweight in the continuous glucose monitoring system group (*P*=.37), whereas Cordua et al [24] (SQ) found a lower mean birthweight in their control group (*P*=.19).

Macrosomia rates were lower in intervention (Feig et al [25], MQ, IG: 23%; CG: 27%; *P*=.62) and real-time continuous glucose monitoring system (Petrovski et al [26], SQ, *P*>.05) groups.

Feig et al [25] found rates for large for gestational age were significantly lower in the intervention groups (*P*=.021), whereas Cordua et al [24] found no significant differences (*P*=.08).

Type 1 Diabetes: Continuous Subcutaneous Insulin Infusion

In general, 2 cohort studies [27,28], 1 randomized controlled trials [29], 1 randomized crossover trial [30] analyzing 148 intervention and 495 control participants were identified.

Glycemic Control Outcomes

Overall, 3 studies found positive effects on HbA_{1c} levels in favor of continuous subcutaneous insulin infusion. Jotic et al [28] (SQ) found a significant lower mean HbA_{1c} level in their intervention group than that in the control group at follow-up (6.5% intervention vs 6.8% control, *P*=.002). Cyganek et al [27] (SQ) also reported significant improvements in HbA_{1c} within all their treatment groups but did not find significant differences between groups.

Gutaj et al [30] (SQ) found significant lower insulin doses in the intervention group (0.54 U/kg/day intervention vs 0.63 U/kg/day control, *P*=.02), whereas Cyganek et al [27] (SQ) showed significantly lower daily insulin doses within each treatment group but no significant differences between groups.

Jotic et al [28] (SQ) reported that in early pregnancy, the majority of women on continuous subcutaneous insulin infusion had significantly fewer instances of hypoglycemia (*P*<.01), but Cyganek et al [27] (SQ) found fewer instances of severe hypoglycemia in their control group (*P*=.04).

Pregnancy- and Birth-Related Outcomes

Cyganek et al [27] (SQ) found less weight gain (+13.0 kg) in women in the control group receiving multiple daily injections than in the other groups (+14.7 kg for those only continuous subcutaneous insulin infusion; +15.2 kg for those moving from multiple daily injections to continuous subcutaneous insulin infusion; *P*=.005), and Feig at al [29] (MQ) did not find significant differences between groups (IG: mean +13.5 kg, SD 5.4 kg; CG: mean+13.5 kg, SD 0.7 kg; *P*=.48).

The studies could not find any clearly positive effects regarding cesarean deliveries in favor of continuous subcutaneous insulin infusion. Cyganek et al [27] (SQ) reported that the proportion of cesarean deliveries was larger in women using insulin pumps (no *P* value reported) because of clinical factors such as age, duration of diabetes, and microvascular complications. Feig et al [29] (MQ) (IG: n=81 vs CG: n=74, *P*=.32) and Jotic et al [28] (SQ) (IG: n=12 vs CG: n=13, *P*=.20) found no significant differences between groups.

There were no significant differences in preterm births between groups (*P*=.30 [27]; pump: n=39, 35%, vs multiple daily injections: n=35, 30%, *P*=.10 [29]; continuous subcutaneous insulin infusion n=13, 27.7%, vs multiple daily injections n=13, 16.3%, *P*=.17 [28]).

Feig et al [29] (MQ) found significantly fewer women with hypertension in the control group (IG: 14.4% vs CG: 5.2%; *P*=.025), whereas Jotic et al [28] (SQ) reported a lower, but not significantly so, rate of women with hypertension in their intervention group (*P*=.09). Feig et al [26] (MQ) also found fewer women with preeclampsia in the control group (*P*=.31), whereas Jotic et al [28] (MQ) noted fewer women with preeclampsia in the intervention group (IG: n=1, CG: n=3, *P* value not available).

Neonatal Outcomes

Neonatal birthweight was marginally higher in intervention groups (Feig et al [29], MQ, *P*=.91; Jotic et al [28], SQ, *P*=.98).

Jotic et al [28] (SQ) found fewer instances of macrosomia in the intervention group (*P*=.46), while Feig et al [29] (MQ) found slightly more instances in the intervention group (*P*=.89).

Jotic et al [28] reported fewer instances of newborns being large for gestational age in the intervention group (*P*=.59 [28]), whereas Feig et al found slightly more newborns who were large for gestational age in the interventions group (*P*=.55).

Jotic et al [28] (SQ) found no instances of newborns being small for gestational age in the intervention and 5 (4%) instances of newborns being small for gestational age in the control group (*P* value not available), whereas Feig et al [29] (MQ) observed 3 and 1 instances of newborns being small for gestational age in the intervention and control groups, respectively (*P* value not available).

Feig et al [29] (MQ) and Jotic et al [28] (SQ) found differences in admissions to higher level neonatal care in favor of the control groups (IG: 44.5% vs CG: 29.6%, *P*=.02 [29]; and *P*=.28 [28]).

Jotic et al [28] (SQ) found slightly fewer instances of neonatal hypoglycemia in the intervention group (IG: n=5, CG: n=6, *P*=.54), whereas Feig et al [29] (MQ) reported a significant difference in favor of the control group (IG: 31.8% vs CG: 19.1%, *P*=.05).

Type 1 Diabetes: Closed-Loop Systems

Closed-loop systems were investigated in 2 randomized crossover trials including a total of 32 women comparing

closed-loop systems with sensor augmented insulin pumps [29,31].

Stewart et al [31] found a significant difference between groups in percentage of time that blood glucose levels were between 63 and 140 mg/dL for overnight evaluation (*P*=.002) as well as day and night evaluation (*P*<.001) in favor of the closed-loop group [31], while Stewart et al [29] (MQ) found no significant difference (closed-loop: 62.3% vs sensor augmented insulin pumps: 60.1%, 95% CI 24.1% to 8.3%, *P*=.47).

Stewart et al [32] (MQ) reported significant fewer hypoglycemic events during the closed-loop treatment (n=8 vs n=12.5, *P*=.04) [32], whereas Stewart et al [31] (MQ) found no significant differences in overnight analysis (closed-loop: median 3.0; sensor augmented insulin pumps: median 2.5, *P*=.68) or day and night analysis (closed-loop: median 11.0, sensor augmented insulin pumps: median 12.0, *P*=.19).

Neither Stewart et al [32] (MQ) (closed-loop 43.7 vs sensor augmented insulin pumps 41.5 units/day, *P*=.56) nor Stewart et al [31] (MQ) (closed-loop 58.2 vs sensor augmented insulin pumps 59.8 units/day, *P*=.56) found significant differences between treatments regarding insulin dose [31,32].

Gestational Diabetes: Overview

In general, 4 studies focused on continuous glucose monitoring system, and 6 studies focused on mHealth apps (overall: IG: n=555; CG: n=609).

Gestational Diabetes: Continuous Glucose Monitoring Systems

We identified 4 randomized controlled trials (IG: n=147, CG: n=154). Whereas 3 studies used self-monitoring blood glucose as control [33-35], 1 study used blinded continuous glucose monitoring system which did not display the glucose readings to the participant [36].

Glycemic Control Outcomes

All studies reported clearly lower HbA_{1c} values in their intervention groups. Paramasivam et al [34] (MQ) found a significant difference in favor of the intervention group (mean 5.2%, SD 0.4% vs mean 5.6%, SD 0.6%; *P*=.006). Alfadhli et al [33] (*P*=.168) (MQ) and Lane et al [36] (*P*=.3) (SQ) found lower mean HbA_{1c} values in their intervention groups (*P*>.05).

Paramasivam et al [34] (MQ) (*P*=.101) and Alfadhli et al [33] (*P*=.092) (MQ) found lower fasting blood glucose values in the intervention groups.

Pregnancy- and Birth-Related Outcomes

Alfadhli et al [33] (MQ) (IG=16.3%, CG=9.5%, *P*=.373), Paramasivam et al [34] (MQ) (IG: n=3, 12%; CG: n=1, 4%; *P*=.609) and Lane et al [36] (SQ) (IG: n=1, 9.1%; CG: n=2, 16.7%; *P*>.999) found no significant differences in the occurrence of preterm births.

Paramasivam et al [34] (MQ) reported clearly more vaginal deliveries in the intervention group (*P*=.258) [34], while Wei et al [35] (MQ) (*P*=.370) and Lane et al [36] (SQ) (*P*>.999) noted slightly more cesarean deliveries in the control groups.

Both studies showed positive effects on maternal weight gain. Wei et al [35] (MQ) reported that the intervention participants had significantly more appropriate and less excessive weight gain (*P*=.039) and Paramasivam et al [34] (MQ) mentioned slightly less weight gain in the intervention group (*P*=.917).

Neonatal Outcomes

Wei et al [35] (*P*=.084), Alfadhli et al [33] (MQ) (*P*=.130) and Paramasivam et al [34] (MQ) (*P*=.311) reported a lower, yet not significant, mean birthweight of newborns in the intervention groups. Lane et al [36] (SQ) reported a higher mean birthweight of newborns in the intervention group (*P*=.4).

Wei at al [35] (MQ) (*P*=.410) and Alfadhli et al [33] (MQ) (*P*=.488) reported fewer instances of macrosomia in the intervention groups, while Lane et al [36] (SQ) noted more instances of macrosomia in the intervention group (*P*=.2), and Paramasivam et al (MQ) [34] found none.

Wei et al [35] (MQ) (*P*=.071) and Paramasivam et al [34] (MQ) (*P*=.490) found clearly fewer instances of newborns being large for gestational age in their intervention groups and, in contrast, Lane et al [36] (SQ) found more instances of newborns being large for gestational age in the intervention group (*P*=.2).

Lane et al [36] (SQ) (*P*>.999) and Wei et al [35] (MQ) (*P*>.999) reported very slightly fewer instances of newborns being small for gestational age in the intervention groups. Paramasivam et al [34] reported none.

Alfadhli et al [33] (MQ) (*P*=.653) reported slightly more admissions, Lane et al [36] (*P*>.999) noted slightly fewer, and Paramasivam et al [34] (MQ) (both groups n=1, 4%) observed the same number of admissions (*P*>.999) to a higher level of neonatal care.

Wei at al [35] (MQ) (*P*=.410) and Paramasivam et al [34] (MQ) (*P*>.999) reported slightly fewer instances of neonatal hypoglycemia among intervention participants whereas Alfadhli et al [33] (MQ) (*P*=.758) found slightly fewer instances of neonatal hypoglycemia in the control group.

Gestational Diabetes: mHealth Apps

We identified 5 randomized controlled trials and 1 controlled clinical trial investigating a total of 408 women in the intervention and 405 women in the control groups.

Glycemic Control Outcomes

Overall, the intervention groups showed lower HbA_{1c} values than the control groups. Guo et al [37] (SQ) displayed a significant difference in favor of the intervention group (–1.3% intervention vs –0.6% control, *P*<.001), while Mackillop et al [38] (WQ) recognized a slight increase in both groups (IG: 0.02% per 28 days; CG: 0.03% per 28 days; 95% CI –0.05 to 0.03).

Both Yang et al [39] (MQ) (*P*<.001) and Bromuri et al [40] (MQ) (*P*<.001) found clear, significant differences in fasting blood glucose levels favoring the intervention groups.

Miremberg et al [41] (SQ) (*P*<.001) as well as Guo et al [37] (SQ) (*P*<.001) found significant differences in off-target fasting

blood glucose measurement favoring the intervention groups [37,41].

Guo et al [37] (SQ) (*P*<.001) and Miremberg et al [41] (SQ) (*P*<.001) reported significant differences in support of the intervention groups in patient compliance (defined as ratio between actual and instructed blood glucose measurements×100).

Pregnancy- and Birth-Related Outcomes

All intervention groups showed lower rates of pregnancy-induced hypertension or preeclampsia, but no significant differences were found by Mackillop et al [38] (WQ) (*P*=.22), Miremberg et al [41] (SQ) (*P*>.99), or Yang et al [39] MQ) (*P*=.347).

Overall, there were fewer preterm births in the intervention groups, but neither Yang et al [39] (MQ) (*P*=.248) nor Mackillop et al [38] (WQ) (*P*>.05) found significant differences.

Positive intervention effects—more vaginal deliveries and less cesarean sections—were observed in almost all studies [37-39,41,42]; 2 studies showed statistical significance (Borgen et al [42], WQ, *P*=.03; Mackillop et al [38], WQ, *P*=.005).

Neonatal Outcomes

The results show a clear trend toward lower birthweight in the newborns of the intervention groups, but no significant differences were found by Mackillop et al [38] (WQ) (*P*=.18), Miremberg et al [41] (SQ) (*P*=.878), or Yang et al [39] (MQ) (*P*=.988).

Fewer instances of macrosomia occurred in the intervention groups than in the control groups, but no significant differences were found by Guo et al [37] (SQ) (*P*=.295), Yang et al (MQ) [39] (*P*=.542) and Borgen et al [42] (WQ) (*P*=.69).

In general, most studies showed positive intervention effects. Guo et al [37] (SQ)(*P*=.185), Mackillop et al (WQ) [38] (*P*=.42) and Yang et al (MQ)[39] (*P* value not available) observed slightly fewer instances of neonatal hypoglycemia for intervention participants.

The results show a trend toward infants of mothers in the interventions groups being transferred less often to neonatal intensive care units (Borgen et al [42], WQ, *P*=.38; Mackillop et al [38], WQ, *P*=.08; Miremberg et al [41], SQ, *P*>.99; Yang et al [39], MQ, *P*=.657).

Type 1 and Type 2 Diabetes: Overview

In total, 3 studies analyzing 141 women in the intervention and 126 women in the control groups were included [43-45]. Two studies observed continuous glucose monitoring system and one insulin pumps.

Type 1 and Type 2 Diabetes: Continuous Glucose Monitoring Systems

Overall, 2 randomized controlled trials analyzed 117 intervention and 108 control participants. Secher et al [45] included 123 women with type 1 diabetes and 31 women with type 2 diabetes, while Murphy et al [44] included 45 women with type 1 diabetes and 25 type 2 diabetes.

Glycemic Control Outcomes

Murphy et al [44] (MQ) noted that HbA_{1c} levels were consistently and significantly lower in the intervention group (gestation 32-36 weeks: *P*=.007), while Secher et al [45] (MQ) reported comparable HbA_{1c} values (IG: 6.1%, 95% CI 5.1%-7.8%; CG: 6.1%, 95% CI 4.8%-8.2%; *P*=.39).

Median self-monitored plasma glucose levels at 33 weeks were comparable between groups (IG: 6.2 mmol/L, 4.7-7.9; CG: 6.2 mmol/L, 4.9-7.9) [45].

Pregnancy- and Birth-Related Outcomes

Secher et al (MQ) and Murphy et al (MQ) observed very slightly more instances of preeclampsia in the treatment groups (*P*=.83 [45] and *P*=.5 [44], respectively).

Secher et al [45] (MQ) observed a lower rate of cesarean delivery (*P*=.30) and Murphy et al [44] (MQ) reported a lower emergency cesarean delivery rate (*P*=.3) in the intervention group.

Murphy et al [44] (MQ) observed slightly fewer preterm births (*P*=.8), whereas Secher et al [45] (MQ) reported slightly more preterm births (*P*=.47) in the treatment group.

Neonatal Outcomes

Murphy et al [44] (MQ) found significantly lower median birthweight percentile in the intervention group (69 vs 93, *P*=.02), whereas Secher et al [45] (MQ) found the birthweight was slightly higher in the intervention group (3510 g vs 3436 g, *P*=.80).

Murphy et al [44] (MQ) reported that fewer newborns who were extremely large for gestational age (≥97.7th percentile) were born to intervention participants (14% vs 30%, *P*=.1]), whereas Secher et al [45] (MQ) reported slightly more newborns who were extremely large for gestational were born to participants in the treatment group (*P*=.19 [45]).

Both studies reported clearly fewer instances of neonatal hypoglycemia in the intervention groups (36% vs 40%, *P*=.62 [45]; and 8% vs 17%, *P*=.5 [44])

Type 1 and Type 2 Diabetes: Continuous Subcutaneous Insulin Infusion

One study [43] examined continuous subcutaneous insulin infusion compared to conventional insulin therapy (intervention n=24 vs control n=18). Kernaghan et al [43] (SQ) included n=1 women with type 2 diabetes.

The intervention group showed lower mean HbA_{1c} levels in the first (*P*=.41) and second (*P*=.27) trimester. The birthweight *z* score was slightly lower in the control group (*P*=.86). The mean estimated fetal weight *z* score was lower in the intervention group (*P*=.16).

Discussion

Principal Results

In general, technologies seemed to have particularly positive effects on glycemic control in all types of diabetes, as shown

by studies of strong and moderate quality. For type 1 diabetes, there were no studies evaluating the effectiveness of mHealth apps and, for gestational diabetes, there were no studies that evaluated the effectiveness of continuous subcutaneous insulin infusion or closed-loop systems. It is particularly useful for women with pregestational diabetes to use mHealth apps, as they can become familiar with them before pregnancy. Furthermore, there is a lack of research focusing on the effectiveness of technologies for pregnant women with type 2 diabetes.

Type 1 Diabetes

Continuous Glucose Monitoring Systems

Overall, glycemic control improved with continuous glucose monitoring systems in strong and moderate quality studies, especially HbA_{1c}. Positive trends were observed for hypoglycemia and insulin dose. Intermittent continuous glucose monitoring systems seemed to be preferable to real-time continuous glucose monitoring systems, with fewer cesarean deliveries and more vaginal deliveries; however, the findings were not statistically significant. Regarding maternal weight gain and preterm births, improvements seem to be possible through the use of continuous glucose monitoring system, especially intermittent continuous glucose monitoring systems. Birthweight, large for gestational age, macrosomia, and neonatal hypoglycemia rates showed trends for improvement with continuous glucose monitoring system, as some moderate and strong quality studies showed nonsignificant, positive effects.

Continuous Subcutaneous Insulin Infusion

Overall, continuous subcutaneous insulin infusion improved glycemic control, especially HbA_{1c} and insulin dose, as most strong and moderate quality studies showed positive intervention effects. In the case of maternal hypoglycemia, one study [28] found significantly fewer instances in the intervention group, but another study [27] found fewer instances in the control group.

No clear trend regarding the effectiveness of continuous subcutaneous insulin infusion can be derived regarding pregnancy- and birth-related outcomes such as maternal weight gain, preterm births, cesarean delivery, maternal hypertension, or preeclampsia. There were no clear trends in relation to neonatal outcomes such as birthweight, large for gestational age, small for gestational age, macrosomia, hypoglycemia, and admission to high-level neonatal care because too little data were available.

Closed-Loop Systems

A trend toward improved glycemic control was shown in moderate quality studies, but the sample size was very small (n=32 patients).

Gestational Diabetes

Continuous Glucose Monitoring Systems

In general, continuous glucose monitoring system improved glycemic control, particularly HbA_{1c} and fasting blood glucose levels in strong and moderate quality studies; however, there was no obvious trend regarding 2-hour plasma blood glucose level and insulin dose. There were also no clear trends regarding preterm births or cesarean and vaginal deliveries. Both studies examining maternal weight gain showed positive but nonsignificant intervention effects.

Moreover, continuous glucose monitoring system improved birthweight, macrosomia, large for gestational age, small for gestational age, and neonatal hypoglycemia measures compared to those in control groups, though not significantly. Overall, there was no clear trend with respect to admission to higher level of neonatal care.

mHealth Apps

Gestational diabetes–specific mHealth apps displayed positive, significant effects in glycemic control outcomes such as HbA_{1c} level, fasting blood glucose level, off-target blood glucose measurement, and patient adherence (actual vs instructed blood glucose measurements) in strong and moderate quality studies. mHealth apps improved pregnancy-induced hypertension or preeclampsia and preterm birth outcomes, but not significantly. In addition, the treatments showed positive effects regarding vaginal deliveries and cesarean deliveries. Gestational diabetes–specific mHealth apps indicated noticeable positive, but not significant effects, on neonatal outcomes such as birthweight, macrosomia, hypoglycemia, and rate of admission to a higher level of care.

Type 1 and Type 2 Diabetes

Continuous Glucose Monitoring Systems

The sample sizes of the studies were very small. One moderate-quality study [45] could not find any clear differences in HbA_{1c} values between intervention and control group, while another moderate-quality study [44] showed significant positive intervention effects. Cesarean deliveries were required less often. There was no obvious trend regarding preeclampsia and preterm births. While no clear effects were found regarding birthweight and being large for gestational age, continuous glucose monitoring system showed an improvement in terms of neonatal hypoglycemia outcomes, but not significantly.

Continuous Subcutaneous Insulin Infusion

One strong-quality study [43] indicated positive trends in terms of HbA_{1c}, birthweight *z* score, and estimated fetal weight *z* score.

Strengths and Limitations

To our knowledge, this is the first systematic review of different technologies for diabetes that differentiated between various types of diabetes. Hence, our review opens up new perspectives on the topic hyperglycemia in pregnancy. However, the body of research included in this review may be limited depending on the type of diabetes and technology. Further research, with larger sample sizes and that takes into account women in the pre-conception phase, is needed, especially. Furthermore, we included only German and English papers, and we performed a qualitative analysis.

Comparison With Prior Work

Our results are in line with those from other reviews. In their systematic review, Feig et al [46] also reported that continuous

glucose monitoring system improved HbA_{1c} values in patients with type 1 diabetes. Furthermore, they showed lower rates of large for gestational age, higher time in range, and fewer adverse neonatal outcomes [46].

In their meta-analysis, Rys et al [47] investigated HbA_{1c} values in pregnant women with type 1 diabetes using continuous subcutaneous insulin infusion or multiple daily injections. They reported lower HbA_{1c} in the first trimester for continuous subcutaneous insulin infusion users (weighted mean difference: −0.45%; 95% CI −0.62 to −0.27).

Research on gestational diabetes–specific mHealth apps is very limited. Skar et al [48] reported gestational diabetes–specific mHealth apps to be effective in increasing the confidence of women with gestational diabetes in their self-management and their motivation for behavior changes. In addition, Chen et al [49] concluded that gestational diabetes specific mHealth apps can provide time- and cost-efficient personalized interventions to improve gestational diabetes management and clinical outcomes. Yu et al [50] reported a clear superiority of continuous glucose monitoring system compared to self-monitoring blood glucose in detecting hypo- and hyperglycemic episodes.

Conclusions

Technologies for diabetes seem to have a particularly positive effect on glycemic control in all types of diabetes. In pregnant women with type 1 diabetes, continuous glucose monitoring system as well as closed-loop systems seem to improve glycemic control. In women with gestational diabetes, the use of continuous glucose monitoring system systems has been shown, by this review, to improve glycemic control. mHealth apps can also improve glycemic control as well as certain pregnancy and birth related and neonatal outcomes in women with gestational diabetes.

Furthermore, this review showed that there is a lack of research on the clinical effectiveness of technologies for pregnant women with type 2 diabetes. In addition, sample sizes were, in many cases, rather small. Further research is needed to gain more firm evidence on the clinical effectiveness of diabetes technologies in pregnant women.

Abstract

Background: The population is aging on a global scale, triggering vulnerability for chronic multimorbidity, balance disorders, and falls. Falls with injuries are the main cause of accidental death in the elderly population, representing a relevant public health problem. Balance disorder is a major risk factor for falling and represents one of the most frequent reasons for health care demand. The use of information and communication technologies to support distance healthcare (eHealth) represents an opportunity to improve the access and quality of health care services for the elderly. In recent years, several studies have addressed the potential of eHealth devices to assess the balance and risk of falling of elderly people. Remote rehabilitation has also been explored. However, the clinical applicability of these digital solutions for elderly people with balance disorders remains to be studied.

Objective: The aim of this review was to guide the clinical applicability of eHealth devices in providing the screening, assessment, and treatment of elderly people with balance disorders, but without neurological disease.

Methods: A systematic review was performed in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) statement. Data were obtained through searching the PubMed, Google Scholar, Embase, and SciELO databases. Only randomized controlled trials (RCTs) or quasiexperimental studies (QESs) published between January 2015 and December 2019 were included. The quality of the evidence to respond to the research question was assessed using Joanna Briggs Institute (JBI) Critical Appraisal for RCTs and the JBI Critical Appraisal Checklist for QESs. RCTs were assessed using the Cochrane risk of bias tool. We provide a narrative synthesis of the main outcomes from the included studies.

Results: Among 1030 unduplicated articles retrieved, 21 articles were included in this review. Twelve studies explored different technology devices to obtain data about balance and risk of falling. Nine studies focused on different types of balance exercise training. A wide range of clinical tests, functional scales, classifications of faller participants, sensor-based tasks, intervention protocols, and follow-up times were used. Only one study described the clinical conditions of the participants. Instrumental tests of the inner ear were neither used as the gold-standard test nor performed in pre and postrehabilitation assessments.

Conclusions: eHealth has potential for providing additional health care to elderly people with balance disorder and risk of falling. In the included literature, the heterogeneity of populations under study, methodologies, eHealth devices, and time of follow-up did not allow for clear comparison to guide proper clinical applicability. This suggests that more rigorous studies are needed.

KEYWORDS

balance disorders; falls; elderly; eHealth; telemedicine

Introduction

Background

Aging and Balance Disorders

The improvement of health conditions and the increase in life expectancy have led to an aging global population, although this is not always accompanied by an increase in healthy life years [1-4].

Aging is associated with functional deterioration, including in the peripheral sensory structures, thereby affecting vision, hearing, and balance [5,6]. Additionally, elderly individuals are more likely to suffer from multiple chronic conditions, which often leads to frailty with risk of falls [1-4]. Falls in elderly people represent a serious public health problem as the main cause of accidental death in this population. The risk of falling increases with age [1,7-9]. Each year, approximately one in every three elderly people experiences a serious fall. Moreover, falling can lead to deterioration of the quality of life, anxiety, depression, restriction in daily activities, decreased mobility, social isolation, increased consumption of medications, and increased dependence on medical services and informal caregivers [1,2].

Several causes of falls in the elderly population have been identified, including age, environmental factors (eg, wet paths), inappropriate clothing and shoes, incorrect behavior (eg, climbing chairs), excessive alcohol consumption, inadequate use of medications, deteriorating chronic illness, and balance disorders [1,6,10].

Various clinical conditions are associated with balance disorders in elderly people, including age-related decline in balance function (prebyvestibulopathy); medications; and cardiovascular, metabolic, musculoskeletal, neurologic, and otologic diseases [5,6].

Although dizziness and vertigo are recognized as significant factors increasing the risk of falling and are common symptoms among the elderly, epidemiological studies have revealed large variability in the prevalence of balance disorders in this population [11-13]. It is estimated that at least 30% of individuals above 60 years old suffer from vertigo and dizziness, increasing to 50% for those above 85 years old [13]. According to the 2008 National Health Interview Survey, 33 million US adults had balance disorders, 26% of whom were elderly people (above 65 years) [14]. Approximately 20% of elderly people in the United States have a balance disorder event annually [15]. In fact, dizziness is a common complaint among the elderly population and is a strong predictor of falling events with a negative impact on quality of life [16]. Poor balance is frequently associated with falling [17,18]. In particular, asymmetrical vestibular function may often contribute to falls and fractures in elderly people [19-21].

Balance disorders and consequent falls have progressively represented a burden of disease, accompanied by high costs and pressure on the social services and health care systems related to medical care. This includes repeated consultations, excessive use of diagnostic imaging, and emergency care [22-24]. For example, the first national study in the context of dizziness and vertigo in the Emergency Services of United States of America for 2011 revealed that 25.7% of patient complaints of dizziness and vertigo were associated with balance disorders. The cost was estimated at about US $768 per episode, translating to an annual national cost of US $757 million. In the same context, cardiovascular diseases (linked to 16.5% of these episodes) represented a cost of approximately US $1489 per episode for an annual cost of US $941 million. By comparison, cerebrovascular diseases only accounted for 3.1% of these episodes, but with a cost per episode of approximately US $1059 or an annual cost of US $127 million. With the progressive aging of the population, worsening of this situation is expected in the future [25]. Indeed, vertigo is already contributing to the increasing trend of health care costs, which is linked to the aging of the population [23,24].

In this scenario of global aging, the use of digital solutions has been encouraged. Moreover, the additional pressure of the current COVID-19 pandemic has motivated the broader use of eHealth technologies [26].

Digital Health Care and the Elderly

The aging trend represents a relevant challenge to both patients and their families, and to the sustainability of health care systems globally. This is linked to the goal of global health policies for achieving a more active and healthy aging society with autonomy and independence [27,28]. The provision of new health care models, including eHealth services, has been encouraged to tackle access inequities, optimize health outcomes, and ensure autonomy and social support for elderly people. The use of eHealth seems to decrease costs associated with both institutionalization and unnecessary hospital visits [27-29].

eHealth consists of the use of information and communication technologies (ICTs) to support a health care communication channel at a distance, allowing for more efficient delivery of care services with optimized resource allocation. eHealth often contributes to improving the quality of health care services, including faster access to health information, promotion of the globalization of health care, and better health outcomes [30]. The World Health Organization has also recommended eHealth to promote universal health coverage, envisaging higher health care services availability with fewer resources and larger patient interaction. To date, eHealth has been used in the management of many conditions from health literacy promotion to teleconsultations [31]. The remote access systems can actively monitor elderly people in a real-life environment, leveraging the fact that there is an increasing interest and engagement of the elderly with technology. Moreover, eHealth technologies can enhance medical-patient interactions and mitigate many care access inequities. However, digital training of elderly people and caregivers is essential [4,32-34].

Assessment and Rehabilitation for the Elderly with Balance Disorders

There are several clinical tests and functional scales, including the Timed Up and Go Test (TUGT), Unipedal Standing Test, and Berg Balance Scale, that allow for assessments of balance,

gait, and risk of falling [5,35]. The use of sensors can improve the data quality of these tests and scales [36,37]. Additionally, functional tests of the inner ear, such as videonystagmography or the Video Head Impulse Test, are essential to identify and measure balance disorder cases, including an age-related decline in balance function (prebyvestibulopathy) [6].

Personalized balance training is a relevant option for the treatment of elderly people with balance disorders and risk of falling [5]. This training consists of an exercise-based program to address an individual's specific balance disorder, with goals of increasing postural stability, improving activities of daily living, and decreasing symptoms. Balance training should be focused on the functional deficiencies identified. Therefore, a prior medical evaluation is necessary to identify the clinical conditions related to poor balance as mentioned previously [38-41]. Moreover, these clinical conditions can affect the outcomes. For example, intervention success is more difficult when the patient has a disorder of both inner ears or has limited mobility due to an osteoarticular disease [38-41]. Exercises delivered through video games can be a promising intervention to achieve greater access and adherence among elderly people [42,43].

Several reviews have addressed the potential of digital solutions to improve the clinical observation and evaluation of balance disorders, and to promote the remote balance rehabilitation of elderly people [36,37,42-47]. However, most of these reviews included studies using a younger population as a preliminary assessment [42,44-47], and the majority did not describe the clinical conditions of the participants that might interfere with the outcomes, especially in the context of balance rehabilitation. Additionally, the clinical applicability of these devices was not assessed [36,37,42-47].

Therefore, there is a gap in this field in terms of evaluating the overall applicability of digital solutions according to the clinical conditions of elderly people with balance disorders and without neurological disease.

Objectives

The aim of this review was to evaluate and guide the clinical applicability of eHealth devices in the screening, assessment, and treatment of elderly people with balance disorders but without neurological disease.

Methods

Design

This systematic review was performed in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) statement [48] with the following steps: development of research questions, development of a search strategy with eligibility criteria, data selection, and qualitative analysis.

The protocol for this systematic review was registered in the International Prospective Register of Systematic Reviews (PROSPERO; CRD42019120774) and the complete protocol is available on the National Institute for Health Research program website.

This review focused on answering the following specific research questions, according to the PICO (Population, patient, or problem; Intervention; Control, Comparison, or Comparator; Outcome) strategy [49] (Textbox 1): (1) What are the main contributions of eHealth to elderly people with balance disorders with risk of falling? and (2) Is there any evidence that eHealth improves the quality of health care services in this context? If not, what are the reasons?

Textbox 1. Description of the PICO components.

- P (Population, Patient, Problem): Elderly people (over 60 years old) with balance disorders and risk of falling; studies with elderly people with functional limitation by neurological disease were excluded
- I (Intervention): eHealth devices for remote health education, screening, assessment, monitoring, or rehabilitation of elderly people with balance disorders with risk of falling
- C (Control, Comparison, Comparator): No intervention, paper booklet information, clinical evaluation, conservative balance training
- O (Outcome): Clinical applicability, increased fall prevention literacy, early identification and evaluation of balance deficits and risk of falling, improved balance and gait performance, reduced rate of falling, increased rehabilitation adherence, increased independence in daily activities

Definition of Concepts and Keywords used in the Search Strategy

In this study, we defined elderly people as those over 60 years of age [50]. Knudson [51] defined balance as a "person's ability to control their body position relative to some base of support." According to Agrawal et al [6], vertigo and dizziness are defined as "sensation of self-motion when no self-motion is occurring or the sensation of distorted self-motion during an otherwise normal head movement" and "sensation of disturbed or impaired spatial orientation without a false or distorted sense of motion," respectively. Falls refer to "inadvertently landing on the ground, floor or other lower level" [10]. Gait is defined as "the pattern of movement of the body during locomotion" [52].

Telemedicine is defined according to the World Health Organization Group Consultation on Health Telematics [53] as "delivery of health care services using ICT for the exchange of valid information for diagnosis, treatment and prevention of disease and injuries, research and evaluation, and for the continuing education of health care providers." eHealth is defined according to Eysenbach [54] as:

> *an emerging field in the intersection of medical informatics, public health and business, referring to health services and information delivered or enhanced through the Internet and related technologies. In a broader sense, the term characterizes not only a technical development, but also a state-of-mind, a*

> *way of thinking, an attitude, and a commitment for networked, global thinking, to improve health care locally, regionally, and worldwide by using information and communication technology.*

Teleconsultation is defined as "synchronous or asynchronous consultation using ICT to omit geographical and functional distance" [55]. Finally, a sensor is defined as a "device that responds to a physical input of interest with a recordable functionally related output that is usually electrical or optical" [56].

Search Strategy

Articles were retrieved through searching the PubMed, Google Scholar, Embase, and SciELO databases. The search algorithm included multiple group combinations, as shown in Table 1.

Table 1. Search strategy.

Concept	Keywords
Elderly people	("elderly" OR "older" OR "aged")
Balance	("Balance" OR "balance disorder" OR "balance problem" OR "vertigo" OR "dizziness) and/or ("falls" OR "fall detection" OR "fall prevention") and/or ("gait")
Telemedicine	("Telemedicine" OR "eHealth" OR "teleconsultation" OR "technology" OR "sensor")

Selection Criteria

The inclusion criteria were randomized controlled trials (RCTs) or quasiexperimental studies (QESs) published in English between January 2015 and December 2019, studies related to use of eHealth in the context of balance and falls, and the sample was restricted to an elderly population (60 years old and above).

The exclusion criteria were: (1) review articles, brief reports, protocols, proof-of-concepts, pilot studies, conference papers, and letters to the editor; (2) studies including elderly people with a reported functional limitation due to a neurological disease; and (3) articles without an age sample reference or with participants aged below 60 years.

Screening Process and Data Extraction

First, both authors screened the papers independently, looking at titles, abstracts, and methods, and agreed about their inclusion or exclusion according to the eligibility criteria. Second, the potentially relevant papers were retrieved for full-text evaluation against the eligibility criteria. Any articles that were deemed to be questionable in the first stage were included for further evaluation in the second stage. The selection of papers was performed by checking the extracted data and risk of bias.

Outcome Measures

The main outcomes included population characteristics, balance disorder, identification of faller participants, eHealth platform and services, health benefits, and fall prevention literacy.

Risk of Bias Assessment

The quality of the evidence to respond to the research questions was independently assessed using the Joanna Briggs Institute (JBI) Critical Appraisal for Experimental Studies and JBI Critical Appraisal Checklist for Quasi-Experimental Studies tools [57]. The two researchers discussed the results of the quality appraisal, reaching a consensus in case of any divergence. The included RCTs were assessed using the Cochrane risk of bias tool [58] to evaluate the risk of internal bias for a series of domains: selection bias, performance bias, detection bias, attrition bias, and reporting bias. Disagreements were solved by consensus between the two researchers.

Data Analysis

We provide a narrative synthesis of the main outcomes from the included studies. First, the articles were categorized according to the study design. Second, the articles were categorized based on the focus of eHealth services (screening/assessment and treatment/rehabilitation) for comparison of clinical use and applicability according to digital devices.

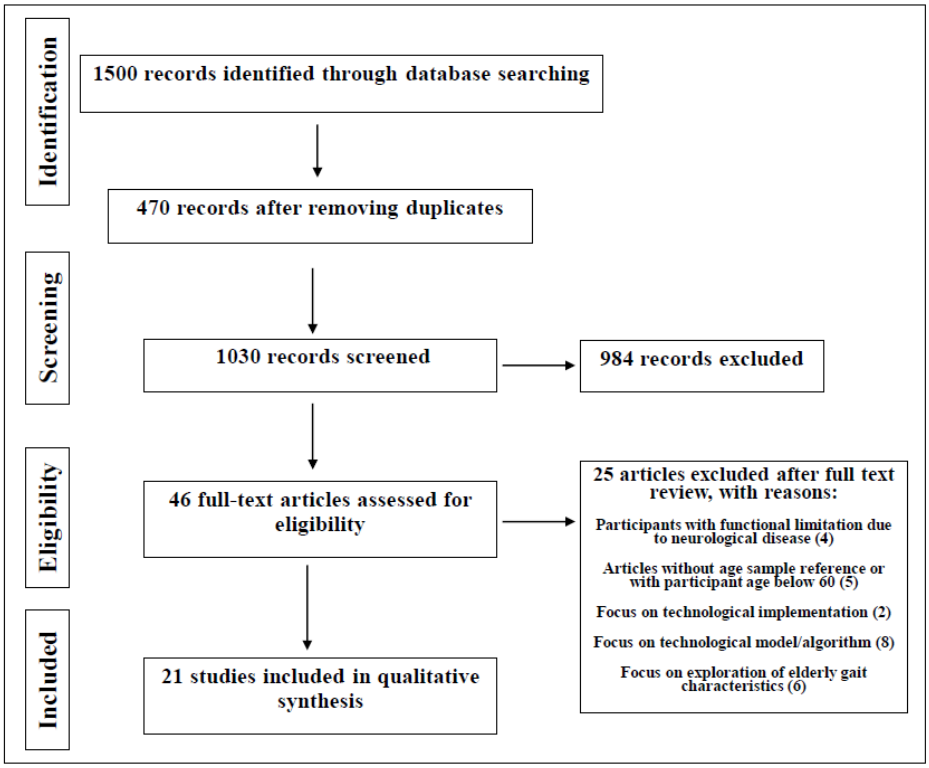
Results

Search Results

A total of 1030 unduplicated articles were identified, 984 of which were excluded after title and abstract screening. Among the 46 full-text publications assessed for eligibility, 25 articles were excluded owing to functional limitations due to neurological disease (n=4), age of participants (n=5), focus on technological implementation (n=2) or model/algorithm (n=8), and specific descriptions of elderly gait parameters (n=6).

Twenty-one articles [59-79] were ultimately included in the review (Figure 1).

Figure 1. Flow of selection for studies included and excluded in the review.



Study Design

RCT Design

Seven studies were RCTs [59-65], including one cross-over trial without a washout term [64] and one multicenter study [60].

Not all authors clearly described the randomization process [62] and the allocation concealment [62,64] (Tables 2 and 3).

The inclusion criteria were mentioned in all articles. However, the clinical conditions of the participants were only described in one study [60]. The function of the inner ear was never mentioned. Thus, the expected similarity between the control and intervention groups was not clear. This is relevant because various clinical conditions (eg, cardiovascular, metabolic, inner ear disease, medication) can interfere with the outcomes of balance rehabilitation [38-41]. Therefore, the lack of information about clinical conditions of the participants, including the lack of data about function of the inner ear, was considered as "other bias" and was a common weakness of all included RCTs (Table 3 and Figure 2). This approach led to a worse classification of the quality of these studies.

Additionally, the blinding of participants, personnel, and outcome assessment were unclear in some of these studies.

In the control and intervention groups of all RCTs, a few dropouts for medical and personal reasons were mentioned. However, this was not considered to be sufficiently relevant to have an impact on the results. Only two papers reported intention-to-treat analysis [60,63].

All outcomes were measured in a reliable manner and were considered to have been properly analyzed.

QES Design

Fourteen studies were QESs [66-79]; only one of these was a multicenter study [73]. Twelve of these studies used the same group of participants [66,68-77,79]. One study used two groups with different participants [67] and another had a control group and an intervention group [78]. However, the expected similarity between the groups was not clear because there was no description of the clinical conditions of the participants, including function of the inner ear. Loss to follow-up was also not mentioned for any of these studies (Table 4).

[a]Question 1: Is it clear in the study what is the "cause" and what is the "effect" (ie, there is no confusion about which variable comes first)?

[b]Question 2: Were the participants included in any similar comparisons?

[c]Question 3: Were the participants included in any comparisons receiving similar treatment/care other than the exposure or intervention of interest?

[d]Question 4: Was there a control group?

[e]Question 5: Were there multiple measurements of the outcome, both pre and post the intervention/exposure?

[f]Question 6: Was follow-up completed and if not, were differences between groups in terms of their follow-up adequately described and analyzed?

[g]Question 7: Were the outcomes of participants included in any comparisons measured in the same way?

[h]Question 8: Were outcomes measured in a reliable way?

[i]Question 9: Was appropriate statistical analysis used?

[j]Y: yes.

[k]N: no.

[l]U: unclear.

Multiple different measurements of the outcomes were used (Table 4). However, the instrumental inner ear tests were not used as the gold-standard test. This lack of comparison was considered to be a weakness of all of the included QESs. The most commonly applied tests were the TUGT and walking over different distances. One study assessed 1-week daily-life walking [73]. Only one study explored the activities of daily living [75] (Table 5).

The outcomes were considered to have been measured in a reliable manner and were properly analyzed.

Table 5. Quasiexperimental studies focused on screening/assessment.

Reference	Population and setting	Participants, N (male/female)	Technology/sensor used (location)	Completed sensor-based procedures	Comparison with fall history or a gold-standard test
Zacaria et al [66]	Hospital	38 (20/18)	WIS[a] accelerometer and gyrosensor (L2 vertebra)	TUGT[b] (sensor analysis of performance of each phase)	Classification of faller/nonfaller based on total duration for TUGT completion
Howcroft et al [68]	CDEP[c]	100 (44/56)	Wearable pressure-sensing insoles (pressure sensors-plantar); WIS, 4 triaxial accelerometers (head, pelvis, shanks)	7.62 m walk and 7.62 m walk with cognitive load (ST[d] and DT[e] gait)	Classification of faller/nonfaller based on retrospective fall occurrence
Lee et al [69]	CDEP	65 (16/49)	WIS (1 triaxial accelerometer belt around waist, pelvis, sacrum, L3-L5 vertebrae)	TUGT	Short-form BBS[f] (7 activities), TUGT
Ponti et al [70]	CDEP	36 (11/25)	WIS (1 triaxial accelerometer, waist)	ST TUGT, DT manual TUGT, DT cognitive TUGT	Faller/nonfaller based on retrospective fall occurrence, FES[g]
Similä et al [71]	Senior house/senior physical exercise group	35 (0/35)	WIS (2 accelerometers L3-L5 vertebrae, right hip)	BBS + TUGT + 4 m walk and follow-up after 1 year	Background questionnaire, interview, balance platform assessment with Kinect recording
Shahzad et al [72]	CDEP	23 (7/16)	WIS (1 triaxial accelerometer, L3-L5 vertebrae)	TUGT, STS-5[h], AST[i]	BBS
Brodie et al [73]	CDEP	96 (39/57)	Pendant sensor 3D accelerometer and barometer (sternum)	1-week daily life walking	Fall history, comparison with TUGT and 10 m walk test
Howcroft et al [74]	CDEP	75 (31/44)	Wearable pressure-sensing insoles (pressure sensor, plantar), WIS 4 triaxial accelerometers (head, pelvis, shanks)	7.62 m walk under ST, 7.62 m walk under DT (verbal-task cognitive load)	Classification of faller/ nonfaller based on prospective fall occurrence
Chigateri et al [75]	Frail elderly people from independent-living retirement homes	23 (6/17)	WIS 1 triaxial accelerometer (L5 vertebra)	TUGT, STS[j], activities of daily living	Synchronized videos with accelerometer (identification of the beginning of TUGT and of walking episode)
Qiu et al [76]	CDEP/social welfare centers	196 (0/196)	WIS 5 sensors with 3-axis-acceleration, 3-axis angular velocity, 3-axis magnetism each (low back, upper legs, lower legs)	Sensory integration test, limits of stability forward reach, STS-5, TUGT, motor function	Classification of faller based on self-reported history
Hiesh et al [77]	Healthy elderly people	30 (12/18)	Smartphone technology, 1 accelerometer (sternum)	Balance tests standing on a force plate and holding a smartphone against the chest: eyes open/closed DT, semitandem, tandem stance, single-leg stance	Comparison between force plate and smartphone data
Nightingale et al [79]	Local community centers/health care provider offices/senior centers	51 (unknown)	OptoGait system photoelectric technology	10 m walk	TUGT

[a]WIS: wearable inertial sensor.

Focus of eHealth Services

The 12 QESs were focused on screening and assessment. These studies compared the use of sensors in participants with a history of falling, or with clinical tests and functional scales [66,68-77,79] (Table 5). No instrumental test of the inner ear was performed as a gold-standard test. All RCTs [59-65] and two QESs [67,78] were focused on balance treatment or rehabilitation (Table 6). Again, no instrumental test of the inner ear was used in pre and postrehabilitation assessments.

Table 6. Studies focused on treatment/rehabilitation.

Reference	Study type	Setting and population	Participants, N (male/female)	Tested technology	Tested sensor architecture	Sensor-based procedures	Outcome measurements
Eggenberger et al [59]	RCT[a]	CDEP[b] and retirement homes	71 (25/46): dance group n=24, memory group n=22, control group n=25	VR[c] video game dancing + Impact Dance Platform treadmill walking + computer screen + training software	VR video game dancing + pressure sensitive platform, treadmill + training software	VR video game dancing with simultaneous cognitive-physical training; treadmill walking with simultaneous verbal memory training; treadmill walking (control)	Gait analysis: ST[d]/DT[e] 7.3 m walking, Short Physical Performance Battery, fall frequency, 6-minute walk test, measure of fall fear
Gschwind et al [60]	RCT	CDEP	153 (60/93): intervention group n=78, control group n=75	iStoppFalls system: computer + Google TV set top box + Microsoft Kinect + senior mobility monitor + android tablet	Kinect-based system (3D depth sensor), Senior Mobility Monitor (3D accelerometer, barometer)	16-week home-based balance exergames and muscle strength exercises + education booklet (intervention) or education booklet + usual activities (control)	Estimated risk of falling; mobility, self-care, usual activities, pain, discomfort, anxiety, depression, health questionnaires, cognitive performance, walking task, STS-5[f], TUGT[g], technology use
Gschwind et al [61]	RCT	CDEP	124 (42/82): step-mat training group n=39, Microsoft-Kinect group n=24, control group n=61	Input device, computer, USB modem, TV, exergames, Microsoft Kinect or electronic mat	Pressure-sensitive electronic mat, Kinect-based system (3D depth sensor)	Unsupervised 16-week home exercise using exergames or educational booklet about evidence-based health and fall prevention advice + usual activities (control)	Risk of falling, health and disability measure, STS-5, TUGT, cognitive performance
Hall et al [67]	QES[h]	CDEP	16 (0/16): group A n=8, group B n=8	Nintendo Wii Fit System: computer interface + monitor + Wii balance board + games Ski Slalom/ Table Tilt	*Balance* Board: force platform	Wii Fit balance test + games, followed by SOT[i] and LOS[j] test, CDP[k] (group A); SOT and LOS test, CDP, followed by Wii Fit balance test + games (group B)	Dynamic Gait Index, TUGT, gait speed
Lim et al [62]	RCT	CDEP	36 (11/25): intervention group n=18, control group n=18.	Wearable balance biofeedback (system (vibrotactile, auditory and visual biofeedback)	Biofeedback headband: 8 vibrotactile actuators, 2 bone-conducting acoustic transducers, 3 light-emitting diodes; and gyroscopes (lower back)	2-week training with real-time multimodal biofeedback of trunk sway or 2-week training without biofeedback (control)	Standing:1 leg (eyes open), feet together, firm surface and foam, tandem stance (EC[l]); self-paced 8 m walking (EC); 8 m walking with head turning; 8 tandem steps (EC)
Oesch et al [63]	RCT	Geriatric rehabilitation center	54 (29/25): intervention group n=26, control group n=28	Windows Kinect (exergame)	Kinect-based system (3D depth sensor)	10-day self-regulated training with exergames or 10-day self-regulated conventional training with instruction leaflets (control)	Adherence, motivation, enjoyment, sensor-based walking test

Reference	Study type	Setting and population	Participants, N (male/female)	Tested technology	Tested sensor architecture	Sensor-based procedures	Outcome measurements
Ozaki et al [64]	RCT	Prefrail or frail CDEP	27(7/20): intervention group n=14, control group n=13	BEAR[m] system: Stand-and-ride transport robot + wearable helmet and suspending device + software	Stand-and-ride transport robot with two inverted wheel motors	6-week based BEAR training first group or 6-week based conventional balance training first group (control)	Gait speed, tandem gait speed, functional reach test, TUGT
Hong et al [65]	RCT	CDEP	23 (0/23): intervention group n=10, control group n=13	tablet, web app, signaling server module network address translator traversal module	Web Real-Time Communication (WebRTC) technology	12-week telepresence exercise sessions or maintained lifestyle (control)	Senior fitness test, BBS[n], fall-related self-efficacy, FES[o], Fear of falling questionnaire
Maneproom et al [78]	QES	Senior housing	64 (13/51): intervention group n=32, control group n=32	robot, robot-installed fall prevention software	8-inch touchscreen installed at robot head	robot-installed fall prevention software + personal coaching + fall prevention handbook or fall prevention handbook only (control)	TUGT, BBS, fall prevention questionnaire

[o]FES: Fall Efficacy Scale.

Population Characteristics

The included studies had large differences in sample sizes, ranging from 23 to 153 participants [59-65] among RCTs and from 16 to 196 participants [66-79] among QESs. As shown in Tables 5 and 6, many studies included a small sample size that was described as a limitation.

The age range was 60-91 years for the RCTs and 60-92 years for the QESs. Most of the studies included more women than men. In four studies, only women participated [65,67,71,76]. The decision to only recruit women was explained in one study as “to avoid the influence of gender differences on risk of falling” [76]. Two studies excluded the few male participants [67,71] and the remaining article did not describe the reason for the exclusive participation of women [65]. One study did not describe the age range or the gender distribution of the participants [79].

The participants (≥60 years old) were recruited from the community [60-62,64,65,67-70,72-74,76,77], gerontology services [71,75,78], both [59,79], or at a hospital [66]. One study included participants who were referred for geriatric inpatient rehabilitation [63].

Most of the studies did not describe the characteristics of health conditions of the sample [59,62,64-66,68-72,74-77,79]. Only some authors provided quantitative data about the participants’ medication use [60,61,73,78] and their comorbidities [60,61,63,67,73,78]. One study [60] highlighted the following comorbidities of the participants: heart problems, high blood pressure, osteoporosis, lower back pain, hip pain, knee and/or leg pain, and foot pain. Two studies excluded participants with self-reported balance disorders [62,63]. Two other studies included frail or prefrail elderly adults [64,75].

Balance Disorder and Identification of Faller Participants

The included studies used functional balance tests, with or without sensors, to evaluate balance and risk of falling. An objective identification via exploration and quantification of the function of the inner ear by instrumental tests was not employed in any of the considered studies, as mentioned above.

Therefore, the presence of prebyvestibulopathy or other balance disorders was not known.

Some authors highlighted the potential of sensor-based tests in identifying early balance deficits [71] and in evaluating the risk of falling [66,72,73,76,77]. Improved balance and gait with technology-based training were mentioned in some studies [59,62,64].

The identification of faller participants based on retrospective [68,70,73,76] or prospective occurrence of falling [74] was employed to compare the technology results. The benefits of virtual training in reducing the risk of falling was also described [60,61,65,78].

No study focusing on detection of falling fully complied with the inclusion criteria of this review (RCTs or QESs, published in English between January 2015 and December 2019, restricted to the population 60 years or older).

eHealth Platform and Services

Different platforms were used for the provision of eHealth services. The main platforms identified were computer-based apps, either via the internet or mobile based platforms (Tables 5 and 6).

As mentioned above, 12 studies focused on screening or assessment [66,68-77,79] using different types (wearable inertial, wearable pressure, pendant, smartphone), quantities (range 1-5), and locations (head, sternum, lumbar vertebra, pelvis, hip, leg, shanks, foot) of sensors. Single or combined sensor-based tasks were employed. Only two studies [73,75] evaluated activities in a real-life environment (Table 5).

Nine studies explored balance rehabilitation [59-65,67,78] with different exercises and duration of training. The follow-up time was short (less than 6 months) in most of the studies, with the longest follow-up of 1 year [59]. The development of eHealth services was explored both inside and outside the laboratory environment (Table 6).

One study used a robot to provide information about training and fall prevention. However, the authors pointed out that the screen and the volume speaker were not adequate for use by elderly people [78].

The use of technical language and the presence of disabilities such as visual and hearing impairment were highlighted as the main barriers in using eHealth [78].

Health Benefits

Only one study did not report better adherence, enjoyment, motivation, and balance performance with virtual training. This was explained by the possible fragility of the sample included in the study and by the short duration of the training intervention [63].

The remaining papers emphasized the potential contribution of digital solutions to improve balance performance and risk of falling. The sensors used during balance tests improved the evaluation of balance and gait [66,68,69,71,72,79] and improved the identification of potential faller participants [70,73-77]. In addition, the use of eHealth devices for balance rehabilitation increased balance and gait performance [59,60,62,64,65,78], and reduced the risk of falling [60,61]. However, no long-term follow-up was reported. Virtual programs of falls prevention seemed to increase knowledge on the subject [78] (Table 7).

Table 7. Health benefits: conclusions from all studies.

Reference	Study type	Conclusions
Zacaria et al [66]	QES[a], screening	Single wearable sensor during TUGT[b]: an improved tool in evaluating fall risk
Howcroft et al [68]	QES, screening	Sensor-based gait assessment: potential of identification of gait changes
Lee et al [69]	QES, screening	Advantages of wearable sensor as an outside laboratory tool
Ponti et al [70]	QES, screening	Improved potential of identification of fallers with single sensor-based DT[c] TUGT
Similä et al [71]	QES, screening	Sensor-based walk test: a screening tool to identify early signs of balance deficits
Shahzad et al [72]	QES, screening	Importance of sensor-based TUGT, STS-5[d], and AST[e] on fall risk estimation
Brodie et al [73]	QES, multicenter screening	Better sensor-based daily-life gait assessment to discriminate fallers
Howcroft et al [74]	QES, screening	Sensor: potential to discriminate differences between ST[f] and DT gait and between prospective fallers and nonfallers
Chigateri et al [75]	QES, screening	Wearable accelerometer: useful for nonsedentary activity recognition and gait detection in frail older adults outside lab facilities
Qiu et al [76]	QES, screening	Potential use of wearable inertial sensor-based systems for elderly fall risk assessment
Hiesh et al [77]	QES, screening	Validity of smartphone for evaluation of postural stability and fall risk stratification in older adults
Nightingale et al [79]	QES, screening	Using Optogait system: TUGT as a tool for screening balance deficits
Eggenberger et al [59]	RCT[g], rehabilitation	Virtual reality game dancing with simultaneous cognitive-physical training and treadmill walking with simultaneous verbal memory training: potential to enhance gait variables
Gschwind et al [60]	RCT, rehabilitation	iStoppFalls program reduced physiological fall risk and improved postural sway
Gschwind et al [61]	RCT, rehabilitation	Step-mat-training and Microsoft-Kinect exergames reduced fall risks, Step-mat-training improved specific cognitive functions; neither intervention improved balance control
Hall et al [67]	QES, rehabilitation	WiiFit feasible to safely use, Ski Slalom game similar effect as computerized dynamic posturography
Lim et al [62]	RCT, rehabilitation	Balance training with biofeedback: most beneficial for the most difficult tasks but with few long-term benefits
Oesch et al [63]	RCT, rehabilitation	Superior results of conventional training with respect to adherence, enjoyment, and motivation; no difference of balance during walking between conventional and training with exergames
Ozaki et al [64]	Crossover trial without a washout term, rehabilitation	BEAR[h] training more effective for improving dynamic balance and lower extremity muscle strength
Hong et al [65]	RCT, rehabilitation	Telepresence exercise program: effective to improve balance and reduce fear of fall; no significant difference of fall efficacy between intervention (telepresence exercise sessions) and control group (maintained lifestyle)
Maneproom et al [78]	QES, rehabilitation	Robotic fall prevention program increased fall prevention knowledge, promoted exercises, and improved balance

[a]QES: quasiexperimental study.

[b]TUGT: Timed Up and Go Test.

[c]DT: dual task.

[d]STS-5: Five Times Sit-to-Stand test.

[e]AST: Alternative Step Test.

[f]ST: single task.

[g]RCT: randomized controlled trial.

[h]BEAR: Balance Exercise Assist Robot.

Fall Prevention Literacy

None of the studies explored the previous health literacy of the participants. Only two papers described the educational level of the participants [60,78].

One study compared use of a fall prevention software to a conventional handbook to evaluate the improvement of knowledge on fall prevention. Both the intervention and control groups showed improvement in knowledge, without a significant difference [78].

Discussion

Principal Findings

Population aging, and the associated vulnerability to the development of multiple chronic pathologies and balance disorders, have motivated research and the implementation of new strategies for the provision of health care. eHealth devices have been studied to help assess balance and gait performance, risk of falling in and outside a laboratory setting, and to perform in-home balance rehabilitation. In this review, we confirmed the potential of eHealth to complement the health care of elderly people. However, most of these studies were not designed to provide clinical guidelines.

Despite growing interest about this subject in the last 20 years, we decided to focus on studies published in the last 5 years (RCTs and QESs), taking into consideration both continuous advances in technological innovation and the opportunity to apply new clinical applications in balance disorder and risk of falling for the elderly population.

Unlike other reviews, our eligibility criteria ruled out many initially retrieved articles, especially studies with participants under 60 years old, those without reporting the age of participants, or with participants having a functional limitation due to neurologic disease. Therefore, only 21 articles fully complied with the requirements of this review [59-79].

Except for one study [63], the others showed the potential of eHealth to evaluate balance assessment and risk of falling of elderly people and to promote balance training. The eHealth devices allowed collecting additional information about the balance, gait, and risk of falling of elderly people, and to monitor their daily activities.

In particular, eHealth seems to provide an opportunity for increasing medical-patient interactions and to reduce access inequities [30]. In 1996, Viierre et al [80] had already mentioned the potential of eHealth in this field: “remote medical diagnosis and treatment facilities could make the few vestibular disorder specialists much more available to patients.” However, as observed in other reviews [36,37,42-47], the differences in methodologies and of variables included in the studies did not allow for a proper comparison to guide clinical applicability.

First, there was a broad range of sample sizes, which were generally quite small (ranging from 16 to 196 participants). A small sample of participants is considered a limitation for extrapolating the results, especially for the exploration of risk of falling.

Second, there were missing data about the clinical conditions of the participants. Except for one study [60], several volunteers were recruited from the community and were defined as “healthy” elderly people only based on a self-reported assessment. There were also participants recruited from geriatric services without reference to their clinical conditions. Despite the exclusion of participants with self-reported balance disorders in two studies [62,63], we consider that the exclusion rules should be more rigorous and based on objective data such as instrumental inner ear tests. We have to take into consideration that elderly people can have instability due to many conditions, including the normative aging process, and therefore the outcomes from a balance rehabilitation intervention could be sensitive to these differences [38-41].

Third, different research methodologies were used for screening and assessment. We observed a wide range of clinical tests, functional scales, faller classifications, and sensor-based tasks among the included studies. The lack of homogeneity of these variables limited an appropriate comparison among the studies. Moreover, functional inner ear tests were not used as the gold-standard test. We consider this as a weakness common to all studies.

Fourth, different types of sensors were used for screening and assessment. Similar to the findings of other reviews [36,37,44-47], the studies employed mainly accelerometers, with variations in both number and body location.

Fifth, as observed previously [42,43], studies focusing on treatment and rehabilitation used different devices, training durations, and follow-up times. Some authors employed supervised training. In one study, this was used a telepresence-based exercise platform [65]. Others employed in-home self-regulated exercises training [61], thereby avoiding the need for participants to travel to the rehabilitation center. None of the studies described pre and postintervention data about the function of the inner ear. The studies did not verify the long-term effect of training, especially with respect to fall occurrence. Only two studies explored a sensor used in real-life activities [73,75], which is relevant since it allowed for a better evaluation of the remote interaction and monitoring of daily activities.

Additionally, we observed a constraint related to the use of devices that are not fully adequate to match the abilities of elderly people [78]. We also highlight the importance of providing a better definition of the eHealth user profile to improve adherence.

Future studies in this field should consider the above topics as a starting point, as well as for health policy implementations on eHealth apps for elderly people with balance disorders.

The use of eHealth can play an important role as a complementary method to provide health care services, encouraging health promotion and patient participation, as well as allowing for the remote management of balance disorders.

Recommendations

Based on this review, we can provide the following recommendations to improve studies and applications of eHealth for preventing fall risk in the elderly population.

First, this review highlights the need for further research on the use of eHealth devices in proper clinical settings. This represents an opportunity to be explored, reaching out to elderly people with balance and risk of falling.

Second, despite several efforts to explore balance among the elderly, there is still a need for better characterization and description of the health condition of the population under study. In particular, we recommend future studies to include the results of functional tests of the inner ear as a gold-standard test or for comparison of the outcome before and after remote balance rehabilitation. Most of the interventions were developed with only functional balance tests. Future studies should also focus on the real-life environment, allowing for additional information of the daily activities among elderly participants.

Third, a longer follow-up time is important to evaluate the long-term benefits of eHealth tools on the balance performance and risk of falling of elderly people.

Finally, the eHealth devices should be user-friendly to improve adherence among elderly people.

Limitations

This review was limited to articles written in the English language and available on the PubMed, Google Scholar, Embase, and SciELO databases for the last 5 years; therefore, it is possible that relevant studies were missed.

Conclusions

The inclusion of eHealth services can play a critical role for the better provision of health care to elderly people with a balance disorder and risk of falling. The differences in populations, methodologies, eHealth devices, and follow-up times of the included studies did not allow for a clear comparison between results, therefore limiting the possibility of obtaining valid guidance for clinical applicability. More rigorous studies are recommended.

Abstract

Background: Contemporary personal health record (PHR) technologies offer a useful platform for individuals to maintain a lifelong record of personally reported and clinically sourced data from various points of medical care.

Objective: This paper presents an integrative review and synthesis of the extant literature on PHRs. This review draws upon multiple lenses of analysis and deliberates value perspectives of PHRs at the product, consumer, and industry levels.

Methods: Academic databases were searched using multiple keywords related to PHRs for the years 2001-2020. Three research questions were formulated and used as selection criteria in our review of the extant literature relevant to our study.

Results: We offer a high-level functional utility model of PHR features and functions. We also conceptualize a consumer value framework of PHRs, highlighting the applications of these technologies across various health care delivery activities. Finally, we provide a summary of the benefits of PHRs for various health care constituents, including consumers, providers, payors, and public health agencies.

Conclusions: PHR products offer a myriad of content-, connectivity-, and collaboration-based features and functions for their users. Although consumers benefit from the tools provided by PHR technologies, their overall value extends across the constituents of the health care delivery chain. Despite advances in technology, our literature review identifies a shortfall in the research addressing consumer value enabled by PHR tools. In addition to scholars and researchers, our literature review and proposed framework may be especially helpful for value analysis committees in the health care sector that are commissioned for the appraisal of innovative health information technologies such as PHRs.

KEYWORDS

electronic personal health records; PHR; functionality synopsis; value analysis; consumer health informatics

Introduction

Among the many technology applications available to individuals today for managing their own health and wellness, electronic personal health records (PHRs) offer a valuable means to facilitate active participation of health care consumers, including patients and their caregivers. By virtue of their potential capabilities to help individuals track their health conditions, provide access to patient medical record information (PMRI), and offer communication tools to interact with health care providers, PHRs have been regarded as a paradigm shift toward consumer-centric and patient-oriented health and medical services [1,2].

Although the consumer adoption of PHR systems has been slower than originally expected [3,4], these technologies are gaining traction in many countries worldwide [5-9]. Government eHealth initiatives in many countries are currently focused on the implementation of these technologies to foster greater patient engagement with personal health information (PHI) management and care coordination. An example of such an initiative is the

Stage 3 Meaningful Use program under the US Health Information Technology for Economic and Clinical Health initiative. This program calls for improving patient engagement through functionality, such as patient access to medical records, patient communication tools, and interoperability with hospital electronic health records (EHRs) [10,11]. Across the border, in Canada, several federally funded projects sponsored by the Canada Health Infoway are also geared toward the deployment of consumer-focused digital health technologies, including patient health information records, patient-physician communication tools, and remote patient monitoring [12]. Along similar lines, the p-medicine and eHealthMonitor projects funded by the European Union also aim to support personalized medicine through technologies such as PHRs [7].

The overarching vision behind PHR technology offerings is to enable patient empowerment, reduce health care costs, and provide better continuity of care [3] through access to timely, reliable, and comprehensible health information for patients and streamlined communication between patients and health care providers [13,14]. The objective of this paper is to offer a review of the utility, value, and benefits of PHR systems through a discussion of their features and functions and to deliberate how PHR functionality can potentially translate into value for the health care consumer and benefits for the health care system as a whole. Our review comprises both an analysis and a synthesis-oriented exposition on the current landscape of PHR technologies. The *Methods* section outlines our review approach and the ensuing structure of this study.

Methods

Overview

In characterizing the type of review offered in this paper, our discussion aligns with an integrative review, in which literature pertinent to a subject area is critically analyzed and synthesized to theorize alternative perspectives of the subject [15]. Although integrative literature reviews may serve multiple purposes, their essence is to review existing literature to elicit new insights, inquiries, or answers through the integration and synthesis of existing literature [16]. Integrative reviews are commonly used in health research [17-19], and such reviews have been purported to enhance the development of health care theory, policy, and practice [19]. Our integrative review was structured along the following 5 recommended phases [19]: problem identification, literature search, data evaluation, data analysis, and presentation of the results. The procedures followed are summarized below.

Problem Identification

Specific to our study, the purpose of our review is to extensively research pertinent PHR literature and provide an assessment of the product utility, consumer value, and industry benefits of these systems. Toward this, and in line with integrative reviews, we developed a protocol for the search and selection of relevant literature [15,16], deliberated the capabilities of PHR systems using several lenses of analysis, and then classified and synthesized a typology to formulate conceptual frameworks that explicate the utility and value of PHR systems. Typologies that offer a conceptual classification of constructs are recommended as useful theory-building tools [20] and a valuable form of synthesis in integrative reviews [15].

To guide our review process, we formulated 3 research questions that we aimed to answer through our analysis and synthesis of the extant literature. Table 1 below is the three-step approach that we adapted for our review based on suggested guidelines for the reviews of emerging HITs [21,22]. The *Results* section of this paper discusses the findings and outcomes from our review, as noted in Table 1.

Table 1. Research questions and guidelines followed for the review and synthesis.

Review perspective	RQ[a]	HIT[b] assessment review guidelines	Review and synthesis outcomes
Product utility	RQ1. What features and functions are available in contemporary PHRs[c], and how has this functionality evolved over time?	1. Technology definition and literature search	• Literature selection procedure • PHR working definition • Functional utility model of PHR technologies
Consumer value	RQ2. What is the potential value of various PHR functionalities to health care consumers?	2. Conceptual analysis and framework formulation	• Functional utility model of PHR technologies • PHR consumer value framework
Industry benefits	RQ3. How can the mainstream deployment and use of PHR systems translate into benefits for the health care system as a whole?	3. Reflective synthesis and summary	• Value propositions and benefits of PHR systems

[a]RQ: research question.

[b]HIT: health information technology.

[c]PHR: personal health record.

Search Strategy

Our academic article search was conducted using digital library databases, including PubMed, Web of Science, ScienceDirect, and Scopus. In addition, to ensure the breadth and validity of our search results, we explored the publications cited in previous scoping and systematic reviews of PHRs [23-25] and included any relevant articles that had been overlooked in our own search.

Our search techniques used various terms and keywords related to PHRs, including acronyms as well as expanded terms, such as PHR, personal health record, EPHR (electronic personal health record), patient portal, personal medical record, personally controlled health record, PCHR, personal health information, and PHI.

Data Evaluation

Both authors independently screened titles, keywords, and abstracts to determine whether publications should be included in the review. Our review included studies that explicitly discussed features, functions, utility, value, and benefits of electronic PHRs, whereas it excluded publications focusing on paper-based PHRs or studies solely focusing on psychosocial aspects of end users' PHR adoption or technical system design practices for PHRs. Following the first round of screening, we refined our search criteria and examined articles pertaining to consumer health informatics as a general field of study. Our initial review indicated that some publications pertaining to consumer health informatics directly discuss the benefits of PHR technologies [13,26-30]. In the second round of screening, each author assessed mutually exclusive but collectively exhaustive subsets of all publications identified as potentially relevant, and we ensured that the articles were indeed pertinent to our review.

Data Analysis and Synthesis

Following the selection of relevant literature, our review process began with an iterative concept-centric analysis of the attributes and benefits of PHR systems. We analyzed the literature at the product level by identifying various features and functions of PHR systems described in the extant literature, at the consumer level by deliberating the value of various PHR system functionalities, and at the industry level by identifying the benefits provided by PHR technologies to various health care industry constituents. A codebook was created to facilitate the analysis and extraction of data into systematic categories. The authors collaborated on the conceptual synthesis of the 3 classification systems for functional utility, consumer value, and industry benefits. These conceptual classifications were refined iteratively through simplification, abstraction, and focusing procedures, constituting the constant comparison method commonly recommended for integrative reviews [19].

Presentation and Paper Structure

In the final phase of the integrative review, the results from our analysis and synthesis were summarized and depicted using visual models and concept matrices. These are presented and discussed in the *Results* section of this paper.

We first provide a working definition of PHRs that was used as a touchstone to guide our literature search and subsequent discussion. Drawing upon that definition, we retrieved relevant peer-reviewed publications and industry reports that discussed the functionality, utility, value, and benefits of PHR technologies.

The outcome of our review of PHRs from a product utility perspective comprised an evaluation of various features and functions of PHR systems. The output from this evaluation is conceptualized as a high-level functional model of PHRs that summarizes the myriad of features and functions available in contemporary PHR systems.

Next, we discuss the capabilities of PHR systems from a consumer value orientation by juxtaposing the functionality of PHR systems alongside health care delivery activities ranging from prevention to the diagnosis and ongoing management of illnesses.

Finally, the *Results* section provides an industry-level viewpoint that summarizes various value propositions and benefits related to the use of PHR technologies at the micro, meso, and macro levels. The synthesis offers a discussion of how the effective deployment and use of PHR technologies can potentially translate into benefits for different constituents in the health care delivery chain, including consumers, providers, payors, and public health agencies.

Results

Defining Characteristics of PHRs

As a working definition, this paper adopts one of the earliest and most commonly cited characterization of a PHR as "an electronic application through which individuals can access, manage and share their health information and that of others for whom they are authorized, in a private, secure and confidential environment" [31]. In addition, PHR are sometimes referred to as personally controlled health records (PCHRs) comprising information and communication technologies that can potentially help all types of end users in maintaining health and wellness and specifically facilitate patients in managing their ongoing illnesses [32].

To further delineate the representative attributes of PHRs, we also differentiate between 3 similar yet distinct technologies related to patient records: electronic medical records (EMRs), EHRs, and PHRs. Depending on the health care setting, although these 3 technologies may be used as components in an integrated health information system (HIS), each of them can be differentiated from the other based on its custodianship and level of patient centricity. EMRs are often considered as digital versions of paper charts in a clinician's office [33]. These patient medical records in this instance are provider-centric [33,34] and are rarely accessible to other health care providers or to the patients themselves. In contrast, EHR systems offer a broader view of a patient's care by facilitating integration with HIS beyond the organization that originally collected and compiled the patient information [33]. These systems can aggregate patient data from multiple health care facilities to create a unified patient record that can be accessed by health care providers [35,36]. Finally, PHRs function under the custodianship of patients or their caregivers, and these systems comprise full or partial health information about patients over their lifetime [35,37]. Hence, PHRs specifically pertain to digitally stored health care information about an individual patient under the control of that patient or their caregiver [7,38], whereas EMRs and EHRs are typically maintained by health care providers or payor organizations [39].

Drawing upon these characteristics of PHR systems, this study adopts a consumer-oriented perspective and uses the term PHR to refer to both the underlying patient record and its data elements as well as the software that provides functionality to maintain that record. As such, we do not differentiate between the data (PHR) and PHR-S (software components of PHR), as sometimes done in the industry standard documentation such as HL7 (Health Level Seven) [40,41]. Furthermore, although we note that there may be differences among PHR systems in terms of front-end technology features, back-end information sources, patients' scope of access, and storage locations of online records, we consider electronic access (desktop, web, or mobile) and patient control over health records to be the defining characteristics of PHR systems.

To help understand the functional scope of the current PHR systems, researchers have classified these technologies into 3 main categories: *standalone*, *tethered*, and *interconnected* [32,37]. The main attributes that differentiate these categories are data control, record portability, and system interoperability. The key differences among these categories are outlined below.

Standalone PHRs require users to manually enter data to populate their own health information and medical history. Hence, the content of these applications is under direct physical control and ownership of the consumer. These PHR systems require a considerable long-term commitment from end users who need to be motivated to maintain their PHI in an accurate and complete fashion [37,42]. Although these technologies may be portable in allowing users to access their PHI anytime and anywhere, they lack interoperability because data must be manually imported or exported from other HIS.

Tethered PHR systems are typically offered as extensions of a health care institution's own back-end EHR or EMR system, providing users access to parts of their own EHRs. These systems are also referred to as patient portals. In addition to providing access to patient data, these systems may also include additional functionality, such as communication tools for email, messaging, appointment scheduling, and prescription renewals [37]. Access to these PHRs is typically provided through a web portal interface [32,43]. The data in tethered PHR systems are under the control of the health care provider, hence limiting the portability of patient records, and these technologies may not be fully interoperable with other HIS.

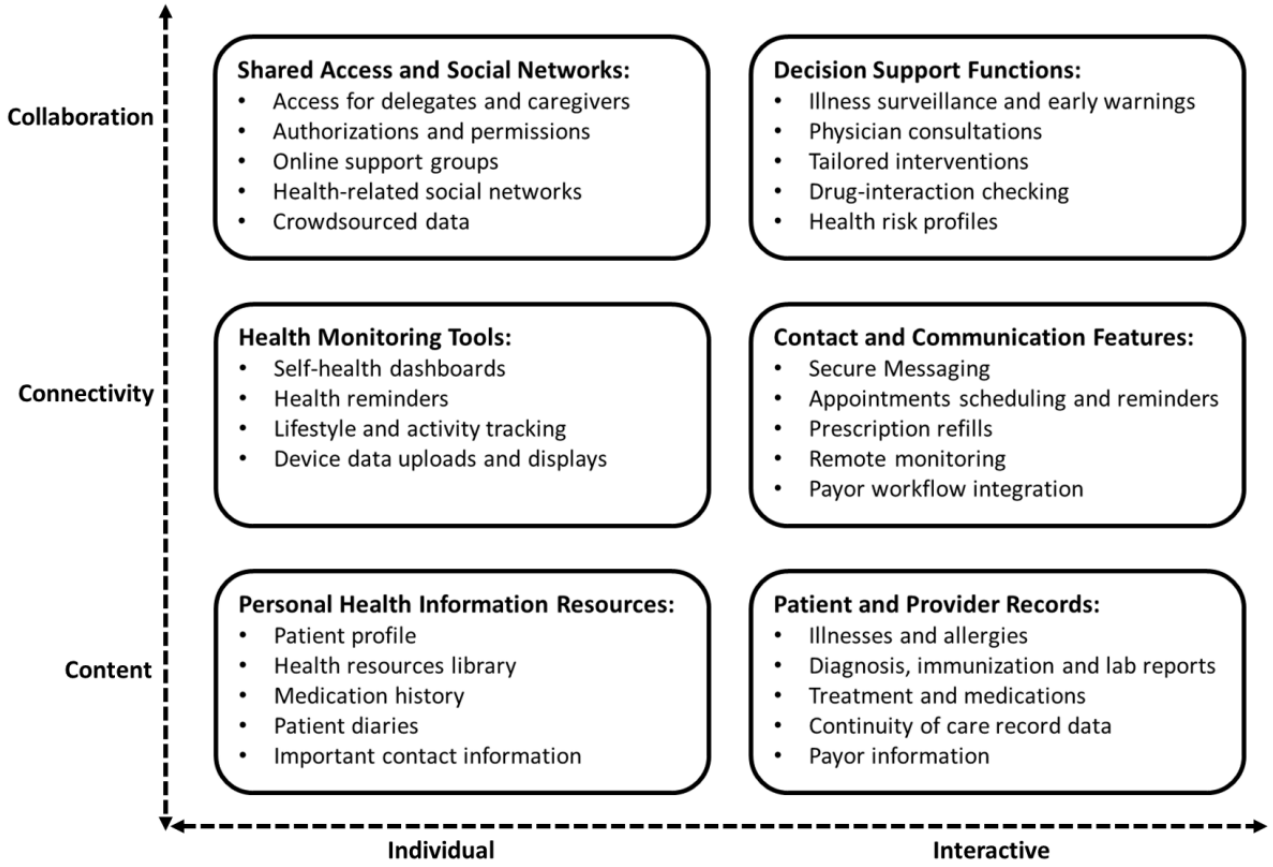
Interconnected PHRs are often described as the ideal or preferred type of PHR in terms of data control, record portability, and system interoperability [7,37,44,45]. These systems can usually be populated with patient information from a variety of sources, including physician EMRs, hospital EHRs, insurance carriers, health plan sponsors, labs, and pharmacies [29,37]. In addition, users can enter their own information in the selected areas of the PHR. These PHR systems offer consumers adequate control over parts of their health records and also alleviate the need for manual data entry. In addition, because of the established electronic linkages among some HIS, records can usually be easily transferred from one provider to another. Despite the limited offerings in this space, the functionality of these integrated systems is expected to translate into a wider range of convenience benefits and improved health outcomes for consumers as well as operational efficiencies for providers.

Product Utility of PHR Systems

On the basis of the discussion above on different types of PHR systems, one may be led to believe that tethered or interconnected PHRs offer considerably advanced functionality in comparison with standalone PHR systems. Although this is certainly true in the context of system capabilities that require back-end integration with provider EMR or EHR systems, there may be a range of other PHR features and functions that do not depend on such integration, and these can be offered through stand-alone PHRs just as well. For example, certain stand-alone PHR products provide a deeper functionality related to health resource libraries, patient-centered health monitoring, and linkages with web-based support groups—features that do not necessarily need high levels of system interoperability with other HIS.

In this section, we draw upon the extant academic literature as well as the current industry PHR software offerings to provide an overview of various functionalities that may be available in contemporary PHR systems. To aid our discussion, we organize the different PHR capabilities into different categories based on the consumers' modalities of use and functional characteristics of system features and functions. Figure 1 depicts the conceptualization of a high-level functional utility model of PHR systems. The elements of the model are briefly described below. It should be noted that our model does not aim to provide a system specification or technical architecture of PHR systems. These have been described elsewhere in the extant literature [30,45,46]. Our model simply aims to provide a scaffold to aid a high-level understanding of PHR systems at the consumer level.

Figure 1. A high-level functional utility model of personal health record systems.



In terms of modalities of use, our model differentiates between the *individual* and *interactive* modes of using PHR functions. Although individual modes of use entail highly personalized user-initiated tasks, interactive modes usually comprise bidirectional exchanges between the consumer and other care delivery constituents, including physicians, providers, or payors. Most of the individual tasks are performed in an asynchronous style with frequent individual interventions, whereas interactive exchanges usually occur in a dynamic and synchronous fashion.

Our model also characterizes PHR functions as being primarily *content*-, *connectivity*-, or *collaboration-oriented*. Content-rich features refer to PHR technologies that are primarily used for information management. Information can be pushed automatically or retrieved on an as-needed basis or it can be maintained within the PHR by users on their own. In connectivity-based applications, information is exchanged, and transactions are conducted in a 2-way flow between applications, devices, organizations, or people. Finally, collaboration-based mechanisms subsume other functional modes and offer tools for interpersonal exchanges and decision support, thereby enabling consumers to proactively manage their health and wellness. On the basis of these criteria for classification, we categorized various PHR features and functions into 6 groups: PHI resources, patient and provider records, health monitoring tools, contact and communication features, shared access and social networks, and decision support functions.

PHI Resources

At their core, most PHR systems comprise a repository of PHI that allows consumers to maintain their own profiles and medical history data. Various tools such as digital diaries to manage the lists of drugs and track personal data such as weight, glucose, and cholesterol levels allow consumers to exercise control over their medical information [47-49]. Additional functionality with links to web-based health information can help consumers create a library of health information resources pertinent to them [50,51].

Patient and Provider Records

For PHRs with electronic links to other HIS from providers, pertinent PMRI can be seamlessly added to the PHR system. Data from patient diagnosis, treatments, and medications can be added from physicians' EMRs or providers' EHR systems [50,52-57]. Patient health summary standards such as the CCR (continuity of care record) can provide guidelines for PHR pertinent data that would provide a holistic view of patient care and consequently improve the portability of patient health information [42,55,58].

Health Monitoring Tools

Beyond self-managed health information, many PHR technologies also facilitate connectivity with a range of medical and lifestyle tracking devices. Data from these devices can be uploaded to PHRs to enable consumers to keep track of their health and wellness [55,56,59-62]. In addition, these behavior management tools can help consumers track their health indicators via a dashboard style interface and also set up various notifications and alerts for any anomalies or items that require their attention [63-65].

Contact and Communication Features

The tools in this category are considered extremely useful by consumers for interconnected PHRs linked to provider EMR and EHR systems [7,45,52,59,60,64]. Although features such as patient-physician and patient-provider secure messaging and appointment scheduling provide convenience to users, other tools for prescription refills and insurance claims processing can help streamline process workflows for all constituents in health care delivery [66-68]. Advanced PHR offerings also provide telehealth features for patients to provide the results of basic health assessments from home and to transfer data from connected medical devices [37,64,69].

Shared Access and Social Networks

Most PHR systems provide a core set of collaboration tools to help consumers share their health information with other authorized people, including caregivers and designated family members. They do so by delegating access rights and permissions to the specific parts of their PHR [37,64,69]. More recently, social networking tools have been integrated with some PHRs to provide patients with more access to information from practitioners as well as from other patients with similar medical conditions [29,70]. The range of possibilities for social networking features in PHR offerings span a wide spectrum from basic moderated health discussion forums for questions and answers [59] to sophisticated sites that crowdsource patient data from connected devices to foster an active dialog among patients or to contribute to further research about illnesses [71].

Decision Support Functions

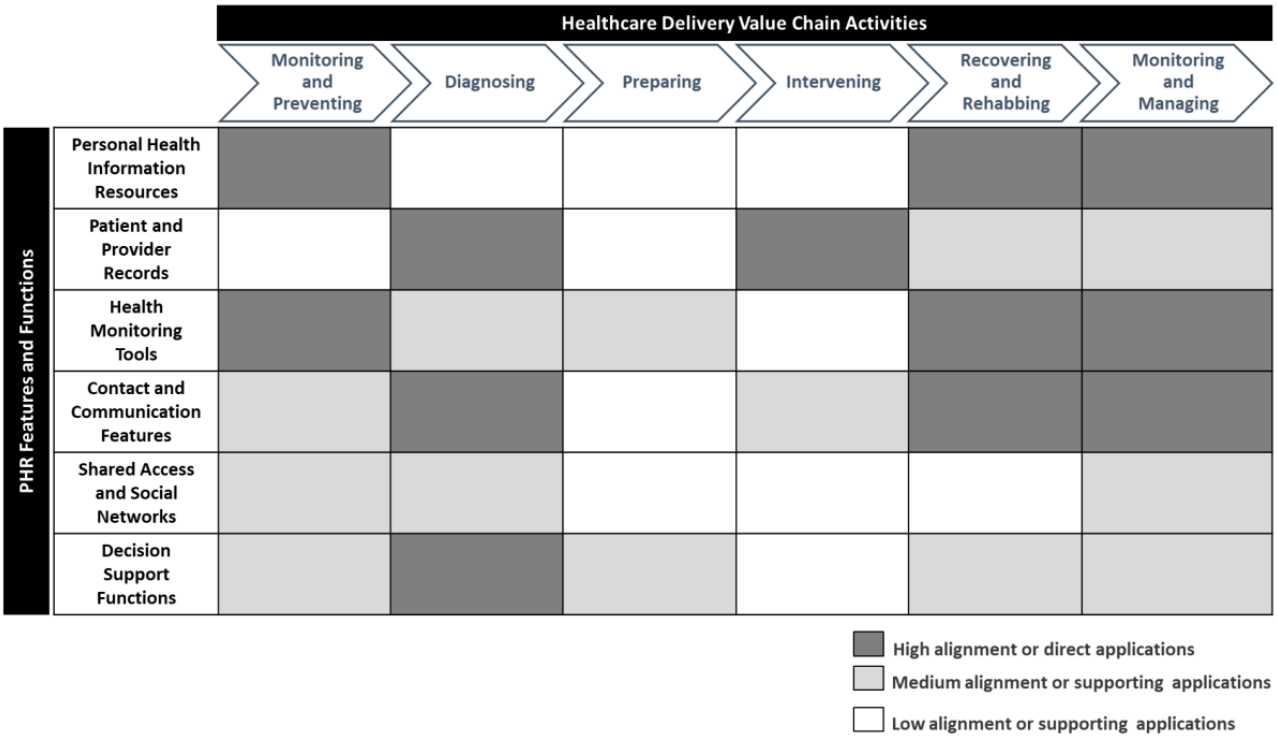
In interconnected PHR systems, collaborative interactions between patients and clinicians can be enabled through decision support features that include illness surveillance, virtual consultations, and computerized tailored interventions [29,72]. In addition, rule-based engines can also provide input to the decision-making processes through tools such as patient health risk profiles and drug-interaction checking [7,73-75]. By using patient data from other parts of the PHR and leveraging practitioner expertise, such tools can help in evaluating the harms and benefits of specific treatment options [37,63,76], issue health warnings through personalized clinical decision support (CDS) notifications [29,77], and recommend alternative treatments [37,73,78]. Recent studies have also shown that personalization-focused PHR functions such as tailored interventions with highly individualized communication, therapy, or medications can be extremely effective in inducing behavioral changes and improving patient health [79,80].

Consumer Value of PHR Systems

Drawing upon the review of the features and functions of PHR systems at the product level, this section discusses a consumer-centric viewpoint of the potential value that might be realized through the effective use of these technologies. To facilitate this viewpoint, we appropriate the conceptual framework of the *care delivery value chain* (CDVC) [81-83], which offers a systematic approach to delineate and analyze health care services and activities that jointly determine the overall success of health outcomes for consumers [81]. According to the CDVC framework, the value for the health care consumer is determined by the results and outcomes rather than the inputs and volume of the range of health care services provided [84]. Using a similar reasoning, we maintain that in the case of PHRs, the consumer value is determined not by the functions and features of technologies per se but also by their potential to address the needs, expectations, and preferences of consumers during the various health care delivery activities. The CDVC classifies these activities into 6 main areas: prevention, diagnosis, preparation, interventions, recovery, and ongoing management of illnesses [82,83].

Figure 2 presents a visual depiction of our conceptualization of the PHR consumer value framework that juxtaposes various PHR features and functions (described in the *Decision Support Functions* section) alongside the CDVC-defined 6 core activities in the health care delivery value chain. The relationships between PHR functionality and health care activities are depicted as lightly or darkly shaded intersections. The latter represents a high (direct) alignment or mapping between specific PHR functionality and health care delivery activity, as evidenced by strong support in the extant literature. To determine the strength of mapping between PHR functional categories and CDVC activities, we identified different use cases for PHR features and functions from the extant literature. These use cases are listed in Multimedia Appendix 1, which serves as a foundation for the summary depicted in Figure 2. A brief overview of the applications of PHR functionalities in different health care delivery activities is provided below.

Figure 2. Personal health record consumer value: a mapping of personal health record functionality to the health care delivery value chain. PHR: personal health record.



Monitoring and Preventing

These activities are primarily concerned with tracking an individual's current conditions and assessing health risks to proactively prevent or reduce the seriousness of illness or injury [81]. Comprehensive patient profile and medical history information sourced from personally reported data as well as patient clinical records can directly help in the early detection of illnesses or reducing the need for medical treatments [7,48]. Furthermore, the integrated use of health devices and self-management dashboards can help track lifestyle-or illness-related risk factors such as diet patterns, blood pressure, and glucose levels, which can help support preventive health care activities [48,55,59,85,86]. Social networks can also help support the proactive posture of patients by helping source relevant information about health conditions and treatments from practitioners and other patients [29,71]. Decision support tools offer an additional functionality to help with the proactive detection and resolution of potentially threatening health conditions through CDS advisories and virtual counseling from experts about potential future health risks [55,74,75,81].

Diagnosing

Diagnosing activities in the care cycle comprise a range of processes, such as laboratory testing, medical history evaluation, consultations with specialists, and the formulation of treatment plans. As depicted in Figure 2, there is a strong support in the extant literature that multiple PHR functionality groups have direct or indirect applications in diagnosis-related care activities. The ready availability of PMRI in interconnected PHR systems can help facilitate these activities [47,52,53,70]. These activities can also be enabled through decision support tools, such as virtual physician consultations and computerized tailored interventions [29,55,70,75]. Finally, in terms of supporting functionalities, personally tracked and self-reported personal information and family medical history shared through the PHR can also help in improving the overall quality of diagnostic processes [47,55,70,75,87].

Preparing

These activities refer to all setup procedures and processes that need to be completed before medical intervention. In the original CDVC framework, the authors note that this set of activities is often overlooked in the health care system [81,82]. Perhaps this is why our review also yielded very little direct evidence of PHR applications in this area. Nonetheless, we believe that PHR functionality related to health monitoring tools and decision support functions can help in supporting such preparatory activities. The former can help with the tracking of important health data from lifestyle health data dashboards and connected medical devices [61,62,65], whereas the latter can facilitate reviews of health profiles, interactions with specialists, and verification of potential drug interactions [29,73].

Intervening

Intervention processes and procedures are targeted at reversing or mitigating a health condition [81], and they typically include the initiation of therapy, treatment, or medication and the management of potential infections or associated illnesses. PHRs can play an important role in improving the quality of medical interventions by providing up-to-date medical history and PMRI across various points of care and by facilitating continuity of care [42,54,66,68]. In addition, contact and communication features in PHR systems can help patients receive regular and situational counseling on treatment and prognosis and can help attending physicians ensure treatment compliance [81,83].

Recovering and Rehabbing

These services are an essential component of care for all medical conditions [81], and the procedures are important for ensuring effective recovery and positive health outcomes for patients in the long term. PHR systems can help in achieving these health outcomes through an improved health monitoring of risk factors and lifestyle data [55-57,61,65,86,88,89] and by seamlessly connecting patients to providers for referrals, follow-ups, and prescription refills [63]. These features are also complemented well by decision support functions that can facilitate the development of tailored interventions and help in tracking and resolving treatment side effects [62,73,75,90].

Monitoring and Managing

Activities that constitute the final part of the care delivery chain aim to manage patient conditions and monitor therapy compliance on an ongoing basis [83]. As shown in Figure 2, PHI resources, health monitoring tools, and contact and communication features can potentially play a significant role in enabling these monitoring and managing activities [56,57,85,89,91,92]. Multiple studies pertaining to chronically ill patients using PHR technologies have demonstrated the usefulness of features such as personal logs and links to educational resources as well as tools such as web-based appointment scheduling, meeting reminders, and email communication with health care professionals [85,91,93]. Together, these tools can play a vital role in minimizing long-term health risks related to chronic illnesses [56,57,82,89,92].

Overall, the effective deployment and adoption of PHRs can potentially enable improved integration across health care activities that constitute the full cycle of care for a consumer. Such integration across the entire chain has been posited as the major driver of health care consumer value [83].

Our analytical framework highlights the similarities and complementarities among various PHR functions and features by conceptualizing the direct and supporting applications of PHRs in different health care activities. Furthermore, a circumspect inspection of the framework shows that the consumer value from contemporary PHRs primarily relates to care activities with a proactive health management orientation. Monitoring activities at the beginning and end of the care delivery chain has a high number of associated PHR applications, followed by activities related to diagnosis and recovery. From the viewpoint of various PHR functional categories, contact and communication features appear to have the most recurrent use cases, followed by personally and clinically sourced health record information as well as health monitoring tools. Our analysis supports previous research that indicates that PHR users consider connectivity features that facilitate health care processes to be the most useful tools [48,94].

Industry Benefits of PHR Systems

Having discussed the functionality of PHR systems and their applications in various health care activities, this section of the paper offers a summary of the benefits of PHR systems for the health care industry. In deliberating these benefits, we underscore our assertion that the value-producing potential of PHRs is not only dependent on the adoption of these technologies by consumers but also on the active participation for the provision and use of these technologies by multiple health care delivery constituents, such as hospitals, labs, pharmacies, insurance companies, and government agencies. Consequently, the effective deployment and adoption of PHRs can result in a variety of benefits for these constituents [95].

The lens of analysis used to outline the industry benefits of PHRs is based on an extension of the health care value chain described in the *Monitoring and Managing* section. However, rather than focusing on care delivery activities, we adopt a channel partner perspective and highlight the benefits of PHR technologies to various entities that comprise the health care system. Using standard health care industry nomenclature [96,97], we refer to providers as any clinicians, allied health professionals, or organizations that render direct health care services to consumers; payors as entities that finance the cost of health services (eg, insurance carriers or health plan sponsors); and public health agencies as government institutions concerned with research and policy issues for the social well-being of communities as a whole [97].

Table 2 offers a review summary of the industry benefits of PHRs by outlining the core value propositions and the principal benefits of these technologies to different constituents. Value propositions pertain to micro-level benefits for consumers, meso-level benefits for providers and payors, and macro-level benefits in the realm of public health. These are briefly discussed herewith.

Table 2. Value propositions and benefits of personal health record systems to health care delivery constituents.

Value propositions and benefits	Literature support	Health care delivery constituents			
		Consumers	Providers	Payors	Public health agencies
Consumer empowerment and patient engagement					
Promote consumer health education	[14,50,57,68,76]	✓[a]	✓		✓
Enable patients to become informed health care consumers	[5,42,44,66,98]	✓			✓
Enhance understanding of medical conditions	[29,42,57,66,74,75,99,100]	✓	✓		
Simplify and clarify patient instructions	[29,42,57,66,74,75,99,100]	✓	✓		
Provide a greater control over health outcomes	[3,56,101,102]	✓

[a]Mapping of value propositions and benefits of personal health records to various health care delivery constituents.

Consumers

From the perspective of *consumers*, PHR users are not only likely to be better informed about their health conditions [5,63,123], but they also actively participate and increasingly contribute toward their own health management activities [57,102]. PHRs have the potential to provide patients with a better understanding of health information and clearer health care instructions [74,100]. PHRs can also assist users in monitoring daily self-care activities and enable patients to collaborate and share their experiences with their providers and caregivers. As an integrated patient-centered technology, PHRs also offer the means for increased patient engagement through improved provider-patient and physician-patient communication [14,54,66,68,74], thus leading to greater personalization of care [3].

Providers

From the perspective of *providers*, a primary benefit of PHR systems is that these technologies address a significant gap in the current health information exchange mechanisms. In the absence of stable and formal technology standards that allow the transfer of patient records from one provider to another, PHRs can offer an alternative means to achieve this purpose [44,63,107]. Patients can access their health records as, when, and where needed. PHR systems can also help reduce health care costs and inefficiencies, especially those associated with inaccurate information and effort duplication [42,57,59,113]. Patients can directly verify health data, and a complete access to patient history from across providers can assist in avoiding unnecessary laboratory tests and medical procedures.

Payors

Providers and *payors* can also benefit from the patient adoption of PHRs because the use of these systems is likely to improve patient safety through an early identification of health risks [76,90,103,114], reduce the cost of chronic disease management [32,110], and enable health care institutions to better handle emergency situations [115,116]. Access to unified PMRI across health care providers can help alleviate medical treatment disruptions for patients with chronic conditions [124], and features such as remote monitoring and eHealth consultations can enable earlier and efficient hospital discharge and long-term patient monitoring processes [64,69].

Public Health Agencies

From the viewpoint of *public health agencies* at a macro level, the mainstream adoption of PHRs can lead to a variety of benefits for population health [95]. These technologies can help in reducing health care disparities across demographic, economic, and regional divides, and these technologies offer a means of access to high-quality health care for all [124]. By helping overcome structural barriers to quality health care, PHR technologies can potentially improve the health status of underserved communities and populations [69,124]. From a cost perspective, proactive care delivery made possible through these technologies can help in reducing the burden on public health institutions and resources [3,59,63,76].

Finally, from a population health research standpoint, consumer consent to sharing health care information and the subsequent widescale accumulation of PHR data have the potential to act as a valuable source of public health information for promoting healthy lifestyles and for detecting and preventing infectious diseases [119]. Through appropriate privacy and consent mechanisms, patient data available through an integrated health care network can be used to facilitate public health research on individuals and their communities as well as help with regional and global illness surveillance and screenings [55,90,121].

Overall, PHR systems can play a transformative role in facilitating complex information management processes across various health care delivery constituents. The mainstream deployment and adoption of these technologies has the potential to improve clinical and population health outcomes by streamlining medical and operational processes across the health care system.

Discussion

Although several previous studies on PHR technologies have alluded to a distinction among the functionality, utility, and value of these technologies [5,47,125], our review of the literature did not reveal any formal treatise of this subject at a theoretical or an empirical level. Our study aims to address this gap through a review and synthesis of the literature.

This paper presents a review of the extant literature on PHR systems, with the objective of providing an overall assessment of the functionality, utility, value, and benefits of contemporary PHRs. Toward this end, we offer a conceptual high-level functional utility model of PHRs outlining their features and functions categorized according to different use modalities. In addition, we deliberate on the value of PHR technologies to consumers by highlighting their applications across the spectrum of health care delivery activities. Finally, we provide a holistic summary of the value propositions and benefits of PHR systems to various health care industry constituents, including consumers, providers, payors, and public health agencies.

Our review indicates that PHR systems have made considerable progress over the past decade in terms of technology features and functions available at the product level. Compared with early PHR products that simply offer a basic functionality to maintain PHI [47,70], contemporary technologies offer a myriad of content-, connectivity-, and collaboration-based features and functions. Consequently, in recent years, the academic community has paid increasing attention to PHR functionality related to health monitoring tools, social networking features, and CDS functions.

From a value perspective, our analysis demonstrates that the value-generating potential of PHR systems arises from their role as an enabler for the integration of health care delivery activities across the full cycle of care for the health care consumer. These technologies can offer a useful mechanism for information exchange and care coordination among providers, thus leading to improved health outcomes for consumers. The consumer value framework conceptualized in this paper highlights that PHR functions have the potential to enhance patient experience through various touchpoints in health care delivery.

Our review also shows that although *consumers* are the primary beneficiaries of the functionality provided by PHR technologies, their overall value and benefits span across the activities and constituents of the health care delivery chain. At the consumer level, PHR systems can facilitate improved consumer health outcomes through the self-management of health and wellness as well as through enhanced quality of care. Moreover, these technologies can also generate channel partner value for providers and payors by enabling operational efficiency and reducing the cost of care. Finally, long-term and effective use of PHRs can also produce societal value in the form of improved public health outcomes.

This study offers several opportunities for research and potential practical applications. In terms of future research directions, we encourage researchers to undertake an empirical assessment of

our conceptualized functional utility and consumer value frameworks for PHR technologies. In particular, our literature review indicates a significant dearth of studies addressing the issue of consumer value of PHR offerings. Our study offers a possible starting point for this type of research. For health care practice, our review may be relevant to health care professionals associated with value analysis committees that are commissioned for the appraisal and recommendation of innovative HITs. A value framework such as the one proposed in this paper that integrates functional attributes, use cases, and applications in health care delivery activities can potentially be applied to the value assessment of other HITs as well.

Abstract

Background: Internet-delivered cognitive behavioral therapy (ICBT) is an effective treatment that can overcome barriers to mental health care. Various research groups have suggested that unguided ICBT (ie, ICBT without therapist support) and other eHealth interventions can be designed to enhance user engagement and thus outcomes. The persuasive systems design framework captures most design recommendations for eHealth interventions, but there is little empirical evidence that persuasive design is related to clinical outcomes in unguided ICBT.

Objective: This study aims to provide an updated meta-analysis of randomized controlled trials of unguided ICBT for depression and anxiety, describe the frequency with which various persuasive design principles are used in such interventions, and use meta-regression to explore whether a greater number of persuasive design elements predicts efficacy in unguided ICBT for depression and anxiety.

Methods: We conducted a systematic review of 5 databases to identify randomized controlled trials of unguided ICBT for depression and anxiety. We conducted separate random effects meta-analyses and separate meta-regressions for depression and anxiety interventions. Each meta-regression included 2 steps. The first step included, as a predictor, whether each intervention was transdiagnostic. For the meta-regression of ICBT for depression, the first step also included the type of control condition. The number of persuasive design principles identified for each intervention was added as a predictor in the second step to reveal the additional variance in effect sizes explained by persuasive design.

Results: Of the 4471 articles we identified in our search, 46 (1.03%) were eligible for inclusion in our analyses. Our meta-analyses showed effect sizes (Hedges *g*) ranging from 0.22 to 0.31 for depression interventions, depending on the measures taken to account for bias in the results. We found a mean effect size of 0.45 (95% CI 0.33-0.56) for anxiety interventions, with no evidence that the results were inflated by bias. Included interventions were identified as using between 1 and 13 persuasive design principles, with an average of 4.95 (SD 2.85). The meta-regressions showed that a greater number of persuasive design principles predicted greater efficacy in ICBT for depression (R^2 change=0.27; B=0.04; P=.02) but not anxiety (R^2 change=0.05; B=0.03; P=.17).

Conclusions: These findings show wide variability in the use of persuasive design in unguided ICBT for depression and anxiety and provide preliminary support for the proposition that more persuasively designed interventions are more efficacious, at least in the treatment of depression. Further research is needed to clarify the role of persuasive design in ICBT.

Introduction

Background

Depression and anxiety are highly prevalent and represent the leading and the sixth leading causes of disability worldwide, respectively [1]. Despite the demonstrated efficacy of psychotherapeutic and pharmacological interventions for depression and anxiety [2-4], many people face structural barriers to accessing mental health care (eg, financial barriers, transportation barriers, inconvenience, and limited availability of services) [5,6]. Internet-delivered cognitive behavioral therapy (ICBT) is the most common type of internet intervention and an effective treatment for several common mental health problems, including depression and anxiety [7]. Unlike traditional cognitive behavioral therapy (CBT), ICBT enables users to access treatment materials privately at a time and location that is convenient for them, allowing it to be administered economically on a large scale and circumvent barriers to traditional forms of mental health care [8-10]. ICBT can be therapist guided or unguided. Guidance appears to improve adherence and clinical outcomes [11], but unguided ICBT is economical, highly scalable, and believed by many researchers to have considerable potential for improving public health [12-15].

Since the early 2000s, various research groups have suggested that eHealth interventions such as unguided ICBT can be designed in ways that improve user engagement and thus outcomes. In 2003, Fogg [16] presented the *functional triad* principle, suggesting that technology can function as a tool, a medium for relaying content, and a social actor to help facilitate behavior change. In 2009, Oinas-Kukkonen and Harjumaa [17] developed the *persuasive systems design* (PSD) framework, which elaborated on the functional triad and included 28 recommended design principles to produce more persuasive and engaging technological systems. They divided these principles into 4 categories: (1) *primary task support* principles, which facilitate the completion of the primary tasks of an intervention or other system; (2) *dialogue support* principles, through which an intervention or other system supports a user to help them enact their target behavior; (3) *system credibility support* principles, which facilitate a more credible and persuasive intervention or other system; and (4) *social support* principles, which leverage principles of social psychology to help users of an intervention or other system motivate one another. The 28 principles are described in Multimedia Appendix 1 [17].

Several other research groups have provided their own design recommendations for eHealth interventions. Despite using different terminology, most of these recommendations appear to align closely with the principles included in the PSD framework. Examples include recommendations related to *personalization* [18-22], *tailoring* [19,21,22], *reminders* [19,20], *self-monitoring* [18,23], *liking* [19,22,24], and various *dialogue support* principles [18,19,23]. A few design recommendations are not captured in the PSD framework (eg, time-limited access [20] and greater use of metaphors [22]), but to our knowledge, none of these have been proposed by 2 or more research groups; that is, the PSD framework appears to capture most common recommendations. Various groups' recommendations and the related PSD framework principles are displayed in Multimedia Appendix 2 [18-24].

In 2012, Kelders et al [25] used the PSD framework to assess whether the persuasive design principles used in 83 eHealth interventions for chronic conditions, lifestyle changes, and mental health predicted adherence. They conducted a meta-regression, finding that a greater number of dialogue support principles predicted greater adherence to eHealth interventions. However, to our knowledge, there is no empirical research demonstrating a relationship between persuasive design and symptom change in eHealth interventions.

Objectives and Hypothesis

This study aims to (1) present a systematic review and meta-analysis of randomized controlled trials of unguided ICBT for depression and anxiety among adults, (2) systematically examine the frequency with which various persuasive design principles are used in such interventions, and (3) use meta-regression to examine the extent to which persuasive design could explain the variability in effect sizes identified through the meta-analysis. Thus, the overarching objective of this study is to review the efficacy, the use of persuasive design, and the relationship between efficacy and persuasive design in unguided ICBT for depression and anxiety. We hypothesized that using a greater number of persuasive design principles would predict greater efficacy among the included studies.

Methods

Study Design

This study consisted of a systematic review, 2 meta-analyses, and 2 meta-regressions. The methods used in each phase of the study are described in the following sections. We registered the methodological protocol for this study on PROSPERO on October 24, 2019 (ID: 153466), before commencing the literature search, and kept a log of revisions to the original protocol throughout the course of this research (Multimedia Appendix 3 [26-28]). We followed the guidelines outlined in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement in the preparation of this paper [29].

Systematic Review Methods

Eligibility Criteria

We searched for randomized controlled trials of unguided ICBT interventions for symptoms of depression and/or anxiety among adults that had been published in English in academic journals since 2000. We included trials of ICBT targeting symptoms of any type of depressive or anxiety disorder, as defined in the fifth edition of the Diagnostic and Statistical Manual of Mental

Disorders [30], with various kinds of control conditions (eg, waitlist, treatment as usual, and active control). Studies involving samples with a mean age of less than 18 years were excluded.

Although we excluded studies in which ICBT was delivered with guidance from a therapist or coach, we did not exclude studies involving diagnostic interviews or contact of a logistical nature between participants and research teams. Interventions that used a CBT model of treatment and were delivered via the internet were considered ICBT interventions regardless of whether the authors of trials identified them as such. We included interventions using third-wave CBT approaches (eg, mindfulness-based CBT and acceptance and commitment therapy) [31] because prior research has not demonstrated significant differences in outcomes between traditional CBT and third-wave approaches [32,33].

Literature Search

On October 29, 2019, we conducted a literature search on MEDLINE, PsycINFO, PubMed, Web of Science, and PsycArticles. To be identified, articles were required to include the words "CBT," "internet," "trial," and "depression" or "anxiety" or one of several similar phrases for each of these terms in their titles, keywords, or abstracts. The search terms are shown in detail in Multimedia Appendix 4. This search was updated on July 2, 2020.

Study Selection

After removing duplicates of studies identified in 2 or more databases, HCM and CRFS independently screened the studies in 3 stages: by title, by abstract, and by full text. Wherever the 2 screeners reached different decisions about whether to retain or exclude a study, that study was included in the next stage of screening. Differences in decisions on the full-text screening were resolved through discussion.

Data Extraction

HCM extracted several types of data from each study: study characteristics (eg, type of control condition and time between pretreatment and posttreatment measures), risk of bias [34], general intervention characteristics (eg, target symptoms and medium of delivery), persuasive design principles [17] as operationalized by Kelders et al [25], and efficacy data. Consistent with the approach of Kelders et al [25], we did not code principles in the *system credibility support* category of the PSD framework because they were reported very infrequently and would have been challenging to code objectively (eg, a system should have a "competent look and feel" and "provide endorsements from respected sources" [17]). In most cases, we coded persuasive design principles as present or absent based on the descriptions of interventions in the included studies, although we consulted other available sources of information when possible (eg, intervention websites and study protocols). The complete list of data items is provided in Multimedia Appendix 5. The persuasive design principle *tunneling*, which refers to the sequential presentation of treatment elements in a structured, linear manner, was not counted toward the total number of persuasive design principles in this study. This is because researchers have recently proposed that eHealth interventions can be made more engaging by providing users with greater flexibility and control concerning the modules or features they wish to use [19,22], which contrasts with the principle of *tunneling*.

Risk of Bias Assessment

We assessed the risk of bias among included studies using the Cochrane risk of bias tool [34]. We did not assess the risk domain *blinding participants and personnel* because it is not possible for participants to be blind to their conditions in psychotherapy research [35]. Furthermore, we did not assess the risk domain *blinding of outcome assessment* because all outcome measures were self-report measures, and participants could thus not be blinded. Self-report measures are generally considered equivalent to blind clinical observers in psychotherapy research, and research suggests that they do not result in inflated effect sizes [35].

Meta-analysis Methods

We conducted meta-analyses using Comprehensive Meta-Analysis software (Biostat Inc) [36]. As prior research suggests that ICBT for generalized and social anxiety is more efficacious than ICBT for depression [7,37], we conducted separate meta-analyses of ICBT for anxiety and ICBT for depression. Given the availability of symptom change data for both anxiety and depression, trials of ICBT designed to treat both conditions were included in both meta-analyses. We measured heterogeneity in the effect sizes of the included studies using the I^2 index and formally tested the degree of heterogeneity using the Q statistic [38]. In each of the 2 meta-analyses, we used a random effects model, used between-groups effect size (Hedges g) as the summary measure, and weighted each study by the inverse of the within-study variance of the primary outcome measure plus the between-study variance. Several studies evaluated 2 unguided ICBT interventions; in such cases, we treated the evaluation of each intervention as a separate study, except we divided the control group sample size by 2, such that each control group participant was included only once in the analyses [39]. We evaluated the risk of publication bias using funnel plots and accounted for publication bias using the trim and fill technique [40]. We explored the influence of study-level bias on outcomes by repeating the meta-analyses without studies deemed to be at high risk on one or more dimensions of the Cochrane tool for assessing risk of bias [34].

Meta-regression Methods

We conducted 2 meta-regressions using Comprehensive Meta-Analysis [36]—one for depression interventions and one for anxiety interventions—to determine the degree to which persuasive design principles could explain variance in effect sizes among studies. Paralleling the approach taken to the meta-analyses, we included trials of ICBT designed to treat both depression and anxiety in both meta-regressions, given the availability of symptom change data for both conditions. We also weighted each study by the inverse of the within-study variance of the primary outcome measure plus the between-study variance, as in the meta-analyses.

We used 3 predictor variables. Our main predictor of interest was the total number of persuasive design principles identified for each intervention. We were unable to include the number of persuasive design principles in each category of the PSD framework as separate predictors, as Kelders et al [25] did, because of the risk of overfitting, given the limited number of included studies. We also input a binary variable reflecting whether each intervention was transdiagnostic (ie, designed to treat symptoms of both depression and anxiety). We did this to account for the possibility that unguided ICBT focused on treating a narrower range of symptoms (ie, anxiety or depression) may be more efficacious for treating those symptoms than transdiagnostic unguided ICBT designed to treat a broader range of symptoms (ie, both depression and anxiety). Our final predictor was a binary variable reflecting whether each study used a control condition with active elements (eg, psychoeducation and mood monitoring) because a previous meta-analysis of unguided ICBT found a large mean effect size among studies using passive control conditions and a small mean effect size among studies using active control conditions [41]. However, the control condition type was not included as a predictor in the meta-regression of ICBT for anxiety because there were insufficient studies to justify an additional predictor variable (eg, because of the risk of overfitting), following most recommendations concerning acceptable *subjects per variable* ratios in linear regression analyses [26].

We conducted each meta-regression in 2 steps. The first step included transdiagnostic status and, for the meta-regression of ICBT for depression, the control condition type. In both meta-regressions, the number of persuasive design principles identified was then added in the second step. This 2-step approach was used to reveal the amount of additional variance persuasive design explained in the second step after accounting for the other variables in the first step.

We conducted 5 assumption tests at each step of each meta-regression. First, we examined Pearson *r* correlations and scatterplots to test the assumption of linearity of the relationship between each continuous predictor variable and Hedges *g* [42]. Second, we checked Cook distance values to identify any outlier studies that had unduly large influences on the results [43]. Third, we inspected the distribution of studentized residuals using a histogram to ensure that the residuals were normally distributed [42]. Fourth, we inspected scatterplots plotting studentized residuals against predicted values to test the assumption of homoscedasticity [42]. Finally, we examined variance inflation factors to check for multicollinearity [42].

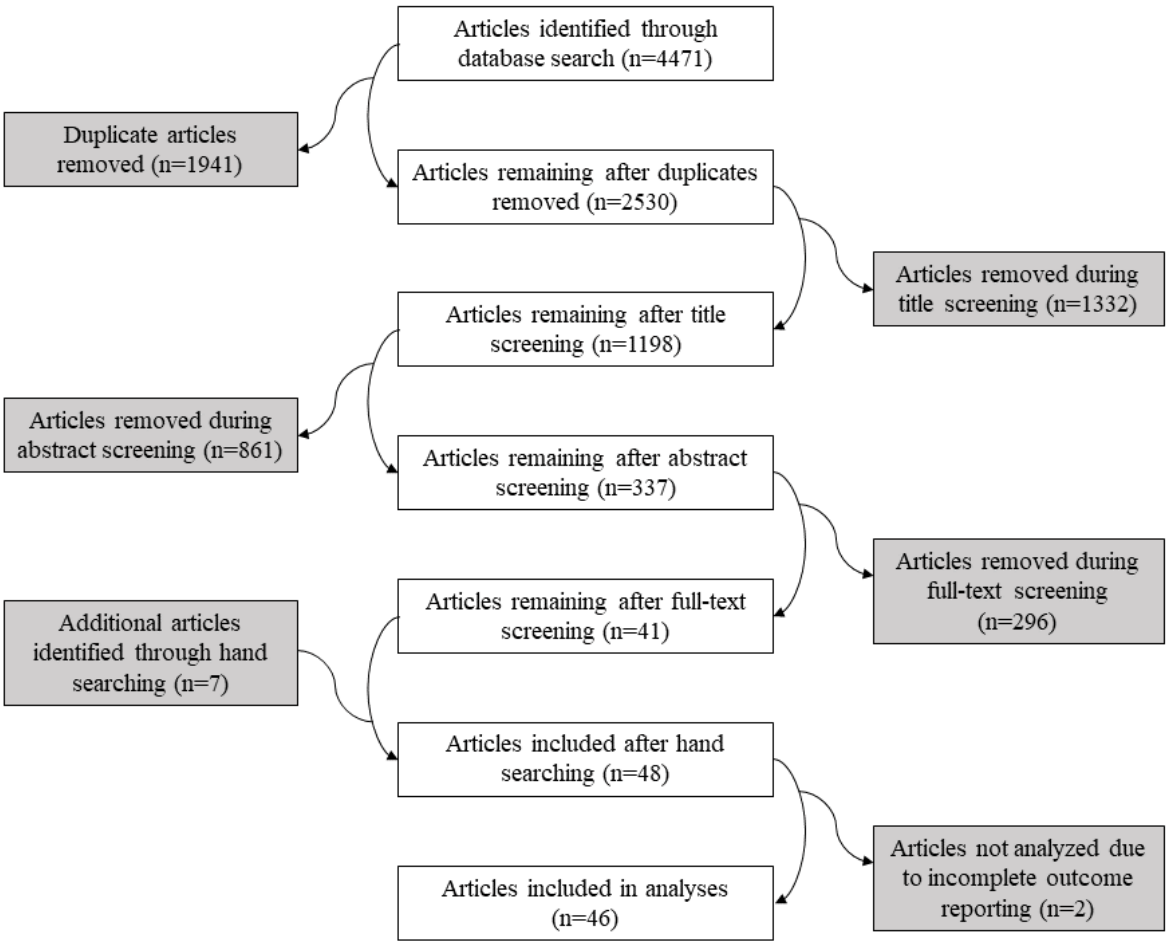
Results

Systematic Review Results

Study Selection

Between the original and updated literature searches, we identified 4471 articles, 39 of which were found eligible for analysis. Having found another 7 eligible articles through a hand search, we included a total of 46 articles. The flow of studies through the study selection process is shown in Figure 1. Separate flowcharts for the original and updated literature searches are shown in Multimedia Appendices 6 and 7, respectively. The 2 screeners (HCM and CRFS) made the same screening decision (ie, retain or remove) for 81.66% (2066/2530) of articles during the title screening, 86.39% (1035/1198) of articles during the abstract screening, and 81.9% (276/337) of articles during the full-text screening.

Figure 1. Flow of studies through the study selection process.



Study Characteristics

The 46 eligible studies included 16,632 participants, excluding participants assigned to experimental groups irrelevant to this study (eg, guided ICBT groups). Studies were most often published in or after 2017 (24/46, 52%); included samples drawn from the general population (26/46, 57%), clinical populations (14/46, 30%), or both (6/46, 13%); and most often used waitlist control conditions without active elements (28/46, 61%). The characteristics of each study are presented in Table 1.

[a]For the purpose of this table, n was calculated as the number of participants assigned to the intervention identified in each row plus the number of participants assigned to the control condition (ie, excluding participants assigned to use other interventions).

[b]Study duration expressed in days was divided by 7. Study duration expressed in months was multiplied by 4.35 (the average number of weeks in a month during a 365-day year).

[c]Some studies reported data from multiple posttreatment time points; for such studies, the duration, as shown in this table, is the number of weeks between pretreatment and whichever posttreatment time point was selected for use in the analyses reported in this study.

[d]ICBT: internet-delivered cognitive behavioral therapy.

[e]ODIN: Overcoming Depression on the Internet.

[f]Data were not reported.

[g]Todac Todac translates to “Tap Tap.”

[h]Sonreír es Divertido translates to “Smiling is Fun.”

[i]Allesondercontrole translates to “all is under control.”

[j]PAXPD: PAXonline Program for Panic Disorder.

[k]Ångesthjälpen translates to “The Anxiety Help.”

Risk of Bias

We evaluated the risk of bias among included studies using 5 of the 7 domains in the Cochrane risk of bias tool [34]. Of the 46 included studies, 14 (30%) were identified to be at high risk of bias in at least one domain, whereas only 4 (9%) were found to be at low risk of bias in all domains assessed. Most studies (28/46, 61%) were found to be at low or unclear risk in each domain. The risk of bias identified in each study is presented in Table 2.

Table 2. Risk of bias in included studies.

[a]ICBT: internet-delivered cognitive behavioral therapy.

Intervention Characteristics

In total, 37 unguided ICBT interventions were evaluated in the 46 included studies. Of these 37 interventions, 15 (41%) were designed to treat depression exclusively and 9 (24%) were designed to treat depression and anxiety or stress. Other interventions were designed to treat social anxiety (6/37, 16%), panic (2/37, 5%), fear of public speaking (1/37, 3%), generalized anxiety (1/37, 3%), acrophobia (1/37, 3%), or symptoms of multiple anxiety disorders (2/37, 5%). Most interventions (23/37, 62%) were described as traditional CBT interventions, but many interventions (9/37, 24%) were described as being strongly influenced by elements of third-wave CBT (eg, mindfulness) or other therapeutic approaches (eg, positive psychology), and several interventions were based on behavioral activation (2/37, 5%), cognitive therapy (2/37, 5%), or problem-solving therapy (1/37, 3%). Half of the interventions (19/37, 51%) were delivered via a web browser, but many interventions were delivered via a mobile app (11/37, 30%) or both a browser and an app (5/37, 14%). Of the 37 interventions, it was unclear how 2 (5%) interventions were delivered. The characteristics of each intervention are presented in Table 3.

Table 3. Intervention characteristics.

[a]CBT: cognitive behavioral therapy.

[b]Allesondercontrole translates to “all is under control.”

[c]Ångesthjälpen translates to “The Anxiety Help.”

[d]N/A: not applicable.

[e]Bluepages was offered as a complement to MoodGym in studies by Farrer et al [52] and Lintvedt et al [55] but was omitted from this table (and all analyses) because it is a psychoeducation package and not an internet-delivered cognitive behavioral therapy intervention.

[f]ODIN: Overcoming Depression on the Internet.

[g]PAXPD: PAXonline Program for Panic Disorder.

[h]Sonreír es Divertido translates to “Smiling is Fun.”

[i]Todac Todac translates to “Tap Tap.”

Persuasive Design

On average, interventions included 4.95 (SD 2.85) persuasive design principles (excluding *tunneling*). The total number of persuasive design elements ranged from 1 to 13. Principles in the *primary task support* category were the most common (mean 2.86, SD 1.32), followed by principles in the *dialogue support* category (mean 1.27, SD 1.19) and *social support* category (mean 0.81, SD 1.60). The number of interventions in which each persuasive design principle was identified is presented in Table 4.

Table 4. Persuasive design principles identified.

Persuasive design principle	Brief description[a]	Interventions used, n (%)
Primary task support		
Reduction	Divides target behavior into simple steps	35 (95)
Tunneling	Delivers content in a step-by-step format	29 (78)
Tailoring	Provides content adapted to user group	2 (5)
Personalization	Provides content that is adapted to one user	18 (49)
Self-monitoring	Provides ability to monitor progress or status	20 (54)
Simulation	Provides ability to observe relevant behavior	6 (16)
Rehearsal	Provides ability to rehearse a behavior	25 (68)
Dialogue support

Meta-analysis Results

Meta-analysis of Unguided ICBT for Depression

We conducted a meta-analysis of 37 comparisons across 34 trials of unguided ICBT for depression. There was statistically significant heterogeneity in Hedges *g* among the studies (Q=89.85, df=36; P<.001). An I^2 statistic of 59.93 indicated that a moderate proportion of variability was attributable to true heterogeneity rather than sampling error [90,91]. The weighted mean between-subjects effect size was small to moderate (Hedges g=0.31; SE 0.04; 95% CI 0.24-0.38). The forest plot for this meta-analysis is shown in Figure 2. Weighted mean effect sizes after excluding studies deemed to be at high risk of bias and after adjusting for publication bias using the trim and fill technique [40] are presented in Table 5.

Figure 2. Meta-analysis of unguided internet-delivered cognitive behavioral therapy for depression.

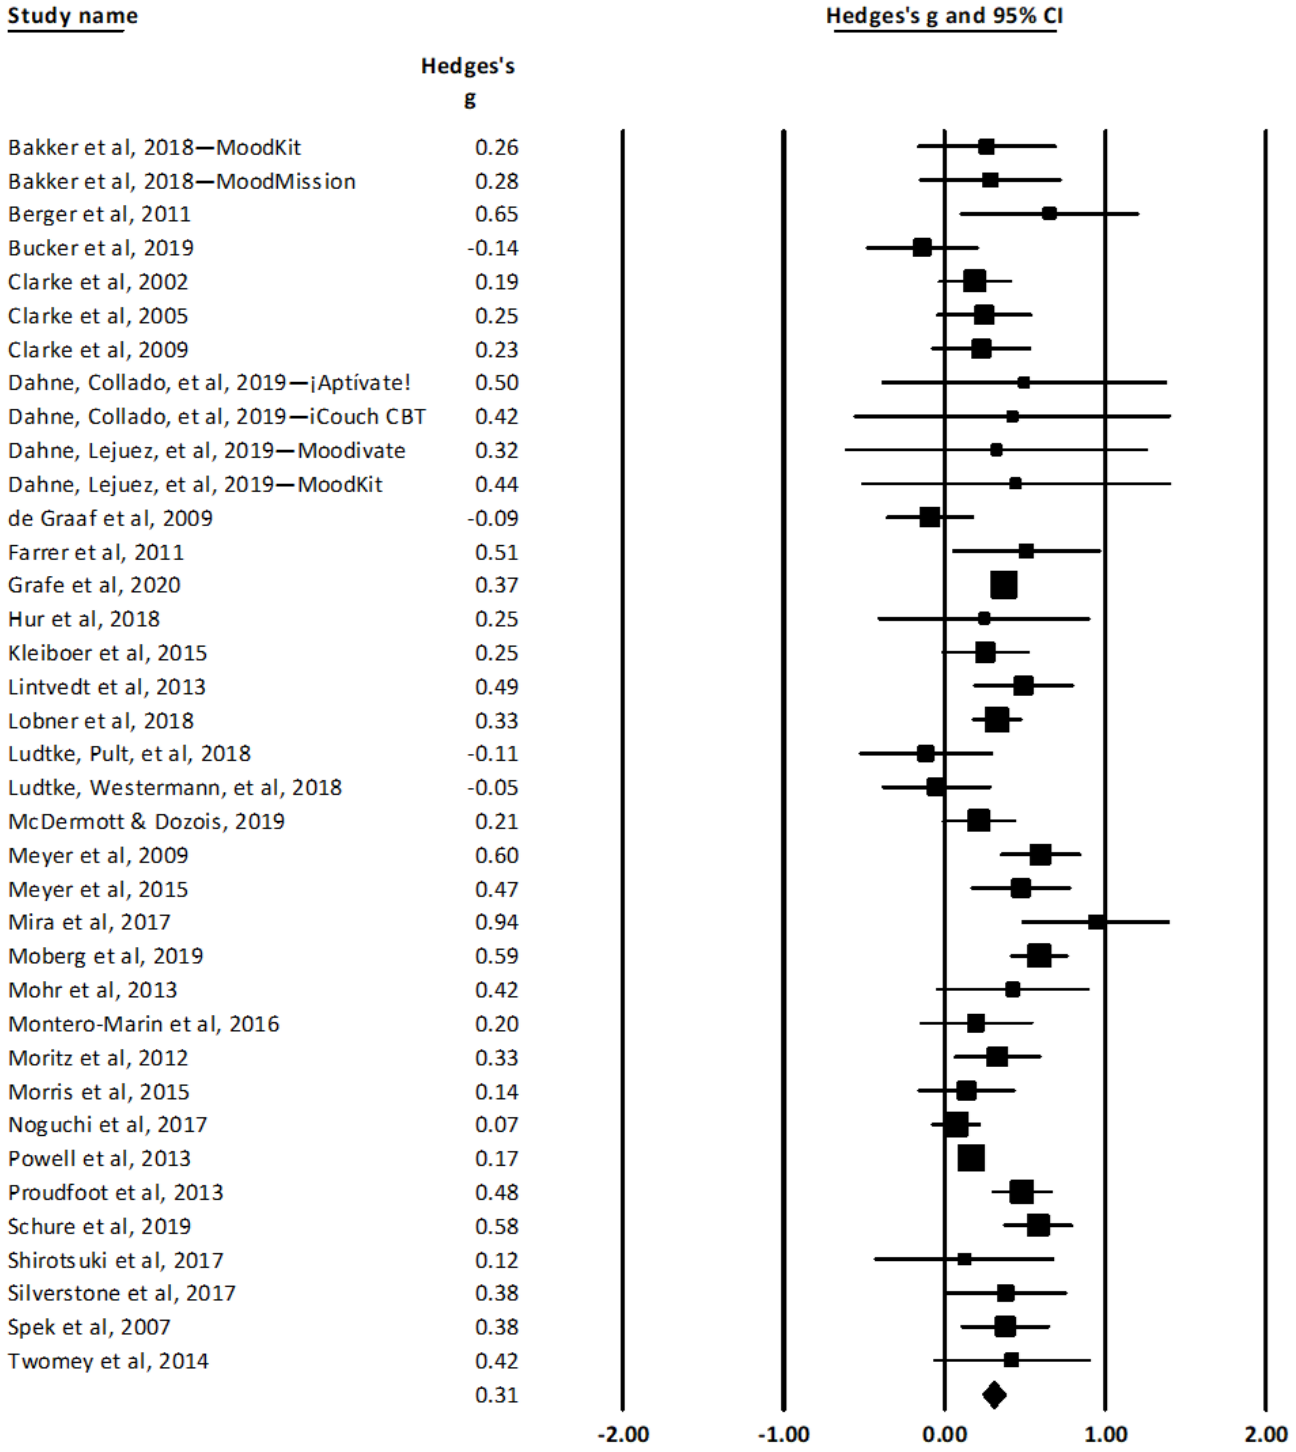

Table 5. Summary statistics of meta-analyses with and without bias corrections.

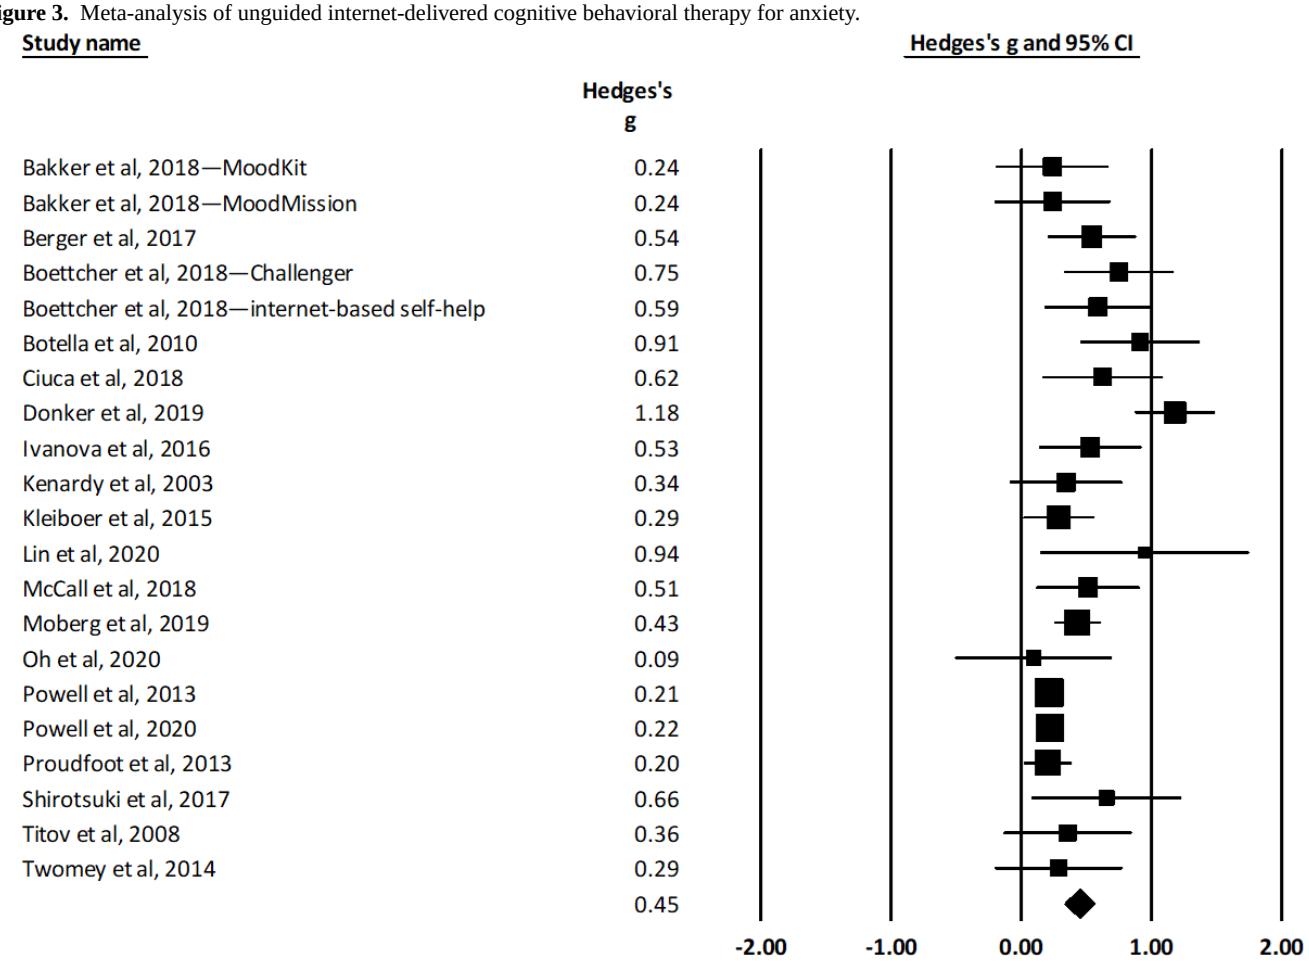
Meta-analysis	Hedges *g* (95% CI)
Meta-analysis of ICBT[a] for depression	
All studies of ICBT for depression	0.31 (0.24-0.38)
All studies with trim and fill adjustment	0.23 (0.16-0.31)
Studies with high risk of bias excluded	0.28 (0.20-0.36)
Studies with high risk of bias excluded, with trim and fill adjustment	0.22 (0.14-0.31)
Meta-analysis of ICBT for anxiety	
All studies of ICBT for anxiety	0.45 (0.33-0.56)
All studies with trim and fill adjustment	0.45 (0.33-0.56)
Studies with high risk of bias excluded	0.54 (0.29-0.79)
Studies with high risk of bias excluded, with trim and fill adjustment	0.54 (0.29-0.79)

[a]ICBT: internet-delivered cognitive behavioral therapy.

Meta-analysis of Unguided ICBT for Anxiety

We included 19 studies that reported 21 comparisons in a meta-analysis of unguided ICBT for anxiety. The results indicated statistically significant heterogeneity of Hedges *g* among studies (Q=68.47, df=20; P<.001). The corresponding I^2 statistic of 70.79 suggested that a substantial proportion of the variability represented true heterogeneity [90,91]. The weighted mean between-subjects effect size was moderate (Hedges g=0.45; SE 0.06; 95% CI 0.33-0.56). A forest plot is shown in Figure 3. Additional weighted mean effect sizes accounting for publication- and study-level bias are presented in Table 5.

Figure 3. Meta-analysis of unguided internet-delivered cognitive behavioral therapy for anxiety.



Meta-regression Results

Meta-regression of Unguided ICBT for Depression

The meta-regression of ICBT for depression, like the meta-analysis of ICBT for depression, included 34 studies reporting 37 comparisons. We used 3 predictors in this meta-regression: the total number of persuasive design principles (mean 3.90, SD 2.33), whether each intervention was designed to treat symptoms of both depression and anxiety (19/37, 51%) or only depression (18/37, 49%), and whether each study used an active control condition (13/37, 35%) or a passive control condition (24/37, 65%). The results for both steps of the meta-regression are presented in Table 6. With the possible exception of very minor heteroscedasicity of residuals at one or both steps, all assumptions were met, as detailed in Multimedia Appendix 8.

Table 6. Meta-regression of unguided internet-delivered cognitive behavioral therapy for depression.

Step and variable	Model				Predictors				
	Model summary		R^2	R^2 change	B [a]	SE	95% CI	P value	Variance inflation factor
	Q (df)	P value							
Step 1	1.05 (2)	.59	0.0	N/A[b]					
Constant					0.28	0.07	0.15 to 0.41	<.001	3.03
Active control condition					−0.02	0.08	−0.19 to 0.14	.79	1.11
Transdiagnostic intervention					0.07	0.08	−0.09 to 0.23	.40	1.11
Step 2	6.74 (3)	.08	0.27	0.27					
Constant					0.10	0.10	−0.09 to 0.29	.32	8.63
Active control condition					−0.01	0.07	−0.16 to 0.13	.85	1.14
Transdiagnostic intervention					0.13	0.08	−0.02 to 0.28	.09	1.36
Persuasive design principles					0.04	0.02	0.01 to 0.07	.02	1.22

[a]Unstandardized β coefficient.

[b]N/A: not applicable.

Meta-regression of Unguided ICBT for Anxiety

Similar to the meta-analysis of ICBT for anxiety, the meta-regression of ICBT for anxiety included 19 studies reporting 21 comparisons. We used 2 predictors: the total number of persuasive design principles (mean 5.05, SD 3.17) and whether each intervention was designed to treat symptoms of both depression and anxiety (8/21, 38%) or only anxiety (13/21, 62%). The results for both steps of the meta-regression are presented in Table 7. The assumption of normality of residuals may not have been met fully at both steps, although the residuals roughly approximated normal distributions. The assumption of homoscedasticity of the residuals was violated in step 1. The assumption tests for this meta-regression are detailed in Multimedia Appendix 9.

Table 7. Meta-regression of unguided internet-delivered cognitive behavioral therapy for anxiety.

Step and variable	Model				Predictors				
	Model summary		R^2	R^2 change	B [a]	SE	95% CI	P value	Variance inflation factor
	Q (df)	P value							
Step 1	4.80 (1)	.03	0.0	N/A[b]					
Constant					0.57	0.08	0.41 to 0.73	<.001	1.77

Discussion

Principal Findings

Recent years have witnessed a proliferation of randomized trials of eHealth interventions, including many trials of unguided ICBT for depression and anxiety. Indeed, most of the studies included in this review were published in or after 2017. There was considerable diversity in the design of both studies (eg, study duration and type of control condition) and interventions (eg, mode of delivery and use of persuasive design principles).

The results of the meta-analysis of unguided ICBT for depression were consistent with the results of previous meta-analyses. We reported 4 mean effect sizes (Hedges *g*) for unguided ICBT for depression, ranging from 0.22 to 0.31, based on the corrections we made for publication bias and study-level bias. Previous meta-analyses of unguided ICBT for depression have found comparable mean effect sizes (Hedges *g* or Cohen *d*) ranging from 0.24 to 0.36 [12,92-95]. Our meta-analysis of unguided ICBT for anxiety yielded a mean effect size of 0.45. There was no evidence of publication bias, and the mean effect size was greater (Hedges *g*=0.54) after excluding studies found to be at a high risk of bias. Several previous meta-analyses of ICBT for symptoms of anxiety disorders found effect sizes between 0.70 and 1.12 [41,96-98]; however, all these meta-analyses included trials of guided ICBT interventions, which likely explains the greater mean effect sizes, at least in part. We are aware of only 1 meta-analysis that has included a subgroup analysis of *unguided* ICBT for anxiety—social anxiety, specifically—finding mean effect sizes (Hedges *g*) of 0.78 and 0.19 for studies using passive and active control conditions, respectively [41]. It is worth noting that our review included many transdiagnostic interventions designed to treat symptoms of both depression and anxiety. The meta-regressions showed that these interventions were significantly less efficacious for treating anxiety symptoms compared with interventions designed to treat anxiety symptoms only; however, their efficacy in treating depression did not significantly differ from interventions designed to treat symptoms of depression only.

We identified wide variability in the use of persuasive design in unguided ICBT for depression and anxiety, with several interventions using only 1 persuasive design principle and others using as many as 13. The intervention identified as having the greatest number of persuasive design principles (ie, 13), called *Challenger*, was specifically designed to be engaging, with many features inspired by the literature on gamification [79,99]. The mean number of persuasive design principles identified across interventions (4.95, excluding the principle of *tunneling*) was comparable with the mean of 5.4 principles identified by Kelders et al [25] among mental health interventions in their review. The mean number of persuasive design principles identified in the primary task support (mean 2.86, SD 1.32; excluding tunneling), dialogue support (mean 1.27, SD 1.19), and social support (mean 0.81, SD 1.60) categories were also roughly comparable with the corresponding means identified among mental health interventions by Kelders et al [25] (2.6, 1.6, and 1.3, respectively).

Persuasive design was a significant predictor of effect size in the meta-regression of ICBT for depression. The unstandardized β coefficient (*B*) of 0.04 suggested that for each additional persuasive design principle an intervention uses, one could predict the effect size (Hedges *g*) for that intervention to increase by 0.04, compared with a control condition in a randomized trial. However, meta-regression is an inherently observational procedure [100], and the results therefore could not show whether persuasive design *caused* certain ICBT interventions for depression to be more efficacious than others. Persuasive design did not predict efficacy in the meta-regression of ICBT for anxiety. However, it is worth noting that the meta-regression of ICBT for anxiety included far fewer studies than the

meta-regression of ICBT for depression and had limited statistical power to identify an effect. Indeed, persuasive design had an unstandardized β coefficient of 0.03 in the meta-regression of ICBT for anxiety, which—although not statistically significant—was comparable in magnitude with that of the meta-regression of ICBT for depression. The results of the meta-regression of unguided ICBT for anxiety should be interpreted cautiously because assumption tests showed that certain assumptions were unmet. Nonetheless, our results suggest that persuasive design is more closely related to outcomes in interventions for depression than anxiety. Given that persuasive design is purported to motivate engagement in treatment [17] and that lack of motivation is a hallmark of depression, it is possible that persuasive design is particularly important in ICBT for depression.

Overall, our findings support the hypothesis that persuasive design predicts efficacy in unguided ICBT, at least in the treatment of depression. Our findings also support the validity of the PSD framework [17] by showing that it is meaningfully related to treatment outcomes. Although the results do not demonstrate the importance of any specific persuasive design principles, they support the growing body of theory and data suggesting, broadly, that persuasive design matters in eHealth [18-24]. These findings are encouraging and timely. ICBT has become well established over the last two decades, having now been evaluated in hundreds of trials [101] and currently being funded by many governments around the world [102]. It is clear that ICBT is effective, and a natural next step in ICBT research will be to explore possible avenues for making it more effective. Our findings suggest that enhanced persuasive design may be one such avenue. Notably, because ICBT is highly scalable, particularly when it is unguided, even slight increases in effectiveness can have substantial and wide-reaching implications for public health.

Limitations

This study had several limitations. First, a considerable amount of data was unreported; in particular, it is likely that many interventions used persuasive design principles that were not described in the included studies. Second, although we were able to identify the principles in the PSD framework as present or absent, we did not have access to the interventions themselves, and we were unable to evaluate how effectively persuasive design principles were implemented. Third, we were unable to show, through our meta-regressions, whether specific persuasive design principles predicted efficacy. Finally, only 1 researcher was involved in data extraction; a second extractor would have helped reduce the risk of error, inconsistency, or bias.

Future Directions

Further research will be required to clarify the role of persuasive design in unguided ICBT and other eHealth interventions. First, dismantling studies comparing versions of interventions with and without certain persuasive design principles could evaluate the utility of specific principles. Factorial randomized trials of this kind would allow researchers to efficiently evaluate multiple persuasive design principles in a single study. Second, it would be helpful to explore how intervention users experience persuasive design, which could perhaps be achieved through qualitative research or the development of a self-report questionnaire assessing user experiences of persuasive design. Third, the literature would benefit from a more detailed description of persuasive design in unguided ICBT interventions based on a careful review of the interventions themselves (ie, rather than this study's review of descriptions of interventions from randomized trials). Finally, further research will be required to test our finding that persuasive design predicts efficacy in unguided ICBT for depression but not for anxiety.

Conclusions

The literature on ICBT and other eHealth interventions is evolving rapidly. This review has provided an updated meta-analysis of unguided ICBT for depression and anxiety, generally finding smaller effect sizes for depression than for anxiety. It has also documented the wide variability in the use of persuasive design in unguided ICBT and demonstrated through a meta-regression that persuasive design predicts efficacy in unguided ICBT for depression. Persuasive design is a promising avenue for further optimization of eHealth interventions, including ICBT, and an area of research that is worth investigating further.

Acknowledgments

The authors would like to thank Dr Gordon Asmundson, Dr Donald Sharpe, Dr Swati Mehta, and Dr Janine Olthuis for providing valuable feedback on this research. This research was made possible by scholarship funding provided to HCM by the Social Sciences and Humanities Research Council of Canada. This research was also supported by PSPNET, which is led by HDH and funded by the Canadian Government's Ministry of Public Safety and Emergency Preparedness. HDH holds funding from the Canadian Institutes of Health Research, Saskatchewan Health Research Foundation, Saskatchewan Centre for Patient-Oriented Research, and Craig Neilson Foundation. CRFS is currently employed through funding from AFA Försäkring.

Authors' Contributions

HCM and HDH formulated the idea for this study and developed the search terms. HCM conducted the literature search. HCM and CRFS conducted eligibility screening of the identified articles. HCM extracted and analyzed the data and wrote the first draft of the manuscript with support from HDH. All authors contributed to the revision of the manuscript.

Abstract

Background: Self-harm is a growing issue with increasing prevalence rates; however, individuals who self-harm do not often receive treatment. Mobile health (mHealth) interventions are a possible solution to some of the barriers that individuals face when seeking support, and they have also been found to be effective in improving mental health. Thus far, reviews of mHealth interventions for self-harm have been limited by study type. Therefore, we determined that a broader scoping review will provide a more exhaustive understanding of mHealth interventions for self-harm.

Objective: This scoping review aims to identify mHealth interventions for self-harm within the literature, understand the types and features of interventions that have been developed and evaluated, highlight research findings around mHealth interventions for self-harm, and determine what outcomes are typically used to assess the efficacy of interventions.

Methods: A search was conducted using Embase, PubMed, PsycINFO, PsycEXTRA, Web of Science, and the Cochrane Library. Studies were included if they described an mHealth intervention designed to have a direct (ie, if the intervention was designed for self-harm or for people who self-harm) or indirect (ie, if self-harm was measured as an outcome) treatment effect and if the paper was available in English. There were no exclusion criteria based on the study design.

Results: A total of 36 papers were included in the review, and most of them were randomized controlled trials published within the last 4 years. The interventions were mostly smartphone apps and calling or texting services, with 62% (21/34) having underlying therapeutic models to inform the intervention content. They were generally shown to be promising and appealing, but only 5 were widely available for use. Outcomes focused on a reduction of self-harm and suicidality, mood, and the users' experiences of the intervention. Samples were typically nondiverse, and there was limited variety in the study designs and in the measurements of self-harm recovery.

Conclusions: Promising and appealing mHealth interventions have been developed but are not widely available. Research could benefit from greater diversity as well as a broader and more nuanced understanding of recovery from self-harm.

Introduction

Self-harm

The National Institute for Health and Care Excellence defines self-harm as any act of self-injury or poisoning, irrespective of the motivation behind the act [1]. It is a growing concern that can have great physical, psychological [2], and societal [3] costs. Notably, self-harm has been identified as a significant and persistent predictor of suicide [4]. In recent years, the lifetime prevalence of self-harm in the general English population has seen a sharp increase from 2.4% in 2000 to 6.4% in 2014; this was most common in young adult females who reported an increase in prevalence from 6.5% to 19.7% [5]. Furthermore,

given that individuals are often reluctant to disclose their self-harm behaviors due to the shame and stigma associated with it [6], rates of self-harm may be even higher than what these figures suggest [7].

Help for Self-harm

Tørmoen et al [8] surveyed 11,440 young people aged 14-17 years in Norway and found that only 34% of those who had self-harmed had ever sought professional help, indicating that help-seeking is low among those who self-harm [9,10]. Concerns over being perceived as "attention-seeking" or "crazy" and difficulty talking about their self-harm behaviors have been identified as some of the barriers to seek support by adolescents [11]. Furthermore, a lack of effective interventions for self-harm creates barriers to receive support when an individual seeks professional help. The National Institute for Health and Care Excellence guidelines advise against the use of pharmacological treatments for self-harm, instead recommending psychological interventions tailored to self-harm that may involve problem solving, cognitive behavioral or psychodynamic elements [12]. Despite this, to date, there is limited high-quality evidence suggesting that psychological or pharmacological interventions for self-harm are effective [13,14]. Moreover, increased pressure on services and the resulting difficulties with the availability and accessibility of these interventions can further prevent individuals from receiving support [15].

Use of Mobile Health

The use of mobile health (mHealth) may help overcome the barriers to treatment accessibility and availability. mHealth is a branch of eHealth, defined by the Global Observatory for eHealth as "medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants (PDAs), and other wireless devices" [16]. Given the ubiquity of mobile phone ownership [17,18], providing mental health support in this way has the potential to reach many individuals who may not be receiving help for self-harm. mHealth offers multiple possibilities, including self-help smartphone apps, SMS text messaging with a support service, physical symptom tracking through wearable technologies, and receiving virtual therapy [19]. Clough and Casey [20] found that mHealth users felt that receiving virtual mHealth therapy was more beneficial compared with face-to-face therapy, particularly highlighting the freedom they felt to be completely open and honest with their therapist. mHealth tools also have merit as standalone interventions, with some studies reporting reductions in symptoms of mental health difficulties, including anxiety [21], schizophrenia [22], depression [23], and borderline personality disorder [24].

Studies investigating the efficacy of mHealth interventions for managing self-harm have also been reviewed but they are limited. Witt et al [25] identified only one study that included outcome measures of an mHealth intervention for self-harm, whereas Melia et al [26] identified 2. These reviews focused on randomized controlled trials (RCTs) and pre- and poststudies. Arshad et al [27] focused more closely on self-harm and identified 22 studies; however, this was still limited by their decision to exclude qualitative studies and those where self-harm was not the primary outcome. A broader scoping review will help to identify more mHealth tools available for managing self-harm and broaden our knowledge of them.

Aims

This scoping review aims to (1) identify mHealth interventions for self-harm within the literature, (2) understand the types and features of interventions that have been developed and evaluated, (3) highlight research findings around mHealth interventions for self-harm, and (4) determine what outcomes are typically used to assess the efficacy of interventions.

Methods

Overview

A detailed methodology can be found in the review protocol [28]. The following databases were searched in April 2020: Embase, PubMed, PsycINFO, PsycEXTRA, Web of Science, and the Cochrane Library. The reference lists of all papers identified in the searches were also screened. Multimedia Appendix 1 describes the full and detailed search strategy.

After duplicates were removed, the titles and abstracts were initially screened according to the aims of this review and were progressed for a full screening if they met the following inclusion criteria: (1) the study described an mHealth intervention (eg, SMS text messaging, phone calls, or websites accessible through a mobile device) designed to have a direct (ie, if the intervention was designed for self-harm or for people who self-harm) or indirect (if self-harm was measured as an outcome) treatment effect and (2) the paper was in English.

The full texts of the papers that met these criteria were then screened. Before screening the title and abstract, a pilot screening was performed by all 3 reviewers (BC, JT, and IG) on 20 papers selected at random. An interrated reliability check of at least 75% agreement was required to progress the papers to full screening. Initially, 80% agreement was achieved, and the remaining papers were briefly discussed until 100% agreement was achieved. Each paper was screened by at least two reviewers, with a third reviewer resolving any inconsistencies. During the title and abstract screening, there was 98% agreement between the 2 reviewers on each paper, with the others being discussed and resolved again. The full texts of the progressed papers were screened for eligibility.

Data Charting Process

The reviewers extracted predefined data regarding the study details (eg, year and country), participants (eg, number, age, and ethnicity), type of mHealth intervention, study design, measures, and outcomes. Both before and after data extraction, consistency was checked between reviewers using a random sample of papers. Data extraction was an iterative process in which categories were added or amended in accordance with the aims of the review.

Results

Identify mHealth Interventions for Self-Harm Within the Literature

The search results are summarized in Figure 1. A total of 295 papers were identified. After duplicates were removed, 78% (229/295) of titles and abstracts were left to be screened. About 35% (79/229) of titles and abstracts progressed to a full-text screening, resulting in 54% (43/79) of papers being excluded. Of these, 51% (22/43) did not present an mHealth intervention for self-harm, 21% (9/43) were systematic reviews that did not identify any papers not already identified by our search, and 19% (8/43) were protocols for studies for which a full text had since become available. Of the remaining 4 papers, 2 (5%) were replies or comments on other studies, 1 (2%) was a content analysis of apps that were commercially available with no references to an evidence base, and 1 (2%) was a description of an app that had already been identified. A total of 36 papers met the inclusion criteria and are summarized in Table 1.

Figure 1. Flowchart of search results. mHealth: mobile health.

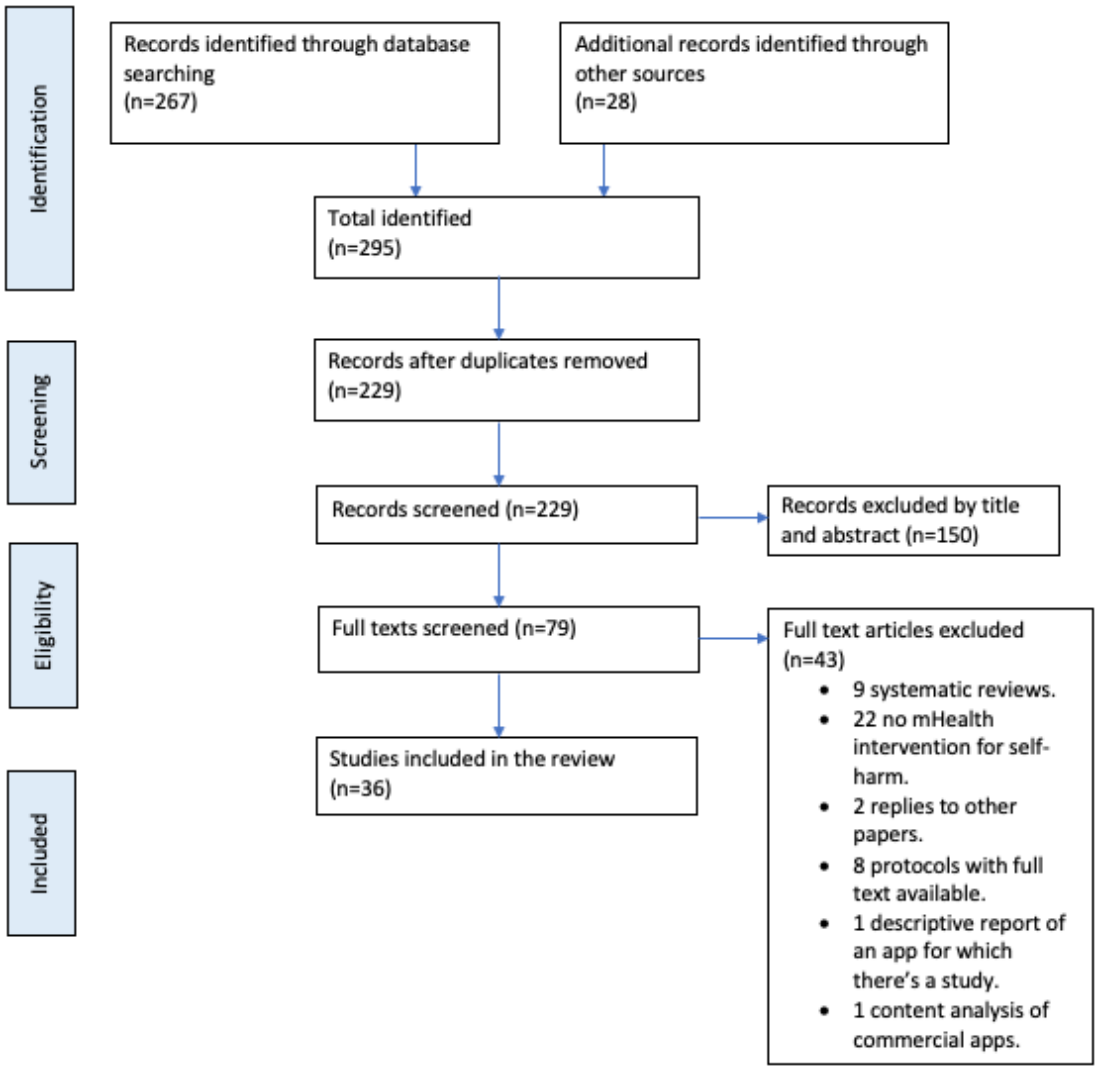

Table 1. Summary of papers (N=36).

Intervention details	Type of intervention	Design	Sample	Type of self-harm	Self-harm measure used	Development	Availability	Improvement in self-harm
Rebound (2019) [29]: *Accessible anytime*[a]	Social network with support from peer workers and clinical psychologists	RCT[b] (protocol)	Youth (aged 14-27 years) in recovery from major depressive disorder–Australia	Suicidal and nonsuicidal self-harm	Risk taking and self-harm inventory	Collaboration with consumers, youth representatives, and clinicians	Not widely available	No data
SIAM (2014) [30]: *9 texts sent, staggered for 6 months following A&E*[c] *discharge*	Supportive and monitoring texts	RCT (protocol)	Adults discharged after suicide attempt–France	Suicidal self-harm	Columbia-Suicide Severity Rating Scale	Developed by the authors	Not widely available	No data
A Virtual Hope Box (2015; 2017) [31,32]: *Accessible anytime*	Smartphone app to help with coping, distraction, relaxation, and positive thinking	Proof of concept; RCT	Army veterans at risk of self-harm or suicide–United States	Suicidal self-harm; suicidal and nonsuicidal self-harm	Semistructured interview; Beck Scale for Suicidal Ideation and Columbia-Suicide Severity Rating Scale	Developed by the Department of Defense National Centre for Telehealth and Technology, with feedback from target users	Free to download	Yes; no
EpxDepression (2017) [33]: *Daily EMA*[d] *for 2-4 months*	Text-based EMA that notifies care team of risk	Proof of concept	Adolescents–United States	Suicidal self-harm	Last question of PHQ[e]-9	Clinicians, researchers, and biostatisticians with feedback from target end users	Available for health care providers on subscription	Yes
Imaginator (2020) [34]: *Accessible anytime*	Smartphone app to promote self-management	RCT	Youth (aged 16-25 years) currently self-harming–United Kingdom	Suicidal and nonsuicidal self-harm	Strength of motivation for reducing self-harm scale, craving experience questionnaire for self-harm, self-harm imagery interview. Self-harm, frequency, severity, and self-efficacy for control were measured with items developed by the enhancer	Codeveloped with youth with lived experience of self-harm	Not widely available	Yes
Therapeutic Evaluative Conditioning (2016) [35]: *Accessible anytime*	Smartphone app to decondition self-harm	RCT	Adults with self-harm–international	Suicidal and nonsuicidal self-harm	Self-injurious thoughts and behaviors interview	Developed by the authors	No longer available	Yes, but did not persist at follow-up
BlueIce (2018) [36,37]: *Accessible anytime*	Smartphone app to help manage urges to self-harm	Pre-post phase 1 trial	Adolescents currently self-harming or at risk of self-harming attending CAMHS[f]—United Kingdom	Nonsuicidal self-harm	Semistructured interview; Self Harm data from clinical records	Coproduced with youth with lived experience of self-harm, with input from clinical staff, academics, and app developers	Available for CAMHS on subscription	Yes
Unnamed (2018) [38]: *Accessible anytime*	Smartphone app for mood monitoring and distraction	Development study	Aged 18-25 years—Australia	Nonsuicidal self-harm	N/A[g]	Designed with target users and clinicians	Not widely available	No data

Intervention details	Type of intervention	Design	Sample	Type of self-harm	Self-harm measure used	Development	Availability	Improvement in self-harm
ClinTouch CareLoop enhance management (2014) [39]: *Accessible anytime; 44 daily ecological momentary assessment alerts*	Smartphone app for mood monitoring and alerting care team of risk	RCT (protocol)	Adults with psychotic disorders—United Kingdom	Suicidal and nonsuicidal self-harm	Unclear	Codeveloped with service users, clinicians, academics, and health professionals	Free to download	No data
Unnamed (2016) [40]: *52 text messages sent twice weekly*	Supportive and informative texts	Intervention study	Adults with suicidal ideation—Japan	Nonsuicidal self-harm	Researchers developed their own questionnaire measuring the presence of self-harm	Psychiatry specialists	Not widely available	Yes
A-CHESS (2017) [41]: *Accessible anytime*	Smartphone app containing safety plan, social network, resources, and interaction dashboard with their therapist	Qualitative study of experience	Presented to emergency department following self-harm—Canada	Suicidal and nonsuicidal self-harm	Last question of PHQ-9, hospital presentations for self-harm	Developed by the network for improvement of addiction treatment with user feedback from focus groups	Available for health care providers on subscription	Yes
Safe Storage Intervention (2015) [42]: *Texts sent daily*	Social contact via phone conversations and texts	Cost-effective analysis (protocol)	Participants recruited to another study–Sri Lanka	Suicidal and nonsuicidal self-harm	Hospital presentations and coroner's data	No data	Not widely available	No data
Brief mobile treatment [43]: *10 staggered phone calls after discharge for 24 weeks; audio messages accessible anytime; text reminders sent weekly*	Phone calls to monitor mood, meditation audio messages, and text reminders of treatment elements	RCT	Aged 15-74 years admitted to hospital after self-harm—Sri Lanka	Suicidal self-harm	Beck Scale for Suicidal Ideation	No data	Not widely available	No
No name (2013) [44]: *Staggered texts that start daily and decline gradually to weekly over 3 months*	Supportive text messages	RCT	Adults in A&E after self-harm—Ireland	Suicidal and nonsuicidal self-harm	Unclear—self-harm repetition	No data	Not widely available	No data
No name (2017) [45]: *Accessible anytime*	Smartphone app to provide care messages, resources, health care contacts, and self-help exercises	RCT (protocol)	Adult in A&E after self-harm—Hong Kong	Suicidal and nonsuicidal self-harm	Hospital presentations and coroner's data	No data	Not widely available	No data
Unnamed (2018) [46]: *12-month treatment period, no further detail*	Smartphone app to augment delivery of problem-solving therapy	RCT (protocol)	Men in A&E after self-harm–Canada	Suicidal and nonsuicidal self-harm	Hospital presentations	No data	Not widely available	No data
TeenTEXT (2016) [47]: *Receiver sets schedule of when texts will be received*	Supportive texts written by the receiver	Feasibility study	Adolescents currently self-harming—United Kingdom	Nonsuicidal self-harm	N/A	Designed with service users with history of self-harm, carers, and clinicians	Not widely available	No data (terminated)

Intervention details	Type of intervention	Design	Sample	Type of self-harm	Self-harm measure used	Development	Availability	Improvement in self-harm
DBT[h] Coach (2016) [48]: *Accessible anytime*	Smartphone app that provides coaching in DBT skills	Pilot	Individuals seeking DBT—United States	Suicidal and nonsuicidal self-harm	SITBI[i], semistructured interviews	Involved DBT experts, target end users, and their clinicians	Available for users on subscription	Yes
Unnamed (2019) [49]: *Delivered over 10-12 sessions*	Audio or video calls to deliver problem-solving CBT[j]	RCT	Aged 16-30 years, depression and self-harm—location unknown	Nonsuicidal self-harm	Urgency Perseverance Premeditation Sensation-seeking Impulsive Inventory urgency subscale	No data	Not widely available	No data (terminated)
MyPlan (2017) [50]: *Accessible anytime*	Smartphone app to store safety plan	RCT (protocol)	Experiencing self-harm—Denmark	Suicidal and nonsuicidal self-harm	Self-reported, no further information	Developed by Skovgaard Larsen et al [51]	Yes (in Denmark and Norway)	No data
SMS SOS (2019) [52]: *Staggered texts that start 48 h after discharge from A&E, declining to monthly for 12 months*	Supportive text messages	RCT (protocol)	In A&E after self-harm—Australia	Suicidal and nonsuicidal self-harm	Hospital presentations	Developed with people with lived experience of self-harm or mental health problems	Not widely available	No data
Crisis Text Line (2020) [53]: *Accessible anytime*	Texting with a crisis counselor	Trend analysis	No criteria—international	Suicidal and nonsuicidal self-harm	N/A	Crisis text line is a global organization	Available globally	N/A
SPARX (2020) [54]: *Must complete program within 6 weeks*	Game-style smartphone app	RCT (protocol)	Year 8 school students—Australia	Suicidal and nonsuicidal self-harm	Self-harm questionnaire	Developed with young people	Yes (in New Zealand)	No data
ERITA (2018) [55]: *12 weeks to complete 11 modules*	Website and companion app to receive treatment for emotion regulation	Pilot	Adolescents with self-harm—Sweden	Nonsuicidal self-harm	Deliberate self-harm inventory	Developed by the authors	Not widely available	Yes
CATCH-IT[k] (2009) [56]: *Recipients had 3 phone calls, no further information*	Therapy provided via website with motivational interviewing phone calls	RCT	Aged 14-21 years with subthreshold depression—United States	Nonsuicidal self-harm	PHQ-A	Developed by the authors	Not widely available	Yes
Unnamed (1999) [57]: *Accessible anytime for 6 months following discharge*	Telephone crisis consultation with on-call psychiatrist	RCT	Adult inpatients with self-harm—United Kingdom	Nonsuicidal self-harm	Hospital presentations	No data	Not widely available	No
Unnamed (2020) [58]: *A module per week for 6 weeks*	Web-based intervention to provide CBT-based modules	RCT	Turkish adults with suicidal ideation—United Kingdom and Netherlands	Suicidal self-harm	Self-harm questionnaire	Developed by van Spijker et al [59] adapted by the authors	Not yet, but will be if findings are positive	Yes
Unnamed (2018) [60]: *Encouraged to write 5mina day for 28 days*	Web-based diary	RCT	Adults on an online forum who self-harm—international	Suicidal and nonsuicidal self-harm	SITBI	Developed by the author	Technique can be adopted	Yes

Intervention details	Type of intervention	Design	Sample	Type of self-harm	Self-harm measure used	Development	Availability	Improvement in self-harm
Uncut (2014) [61]: *Ecological momentary assessment*	App to track mood and practice DBT skills, therapist can monitor progress	Development study	Self-harm experts—Austria, Germany, and United States	Nonsuicidal self-harm	N/A	Developed with international psychological experts	No data	No data
Living under control (2017) [62]: *A module per week for 6 weeks*	Web-based intervention providing 6 modules around managing thoughts and feelings	RCT (protocol)	Adults—Denmark	Suicidal and nonsuicidal self-harm	Hospital records and self-report questionnaire (no further information)	Developed by van Spijker et al [63] with mental health professionals who work with people experiencing suicidality	Not yet, but will be if findings are positive	No data
Crisis Care (2017) [64]: *Accessible anytime*	Smartphone app containing coping skills, distraction activities, and a help me now section	Pilot study	Adolescent psychiatry outpatients—United States	Suicidal self-harm	N/A	Developed by the author	Not widely available	Yes
Monsenso (2020) [65]: *Accessible anytime*	Smartphone app providing DBT skills and mood monitoring; links with clinicians database	RCT (protocol)	Adults with borderline personality disorder and self-harm—Denmark	Suicidal and nonsuicidal self-harm	Self-harm inventory	Developed by the author	Available for health care providers on subscription	No data
Unnamed (2019) [66]: *No details yet*	Supportive text messages	Development study	Adolescents with self-harm—China	Nonsuicidal self-harm	N/A	Developed with youth with lived experience of self-harm	No data	No data
Unnamed (2020) [67]: *Unlimited access every evening*	Peer-supported hotline	Trend analysis	Teenagers—United States	Suicidal and nonsuicidal self-harm	N/A	Founded by mental health professionals	Available to teenagers in the United States	N/A

[a]Italics refer to the intervention duration.

[b]RCT: randomized controlled trial.

[c]A&E: accident & emergency.

[d]EMA: ecological momentary assessment.

[e]PHQ: patient health questionnaire.

[f]CAMHS: Child and adolescent mental health services.

[g]N/A: not applicable.

[h]DBT: dialectical behavior therapy.

[i]SITBI: self-injurious thoughts and behaviors interview.

[j]CBT: cognitive behavioral therapy.

[k]CATCH-IT: Competent Adulthood Transition with Cognitive Behavioural Humanistic and Interpersonal Training.

The 36 papers related to 35 separate studies, 2 of which were published from the same study with one paper detailing the quantitative findings [36] and the other the qualitative findings [37]. They were therefore not removed as duplicates; however, as the study details were the same, the study characteristics were merged to not present the same information twice.

A total of 12 papers reported protocols. The corresponding authors were contacted to request any update or preliminary findings; a preprint paper was received from one, so the protocol was replaced with this and the data were extracted. The remaining 11 protocols had no further data at the time of this review (April-June 2020).

The most common study design was the RCT (20/35, 57%), with most papers published between 2014 and 2020 (33/35, 94%). Studies were most commonly conducted in Europe (14/35, 40%) and North America (7/35, 20%). Most studies measured self-harm using various self-report questionnaires (18/35, 51%) and looked at both suicidal and nonsuicidal self-harm (19/35, 54%).

Participants

The participant data are summarized in Table 2. Sample sizes ranged from 3 to 122,909, involving mostly clinical cohorts (24/35, 69%), and approximately half were adult samples (18/35, 51%), with one focusing specifically on young adults (aged 18-25 years). None of the studies included children aged <12 years and adults aged >65 years. Gender was reported in 18 papers, with the majority including more females than males (14/18, 78%); only 1 study included a nonbinary participant (1/18, 6%). Most papers provided no data on ethnicity (25/35, 71%) and those that did recruited mostly White people (8/10, 80%). Presenting problems screened for or required as inclusion criteria among the samples were primarily self-harm (26/35, 74%), depression (22/35, 63%), suicidal ideation (15/35, 43%), and suicide attempts (15/35, 43%).

Table 2. Participant characteristics (n=35).[a]

Characteristic	n (%)	Study
Age (years)

Understand the Types and Features of Interventions That Have Been Developed and Evaluated

Characteristics of mHealth Interventions

Intervention characteristics are summarized in Table 3 and relate to 34 interventions. As mentioned earlier, another 2 papers reported on different trials of the same intervention. Most studies described apps (15/34, 44%) or texting or calling services (13/34, 38%), and most interventions required a mobile phone (16/34, 47%) or a smartphone (11/34, 32%), whereas the rest required any internet-enabled device (4/34, 12%) or an iPod touch (1/34, 3%). Approximately half of the interventions did not include any face-to-face support (16/34, 47%); of these, 9 were standalone interventions (9/16, 56%), 7 included an element of human support provided digitally (ie, texts from a clinician; 7/16, 21%), and 2 exclusively provided digital support (ie, a hotline; 2/16, 13%). A range of underpinning therapeutic models informing the intervention content were reported, with 21 studies (21/34, 62%) citing at least one approach and cognitive behavioral therapy being the most common (10/34, 29%). Supportive messages or phone calls were the most common elements among the interventions (14/34, 41%). Only 3 (9%) papers specified that the interventions contained a safety plan.

Table 3. Intervention characteristics (n=34).[a]

Intervention characteristics	n (%)	Study

[a]Bush et al (2015) [31] and Bush et al (2017) [32] relate to the same intervention; Grist et al (2018) [36] and Stallard et al (2018) [37] are separate papers from the same study.

Development and Availability

Half of the mHealth interventions were developed with multiple collaborators (17/34, 50%), including mental health professionals (10/34, 29%), target end users (11/34, 32%), and companies or organizations (3/34, 9%). Most interventions were not currently available to the public (20/34, 59%). Conversely, only 15% (5/34) are publicly available, whereas others are available for purchase by health care professionals or services (4/34, 12%) or users (1/34, 3%). Table 1 provides further details on the intervention development and availability.

Highlight Research Findings Around mHealth Interventions for Self-Harm

Study Findings

Of the 19 papers that reported outcomes, 14 (74%) reported positive findings postintervention. Of the 5 studies that did not report positive findings, 2 (26%) were terminated during recruitment due to a lack of feasibility. One study noted that this was due to high levels of depression and the reluctance of participants who self-harmed to engage with mental health services [49], whereas the other suggested it was a good intervention but Child and Adolescent Mental Health Services was the wrong setting due to clinicians' time constraints [47]. Furthermore, 3 studies reported no significant effect of the intervention on self-harm recovery [32,43,57], one of which cited past episodes of self-harm as a barrier to efficacy [57].

Clinician and parental attitudes were typically favorable toward the interventions [31,32,38,41,47,64], with only 2 papers reporting concerns [38,47]. The identified benefits include promoting self-efficacy [32,58], helping difficult disclosure [33], immediate access [43], time and cost benefits [55], encouraging help-seeking [40], being useful in crises [64,66], and having a positive influence on the therapeutic alliance in the face-to-face element within blended approaches [41,58]. Barriers were not commonly mentioned in the papers, although 2 papers did note that digital interventions that were administered by a mental health worker posed challenges due to the lack of engagement with mental health services among people who self-harm [47,49].

Determine What Outcomes Are Typically Used to Assess the Efficacy of Interventions

The study outcomes are summarized in Table 4. Most studies had multiple outcomes related to self-harm (21/35, 60%), suicide attempts (19/35, 54%), suicidal ideation (16/35, 46%), intervention experience (16/35, 46%), and engagement with the intervention (13/35, 37%). Other mental health issues such as depression (16/35, 46%) and anxiety (9/35, 26%) were also considered. Outcomes related to self-harm mostly focused on episode frequency (14/21, 67%), whereas others focused on repeated presentations to hospital (5/21, 24%) or self-harm thoughts or urges (4/21, 19%).

Table 4. Study outcomes (n=35).[a]

Outcome	n (%)	Study
Mental health		
SH[b] frequency	14 (40)	[29,34-37,39,40,42,44,45,54-60,62]

[b]SH: self-harm.

Discussion

Principal Findings

This scoping review identified 36 papers relating to 34 separate mHealth tools for managing self-harm. Papers were primarily RCTs and protocols published in Europe or North America within the last 6 years. This recent increase in papers reflects the growing interest in developing evidence-based mHealth interventions to improve access to psychological therapies. The large number of protocols suggests that this trend will continue as more findings are published in the coming years. Participants were mostly White adult females recruited from clinical populations, with only one nonbinary participant across all the studies, and many did not report the ethnicity of their participants. This is concerning given the high prevalence of self-harm found in both ethnic [68] and gender minorities [69]. It is possible that other nonbinary or gender-diverse individuals participated in these studies, but they were not truly represented in the way that the researchers assessed or reported participant demographics.

Depression and anxiety were the 2 most highly studied comorbidities, which is consistent with research suggesting strong correlations between these disorders and self-harm [70]. The interventions most commonly studied were not blended with any face-to-face support and were mostly text or call-based services or apps used on mobile phones or smartphones. Considering the ubiquity of both mobile phones [17,71] and smartphones [71], this is a positive finding and suggests that there are indeed mHealth interventions that could be more widely accessed. Interestingly, no interventions designed for use on other devices, such as wearable technologies, have been identified. This is despite research suggesting that they are acceptable for treating mental health issues among those who do not typically engage with mental health services [72]. However, this is still a relatively new area, and wearable devices designed to treat or help manage mental health difficulties are predicted to increase over the next few years [73].

Several studies did not specify any underpinning therapeutic models informing the content of their intervention, which raises concerns given the unhelpful and even dangerous advice that

has been found in other freely available mental health apps [74]. Similarly, less than a third of the interventions were developed with individuals who have lived experience of self-harm, despite evidence suggesting that this could lead to more effective interventions being developed. Given the expertise of those with lived experience of self-harm, their input is essential [75,76].

Most studies testing interventions reported overall promising findings, suggesting that mHealth can be a viable tool for people struggling with self-harm. The study outcomes largely promoted a reduction in self-harm frequency over and above others, such as a reduction in self-harm urges or severity. Although reduced frequency is a common measure of self-harm recovery within research, it has been argued that it is not advisable to rely solely on this; a reduction in self-harm episodes may mean that each episode has become more severe or has been replaced with a different type of self-destructive behavior [77]. Overall, there needs to be a more consistent framework to assess outcomes from self-harm research, with further research looking into the maintenance of positive outcomes. Similarly, there was considerable variation in the tools used to measure self-harm across the studies. This makes comparisons between studies difficult; therefore, greater consistency may also be beneficial.

Another commonly observed finding was the clinicians' favorable attitudes toward the intervention. This reflects overall positive attitudes and an eagerness to incorporate technology into practice found in research on clinicians' attitudes toward technology in mental health care [78]. This is important considering that there is research highlighting that clinicians' attitudes are pivotal in intervention implementation [79].

A barrier to the implementation of blended interventions that required clinician involvement was the lack of engagement that people who self-harm have with mental health services. This is consistent with the body of literature that corroborates the lack of professional help-seeking among people who self-harm [8-11] and further emphasizes the need for mHealth interventions for self-harm that individuals can access easily and discretely. Despite many studies having positive outcomes, it seems that not many of the interventions studied are readily available to the general public or even to those attending mental health services. Moreover, few papers made this information apparent, so information on availability was sought from internet and app store searches and by contacting the authors of the papers.

Implications for Future Research

This review identified several limitations in the current literature on mHealth tools for managing self-harm. Notably, research thus far has been limited to White adult females from western societies, yet self-harm has been identified as a significant issue among minority groups [68,69], highlighting the need to diversify research by recruiting understudied groups such as males and minority populations who may also benefit from mHealth interventions. It is also important for future studies to report the ethnicity of participants. Similarly, participants have mostly been from clinical samples; however, given that people who self-harm do not often seek professional help, it is possible that findings from clinical samples may not necessarily be generalizable to wider populations who self-harm. Therefore, it is important to assess the efficacy of interventions in community samples. It is also essential for more intervention developers to collaborate with people who have lived experience of self-harm, given the limited instances thus far highlighted in this review.

Another notable point is that the measurements of self-harm recovery were typically restricted to a reduction in the frequency of episodes and, although this may be a useful assessment, it may also be worth considering measuring other elements as well, such as the severity of self-harming episodes or any other substitute self-destructive behaviors.

Another consideration to take forward from this review is the reliance on RCTs to evaluate digital interventions. Although RCTs have long been considered the gold standard method, the pace at which digital interventions develop and evolve means that the data can be outdated before the trial has been completed [80-82]. Following this, it may be prudent for future research to also consider different study designs, such as pre- and posttests that can keep up with the rapid development of digital interventions. Furthermore, RCTs can indicate whether an intervention is effective but may be limited in their ability to explore the reason [83]. Therefore, it may also be beneficial for future research to apply the NIMH's experimental therapeutics approach or use qualitative studies that can contribute further to the understanding of how and why certain interventions are effective as well as whether they are safe and do no harm. Similarly, the application of the experimental therapeutic approach may contribute further to the understanding of how and why certain interventions are effective [84]. Future work should also focus on the implementation and dissemination of effective interventions, following the lack of availability of interventions within the papers in this review.

Limitations

As the purpose of this review was to collate the data available on mHealth tools for managing self-harm, there was no scope to conduct a quality assessment of the included studies. This means that we cannot verify that the research included here is of sufficient quality to draw concrete inferences from. This review may also have been limited by the decision to not include any papers for which there was no English version available. Nonetheless, this review offers insight into the current evidence base for mHealth interventions for self-harm.

Conclusions

This review has synthesized the current evidence for mHealth tools for managing self-harm. Overall, there are useful interventions that have been developed to promote recovery from self-harm. However, certain limitations pose challenges in drawing firm conclusions from the included studies. Suggestions for how future research can improve upon this have been made, in the hope of developing a robust evidence base so that clinicians and users are better equipped to make informed decisions about which mHealth tools to use. This will hopefully help to overcome some of the barriers that people who self-harm face in accessing support.

Abstract

Background: Mobile health (mHealth) interventions can increase physical activity (PA); however, their long-term impact is not well understood.

Objective: The primary aim of this study is to understand the immediate and long-term effects of mHealth interventions on PA. The secondary aim is to explore potential effect moderators.

Methods: We performed this study according to the Cochrane and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. We searched PubMed, the Cochrane Library, SCOPUS, and PsycINFO in July 2020. Eligible studies included randomized controlled trials of mHealth interventions targeting PA as a primary outcome in adults. Eligible outcome measures were walking, moderate-to-vigorous physical activity (MVPA), total physical activity (TPA), and energy expenditure. Where reported, we extracted data for 3 time points (ie, end of intervention, follow-up ≤6 months, and follow-up >6 months). To explore effect moderators, we performed subgroup analyses by population, intervention design, and control group type. Results were summarized using random effects meta-analysis. Risk of bias was assessed using the Cochrane Collaboration tool.

Results: Of the 2828 identified studies, 117 were included. These studies reported on 21,118 participants with a mean age of 52.03 (SD 14.14) years, of whom 58.99% (n=12,459) were female. mHealth interventions significantly increased PA across all the 4 outcome measures at the end of intervention (walking standardized mean difference [SMD] 0.46, 95% CI 0.36-0.55; *P*<.001; MVPA SMD 0.28, 95% CI 0.21-0.35; *P*<.001; TPA SMD 0.34, 95% CI 0.20-0.47; *P*<.001; energy expenditure SMD 0.44, 95% CI 0.13-0.75; *P*=.01). Only 33 studies reported short-term follow-up measurements, and 8 studies reported long-term follow-up measurements in addition to end-of-intervention results. In the short term, effects were sustained for walking (SMD 0.26, 95%

CI 0.09-0.42; *P*=.002), MVPA (SMD 0.20, 95% CI 0.05-0.35; *P*=.008), and TPA (SMD 0.53, 95% CI 0.13-0.93; *P*=.009). In the long term, effects were also sustained for walking (SMD 0.25, 95% CI 0.10-0.39; *P*=.001) and MVPA (SMD 0.19, 95% CI 0.11-0.27; *P*<.001). We found the study population to be an effect moderator, with higher effect scores in sick and at-risk populations. PA was increased both in scalable and nonscalable mHealth intervention designs and regardless of the control group type. The risk of bias was rated high in 80.3% (94/117) of the studies. Heterogeneity was significant, resulting in low to very low quality of evidence.

Conclusions: mHealth interventions can foster small to moderate increases in PA. The effects are maintained long term; however, the effect size decreases over time. The results encourage using mHealth interventions in at-risk and sick populations and support the use of scalable mHealth intervention designs to affordably reach large populations. However, given the low evidence quality, further methodologically rigorous studies are warranted to evaluate the long-term effects.

Introduction

Background

In recent decades, populations have become increasingly sedentary. The World Health Organization (WHO) recommends 150 minutes of moderate-intensity physical activity (PA) or 75 minutes of vigorous-intensity PA per week for adults and 60 minutes of moderate-to-vigorous physical activity (MVPA) for adolescents per day [1]. An estimated 28% of adults worldwide do not meet these guidelines [2]. The prevalence of inactivity is high in Latin America and many high-income countries, with approximately every second adult inactive in Brazil or Saudi Arabia, and 40% of adults insufficiently active in the United States [2].

According to the WHO, physical inactivity is 1 of the 4 core modifiable risk factors for noncommunicable diseases (NCDs). As such, it is as important to be addressed as tobacco use or obesity and proven to increase the risk of cancer, cardiovascular diseases, diabetes, dementia, and depression [3-6].

In response to the high prevalence and substantial risk posed by physical inactivity, the WHO has formulated a target to reduce physical inactivity by 10% by 2025 as part of its strategy against NCDs [7]. Scaling up PA interventions is key to achieving the WHO target. However, there are various barriers, including cost, resource restrictions, and poorly scalable intervention designs [8,9]. Owing to the increasing dissemination and ubiquity of mobile technology, mobile technology–based interventions, that is, mobile health (mHealth), have been discussed as a solution for overcoming scalability challenges [10,11]. There are only a few examples of nationwide mHealth programs such as the *NHS Diabetes Prevention Program* [12] in the United Kingdom, the 10,000 steps program in Australia [13], and the *National Steps Challenge* and *Live Healthy SG* in Singapore [14,15]. Most governments and health organizations are still hesitant about rolling out mHealth PA programs, as clear evidence for the effectiveness of mHealth interventions for sustainable behavior change is lacking [16,17].

Previous evidence for the effectiveness of mHealth interventions on PA is mixed (Multimedia Appendix 1 [18-31]). Most existing meta-analyses found significant positive effects on PA in sick and at-risk populations, with effect sizes ranging from small to large [18-28]. However, some studies did not find significant effects or reported conflicting results [29-31]. There is limited evidence for the sustainability of increased PA levels beyond the end of intervention. Only 2 studies quantitatively analyzed long-term effects: one review found that PA increases are maintained up to 3-4 years after the intervention [20] and the other did not find significant long-term results [31]. Kirk et al [25] and Romeo et al [30] found that shorter mHealth PA interventions (<16 weeks and <12 weeks, respectively) are more effective than longer ones, indicating that effects might not be maintained in the long term.

We also lack clarity on how population types, intervention design, and control group type moderate the impact of mHealth interventions on PA. Only 3 studies performed subgroup analyses according to population type with mixed results. A total of 2 studies found interventions to be equally effective in sick and healthy populations [23,30], and 1 review found mHealth interventions to be more effective in sick populations; however, the results were not statistically significant [27]. Most studies focused exclusively on sick or at-risk populations [21,22,24-26,28,31], making it difficult to draw clear conclusions.

The design of mHealth interventions influences the degree to which they are scalable. The promise of mHealth is that the technology itself (ie, without costly and limited human resources) promotes active lifestyles. However, these highly scalable interventions miss the element of human-to-human interaction, which is a potentially important active ingredient in behavior change interventions. Current evidence draws an inconclusive picture: existing studies have found no effects on PA when interventions are scalable [24,30] (ie, mHealth interventions without human-to-human interactions), stronger effects when interventions are nonscalable (ie, mHealth interventions with human-to-human interactions) [27,32], stronger effects in scalable interventions [20], or no moderating effects [22]. Thus, we need a comprehensive evaluation of scalable versus nonscalable designs to judge the potential of mHealth technologies in reaching large populations at low costs.

Furthermore, our current understanding of the effects of mHealth PA interventions is limited by the inclusion of different control groups in previous studies. Most previous studies included both

minimal or no intervention control groups and control groups receiving an alternative intervention [18-20,22-29,31]. This makes it impossible to distinguish between the absolute effect of mHealth PA interventions on behavior and the degree to which mHealth interventions are superior to alternative nonmobile designs or the standard of care.

Objectives

Accordingly, we sought to comprehensively collate and analyze trials evaluating mHealth interventions that promote PA in adult populations. Our primary aim is to understand the long-term impact of these interventions on PA. Our secondary aim is to explore potential effect moderators (population type, intervention design, and control group type), to understand which populations can benefit from mHealth interventions, to understand if scalable mHealth intervention designs are effective, and to understand if mHealth interventions produce superior results to nonmobile interventions.

Methods

Overview

This study was performed according to the Cochrane methodology, and the results were reported following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. We searched PubMed, the Cochrane Library, SCOPUS, and PsycINFO for randomized controlled trials (RCTs) on mHealth interventions targeting PA increases (all search strategies are given in Multimedia Appendices 2 and 3) published from database inception to July 3, 2020. We also searched the reference lists of the relevant existing systematic reviews for eligible studies. This study was registered with PROSPERO (CRD 42019124716).

Eligibility Criteria

Studies were eligible if they assessed the impact of mHealth interventions on PA as a primary study outcome in individuals aged 18 years or more and were published in English. Eligible study designs were RCTs or cluster RCTs. Eligible comparators comprised no or minimal interventions and alternative interventions that did not include mobile technologies.

Types of Interventions

mHealth interventions were defined as programs that fully or partly deliver interventions using mobile technology such as pedometers or accelerometers with displays, activity trackers, smartphones, or tablets. We excluded interventions where the use of a mobile device was unclear (eg, telephone or website interventions) or where increasing PA was not the primary outcome. This was to ensure that interventions genuinely aimed to increase PA and to avoid including studies measuring PA only as a supplemental outcome.

Types of Outcomes

Eligible outcome measures were walking, MVPA, total physical activity (TPA), and energy expenditure (EE), as these outcomes are most commonly reported. Multiple outcome units were eligible per outcome measure (eg, walking in minutes and walking in steps). Studies reporting objectively measured or self-reported outcome data were eligible.

Data Collection Process

Abstracts of all identified papers were exported and uploaded into Covidence Systematic Review software (Veritas Health Innovation Ltd, version accessed July 2020) for screening. Two reviewers independently screened the abstracts for eligibility (AM, JNK, or KI). If reviewers doubted whether an article was potentially relevant, it was included for full inspection. Next, full texts of potentially eligible papers were uploaded into Covidence and screened by 2 independent reviewers (AM, JNK, or KI). Conflicts were resolved by discussion or where required by a third reviewer. We contacted authors of potentially relevant articles for further information when needed. All reviewers were trained during a full-day workshop on eligibility criteria and software before screening.

Data Extraction and Management

Data for each study were extracted independently by 2 reviewers (AM, JNK, KI, AJH, or GWT) using standardized extraction forms. Conflicts were resolved by discussion between 2 primary reviewers or with a third, independent reviewer. All reviewers were trained to use the extraction form and Cochrane risk of bias criteria during a full-day workshop. Where reported, data were extracted for all 4 eligible outcome measures (walking, MVPA, TPA, and EE) and time points (end of intervention, short-term follow-up [≤6 months after the end of intervention], and long-term follow-up [>6 months after the end of intervention]). If studies reported both objectively measured and self-reported outcome data, the former were used for meta-analysis. If studies only reported self-reported outcome data, these were extracted, and the quality of evidence was rated as high risk of detection bias. Data were extracted as means and SDs per outcome measure and time point. If SDs were not reported, they were calculated using the RevMan calculator and following the Cochrane Handbook [33]. Respective authors were contacted for any missing data.

Assessment of Risk of Bias in Included Studies

Two reviewers (AM, JNK, KI, AJH, or GWT) independently assessed the risk of bias for each study using the Cochrane Collaboration tool [34]. Additional criteria for cluster RCTs were assessed [35] and documented within the *other bias* domains of the Cochrane Collaboration tool. Discrepancies were resolved by consensus between reviewers or where needed by a third reviewer. We classified studies as overall high risk of bias if they scored high in any bias domain other than *performance bias*, as blinding of participants and personnel is almost impossible in mHealth intervention studies [23]. Blinding of outcome assessors was rated as high risk if outcomes were self-reported.

Statistical Methods

We summarized the intervention and sample characteristics of all the included studies. We quantitatively analyzed the data using RevMan software (Cochrane, version 5.4) and a DerSimonian and Laird random effects model for our meta-analysis [36]. We reported all 4 outcome measures using standardized mean differences (SMDs) and 95% CI. Where

appropriate (eg, if one mHealth intervention was compared with a minimal and alternative nonmobile intervention), we combined means and SDs of control or intervention groups following the Cochrane Handbook [33]. We classified populations into 3 groups based on the reported recruitment criteria: sick, at-risk, and healthy. The sick group included populations experiencing illnesses such as diabetes, cancer, chronic obstructive pulmonary disease, and coronary heart disease. The at-risk group included inactive or sedentary, older, overweight, and obese populations. We classified mHealth interventions into 2 designs: scalable and nonscalable. Scalability is defined as the ability to scale up an intervention without requiring human resources. Consequently, scalable mHealth interventions were defined as interventions that only leveraged automated components without any human-to-human interactions. Nonscalable mHealth interventions included human-to-human interactions, such as coaching, in-person feedback, or group activity sessions. We classified control groups into no or minimal interventions (no intervention or information material only) and alternative (nonmobile) interventions.

Following the recommendations of Richardson et al [37] and the Cochrane Handbook [33], a subgroup analysis was performed based on end-of-intervention values for all outcomes where at least 10 studies were available. We a priori defined 3 subgroup analyses following the population, intervention, comparison, and outcome framework [33] to identify possible effect moderators. Our aim is to understand the impact of population type (sick, at-risk, and healthy), intervention design (scalable and nonscalable), and control group type (no or minimal and alternative).

We present the primary results using forest plots for each outcome and time point. Subgroup analyses were displayed in forest plots using end-of-intervention data. We quantified inconsistencies between studies using the I^2 statistics (ie, the varying effect estimates towing to heterogeneity rather than chance) [33]. We classified I^2>50% as having substantial heterogeneity [38]. We examined the significance of heterogeneity using chi-square tests (P≤.05). We assessed subgroup differences following the guidelines given by Richardson et al [37], which recommend testing for significant subgroup differences (P≤.10) and covariate distribution and comparing heterogeneity and effect sizes between subgroups. Funnel plot analysis was used to detect sampling bias. We used end-of-intervention effect values in our funnel plot analyses, as all studies reported this time point.

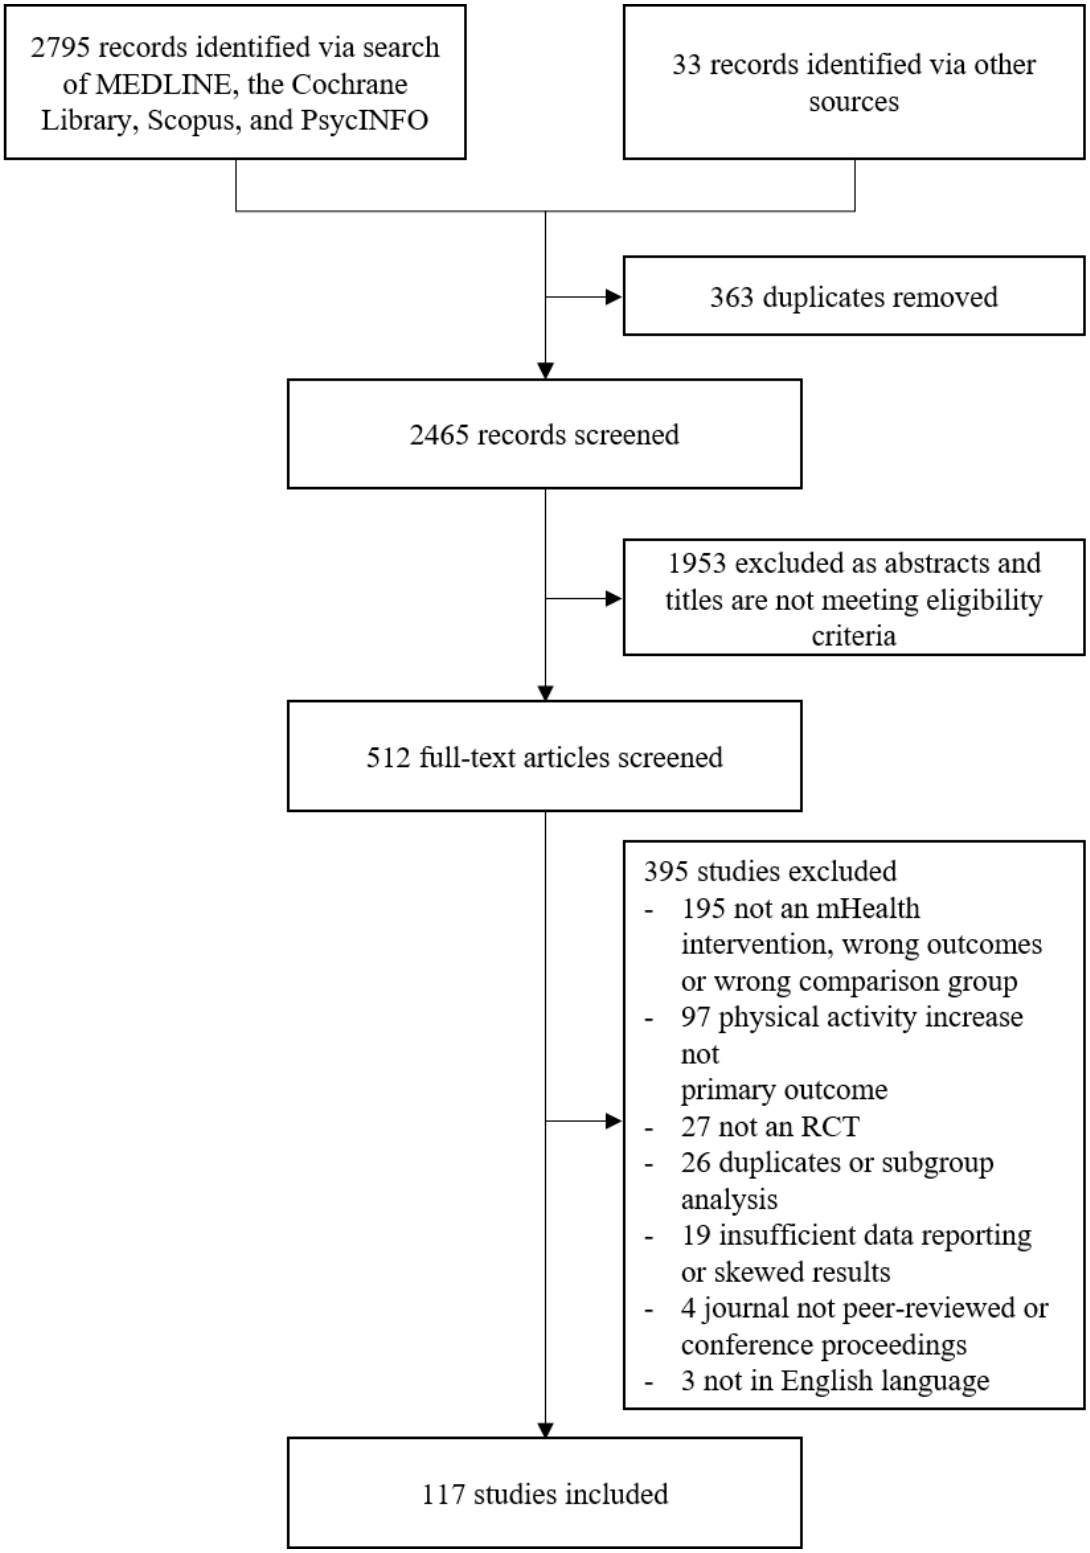
We conducted 3 sensitivity analyses to evaluate the robustness of our primary results: first, we excluded outlier studies; second, we excluded studies with high risk of bias; and third, we excluded studies not reporting long-term follow-up measurements to keep the study sample consistent across all time points. We used the grading of recommendations, assessment, development, and evaluation (GRADE) framework to assess the quality of evidence at the outcome measure level for the end-of-intervention time point and to report the standardized quality of evidence profiles, following the study by Guyatt et al [39].

Results

Overview

Of the 2828 identified studies, 512 full-text articles were screened, and 117 studies were included in the meta-analysis (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) chart. mHealth: mobile health; RCT: randomized controlled trial.



Study Characteristics

Multimedia Appendix 4 [40-156] contains the included studies and their characteristics. The 117 trials represented 21,188 participants with a mean age of 52.03 years (SD 14.14), of whom 58.99% (12,459/21,118) were female. Most studies were conducted in high-income, developed regions such as North America (43/117, 36.8%), Europe (39/117, 33.3%), and Australia and New Zealand (24/117, 20.5%). Very few studies were conducted in Asia (7/117, 6.0%), Latin America (3/117, 2.6%), or Africa (1/117, 0.9%), limiting the representativeness of the evidence for low-income countries. Sample sizes ranged widely (from 15 to 1442), and the intervention duration ranged from 1 week to 2 years. All but one study [40] reported end-of-intervention results, 33 studies reported short-term follow-up results [40-72], and only 8 studies reported long-term

follow-up results [61,72-78]. The mean time point for the short-term follow-up was 4.14 months (SD 2.08) after the end of intervention. The long-term follow-up measurement was taken on average after 13.96 months (SD 11.91).

Walking was the most reported outcome measure (77/117, 65.8%) [41,43,44,48,50-54,58-60,63-65,67-69,72-130], followed by MVPA (62/117, 53.0%) [42,44,46,47,49,51-55,57,59,61-64,68,70-76,78-80,82,84-87,89-91,94,98,104,107,109,112,114,117,125,126,131-147], TPA (33/117, 28.2%) [44,45,50,52,54,56,64,66,72,74,76-78,84,85,89,96,110-112,114,118,131,135,146,148-154,157], and EE (5/117, 4.3%) [61,103,137,155,156]. Most RCTs were conducted in at-risk (48/117, 41.0%) or sick populations (46/117, 39.3%). Only 19.7% (23/117) of the studies tested mHealth interventions in healthy populations within a preventative setting. In most interventions, mHealth technologies were leveraged in nonscalable intervention designs (71/117, 60.7%). Human-to-human interactions included individual coaching, group coaching, PA classes, and physical education classes. Of the 117 interventions, 45 (38.5%) used mHealth technologies without any human-to-human interactions and were thus classified as scalable. In 1 study [75], 2 mHealth interventions (scalable and nonscalable) were combined. Most mHealth interventions only leveraged basic technologies such as pedometers or accelerometers (86/117, 73.5%), text messages (20/117, 17.1%), or websites (20/117, 17.1%). Although some recent studies pioneered innovative mHealth technologies [49,96], overall, only a few studies used advanced mHealth technologies such as automated individualized feedback (19/117, 16.2%), mobile phone apps (15/117, 12.8%), social comparison (10/117, 8.5%), and automated coaching or virtual advisors (5/117, 4.3%). Most studies had no or minimal intervention control groups (83/117, 70.9%). Only a few trials had alternative intervention control groups (22/117, 18.8%). Different control group types were combined into one control group in 12 cases.

Meta-analysis of mHealth Interventions on PA

Overall, mHealth interventions significantly increased PA across all 4 outcome measures at the end of intervention: walking SMD 0.46 (95% CI 0.36-0.55; $P<.001$; $I^2=83\%$, $P<.001$); MVPA SMD 0.28 (95% CI 0.21-0.35; $P<.001$; $I^2=62\%$, $P<.001$); TPA SMD 0.34 (95% CI 0.20-0.47; $P<.001$; $I^2=77\%$, $P<.001$); and EE SMD 0.44 (95% CI 0.13-0.75; $P=.005$; $I^2=60\%$, $P=.04$; Figures 2-9). Short-term effects were sustained (≤6 months after the end of intervention) for 3 of 4 outcome measures: walking SMD 0.26 (95% CI 0.09-0.42; $P=.002$; $I^2=73\%$, $P<.001$); MVPA SMD 0.20 (95% CI 0.05-0.35; $P=.008$; $I^2=72\%$, $P<.001$); and TPA SMD 0.53 (95% CI 0.13-0.93; $P=.009$; $I^2=87\%$, $P<.001$). Only one study [61] reported short-term follow-up measurements for EE, and the results were not statistically significant. In addition, long-term (>6 months after the end of intervention) effects were sustained for 2 of 4 outcome measures: walking SMD 0.25 (95% CI 0.10-0.39; $P=.001$; $I^2=68\%$, $P=.004$) and MVPA SMD 0.19 (95% CI 0.11-0.27; $P<.001$; $I^2=0\%$, $P=.44$). TPA results were sustained, but the effects were just below the significance threshold (SMD 0.19, 95% CI 0.00-0.38; $P=.05$; $I^2=72\%$, $P=.003$). Again, only one study [61] reported long-term follow-up effects for EE, which were not statistically significant. Effect sizes decreased over time, from almost moderate at the end of intervention to small during the long-term follow-up measurement. We found substantial and significant heterogeneity across all outcomes and most time points, with I^2 ranging from 60% to 83% for end-of-intervention measurements (Figures 2-9).

Publication Bias Assessment

Publication bias was assessed using funnel plot analysis for end-of-intervention measurements, as all but one study [40] reported this time point (Multimedia Appendix 5 [54,82,102]). No systematic publication bias was observed. However, the funnel plot analysis revealed 3 outlier studies [54,82,102]. We identified unusually high adherence rates [54], possibly because the research team and the study participants were based on the same campus, and a short intervention duration (only 4 weeks) [82,102] as potential reasons for the high effect scores in the outlier studies. We conducted a sensitivity analysis and excluded these studies across all outcome measures. All effects were found to be stable, and heterogeneity was substantially reduced (Multimedia Appendix 6).

Sensitivity Analyses

Sensitivity analysis by risk of bias was conducted for all outcome measures but for EE, as only one study [155] measuring EE classified as low risk of bias. Results at the end of intervention were found to be robust across outcome measures (Multimedia Appendix 6), with effect sizes substantially increasing for walking, MVPA, and TPA to moderate effect sizes. Short- and long-term follow-up effects were not statistically significant when only studies with low risk of bias were included. Heterogeneity increased and remained substantial. Sensitivity analysis of studies reporting long-term follow-up measurements was conducted for all outcome measures but for EE, as only one study [61] measuring EE reported a long-term follow-up measurement. The results across all time points were robust for all outcome measures.

Subgroup Analysis by Population Type

We used subgroup analysis to evaluate the effect moderators. Table 1 summarizes all results, and Multimedia Appendices 7 [41-154], 8 [41-154], and 9 [41-154] provide detailed forest plots for each analysis. We found that population type moderates the effect of mHealth interventions on PA. The intervention design and control group type were not found to be significant effect moderators. Subgroup analysis by population type revealed statistically significant ($P \leq .10$) quantitative subgroup effects for all outcome measures. The treatment effect at the end of intervention was greater in sick populations (walking SMD 0.44, 95% CI 0.29-0.60, $P<.001$, $I^2=71\%$, $P<.001$; MVPA SMD 0.33, 95% CI 0.21-0.45, $P<.001$, $I^2=55\%$, $P<.001$; TPA SMD 0.59, 95% CI 0.36-0.81, $P<.001$, $I^2=49\%$, $P=.03$; Multimedia Appendix 7) than in healthy populations (walking SMD 0.20, 95% CI 0.04-0.35, $P=.01$, $I^2=78\%$, $P<.001$; MVPA SMD 0.14, 95% CI 0.06-0.23, $P=.001$, $I^2=15\%$, $P=.29$; TPA SMD 0.29, 95% CI −0.10 to 0.67, $P=.14$, $I^2=85\%$, $P<.001$; Multimedia Appendix 7). Within the healthy subgroup, summary effects were only statistically significant for the outcome measures walking and MVPA. The results for at-risk populations were mixed. The outcome measures walking and MVPA exhibited high effect scores, similar to the high effect scores of sick populations (walking SMD 0.59, 95% CI 0.42-0.76, $P<.001$, $I^2=87\%$, $P<.001$; MVPA SMD 0.30, 95% CI 0.18-0.43, $P<.001$, $I^2=72\%$, $P<.001$; Multimedia Appendix 7), whereas effect scores for at-risk populations were lower for TPA (SMD 0.21, 95% CI 0.04-0.38; $P=.02$; $I^2=78\%$, $P<.001$). Although heterogeneity was somewhat reduced within most subgroups compared with the overall outcome heterogeneity, it remained high and significant. The covariate distribution between sick, at-risk, and healthy population subgroups was uneven, as fewer studies investigated preventative mHealth PA interventions in healthy populations.

Table 1. Summary of subgroup analyses results.

Outcome measure and time point	Studies, n (%)	SMD[a] (95% CI)	*P* value	Heterogeneity		Test for subgroup differences (*P* value)

[a]SMD: standardized mean difference.

[b]MVPA: moderate-to-vigorous physical activity.

[c]TPA: total physical activity.

[d]N/A: not applicable.

[e]In subgroups where n=1, heterogeneity cannot be calculated.

[f]No studies with combined subgroups. Thus, no numbers reported.

Subgroup Analysis by Intervention Design

Subgroup analysis by intervention design revealed no significant subgroup differences across 3 outcome measures (walking, *P*=.35; MVPA, *P*=.12; TPA, *P*=.60; Table 1; Multimedia Appendix 8) and did not identify mHealth intervention design as a significant effect moderator. Heterogeneity within subgroups was substantial and significant across all outcome measures (Table 1). Both scalable and nonscalable mHealth intervention designs significantly increased PA at similar levels (scalable walking SMD 0.54, 95% CI 0.34-0.74, *P*<.001, I^2=89%, *P*<.001; scalable MVPA SMD 0.20, 95% CI 0.08-0.32, *P*=.001, I^2=67%, *P*<.001; scalable TPA SMD 0.39, 95% CI 0.06-0.73, *P*=.02, I^2=89%, *P*<.001; nonscalable walking SMD 0.42, 95% CI 0.31-0.54, *P*<.001, I^2=77%, *P*<.001; nonscalable MVPA SMD 0.33, 95% CI 0.24-0.43, *P*<.001, I^2=57%, *P*<.001; nonscalable TPA SMD 0.30, 95% CI 0.18-0.42, *P*<.001, I^2=53%, *P*=.002; Multimedia Appendix 8).

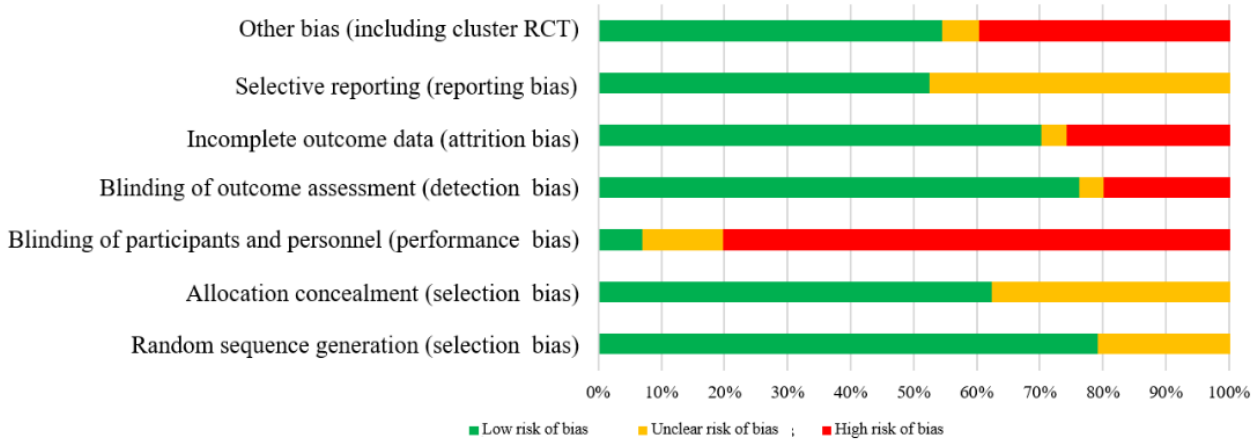
Subgroup Analysis by Control Group Type

Subgroup analysis by control group type found no statistically significant subgroup effect for the outcome measures walking (*P*=.15) and MVPA (*P*=.26). Subgroup differences were only significant for TPA (*P*=.006), where mHealth interventions led to larger effects in studies compared with alternative control groups (SMD 0.48, 95% CI 0.06-0.91; *P*=.03; I^2=83%, *P*<.001; Multimedia Appendix 9) than in studies with no or minimal control groups (SMD 0.34, 95% CI 0.19-0.50; *P*<.001; I^2=76%, *P*<.001; Multimedia Appendix 9). Subgroup analysis did not significantly reduce heterogeneity, and the covariate distribution between the no or minimal intervention subgroup and the alternative intervention subgroup was extremely uneven).

Risk of Bias in Included Studies

Figure 10 shows the overall risk of bias assessment across all included studies. Overall, 94 studies were classified as high risk because of selection bias (14/117, 11.9%), detection bias (37/117, 31.6%), attrition bias (42/117, 35.9%), reporting bias (13/117, 11.1%), and other biases (56/117, 47.9%). These mostly included baseline group indifferences or biases resulting from the respective study design (including potential cluster RCT biases) [35]. Multimedia Appendix 10 [40-156] displays the individual risk of bias assessment by study. GRADE analysis of all 4 outcomes (Multimedia Appendix 11) revealed no evidence of publication bias but evidence of inconsistency for the outcome measure EE. Thus, the overall quality of evidence rating ranged from low (walking, MPVA, and TPA) to very low (EE).

Figure 10. Summary of the overall risk of bias assessment for included studies. RCT: randomized controlled trial.



Discussion

Principal Findings

This systematic review is the most comprehensive study to date of mHealth PA interventions in adult populations. The aims of this study are to understand the long-term impacts of mHealth interventions on PA and to identify important effect moderators.

Overall, our analysis confirms the potential of mHealth interventions to increase PA at the end of intervention. We found small to moderate positive effects (SMD 0.28-0.46), which concur with previous research that reported small to large effect sizes [19,21-24,27,28]. Transforming our results into mean differences based on a representative low risk of bias study [109], we found mHealth interventions to result in 1566 incremental steps per day and an additional 36 minutes of MVPA per week. Previous research found that 1000 incremental steps per day can result in a 10% lower risk of having metabolic syndrome (MetS) and a 6% risk reduction of all-cause mortality, substantiating that mHealth interventions can result in significant

health benefits [158,159]. This study is among the first to find that activity increases are sustained beyond the end of intervention. Increased PA levels remained significant in short-term follow-ups taken on average 4.14 months after the end of intervention for the outcome measures walking, MVPA, and TPA. Long-term follow-up measurements, taken on average after 13.96 months, confirmed these results. However, effect sizes decreased over time and ranged from 0.19 to 0.25 at the long-term follow-up time point, which is equivalent to an incremental 851 steps per day and 24 minutes per week of MVPA. Our results concur with the recent review by Chaudhry et al [20], who also found maintained but decreasing effects of step-count monitoring interventions on PA; however, as Chaudhry et al [20] defined time frames from the start of intervention and this study looks at follow-up measurements after the end of intervention, absolute effect scores cannot be compared. Given the inverse relationship of PA with the prevalence of MetS [158], it can be assumed that mHealth interventions still yield health benefits in the long term. These observations are encouraging and provide initial evidence that mHealth interventions can support sustainable behavioral changes. However, our follow-up effects were not robust when only low risk of bias studies were analyzed because of the limited number of high-quality studies with longitudinal designs. Thus, as the current evidence base for studies with long-term follow-up measurements is very limited, further primary research is needed to confirm the sustained effects of mHealth on PA beyond the end of intervention.

Our analysis of effect moderators found that population type moderates the effect of mHealth on PA, whereas intervention design and control group type were not found to be effect moderators. Our evidence suggests that mHealth interventions might be most effective when targeting sick or at-risk populations, thereby supporting the indicative results by Smith et al [27]—effect sizes in sick and at-risk populations were about twice as high as in healthy populations. However, we still found mHealth interventions to be effective in all population types. These results challenge previous findings by Gal et al [23] and Romeo et al [30], who found no differences in effectiveness by population type, likely owing to the small number of studies reviewed. Previous studies found that baseline activity levels are negatively correlated with activity increases in mHealth interventions [144,160,161]. An underlying driver for the higher effectiveness of mHealth interventions in sick and at-risk populations could thus be lower baseline activity levels usually seen within these populations. However, there could also be further underlying factors, such as higher expectations that increases in PA lead to improved health outcomes (outcome expectancy). Further research is thus needed to understand the variety of underlying factors driving higher effectiveness in sick and at-risk populations. Our results provide helpful guidance to policy makers developing scaled-up mHealth intervention programs. Our results suggest that technology-enabled preventative, population-wide programs (eg, *The National Steps Challenge* [14]) might maximize their public health impact if they specifically target at-risk populations (eg, older or overweight groups). Focusing on at-risk groups should also increase the cost-effectiveness of large-scale mHealth programs.

mHealth technologies are cost-effective and scalable. However, this holds true only if technologies are effective without additional nonscalable intervention components (eg, face-to-face coaching). Previous research has found no effects in scalable mHealth intervention designs [24,30], stronger effects in nonscalable designs that combined technology with human-to-human interactions [27,32], and stronger effects when technology was used stand-alone [20]. We found preliminary evidence that mHealth interventions could be effective in scalable intervention designs. Our analysis found no significant subgroup differences between scalable and nonscalable intervention designs, suggesting that both designs can be equally effective in increasing PA. These results are promising and encourage the development of scalable mHealth intervention designs to efficiently increase PA in large population groups. Within our sample, most scalable mHealth interventions leveraged basic technologies (eg, texting, pedometers, or accelerometers), without taking advantage of more advanced mobile technologies (eg, automated individualized coaching, social comparison, and mobile apps), which could have further increased intervention effectiveness [162,163].

Our analysis is among the first to explore whether mHealth PA interventions produce results superior to alternative nonmobile interventions. We found that across the outcome measures walking, MPVA, and TPA, mHealth interventions led to increased levels of PA compared with alternative nonmobile interventions and no or minimal control groups, which accords with previous findings [21]. These results encourage the addition of mHealth technology to nonmobile PA interventions to increase their effectiveness.

Strengths and Limitations

The strengths of this study are the large number of mHealth interventions analyzed and its rigorous methodology. However, this study has several limitations. First, in line with other studies [164], we encountered large and significant heterogeneity in our results, despite performing several subgroup analyses. Our wide inclusion criteria led us to expect high heterogeneity because of the diverse multicomponent interventions, settings, and intervention durations. In addition, the uneven covariate distribution between subgroups limits the validity of our findings on effect moderators. Second, most of the included studies were classified as having a high risk of bias, and the overall quality of evidence was graded low to very low. The quality of evidence could be improved if future research agreed on standardized reporting of PA outcomes (eg, MVPA in minutes per day) and objective outcome measurement [21]. When replicating our primary results with low risk of bias studies, we could not confirm the effectiveness of mHealth interventions to increase PA beyond the end of interventions, as the available high-quality evidence was limited. Third, we did not attempt to identify unpublished reports or gray literature. Previous research has shown that excluding gray literature might exaggerate the results of a meta-analysis [165]. We tried to mitigate this limitation by conducting a funnel plot analysis to detect potential publication bias. Furthermore, we performed sensitivity analyses to assess the robustness of our results. We detected no systematic publication bias and sensitivity analyses that excluded outlier studies, confirming that our results were robust. Fourth, some

studies included in this study allowed intervention participants to keep mHealth devices after the end of intervention. This might have positively skewed the follow-up effects of our review. Finally, although this study provides initial evidence on the long-term effects of mHealth interventions, it only presents results for follow-up measurements taken on average 13.96 months after intervention, and our analysis included only 8 studies. We found that summary effects decrease over time, thus raising the question about the sustainability of positive effects. Further research is required to evaluate whether behavior change—toward a more active lifestyle—is truly sustainable in long term.

Conclusions

We conclude that mHealth interventions can moderately increase PA in adults at the end of intervention, both compared with alternative nonmobile control groups and no or minimal control groups. PA increases are maintained in follow-up measurements taken after intervention but decrease over time. Population type seems to moderate the effect of mHealth intervention on PA, with higher effectiveness in sick and at-risk populations compared with healthy population samples. mHealth interventions with scalable and nonscalable intervention designs seem to be equivalent in terms of effectiveness. Further high-quality studies investigating scalable mHealth interventions with long-term follow-up measurements are needed to confirm our results. This study concludes that mHealth technologies might not only support sustainable behavior change toward more active lifestyles but also contribute to preventing and controlling chronic disease risk.

Acknowledgments

This study was supported by the National Research Foundation, Prime Minister's Office, Singapore, under its Campus for Research Excellence and Technological Enterprise Programme and by the CSS Insurance (Switzerland). We thank Iva Milhaylova for her support during screening and extraction.

Authors' Contributions

JNK wrote the initial study protocol with inputs from AM and KI. AM wrote the adjusted study protocol. JNK designed and implemented the search strategy. AM, KI, GWT, and AJH screened and coded the primary studies and extracted data. AM analyzed the data and drafted the initial manuscript, supervised by TK. FM and LTC provided methodological guidance and feedback on the manuscript. All authors reviewed and approved the final manuscript.

Conflicts of Interest

JNK, AJH, KI, GWT and TK are affiliated with the Centre for Digital Health Interventions, a joint initiative of the Department of Management, Technology and Economics at ETH Zurich and the Institute of Technology Management at the University of St. Gallen, which was funded in part by CSS Insurance, Switzerland. TK is also a cofounder of Pathmate Technologies, a university spin-off company that creates and delivers digital clinical pathways. However, Pathmate Technologies was not involved in this research. Since January 2021, JNK is associated with CSS Insurance, Switzerland.

Abstract

Vulnerable populations have been identified as having higher infection rates and poorer COVID-19–related outcomes, likely due to their inability to readily access primary care, follow public health directives, and adhere to self-isolation guidelines. As a response to the COVID-19 pandemic, many health care services have adopted new digital solutions, which rely on phone and internet connectivity. However, persons who are digitally inaccessible, such as those experiencing poverty or homelessness, are often unable to use these services. In response to this newly highlighted social disparity known as "digital health inequity," emergency physicians at the University Health Network in Toronto, Canada, initiated a program called PHONE-CONNECT (Phones for Healthier Ontarians iN EDs – COvid NEeds met by Cellular Telephone). This novel approach attempts to improve patients' access to health care, information, and social services, as well as improve their ability to adhere to public health directives (social isolation and contact tracing). Although similar programs addressing the same emerging issues have been recently described in the media, this is the first time phones have been provided as a health care intervention in an emergency department. This innovative emergency department point-of-care intervention may have a significant impact on improving health outcomes for vulnerable people during the COVID-19 pandemic and beyond.

Introduction

The COVID-19 pandemic has highlighted many social disparities encountered by vulnerable populations [1]. Vulnerable populations, such as those experiencing poverty or homelessness, have a higher rate of infection and significantly worse COVID-19–related health outcomes [2]. They have been disproportionately affected during the pandemic by a lack of safe housing for physical distancing or self-isolation, difficulty adhering to public health directives, and significant barriers to accessing health care and social services [3].

Emerging digital solutions adopted by health care providers in response to the pandemic rely heavily on phone connectivity and access to the internet [4]. These include telemedicine, telepsychiatry, and COVID-19–related communications such as testing status updates and contact tracing. Most recently, the Canadian federal government launched a new mobile app for efficient and secure contact tracing, named COVID Alert [5]. Although these new solutions provide exciting opportunities for the future of health care delivery and public health, they may create yet another barrier for those who are unable to afford a phone and phone plan [6]. The inability to access digital

services constitutes a newly explored digital determinant of health: digital health equity [7].

A recent study suggests that targeted access to mobile devices can help mitigate the downstream consequences of this health disparity [8]. Given the urgent needs presented during the COVID-19 pandemic, the emergency department (ED) at the University Health Network (UHN), in Toronto, Ontario, responded with a pilot program to provide free prepaid cell phones to vulnerable patients.

What is PHONE-CONNECT?

Phones for Healthier Ontarians iN EDs – COvid NEeds met by Cellular Telephone, also known as PHONE-CONNECT, is a program founded by UHN emergency physicians to address the health and social needs of vulnerable patients through cellular and digital connectivity. This program was conceived after recognizing that many patients facing digital inequity are at risk for further morbidity despite adequate treatment received in the ED. These risks are compounded by the COVID-19 pandemic wherein contact tracing, physical distancing, and virtual care are heavily reliant on having access to a digital device. The program repurposes donated cell phones and distributes them to eligible patients discharged from the ED as an intervention to address digital health inequity. The aims of the program are to identify people experiencing digital health inequities and address these inequities by improving patients' access to health care services, information, and social services, as well as to improve social connectivity. Additionally, the program seeks to increase patients' capacity to follow public health directives (including self-isolation) and their availability for contact tracing during the pandemic.

To the best of our knowledge, this is the first time cell phones have been distributed from EDs to address the needs of vulnerable patients, and the first time cell phones have been distributed from an ED during a pandemic. Since the program's inception at UHN, PHONE-CONNECT has expanded to include additional Greater Toronto Area sites (ie, St. Michael's Hospital and Michael Garron Hospital) and academic medical centers (ie, McMaster University).

Implementation

The PHONE-CONNECT program was initiated with the donation of 50 smartphones and 200 SIM cards with unlimited talk and text features from a telecommunications company. Additional phone donations were sought by word of mouth and via media coverage of the initiative. Members of the public were invited to mail in their pre-used cell phones. Donated phones were checked for operability and compatibility with the donated SIM cards, cleaned of the previous user's personal information and disinfected. Phone distribution packages (Figure 1) include a cellular device loaded with a SIM card, a compatible phone charger, and a phone manual (when available). A handout explaining the importance of using the phone to connect with health care providers was included, as well as a list of phone numbers for various health and social services.

Figure 1. Phone distribution packages.

Population

Patients are deemed eligible for a phone distribution package if a phone number is not listed on their ED chart. This applies to all patients who do not have access to a telephone and require communication of test results and pending appointments, those who require a phone to facilitate self-isolation, or those who need a device to access follow-up care, virtual or in-person. Health care providers who were trained to administer the phones include physicians, nurse practitioners, physician assistants, registered nurses, social workers, and peer support workers. These providers were informed of the PHONE-CONNECT initiative through daily department huddles, team meetings, and emails. They were given instructions on patient eligibility, administration of phones to patients, and documentation of the patient's new phone number. The same health care providers were responsible for identifying eligible patients during the course of regular clinical care, orienting the patients to their new phone prior to discharge from the ED, and advising them that they would be contacted for consent for a follow-up interview. Once distributed, the new phone number is added to the patient's electronic medical record, and the patient is encouraged to keep the phone turned on, charged, and available should a health care provider need to contact them. Aside from these requests, the patient may use the phone however they choose.

Data Collection

The PHONE-CONNECT pilot project is being assessed through an ongoing research study exploring the impact of the phone on the patient's well-being and their utilization of health care services, as well as the perspectives of the health care providers participating in the PHONE-CONNECT initiative.

Specifically, 2-4 weeks following discharge, research assistants attempt to contact phone recipients through their new device with a maximum of three calls and one SMS text message. A semistructured interview (Multimedia Appendix 1) is then conducted with the phone recipient to explore the role of their new phone in addressing digital health equity. This includes the following: the role of the phone in their ability to self-isolate in the context of COVID-19, their communication with health care providers, their ability to maintain their social networks, and the recipients' self-reported well-being. Quantitative data collected include the number of phones distributed, the number of participants attending virtual and in-person follow-up appointments, nonattendance to prescheduled appointments, as well as the number of participants tested for COVID-19 and who received their results via the phone intervention.

The impact of PHONE-CONNECT on the distributing health care providers is also being explored. The health care providers are asked to complete a questionnaire using 5-point Likert scale questions assessing their perceptions on how giving a phone in the ED affects their ability to provide care to socially complex patients. Additional questions assess the impact of phone distribution on provider burnout.

Review of Similar Initiatives

To the best of our knowledge, prior to the COVID-19 pandemic only one program offered free cellular phones for vulnerable populations. In the United States, free cellular phones are offered to a subset of participants in the Federal Lifeline program [9]. A study of people experiencing homelessness in New York City who received free phones through this program found that beneficiaries viewed these free devices as an important tool to help navigate, engage, and ultimately improve their access to care [10]. More recently, and as a response to the digital disparities experienced by the homeless population during the COVID-19 pandemic, two new programs have been described in the media. In the United Kingdom, a program administered by a charity and a telecommunication company was designed to provide 2500 cell phones to eligible recipients living in England, Scotland, and Wales [11]. More locally, the Social Planning and Research Council (SPARC) of British Columbia distributed 3500 smartphones to persons experiencing homelessness at parks and shelters [12].

Impact

Thus far, 180 devices have been distributed to eligible patients at two sites in Toronto. The personal narratives emerging from our nascent evaluation are compelling and will be highlighted in the publication of a future study. Recipients have used their phones to address their health care needs by connecting with physicians, addictions counsellors, social workers, medical specialists, and Toronto Public Health representatives, and to attend telemedicine appointments. They have accessed suicide hotlines and emergency medical services. They have used their phones to meet their basic needs, by accessing groceries during isolation and securing shelter beds. Furthermore, recipients have strengthened their social networks by virtue of being in regular contact with friends and family.

Limitations

Despite the reported benefits of providing mobile phones to those experiencing homelessness [10], there are several issues that should be addressed as this program finds greater adoption. Not all patients are inherently "tech savvy" and may incur additional stress and anxiety from using a mobile phone for health-related communication. Appropriate matching of user to device by technical confidence level and familiarity should be considered in the initiation of similar programs. Furthermore, "phone-seeking behavior" could be an unfortunate side effect of this program that may increase ED visits, although this has not been our experience.

Finally, as this is an ED point-of-care intervention, clinical demands on ED providers may increase. Empowering other allied health professionals in the ED to provide phones has addressed this concern. Moreover, our experience suggests that any increased clinical burden may be offset by better ease of ED discharge planning for patients now able to access care beyond the ED.

Discussion

The need for phone connectivity will increase as the COVID-19 pandemic continues to impact access to health services. We are concerned that if digital equity needs remain unaddressed, vulnerable patients will continue to experience disparate health outcomes of increasing magnitude during the pandemic and beyond. Although further research into the different aspects of digital health equity is necessary for the creation of universal policies and strategies, this innovative initiative is an achievable first step in overcoming the challenge of accessibility. This project may demonstrate that identification of those who are facing this equity issue can be accomplished in the primary care setting. Moreover, a recent study found that improving primary care access via phone connectivity can reduce avoidable ED visits [13]. Therefore, by facilitating access to outpatient health care and social services, the PHONE-CONNECT program may be an innovative solution to reduce unnecessary ED visits or prolonged ED length of stays.

As we continue to pilot this novel ED point-of-care intervention, we hope to further explore the effects of our program on its recipients. We are particularly interested in understanding the effects of this program on access to and utilization of the health care system, social services, COVID-19–related public health interventions, as well as the impact on overall well-being. We are also interested in determining whether the ED is an appropriate setting for addressing these digital equity issues. Answers to such questions will be elucidated in the currently ongoing associated study. We hope to continue to address digital health inequities by expanding our program to more sites, and by ensuring the ongoing activation of SIM cards currently in circulation.

Acknowledgments

The authors thank Lanujan Kaneswaran and Alexandra McKnight for providing logistical support for the PHONE-CONNECT program. The authors would also like to acknowledge Humaira Nakhuda and Madeline McDonald for their contributions in data collection and patient interviews.

Abstract

Digital technologies have been transforming methods of health care delivery and have been embraced within the health, social, and public response to the COVID-19 pandemic. However, this has directed attention to the "inverse information law" (also called "digital inverse care law") and digital inequalities, as people who are most in need of support (in particular, older people and those experiencing social deprivation) are often least likely to engage with digital platforms. The response to the COVID-19 pandemic represents a sustained shift to the adoption of digital approaches to working and engaging with populations, which will continue beyond the COVID-19 pandemic. Therefore, it is important to understand the underlying factors contributing to digital inequalities and act immediately to avoid digital inequality contributing to health inequalities in the future. The response to COVID-19 represents a sustained shift to adopting digital approaches to working and engaging with populations which will continue beyond this pandemic. Therefore it is important that we understand the underlying factors contributing to digital inequalities, and act now to protect against digital inequality contributing to health inequalities in the future.

Introduction

Background

Technology is transforming the way we live our lives. A digital revolution is underway in the public sector, including the health sector, to facilitate the use of digital solutions to drive efficient systems and improve population health both in the United Kingdom [1-4] and worldwide [5]. The expected benefits to individuals include more rapid access to information and personalized care, more control, and empowerment for their own health. The benefits to health and care systems include opportunities to deliver efficient and effective care closer to patients and target scarce resources in a better manner, using precision medicines, big data, and artificial intelligence.

However, while the application of digital innovation in health care—hereinafter referred to as "digital health"—has gained impetus, the wider social system has received limited consideration, and people most in need of care are also least likely to have access to, or engage with, technology. A failure to acknowledge and address this challenge would imply that the adoption of digital health has the potential to inadvertently widen health inequalities, thus integrating the inverse care law [6] into the digital era as a "digital inverse care law", previously called "inverse information law" [7].

The COVID-19 pandemic has markedly highlighted the vital role of access to the internet and digital technology in enabling the general public to live their everyday lives during the pandemic. The pace of digital innovation and its adoption in health and care among the general public has accelerated. This includes widespread rapid adoption of internet-based health consultations and the development of digital health tools and apps to protect health and well-being. There has also been a demonstrable increase in the proportion of people in the general population who use the internet to search for information; maintain contact with others; support the continuation of work, study, or home-schooling during the COVID-19 pandemic; and access basic needs including shopping and financial support [8,9]. During a period of enforced social isolation, a focus on internet-enabled social responses has implied that people without a presence on the internet are effectively excluded. As we progress towards recovery from the COVID-19 pandemic, there is a risk of leaving behind people who do not engage with digital technologies and are most likely in need of support.

Increasing awareness and improving our understanding of the factors contributing to the digital inverse care law, and how these challenges can be addressed, is of considerable importance in the application of digital health [10,11]. We can expect the increased reliance on digital technologies during the COVID-19 pandemic to be sustained in many ways even after the COVID-19 pandemic; hence, it is important to recognize these issues immediately.

Objective

To help inform action, here we describe the factors contributing to digital exclusion, its contribution to health and social inequalities, and the potential factors that need to be addressed to prevent it. This viewpoint has been informed by the academic and gray literature on technological advancements in the health sector and seeks to highlight the complexity of the drivers of the digital inverse care law and the actions needed across government, public, private, and nonprofit sector organizations to ensure capitalizing on the potential for digital technologies to address health issues and minimize the risk of the exacerbation of health inequalities.

Factors Contributing to Digital Exclusion

We describe digital exclusion as a complex challenge that consists of 3 interconnected components, with inequalities evident in each component: (1) access to digital connectivity and infrastructure, (2) digital skills and literacy, and (3) engagement with digital platforms. Here we consider each of these elements, illustrated within the context of the key opportunities for digital technologies in the National Health Service (NHS) in the United Kingdom [11], with particular reference to the COVID-19 pandemic.

Access to Digital Connectivity and Infrastructure

People worldwide use the internet to stay in touch with others and live their lives during the COVID-19 pandemic. For example, a survey by the Pew Research Center in April 2020 [12] revealed that 53% of people in the United States felt that the internet is essential during the COVID-19 pandemic, and a further 34% felt that it is important but not essential. Nonetheless, only 55% of households worldwide have an internet connection, ranging from 87% of households in high-income countries, 47% in transitional countries, and only 19% in the low-income countries [13].

Even in high-income countries, marked inequalities in internet access are evident. In 2019, 7% of households in the United Kingdom did not use the internet [14], and 10% of adults in the United Kingdom did not use the internet regularly [15]. The same proportion has been reported in the United States, increasing with age to 27% among people aged ≥65 years [16]. A population-wide survey across 17 European countries revealed that 51% of people aged ≥50 years do not use the internet [17].

Internet access can be facilitated by enabling access to internet-enabled technologies alongside a fixed (eg, household) or mobile broadband connection. While internet access through a fixed broadband connection has increased in recent years, the quality and speed of the connection remains poor for many people, and this is particularly the case in rural areas. Data from the European Union suggest that the increase in very-high-capacity network coverage in rural areas remains significantly lower than the total coverage, despite marked improvements in recent years (from 2011 to 2019, very-high-capacity network coverage increased from 2% to 20% in rural areas, compared to an increase from 10% to 44% overall) [18]. In the United Kingdom, residential premises in rural areas have lower coverage of fixed superfast broadband connections (79% of properties in rural areas compared to 97% in urban areas), download speeds exceeding 10 Mbps (83% in rural areas compared to 98% in urban areas), and lower access to high-quality mobile data (4G data services; 41% in rural areas compared to 85% in urban areas) [19]. Regional disparities in broadband access are not a problem exclusive to rural areas. The National Digital Inclusion Alliance's report on the worst connected cities revealed that among 221 large- and medium-sized US cities, at least 30% of households lacked a broadband connection [20].

A lack of rapid, reliable connectivity across fixed and mobile internet services can be a challenge for patients to receive remote care and for health care staff who are mobile and work in patients' homes. In a survey among the members of the Queen's Nursing Institute (n=534) [21], 454 (85%) nursing professionals reported that poor connectivity in patients' homes is the greatest challenge to effective mobile working in the community.

Alongside infrastructure, another factor contributing to internet access is the affordability of internet-enabled digital devices and data plans. Over 25,000,000 mobile phone users in the United Kingdom are pay-as-you-go customers, with the majority of users having a low income. Community organizations have reported examples of vulnerable groups spending up to half the family budget on incurring mobile phone costs [22]. Described as "data poverty," accessing the internet through mobile digital technologies can be an unaffordable essential need and individuals may be reluctant to devote scare data resources to digital health in light of competing demands [23].

The COVID-19 pandemic response has exposed digital poverty with the lack of ownership of digital devices and low

affordability of data plans [24]. In addressing these challenges, the UK Government supported the DevicesDotNow initiative, which asked businesses to donate devices (tablets, smartphones, and laptops) and connectivity (in the form of SIM cards, dongles, and mobile hotspots) to be distributed to households who would otherwise be digitally excluded [25]. In Wales, there has been a rapid roll out of the Attend Anywhere video consultation service, accompanied by the supply of 1000 tablet devices to hospitals, care homes, and hospice settings, to enable vulnerable people to access the service on the internet [26]. In addressing data affordability, telecommunication companies in the United Kingdom have removed the data cap for fixed broadband contracts during the COVID-19 pandemic [27]. However, this did not apply to pay-as-you-go mobile contract holders; therefore, those likely to be in greater need were not able to benefit from this initiative.

Evaluation of the impact of such initiatives would help understand the extent to which such programs reach people who are most in need and address the access and affordability drivers of digital inequalities across all groups.

Digital Skills and Literacy

In 2020, a survey in the United Kingdom revealed that 10,500,000 people (16% of the adult population of the United Kingdom) cannot perform basic activities with digital devices, such as turning on a device, connecting to the Wi-Fi, or opening an app by themselves. In total, 7% of the population of the United Kingdom (3,600,000 people) is almost completely offline [28]. Data from the Digital Economy and Society Index of the European Commission suggest that while the level of digital skills continues to increase across many countries in recent years, progress among different population groups is highly variable. In 2019, 82% of young people (aged 16-24 years) and 85% of those with high formal education have at least basic digital skills, compared to only 35% of people aged 55-74 years [29].

There are a number of specific programs in the United Kingdom [30-32] and worldwide [33,34], which seek to address gaps in digital skills among specific groups of people. Structured programs, such as those provided by the Good Things Foundation [35] and Digital Communities Wales [36], focus on overcoming the barriers to opportunity, access, knowledge, and skills for using technology (particularly the internet). During the COVID-19 pandemic, web-based digital skills programs for the general public, such as Learn My Way [37], have been made available free of charge, thus eliminating financial barriers to internet access. Many other initiatives supporting the best practices in digital skills development across Europe are highlighted in the European Commission annual Digital Skills Awards [38], including, for example, community navigators to help older people living with long-term conditions to access and use technologies [39]. Digital skills programs tend to be focused on the general public; however, there is also the need to develop the digital skills among the NHS workforce, such that they can support patients to engage with a digital health care system and direct them to effective digital solutions. In a study on effective mobile working in the community, 21% of nurses reported that limited or no training for the use of the devices was a key challenge to implementation [21]. Examples of nationwide programs supporting digital skills training among health professionals include the Digital Readiness program of Health Education England [40].

Globally, digital literacy and continuous skill development as technologies evolve has been identified as an important driver of health technology use [5]. Ensuring everyone is equipped with the digital skills needed to effectively engage with digital technology is crucial to address digital exclusion.

Engagement With Digital Platforms

It is important to address internet access and digital skill gaps, but these factors alone are unlikely to be sufficient to ensure all patients have the potential to benefit from services delivered on digital platforms. Many other factors potentially influence an individual's choice to engage with digital platforms; these include levels of awareness, trust, and perceived benefits, the combination of which would differ across age groups, genders, and socioeconomic and cultural backgrounds.

As evidenced by the latest issue of the Consumer Digital Index of the United Kingdom [28], a lack of motivation or interest is one of the key barriers to internet engagement. Over one-third of internet nonusers claim that the internet does not interest them, and 48% claim that "nothing" could motivate them to become internet users. Alongside motivation, there is also a need to consider that different groups of people prefer to engage with different digital platforms. A survey conducted in the United Kingdom reported that although over 50% of adults were willing to have web-based consultations with general practitioners, approximately 25% of people aged over 65 years and 40%-45% of people from households earning less than £25,000 would not opt for a web-based video consultation with their general practitioner [11]. The COVID-19 pandemic has forced many primary care consultations to be carried out remotely through the telephone and web-based or video platforms, leading to widespread implementation of these forms of consultation as practical solutions [41]. Some studies have suggested high satisfaction among people who engage with online care [42]; nonetheless, few studies have evaluated the levels of engagement across different populations, the underlying contributing factors, and the impact on timely access to health information, care, patient experience, and health outcomes. More comprehensive evaluation is needed to understand and inform the development of digital or mixed models of service in a better manner to ensure that digital innovation does not inadvertently contribute to the exacerbation of inequalities in outcomes.

Coproduction is essential to address disparities in the engagement with digitally delivered health care among diverse populations. Tools such as the "Culturally-Informed Design Framework" in the United States are useful guides to encourage developers and providers to consider cultural differences in engagement to optimize the choice of digital platform, functionality, content, and user interface [43].

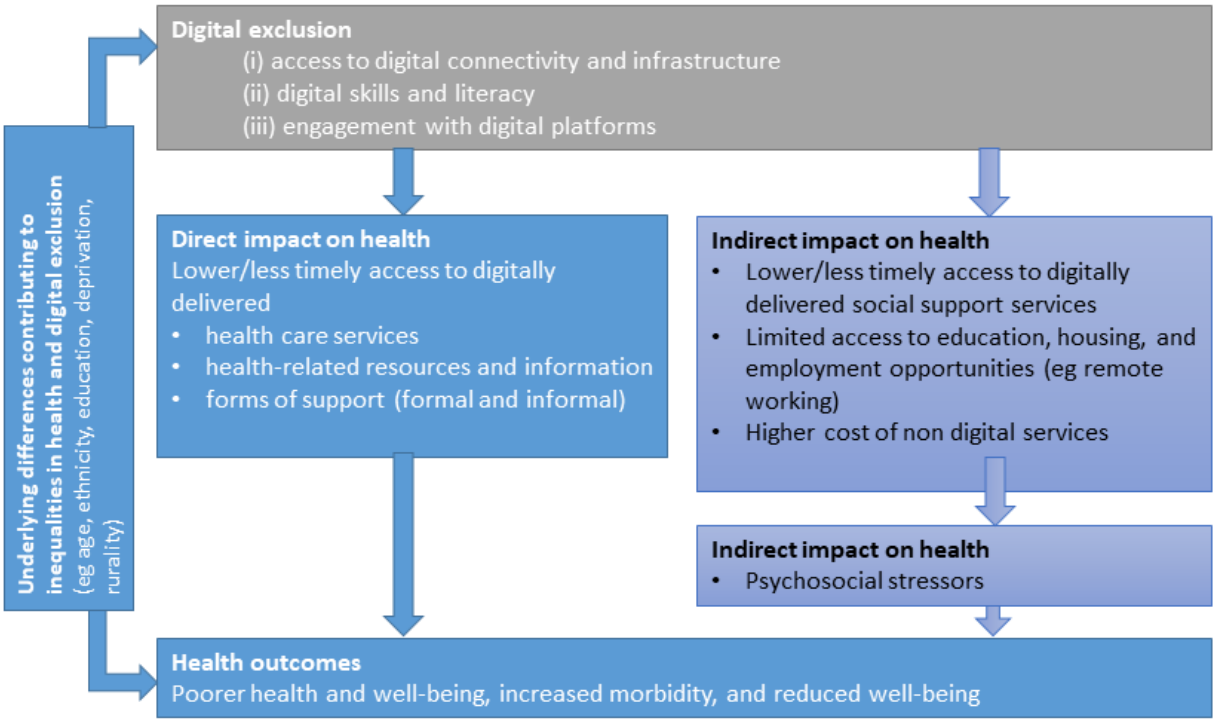
How Digital Exclusion May Exacerbate Health and Social Inequalities

The digital era has transformed and continues to transform society rapidly, influencing our access to information, employment, working conditions, health and care services, and social connections, and in turn the conditions for good health. However, alongside advancements in digital innovation, digital exclusion is increasingly being recognized as an important factor potentially contributing to both health and social inequalities [44].

The evidence summarized here describes how digital exclusion is a complex factor that reflects underlying social and economic inequalities (such as economic barriers to accessing data and devices or variations in regional internet infrastructure) and contributes to social, economic, and health inequalities (as those less able or likely to engage with digital technology are also most likely to need support).

The digital inverse care law [7,45] reflects the direct impact of digital exclusion on health, for example by reducing an individual's access to timely and reliable health information, services, and support (eg, from professionals or peer support groups) delivered on digital platforms (Figure 1). A focus on digitally delivered health systems, without due consideration of digital exclusion, has the potential to prevent "intervention generated inequalities" from reinforcing the underlying inequalities in health [46,47]. In a nationwide representative study of engagement with digital technology for health purposes in Wales, the use of digital technology was lower among groups of people who are likely to have greater health needs, including older people, those living in less affluent areas, those with poorer underlying health, and those reporting health-harming behaviors (ie, smoking, drinking, and physical inactivity) [48]. This has also been highlighted within the context of COVID-19, a period when having an internet presence is crucial to rapidly access not only health information but also digital health consultations and health monitoring apps. Furthermore, people who are at the highest risk of poor health outcomes are also those most likely to be digitally excluded, including older people and those living in more deprived areas [49].

Figure 1. The direct and indirect impacts of digital exclusion on health inequalities. Adapted from McAuley [45].



Digital exclusion can also have an indirect impact on health outcomes, acting through the other social determinants of health [44]. For example, digital exclusion may reduce an individual's access to social support services (eg, income support), education, and employment opportunities, all of which are recognized as underlying social and economic determinants of health (Figure 1). Within the context of the COVID-19 pandemic, during the first 2 weeks of the nationwide lockdown in the United Kingdom, approximately 1,000,000 people sought financial support through universal credit; however, this was only possible on the internet, thus posing a challenge to those who are digitally excluded. When schools, crèches, universities, offices, churches, shops, restaurants, and parks are closed owing to the COVID-19 pandemic, the usual institutions around which people structure their everyday lives and gain support were no longer physically accessible. Many people transitioned to web-based platforms, which was a supportive community inaccessible to digitally excluded people [50].

Digital exclusion is concurrent with Dahlgren and Whitehead's definition of a social determinant of health [51], as a social and economic factor with the potential to increase or decrease social inequities in health. Recognition of digital exclusion as a social determinant of health by governments and systems would increase the visibility of the issue, highlight the need for routine

measurement, report variations across population groups, and focus action on the factors contributing to digital exclusion across policy, health, and social systems. There are examples where health systems display different behaviors in light of increased awareness of digital exclusion, such as addressing data poverty by enabling mobile phone users toll-free access to the NHS and national government health websites [52]. Digitally excluded people would have been hugely impacted without access to rapidly changing and reliable public health advice during the COVID-19 pandemic.

Digital Innovation, COVID-19, and Health Inequalities: an Example

In response to the COVID-19 pandemic, contact tracing digital apps were rapidly implemented in several countries [53] including the United Kingdom [54]. Engagement with the app is dependent on the individual owning a smartphone, having the skills to understand and download the app, and keeping their phone switched on with Bluetooth enabled. However, 6,500,000 adults in the United Kingdom cannot turn on a device, and 5,900,000 adults cannot open an app [28]. A survey carried out by IPSOS Mori for the Health Foundation [55] revealed a clear digital divide by age, occupation, and educational level in public readiness to download the NHS COVID-19 app. Public trust and confidence were also likely to be highly instrumental in adoption. One's motivation to download and use the NHS COVID-19 app would reflect one's views on risk and benefit within the context of a pandemic and, potentially influenced by the views of one's family, social networks, and professionals.

Contact tracing apps are likely to be disproportionately taken up by younger, more affluent, and tech savvy populations. The benefit of the app extends to users and people around them; however, if digital exclusion prevents the most vulnerable people from participating in digital technologies, then the collective societal benefits are not equitable. This highlights the importance of digital innovation being accompanied by nondigital approaches, which are efficient and effective for people who cannot or choose not to engage with digital solutions, and to evaluate the outcome across population groups [56].

Actions to Mitigate the Risk of Digital Inequalities Exacerbating Health Inequalities

There is sufficient evidence to conclude that digital exclusion should be considered across sectors as a social determinant of health, with the potential to exacerbate health inequalities if progress does not consider the structural, economic, social, and behavioral factors contributing to digital exclusion.

The COVID-19 pandemic has clearly highlighted the levels of inequality in the ownership of digital devices and demonstrated that the access to fixed and mobile internet connections is a gateway to essential health information and care and many other key services including education, food delivery, employment, and social support, all of which indirectly impact health. As described here, the underlying inequalities in the access to digital technology and the internet are evident, and if left unresolved, have the potential to exacerbate health and social inequalities in a digital era.

In order to progress towards digital inclusion, one policy approach adopted by certain countries is to declare that access to the internet is a human right [57], whereas others consider technology and the internet as an enabler of rights rather than a right in itself [58]. Declaration of access to the internet as a right may enforce action at national and international levels to address a factor that indirectly contributes to health, placing it at par with other rights including the access to food and safe housing, all of which contribute to health equality.

This study shows that the underlying drivers of digital exclusion are complex, and as such the solution cannot be obtained through a single action or from a single organization. Addressing digital exclusion would require government, public, private, and nonprofit sector organizations to collaborate to ensure that progress toward a digital future does not inadvertently leave some people behind. This will require a comprehensive understanding of the factors contributing to digital exclusion in local populations and how these factors differ among groups, areas, and over time, along with effective engagement with digitally excluded people to coproduce solutions that adequately address the contributing factors such as poverty, access, skills, or motivation.

For example, a common viewpoint is that addressing barriers to internet connectivity will address digital exclusion; however, this is not the case. Inequalities would continue to persist after access is resolved if the complex underlying factors that contribute to the digital divide are not addressed. a crucial first step is to understand the extent and drivers of digital exclusion within and between different populations through data and qualitative insights. Followed by a multidisciplinary and multisectoral response to address structural barriers (such as the lack of infrastructure to support adequate internet access in all areas), financial barriers (eg, costs of devices and data plans), digital skills and literacy, and other barriers to engagement (eg, cultural, concerns regarding trust and data privacy) (Table 1). Embedded evaluation alongside digital innovation is essential to ascertain the impact of each of these actions against key outcomes including differences in uptake, engagement and effectiveness across population groups. For progress to occur, there is a need to bring together actions against these key components in a comprehensive and coordinated plan; for example, the New York City Internet Masterplan [59] is a comprehensive roadmap to close the digital divide through enhanced infrastructure, affordability, and inclusion. To ensure collective progress, it may also be necessary to ensure that the government takes the responsibility for digital equity.

Organizations in the United Kingdom have brought together practical calls to action to mitigate the risk of digital inequalities. The Good Things Foundation has issued a blueprint for a 100% digitally included United Kingdom for a post–COVID-19 economy, focusing on 3 key steps to fix the digital divide: the need to address the digital infrastructure, data poverty, and to develop an inclusive digital strategy [60]. The Carnegie UK Trust has reported 12 recommendations for policymakers,

practitioners, academics, and industry professionals to learn from the lockdown and eliminate digital exclusion [61]. In Wales, the Older People's Commissioner has urged investment in digital inclusion as one of the preconditions for an age-friendly recovery [62]. With an international focus, particularly on low-income countries, the Human Rights, Big Data and Technology Project has postulated 5 urgent principles for leaving nobody behind through technology in the COVID-19 response [63]: guaranteeing internet access as a human right and a public good, increasing the availability and acceptability of the digital infrastructure, increasing the accessibility and affordability of digital services, empowering people by addressing disinformation and hate speech without censorship, and ensuring that internet access is not a cause for more surveillance.

Table 1. Data and insights on the extent and drivers of digital exclusion leading to digital inequalities in population subgroups and potential approaches to address inequalities and to evaluate and understand the uptake and effectiveness of digital technologies and differences across population subgroups.

Driver of digital inequality	Types of digital inequalities	Suggested approaches to address inequalities
Structural barriers (access)	• Inequalities in access to a rapid and reliable internet connection	• Infrastructure investment • Report publicly available data on internet coverage across populations
Financial barriers	• Inequalities in the affordability of internet-enabled digital technology and data plans	• Understand economic barriers including internet access, affordability of technology, data poverty through research, and engagement with service users • Examine the impact of different policies and economic responses (eg, financial support, waived data charges for essential services, subsided costs, market regulations to reduce cost, and data caps)
Digital skills and literacy	• Inequalities in digital skills among service users	• Nationwide and local systems should use existing measures of digital inclusion to understand population needs, such as the general Digital Inclusion Scale [64] or the health-specific eHealth Literacy Scale [65] • Implement structured programs to address skills gaps such as the NHS Widening Digital Participation delivered of the Good Things Foundation [35,37] and Digital Communities Wales [36] • Targeted support addressing essential digital skills among vulnerable groups (eg, through peer-to-peer support, intergenerational mentoring, and localized digital champions [66])
	• Inequalities in digital skills, knowledge, understanding, and awareness among service providers and the workforce	• Develop a model of digital competence across different roles, train and support the workforce to enable a digital future (eg, the NHS Digital Readiness program [40])
Engagement with digital platforms	• Differences in motivation, trust, and perception of risks across populations	• Develop a nationwide standard instrument routinely administered to users to understand factors contributing to engagement • Coproduce digital solutions tailored to service user needs and levels of digital skills or engagement. • Address barriers of trust and risk with transparency and clarity on the collected data and the underlying purpose
Design and development of services	• Incompatibility across different platforms (fixed or mobile) • Inoperability owing to lower internet speeds • Requiring the use of data plans	• Include digital inequality as a factor in the equality impact assessments alongside service development and delivery • Incentivize partnerships across public, private, and nonprofit sector organizations to address digital exclusion • Ensure new service developments considering digital exclusion • Contracts with suppliers to include reports on granular data on service use in local health systems across platforms to identify excluded populations

As health and care systems seek to deliver services through digital platforms, it remains important to monitor and evaluate the levels of engagement to ensure that a focus on digital approaches does not inadvertently reinforce underlying inequalities in health. Within the United Kingdom, the NHS provides a potential opportunity to monitor and address different levels of engagement with digital technology to help understand differences by clinical needs and population groups, an understanding of which could be shared to inform innovation elsewhere.

Based on theoretical frameworks and the lessons learned from the practical examples described here, the actions needed to ensure that digital health innovation helps address, rather than exacerbate, health inequalities are as follows:

1. Understand the extent and drivers of digital exclusion in population subgroups
2. Use existing measures or develop new measures of digital exclusion and digital health literacy
3. Ensure that digital strategies and new service developments consider factors contributing to local exclusion
4. Develop solutions through coproduction for a maximally extensive and appropriate user base
5. Where widespread adoption is required, ensure the technologies used have the characteristics of innovations capable of being rapidly disseminated [67-69]
6. Use realistic and evidence-based models of behavioral science to inform digital health innovation, such as the COM-B system [70].

Conclusion

Digital technology has the potential to revolutionize health and health care with growing interest among policymakers, researchers, and practitioners in exploring how digital technology can be harnessed to improve population health. Countries worldwide have been using digital technologies to respond to the COVID-19 pandemic, for applications including communication of public information, remote delivery of health care, and population surveillance [71]. Greater adoption of technology can also provide additional sources of valuable data for potential use by population health systems to understand health needs more clearly, monitor outcomes, and counter the factors underlying ill health.

Digital innovations should be accessible to everyone, empowering citizens to become active contributors to health and well-being. However, those likely to have the greatest health needs are also least likely to have access to digital platforms and the skills to use and navigate them, and they are hence less likely to engage with such digital platforms. This raises an important question of equity in population health in a digital era, an issue brought into sharp focus by the COVID-19 pandemic. This led us to ask how we can innovate through digital technology and transform population health, while leaving no one behind.

To address this question, we need to better understand who engages with digital technologies, the enablers and barriers, and the direct and indirect impact on health outcomes. The lack of consideration of these factors poses the danger that the pursuit of digital health solutions results in unintended consequences and reinforces existing social and health inequalities. Action is needed across government, public, private, and nonprofit sector organizations to ensure capitalization on the potential for digital technology to address health and minimize the risk of exacerbation of health inequalities.

Conflicts of Interest

MH works for accuRx, a health care communications software supplier. ARD and BG have no conflicts of interest to declare.

Abstract

The application of virtual reality has become increasingly extensive as this technology has developed. In dental education, virtual reality is mainly used to assist or replace traditional methods of teaching clinical skills in preclinical training for several subjects, such as endodontics, prosthodontics, periodontics, implantology, and dental surgery. The application of dental simulators in teaching can make up for the deficiency of traditional teaching methods and reduce the teaching burden, improving convenience for both teachers and students. However, because of the technology limitations of virtual reality and force feedback, dental simulators still have many hardware and software disadvantages that have prevented them from being an alternative to traditional dental simulators as a primary skill training method. In the future, when combined with big data, cloud computing, 5G, and deep learning technology, dental simulators will be able to give students individualized learning assistance, and their functions will be more diverse and suitable for preclinical training. The purpose of this review is to provide an overview of current dental simulators on related technologies, advantages and disadvantages, methods of evaluating effectiveness, and future directions for development.

dental simulator; dental education; virtual reality

Introduction

Dental skills training is a very important part of preclinical learning in dental education and has a long history [1]. Pioneers of dental education began to use extracted teeth in dental skills education in the 1800s [2]. Later, Oswald Fergus invented the first phantom head simulator in 1894, which was used to teach oral anatomy and physiology to dental students [2]. Since then, the phantom head simulator has developed rapidly. Modern phantom head simulators include water spray, dental handpieces, and other necessary items [3], providing students with a more realistic environment for diagnosis and treatment. The dental simulator appeared in the 1990s [4,5] as a result of further research into methods of dental preclinical education, concern for patient safety, improvements in computer technology, and the inappropriateness of a clinical environment for the novice

[1]. The arrival of the dental simulator marked a new era of dental preclinical education.

The dental simulator replicates both soft and hard oral tissues as well as providing a clinical diagnosis and treatment environment through virtual reality (VR). It also simulates the interaction force between the bur and the tooth, the mouth mirror, and soft and hard tissues through force feedback technology to reproduce the whole training process for dental clinical skills as closely as possible [6,7]. In recent years, the dental simulator has mainly been used for adult vocational training and university education [8].

Traditional preclinical dental skills training, which was based on a phantom head, extracted teeth, or plastic teeth [9,10], is generally used for practicing tooth preparation, for which the processes are irreversible. The acquisition of extracted teeth becomes more and more difficult, and the sensory feedback of preparing plastic teeth is different from that of real teeth [3,11]. The dental simulator, simulating realistic clinical conditions via VR and force feedback, makes training reversible, repeatable, and environmentally friendly [12,13]. Training via a dental simulator is varied [14] since different training content and tooth positions are available. These can be displayed in 3D on a computer screen for real-time evaluation by and feedback from teachers.

Technologies Included in Dental Simulators

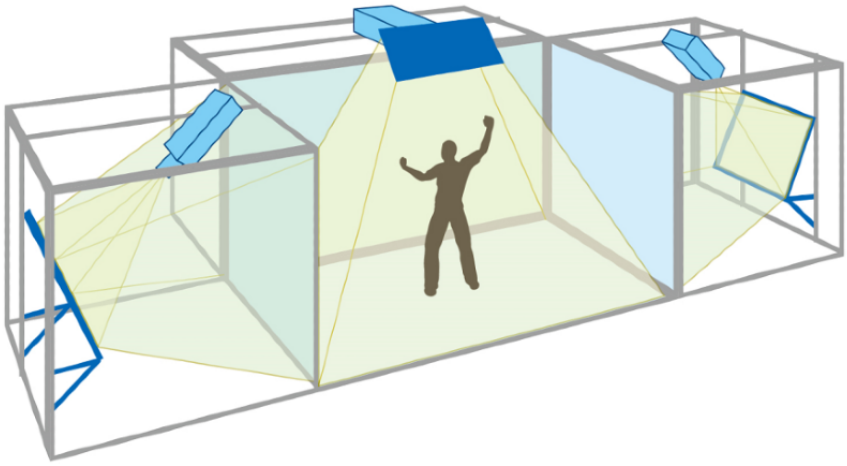
The dental simulator is a deep integration of computer and dental technology, mainly consisting of VR and force feedback technologies [15].

Virtual Reality

VR uses computer technology [16] to generate a digital environment similar to the real environment in the visual, auditory, tactile, and other senses [17], which is used in many different fields. The operator interacts with and feels feedback from the virtual objects using specialized equipment [18]. A complete VR system consists of a stereo display device, a motion tracking device, an input device, and a computing platform. The stereo display device is usually a head-mounted display (HMD; Figure 1) [19]; another type of stereo display is the Cave Automatic Virtual Environment (CAVE; Figure 2) [20]. HMDs are more widely used than CAVEs because HMD application is more flexible and requires less space.

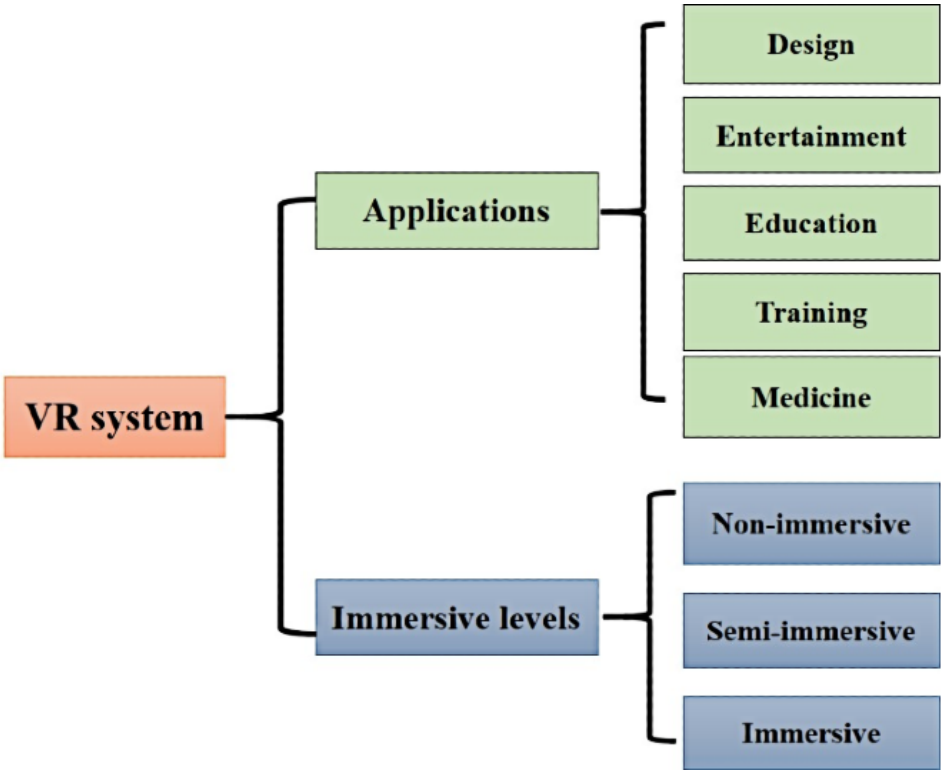
Figure 1. Head-mounted display and body motion sensors.

Figure 2. Cave Automatic Virtual Environment (CAVE).



VR systems are divided into three immersive levels based on the degree of stimulated senses and interactions: nonimmersive system, semi-immersion system, and immersion system (Figure 3) [21]. A nonimmersive system only reproduces images on desktops; an immersion system places the user in a complete virtual environment with the support of several sensory output devices including visual devices such as HMDs, audio devices, and haptic devices [22]; and a semi-immersion system provides the user with a simulated environment between the two above.

Figure 3. Applications and immersive levels of virtual reality (VR) systems.



In the implementation of VR technology, the key points are modeling and interaction. In the medical field, images from computed tomography [7,23], magnetic resonance imaging (MRI) [24], and dental scanners [25] can be used to rehabilitate virtual models. Interactions mainly contain visual interaction and tactile sensation interaction, which are actualized by display device and force feedback device, respectively.

In the medical field, VR and related technology are gradually being applied in surgical training [26] and surgical navigation systems [27]. Combining VR with medical training is a new research field that has emerged with the development of computer science, sensor technology, and automation technology. A virtual operating environment with high fidelity and real-time performance can be created through virtual simulation technology [14]. The system is created and processed by a computer, with dedicated devices such as a helmet display and a force feedback handle that allow the user to observe and interact with the scene while experiencing multisensory feedback that give a near-realistic training effect [28].

Force Feedback

Haptic devices can receive and transmit motion signals to improve the operator's sense of reality [29], which is important for dental training assisted by VR.

To simulate the tactile sense of real dental training as much as possible, the reaction force of the virtual object is calculated using the appropriate force generation algorithm in the VR system [30]. Due to the characteristics of human touch receptors, real-time haptic rendering requires a refresh frequency of at least 1 kHz [31]. For force feedback interaction in dental skills training, several kinds of interaction algorithms have been proposed for various scenarios, including teeth preparation, scaling, and bone drilling [32,33].

Introduction to Existing Dental Simulators

Overview

There is a wide variety of dental education simulators available, each with advantages and disadvantages in terms of training content, training process, hardware device, and software design. These are briefly described in Table 1.

Table 1. Comparison of dental simulators.

Characteristic	DentSim	Virtual Education System for Dentistry	IDEA[a]	Periosim	iDental	Simodont Dental Trainer	VirTeaSy	IDEAL[b]	Voxel-Man
Hardware facility									
Display type	2D display+ phantom head	2D display+ phantom head	2D display	3D glasses+ 2D display	2D display	3D glasses+ 2D display	3D glasses+ 2D display	2D display+ phantom head	3D glasses+ 2D display

[c]VR: virtual reality.

[d]Non: nonimmersive.

DentSim

The DentSim system unit, consisting of a phantom head and dentoform, dental instruments, infrared sensors, infrared cameras, and two computers, was born in 1997 [34]. The infrared cameras can capture the orientation and movement of resin teeth and a handpiece so as to show the students' work virtually on the computer screen in real time. The unit allows students to see the evaluation of their tooth preparation compared with the ideal preparation on the screen, while also providing them the ability to continue working on the resin teeth [35]. The training using DentSim is more efficient and standardized than that using traditional preclinical teaching methods [36]. The disadvantage of this unit is that it relies on physical resin teeth, which are disposable consumables.

Virtual Education System for Dentistry

Virtual Education System for Dentistry is a dental simulator for prosthodontics developed by the Affiliated Stomatological Hospital of Nanjing Medical University and Suzhou Digital-health Care Company. The system contains the Virtual Learning Network Platform (VLNP) and Real-time Dental Training and Evaluation System (RDTES) [37]. Prior to practical work, students are requested to learn courses on the VLNP, including reading the operational instructions and predefined criteria of crown preparation and watching the standard operational videos. Afterwards, students can perform crown preparations on the phantom head under the guidance of the RDTES; the processes and results can be recorded by the RDTES. When the students finish their preparations, the RDTES can automatically assess the procedures and results of preparation based on the predefined tooth preparation criteria. As well, the students can visually compare their own procedures and results with the predefined assessment criteria on the computer screen [37,38].

Individual Dental Education Assistant

Individual Dental Education Assistant (IDEA) is a VR hand flexibility training simulator consisting of a handheld stylus that simulates a dental handpiece and provides force feedback and a computer installed with simulation software. Unlike other dental simulators, IDEA is designed to enable students to be flexible and proficient in the use of dental handpieces by practicing removing predesigned virtual materials with different shapes (eg, straight line or circle). Therefore, IDEA aims to train dental students in hand flexibility, not to train students on a particular teaching component such as crown preparation or scaling. The main advantage of the system is its evaluation system. During the training process, two parameters determine the score obtained: drilling speed and drilling accuracy. Deviation from the trajectory or to an inappropriate depth can lead to a decrease in accuracy, and this is displayed as an accuracy bar on the screen. Complete depletion of the bar means that the student fails the test [39]. Some researchers have reported that IDEA could improve students' performance in the dental skill test; in addition, it can be used to identify students with troubles with hand flexibility at an early stage that may allow for early intervention to prevent failure [40,41].

PerioSim

PerioSim, consisting of a stereoscopic display, a computer, and a haptic device, allows students to use virtual dental instruments to visualize and detect caries and periodontal diseases in a haptic environment [12]. The system is available online for students and allows teachers to upload different training programs, which can be downloaded and replayed by students at any time, making this system convenient and efficient [35]. Steinberg et al reported that the image display and force feedback were very realistic for teeth and dental instruments but not for gingival tissue [42].

iDental

*i*Dental is a periodontal skill education simulator developed by Peking University School and Hospital of Stomatology and Beihang University, which can simulate periodontal examinations and treatment procedures including periodontal probing and calculus detection and removal. Unlike PerioSim, the device mainly uses a 2D monitor. However, it is equipped with an odontoscope handle, so it can be used to practice two-handed cooperative operation, making it realistic. *i*Dental also has a basic periodontal knowledge teaching module, which enables students to review basic knowledge before operation training. A combination of the two training parts improves the teaching effectiveness [43].

Simodont Dental Trainer

Simodont Dental Trainer is a widely used teaching simulator for dental skills training that is currently available in many dental schools. It mainly includes modules for hand flexibility, cariology, crown and bridge preparations, clinical cases, and a full mouth simulation experience [13,44]. One of the highlights of the system is that an X-ray of the working tooth is attached to each individual case, which can allow students to make a diagnosis assisted by both the appearance of teeth and the X-ray films [13].

The system does have some disadvantages. It requires 3D glasses for 3D display. Excessive training on a single tooth fails to create a realistic sense of manipulation. The training process for crown preparation is single-jawed and does not fully mimic the narrow operating space of the mouth. Besides, it cannot be used to train students about positioning requirements because operation postures during training are fixed and visual angle conversion requires manual rotation of the rotary button.

VirTeaSy Project

The VirTeaSy project is a dental implant training simulator and is composed of VirTeaSy Scan Implant and VirTeaSy Implant Pro. VirTeaSy Scan Implant is used for implanting scheme designs by students. Radiographs are used by students to perform the implant treatment plan, including the implant's characteristics (shape, diameter, length) and its location (location, angle, insertion depth) in the jaw. When the treatment plan is complete, it can be compared with the design planned by an expert that is stored in the database to identify where improvements could be made in their own plans. In addition, the device's database contains cases of varying difficulty, so students with different skill levels can use it to practice accordingly [45].

VirTeaSy Implant Pro is a virtual implant surgery training system, which allows students to perform surgery cases planned in VirTeaSy Scan Implant. VirTeaSy Implant Pro is supplemented by an auxiliary system that can alert students if the drilling's location, angle, and depth are incorrect as well as if there is overheating of the bone. In addition, the VirTeaSy Implant Pro has a display through which the teacher can interact with the student in real time and assist the student as necessary. VirTeaSy Implant Pro can improve students' skills in bone mineral density perception through force feedback, thus allowing them to perceive whether their bone density measurements in VirTeaSy Scan Implant match the reality [46]. VirTeaSy Scan Implant and Implant Pro complement each other, forming an efficient learning tool [45].

Internet of Things–Based Education and Learning System

The Internet of Things–based education and learning (IDEAL) system is an oral radiology education simulator. The simulator is mainly used for teaching students to take intraoral X-ray images without using X-rays. The IDEAL system consists of a simulator cone, simulator main body, sensor, detector, and stool. Training contents comprise basic education before X-ray imaging, information on X-ray imaging techniques (such as periapical radiography, bisecting angle technique, and paralleling technique), a test bank, and an evaluation and feedback system. During the training process, students can practice taking X-ray images for different tooth positions by adjusting the angle of the X-ray tube to improve their skills in taking X-ray images. At the end of training, students submit their own imaging results to the system and receive automatic feedback and evaluations from the system. The system allows students to avoid using radiographic devices while learning to take dental films, reducing the risk of radiation exposure to both students and patients. The system is safe and affordable [47].

Voxel-Man Simulator

The Voxel-Man simulator is a VR surgical simulator that primarily consists of a 2D monitor, simulated surgical operating handle, foot pedal, and 3D glasses. At present, the device is mainly used to simulate apical surgery, such as apical resection and apical cystectomy [48].

The system provides different training modes depending on the trainees' level, with different display interfaces and different operating instructions. The three modes to choose from are primary mode, advanced mode, and exam mode. In primary mode, the lesions and surrounding important anatomical structures (such as the alveolar nerve) are marked with bright colors. This not only helps operators to understand the anatomical characteristics of the corresponding surgical area, but also reminds them of the scope and amplitude of the operation at all times to help them avoid damaging these important anatomical structures. When the surgical instrument is close to an important anatomical structure, the system will emit a danger alarm. In advanced mode and exam mode, some of the functions and hints are turned off [48,49].

In addition, the system can record the operation process for later replay so that the operator can identify errors and mistakes to improve on [48]. The operator can stop the operation at any time and can undo a wrong step or restart a new one, saving a lot of time. Cases vary in difficulty, allowing operators with different experience levels to practice.

Advantages of Dental Simulators

Compared to phantom-based traditional training methods, dental simulators have many strengths that will offer students a better learning environment. Besides dental operation skills, students are also able to acquire relevant theoretical knowledge through dental simulators [37]. Since the dental simulators allow repeatable and reversible preclinical training of clinical skills [50,51], they give students a more flexible training experience [14]. They also allow digital objective evaluation and tutorial feedback [34,52] by recording the training processes [53]. In addition, training in dental simulators is more clinically relevant [54] because they recreate situations that are similar to those encountered in a real clinical environment [14]. It is certain that dental simulators can eliminate the risk of treatment and enhance the safety of patients [55,56]. Previous studies showed that training using dental simulators can save the time of faculty [50,57] and allow students to practice repeatedly whenever they want until they achieve mastery. Some studies reported that training in dental simulators can reduce training time compared with traditional training methods [57]. Therefore, the application of dental simulators in teaching can make up for the deficiency of traditional teaching methods and reduce the teaching burden, improving convenience for both teachers and students.

Current Disadvantages of Dental Simulators

The dental education simulators that have been described all have certain disadvantages in terms of both hardware and software.

Disadvantages of Hardware

The Stereo Vision of the Display Is Not Visible Enough and the Resolution Is Not High Enough

Currently, 3D displays in dental simulators are relatively behindhand. To achieve 3D display, most simulators use 3D glasses; these can slightly change the color of the oral tissues and can produce unpleasant effects such as vertigo and nausea [45,58]. In addition, 3D glasses change the image quality to a certain extent, reducing the resolution of the image. The display of oral tissue needs to be precise since the dental operation needs to identify subtle differences between different kinds of tissues, so a lower resolution may result in inaccuracy in the operation [59]. Image display can also affect the VR immersiveness, so it is necessary for researchers to find a higher resolution of 3D display to replace 3D glasses.

No Fixed Physical Finger Rest

A stable finger rest is of great significance in dental operations because of the small intraoral space and the requirement for precise dental operations [15,43]; without it, accidental injury to the surrounding soft and hard tissues may occur. Training on the use of finger rests is crucial in dental skills training, so finger rests should be provided for optimal simulation during dental skill training.

Lack of Bimanual Cooperative Operation

Bimanual operation is extremely important in dental operations. In general, the left hand of the operator manipulates an odontoscope to stretch and protect the soft tissues and reflect light, to ensure accurate and safe intraoral manipulation of the instrument held in the right hand. For optimal simulation of an operation on a real patient, training on bimanual operation in a dental simulator is essential [53,60].

Disadvantages of Software Design

Simulation of Force Feedback Is Not Realistic Enough

In clinical operations, dentists continually judge the process to determine whether to continue the operation by perceiving the different force feedback of the different oral tissues. Therefore, the fidelity of force feedback in the simulator is vital to dental training [27]. At present, the force feedback of oral simulators is based on a force-generating algorithm. This is different from the force feedback of a real instrument in contact with the oral tissue, especially soft tissue. Consequently, researchers need to work on improving the fidelity of force feedback in the future [14,61].

Simulation of Soft Tissue Deformation Is Not Realistic Enough

An oral environment simulation includes simulation of tongue and facial tissue deformation [62]. When a simulated surgical instrument collides with the deformable object, the object needs to deform accordingly. Deformation simulation is based on the physical properties of the soft body, such as density and elasticity. To express these properties, a physical model must be established; these commonly include the mass-spring method [63,64] and the finite element method [65]. The mass-spring method is simple and commonly used, but it is hard to maintain tissue volume information and set the stiffness of the spring. The drawback of the finite element method is that it is hard to use in real-time simulation [65]. Therefore, a physical model with higher calculation efficiency and more accurate simulation that can better represent the physical characteristics of oral tissues needs to be established.

The Training Content Is Insufficient

At present, many dental simulators do not have different degrees of difficulty in training, so students cannot learn step by step in the process of training. Moreover, the simulators have only basic skills training and lack the application of skills in clinical cases, so they cannot assess students' progressive mastery of skills. More comprehensive and systematic training content should be developed in the future [15].

The Evaluation of Training Results Cannot Be Accurately Quantified

It has been reported that professional instruction and performance feedback are beneficial for students' skills acquisition [66,67]. Some simulators cannot give an accurate quantitative evaluation of the student's operational results after training, so students do not know whether their operation results meet the requirement or not.

In summary, a good dental skills training simulator should be able to overcome these shortcomings, and its comprehensive features are summarized in Figures 4 and 5.

Figure 4. Hardware facilities required for a dental simulator. CAVE: Cave Automatic Virtual Environment; HMD: head-mounted display.

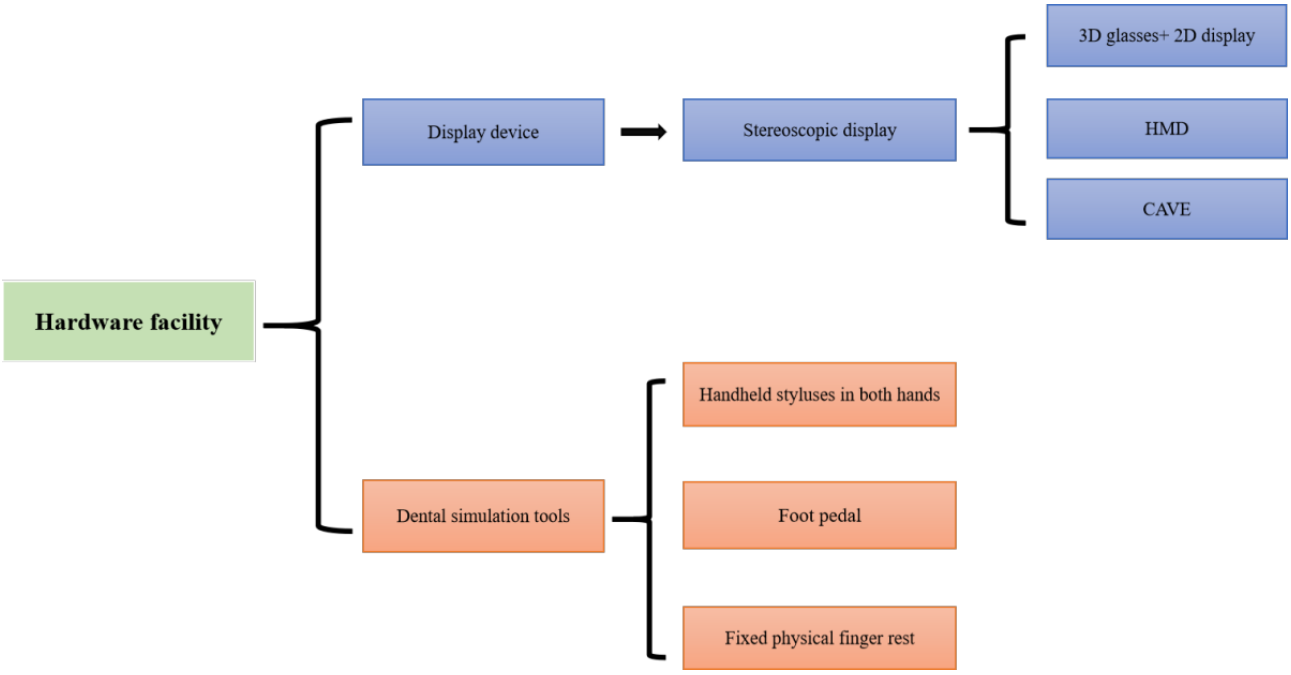

Figure 5. Software design required for an ideal dental simulator.

Effectiveness Evaluation of Dental Simulators

Methods for Effectiveness Evaluation

The effectiveness of VR systems can be evaluated using two analytical methods, qualitative and quantitative [15,43], which can be analyzed by questionnaires and comparative studies, respectively.

Questionnaires

Questionnaires are mainly used to investigate the subjective experience of people using the equipment, providing possible ways to improve the next iteration of the simulator. The content of the questionnaire is mainly based on the relationship between the user and the simulator. The simulator has two categories of users: trainers and trainees. For trainers, the device is a teaching tool and therefore needs to be evaluated for its auxiliary role in teaching, such as whether it reduces teaching cost or improves teaching efficiency. For trainees, the device is a learning tool and needs to be evaluated for learning effectiveness and construction of a learning environment [68]. Therefore, the content of the questionnaire should be designed according to the characteristics of the respondents.

The content of the questionnaire is mainly classified into two categories. The first category is the evaluation of the software and hardware of the device, involving force feedback, 3D modeling, the ease and convenience of using the device, the simulation degree, and the design of the device. Wang et al proposed a qualitative evaluation architecture based on the analysis of function components, which included the performance and usability of the simulator [15]. The second

category is the evaluation of the teaching effect of the device, which involves the subjective evaluation of the equipment effect by users [69]. The main questions in such questionnaires are whether the students think that the simulator assisted their study, improving their understanding of the related curriculum, and whether they are willing to use the simulator in their future study [70]. In addition, Venkatesh et al made the Unified Theory of Acceptance and Use of Technology questionnaire proposal to measure the acceptance of a new technology [71], and Bravo et al applied it to the use of dental simulators and concluded that it can assess the acceptance of dental simulators in dental education [72].

Comparative Studies

Comparative studies are mainly suitable for quantitative evaluation of objective function of a simulator, such as evaluating the role of the simulator in education compared with traditional teaching methods [73,74], the accuracy of the simulator at evaluating different kinds of trainees [46,75], and its accuracy in predicting the skill levels of students [76]. Barsom et al proposed a matrix of validity type to train medical professionals and classified the existing research methods including surface validity, content validity, construct validity, concurrent validity, and predictive validity [77,78].

Construct validity is the most widely used criterion in the functional evaluation of simulators [79]. The objects of the study of construct validity are populations with different clinical experience and skills in a corresponding specialty, such as experts and students [80]. By comparing the relevant parameters of using the simulator in different groups, construct validity of the simulator aims to distinguish different levels of dental skills. Dental trainees with diverse training time in a study by Mirghani et al [75] and dental students in their first year and experienced dentists in a study by Eve et al [45] were chosen to be trained using the simulator to evaluate its construct validity.

Influence Factors

Dental skills training takes the form of gradual acquisition, so the proficiency of training using the simulator can improve along with increasing familiarity with the training content. Urbankova et al concluded that repeating the training led to learning the test content, which could affect the results of the study [40]. Since VR is a new technology, teachers' sensitivity to the simulator may depend on their age, which could affect the results of the experiment. Therefore, questionnaires are often designed to eliminate the influence of these two factors [81].

Training and demonstration before the experiment, which allow objects to know the experimental flow and operational specification and eliminate the interference factors, are necessary [47]. Seymour et al tested trainees' visual ability, perception ability, and mental condition to exclude interference factors that affected experimental results [82].

Effectiveness of Dental Simulators

To date, many pilot tests have been conducted to evaluate the validity of dental simulators in endodontics [3,83], periodontics [12,42,43,84,85], oral and maxillofacial surgery [65,86-88], dental radiography [41], prosthodontics [37,59,85], implantology [89,90], and orthodontics [90]; the specific applications of dental simulators in dental education are summarized in Table 2.

Table 2. Applications of dental simulators in dental fields.

Dental fields	Training contents
Endodontics	• Dental caries detection • Caries removal • Light-curing skills • Endodontic cavity preparation
Periodontics	• Periodontal probing • Calculus detection and removal • Ultrasonic scaling
Oral and maxillofacial surgery	• Dental anesthesia training • Maxillofacial palpation • Dental extraction skills • Orthognathic surgery • Dental surgery
Dental radiography	Intraoral X-ray imaging
Prosthodontics	Tooth preparation
Implantology	• Implanting scheme design • Implant drilling skills
Orthodontics	Training and treatment planning in orthodontics

Many researchers are positive about the roles that dental simulators play in skills training. Al-Saud et al reported that students could gain basic manual dexterity at a quicker pace when they practiced skills with the guidance of experienced faculty, and training with dental simulators helped students to retain the skills they had learned [91]. A study performed by Plessas showed that students could develop a better understanding of the material by using dental simulators since they create a more varied learning environment compared with traditional training methods [74]. Suebnukarn et al evaluated

the effectiveness of dental simulators in cavity preparation and concluded that haptic VR simulators are equivalent to conventional dental phantom heads in reducing operation errors [92]. Other research provided evidence that students can improve their tooth extraction skills [93], dental radiology skills [47], and implant skills [32,90] through dental simulators. Dental simulators were also reported to be able to enhance students' confidence [94] and improve their attitudes toward patients [53] and abilities to discern and solve medical emergencies [70,95,96]. Some studies focused on students' acceptance of dental simulators and found that most students are willing to learn with dental simulators, which would boost their enthusiasm to learn [97]. Therefore, many research studies indicated that dental simulators had the potential to be an alternative to conventional training methods [36,52,98].

However, as mentioned above, there are still some disadvantages of dental simulators that can't be ignored, and these disadvantages may directly influence the effectiveness of dental simulators. In addition, the effectiveness of some dental simulators has not been validated [88,98]. Therefore, it is suggested that dental simulators cannot completely replace traditional skill training methods. The automated evaluation and tutorial feedback offered by dental simulators are considered to be complementary components to traditional methods [84]. Some studies concluded that a combination of traditional and virtual methods would be an optimal approach to choose in skills training [52,99,100].

Prospects of Dental Education Simulators

Current simulators are deficient in stereovision, video resolution, force feedback, instructional content, and outcome assessment; in response to these issues, we offer an outlook for their future development.

Visualized Analyses of Education Data Based on Big Data Technology

By applying big data technology to medical education, we can establish statistical models by the visual analysis method [101] via educational data mining and learning analysis [102], which allow trainers to analyze and understand the learning status of trainees intuitively. Currently, big data technology has been applied in educational analysis of massive open online courses [103] and learning effectiveness prediction for medical courses [101].

A similar big data analysis platform can be set up in dental skills training. We can collect dental operation data and establish a database of correctly performed operations. Then, a scientific evaluation system to score the training results by comparing them with the correctly performed operations can be created. Trainers can identify information on general problems in operations, as well as problems experienced by the individual trainee, to analyze and predict trainees' ability to master the skills, error-prone points, and the pass rate of examinations. Based on the analysis, trainers can create or adjust different plans for all trainees to enhance their learning experience and performance. Therefore, the combination of big data and education will make it possible to deeply understand and study the training process in order to provide more trainees with quality training.

Video Transmission With Quicker Speeds and Less Delay Supported by 5G

The development of 5G technology will allow transmission links with high bandwidth and low delay [104-106]. In the virtual oral training system, calculations are often performed on the server side to improve accuracy. The use of 5G technology will greatly increase the transmission rate of high-definition video data from the server host to the display device, reducing the response delay [107-109]. This will provide users with more reliable visual and tactile feedback and improve comfort [110].

Currently, the 5G quality of experience framework is proposed to solve the problem of transmitting ultra-high-definition video on the 5G network [111]. This could provide a basis for the establishment of a VR dental educational video network. Large-scale synchronous training and one-to-one demonstrations could be performed via 5G transmission to improve training efficiency.

Improvement of the Simulation of Force Feedback by Deep Learning

Deep learning techniques are widely used to find rules from a large amount of data, abstract problems through neural networks, and establish input and output mapping.

In the field of haptics, deep learning has been used to obtain haptic properties of objects from their images [112], whereby force feedback devices can directly generate a sense of force feedback that mimics the real physical properties without having to manually adjust physical parameters.

We can use deep learning to obtain the force feedback properties of teeth and build different deep learning models for different parts of the teeth. Therefore, the instrument would have different force feedback in contact with normal teeth, dental caries, tooth enamel, dentin, and other areas.

Deep learning can also play a role in oral modeling. Now, deep learning has been widely used in medical image analysis and modeling [113]. Through this type of method, we can easily extract relevant regions from computed tomography or MRI data and reconstruct mesh data [114]. These technologies can be transferred to oral cavity modeling, which can greatly facilitate model construction in a virtual surgery system and quickly establish a personalized oral cavity model.

Improvement of the Immersiveness of Dental Simulators by Augmented Reality

Augmented reality technology is an extension of VR technology, combining virtual images with real environments to support interaction with virtual objects in real time.

Nowadays, augmented reality technology has begun to be used in the medical field. Based on an augmented reality helmet (HoloLens by Microsoft), various applications have been developed such as surgical navigation applications [115] and intelligent medical management systems [116]. HoloLens also

supports a display of high-definition video derived from high-performance computing.

The virtual tooth and the phantom head can be combined with augmented reality technology in a dental training system. Students can feel the phantom head directly with their hands and interact with a virtual tooth through a force feedback device. At the same time, high-definition images allow users to observe finer tooth details, which can greatly improve the reality and the immersiveness of the experience. The users can also observe patients from multiple views, which will greatly enhance the trainees' understanding and learning of training objectives [117,118]. Therefore, augmented reality will have a significant effect on dental education in the future.

Strengths and Limitations

The strengths of this paper are as follows: First, we have come up with a summary of comprehensive features that a good dental simulator should possess based on the analysis of the advantages and disadvantages of current dental simulators. Second, this paper proposes the future prospects of dental simulators and provides researchers with new ideas for further studies.

Our paper also has some limitations. First, our paper lists the nine dental simulators that are commonly mentioned and studied in most articles instead of all kinds of dental simulators, which may have a little effect on the results of our study. Second, our study is focused on VR- and haptic-based dental simulators; as a consequence, some relevant papers may not be included due to inappropriate use of keywords.

Conclusion

Despite the fact that dental simulators are not currently able to rival traditional training modalities for skills training in some disciplines, they still have some advantages over traditional methods, and their effectiveness has been validated in some cases. More studies should be conducted to improve the force feedback, video transmission, and immersiveness of dental simulators. With scientific and technological development, dental simulators that gradually combine with big data, cloud computing, 5G, and deep learning technology will offer students individualized learning assistance, and their functions will be more diverse and suitable for preclinical training.

Acknowledgments

This work is supported by the Teaching Reformation Fund of Peking University School and Hospital of Stomatology (2018-ZD-04, HY; 2019-ZD-07, Y Liu), and all authors thank Beijing Unidraw VR Technology Research Institute Co Ltd for providing Figure 1.

Authors' Contributions

Y Li and FY designed the structure of this manuscript and wrote the paper; Y Liu, LL, PZ and XZ collected the data and revised the manuscript; and HY and YZ conceived and revised the manuscript. All authors approved the manuscript.

Abstract

Clinicians spend a substantial part of their workday reviewing and writing electronic medical notes. Here we describe how the current, widely accepted paradigm for electronic medical notes represents a poor organizational framework for both the individual clinician and the broader medical team. As described in this viewpoint, the medical chart—including notes, labs, and imaging results—can be reconceptualized as a dynamic, fully collaborative workspace organized by topic rather than time, writer, or data type. This revised framework enables a more accurate and complete assessment of the current state of the patient and easy historical review, saving clinicians substantial time on both data input and retrieval. Collectively, this approach has the potential to improve health care delivery effectiveness and efficiency.

(J Med Internet Res 2021;23(4):e24179) doi:10.2196/24179

KEYWORDS

electronic medical records; health informatics; information chaos; medical documentation; clinicians; medical notes; electronic medical notes; medical team

Electronic medical record (EMR) documentation is used for clinical, medicolegal, and billing purposes, as well as research, quality improvement, and population health initiatives. Each of these downstream use cases drives documentation requirements and influences day-to-day efficiency, work satisfaction, and quality of patient care. Poorly designed systems lead to the proliferation of out-of-date or incorrect information [1,2], increased time spent searching the medical chart [3], medical errors [2], and clinician burnout [3-5] while limiting the effective use of EMR data for individual and population-level applications.

Many clinicians are intimately familiar with the pathologies of "information chaos" in electronic patient charts [1]: large volumes of duplicate or *copy-pasted* information, scattered information requiring multiple navigation steps to locate, conflicting information, and outright erroneous information. Well-designed systems and workflows should incentivize data entry, storage, and retrieval behaviors that minimize these forms of information chaos. Conversely, when we see rampant information chaos, we should question and re-evaluate our default assumptions about documentation.

Currently, most medical documentation is organized in bundles or containers called "notes": documents containing many distinct but loosely related clinical observations, interpretations, and plans. Although notes lump together varied data from different sources regarding different topics, they are generally stored as indivisible units, written largely by a single author, and are rarely edited after initial creation. In their current form, notes organize information by time, by clinical thread (subject matter or team ownership; eg, primary team vs consultant), and by responsibility (the writer of a note simultaneously attests to the truth of, and takes responsibility for, all assertions within it).

These are the specific organizational principles and design choices that form the *note* paradigm. These principles—and their consequences for documentation—are easy to overlook when the note paradigm is the only paradigm most clinicians know. Notes have been the predominant organizational principle since the era of paper records, but what if *notes* are the wrong organizational paradigm and are largely responsible for the information chaos that plagues modern electronic charts?

Consider a set of notes written by a single clinician over time. Since each note is a disjointed bundle of information, recorded and accessed *separately*, there are two ways for a clinician to treat a set of sequential notes. The first is to treat each note as a complete *state of the patient* at a particular time. This approach has at least one major problem: the vast majority of a patient's medical information remains the same from time t to time t + 1. With this approach, clinicians not only habitually document the new updates but also copy and paste large portions of unchanged information from one note to the next to keep all of the information about the patient's current state in one place. This habit contributes to charts overloaded with duplicate information, makes it difficult for a later reader to easily identify what has changed from time t to t + 1, and makes it onerous to truly expunge errors from the chart because errors now require correction in multiple locations. On the other hand, some clinicians use each note to record only the *new updates* in the patient's state from t to t + 1. This practice scatters data that should be stored in a single place across multiple notes (eg, the time course of a patient's chronic medical problems), making it difficult for later readers to find relevant information and to piece together complicated medical histories. So, in the note's organizational paradigm, clinicians are in a lose-lose situation—forced to choose between large-scale information duplication (if each note is treated as a complete *state of the patient*) or information scatter (if each note is treated as a *bundle of updates*). Most clinicians choose not to adhere strictly to either of these strategies, leading to charts bloated with duplicate and yet seemingly incomplete data, medical histories that are onerous to synthesize, and hard-to-correct errors.

Notes are a poor organizational framework for the individual clinician, but they may be even worse for a collaborative medical team. Although little of a patient's medical information changes depending on the team or physician viewing it, different teams habitually redocument the same information (eg, the history of present illness) in separate notes, representing another large source of duplicated information. When information does differ between teams (eg, differing physical exam findings or a more in-depth cardiology history), it can only be identified by navigating between separate notes. Such practices not only contribute to information scatter and overload but also waste time on duplicate effort and limit optimal collaborative potential within the EMR.

The current note paradigm thus is a key source of information chaos and associated frustrations. We suggest the value of moving toward a nonnote paradigm in a wholesale effort to reimagine what the electronic medical chart should be. First, we suggest organizing information in the chart primarily by topic rather than by time, team, writer, or data type. This means rethinking how information is stored in the chart—not only the narrative text but also the structured data, including orders, medications, laboratory values, imaging, and other diagnostic results. These data should be tightly coupled to the relevant medical problems and associated free-text data, and update in place dynamically.

Next, the narrative medical chart should be reconceived as a dynamic living workspace—a set of shared and editable topics that contain only the most up-to-date information, rather than a set of separate, fixed time slices. Instead of requiring clinicians to painstakingly identify the information in the medical chart that is true at a given time, this approach ensures that the information present at a glance accurately depicts the most current state of the patient by default. However, the past patient states would still be easily accessible, by navigating forward and back through time, with a version history feature or *track changes* functionality (similar to modern word processing software). This feature would enable readers to quickly identify updates to the chart from t to t + 1 or to follow individual medical problems over time at a more granular level than allowed by notes. When documenting, clinicians would update only the changed information and attest to, but not redocument, the unchanged information. This would facilitate granular clinical updates as they occur (eg, a single medication change or a new symptom) without requiring an entirely new note or addendum. This dynamic workspace paradigm would save substantial time on both the data input and retrieval sides while mitigating incentives for information scatter and copy-paste. Problem-based charting is an appropriate but insufficient step toward this ideal.

A nonnote paradigm would also reduce information chaos at the team level. The chart could be reconceived as a fully collaborative workspace where information is, by default, shared among clinicians. Attestation would replace redocumentation as the primary mode of agreement, even across different clinical services. This is something already done in parts of the chart, for instance to confirm the allergies or family history. Disagreements could easily be documented under this system, but in the same topic-defined place, so that future readers can easily see where opinions differ. Customizable views of certain *slices* of information, depending on a user's needs, could facilitate service- or individual–specific dashboards for particular workflows. The version history system would enable granular tracking of which clinicians made which changes to a given chart, allowing for appropriate assignment of responsibility (for clinical, medicolegal, or billing purposes). Such a system could be applied to reduce duplication and scatter within a single hospital stay (consultants collaborating with primary teams) and across clinical contexts (an inpatient clinician collaborating with an outpatient clinician). Under such a system, to copy and paste text from another person's *note* would seem absurd—after all, the two clinicians share and edit the same dynamic workspace.

Deeper than specific software interfaces or billing requirements, our reliance on the note as the primary mode of information organization is a major contributor to clinicians' EMR frustrations. The note is largely a historical relic from the era of physical paper records, which has outlived its usefulness in the digital era. By questioning historical assumptions and

developing alternative documentation paradigms, we can reduce information chaos, promoting improved clinical care, efficiency, and health care worker satisfaction.

Conflicts of Interest

JS, JK, AS, and WB are cofounders of River Records, a health care technology company focused on improving clinician workflows.

Abstract

Background: Virtual reality (VR) and augmented reality (AR) interventions are emerging as promising tools in the treatment of pediatric chronic pain conditions. However, in this young field, there is little consensus to guide the process of engaging in the development and evaluation of targeted VR-based interventions.

Objective: The INOVATE-Pain (Interdisciplinary Network on Virtual and Augmented Technologies for Pain management) consortium aims to advance the field of VR for pediatric chronic pain rehabilitation by providing guidance for best practices in the design, evaluation, and dissemination of VR-based interventions targeting this population.

Methods: An interdisciplinary meeting of 16 academics, clinicians, industry partners, and philanthropy partners was held in January 2020.

Results: Reviewing the state of the field, the consortium identified important directions for research-driven innovation in VR and AR clinical care, highlighted key opportunities and challenges facing the field, and established a consensus on best methodological practices to adopt in future efforts to advance the research and practice of VR and AR in pediatric pain. The consortium also identified important next steps to undertake to continue to advance the work in this promising new area of digital health pain interventions.

Conclusions: To realize the promise of this realm of innovation, key ingredients for success include productive partnerships among industry, academic, and clinical stakeholders; a uniform set of outcome domains and measures for standardized evaluation; and widespread access to the latest opportunities, tools, and resources. The INOVATE-Pain collaborative hopes to promote the creation, rigorous yet efficient evaluation, and dissemination of innovative VR-based interventions to reduce pain and improve quality of life for children.

KEYWORDS

virtual reality; pediatric; chronic pain

Introduction

Background

The integration of digital health technologies into the treatment of acute and chronic pain has accelerated in the last decade. Digital health has the potential to increase patient engagement, reduce access barriers, and enhance patient-centered care, with the central goal of alleviating pain and disability in patients with chronic pain. Among these novel technologies are virtual reality (VR) and augmented reality (AR), which allow users to engage completely (VR) or partially (AR) in immersive and interactive digital experiences. VR and AR-based interventions have been found to be effective in reducing acute pain from medical procedures associated with transient pain (eg, distraction) among adults [1-3] and youth [1,4-6]. In this context, the effectiveness of VR arises from its ability to provide multisensorial engagement that can compete with pain signaling while also eliciting enjoyment and decreasing anxiety and negative mood [7]. Youth are particularly well suited to benefit from VR and AR-based pain interventions given their facility with technology and the ease with which they can engage in imaginative experiences [8].

Applying VR and AR interventions to persistent or chronic pain treatment often provides immersive experiences that go beyond redirecting attention away from a discrete painful stimulus to include physical, cognitive, and affective therapeutic targets [9]. There is growing recognition of the potential benefits of VR and AR for persistent pain, but our understanding of the mechanisms of effect and efforts to maximize the potential of these approaches for patients with persistent pain is just beginning to emerge, with those targeting youth with chronic pain being rare. To address this gap, we convened a group of pediatric pain experts to review the state of the field, identify important directions for research-driven innovation in VR and AR clinical care, and establish a consensus on best methodological practices to adopt in future efforts to advance the research and practice of VR and AR in pediatric pain. This paper summarizes the processes and outcomes of this meeting. Specifically, we outline key gaps in the field, examine models of collaboration to advance the development and evaluation of targeted VR technology, and offer recommendations for best practices for future efforts to advance the study and use of VR and AR in the treatment of pediatric chronic pain.

VR and AR interventions for the acute pain context rely primarily on VR's immersive capabilities to distract from the discomfort of the pain experience. In the context of persistent pain, intervention targets must be broad in scope (eg, address pain-related functioning) and enduring in their effects (eg, providing a sustained reduction in pain and/or improvement in functioning lasting beyond the time spent in the VR environment). In a recent systematic review of VR and AR for pain in adults (which included chronic pain cohorts), Mallari et al [2] concluded that VR appears to reduce chronic pain intensity while VR exposure is ongoing, but there is weak evidence for any lasting post-VR exposure effects on pain intensity with existing protocols. Of 10 studies on VR and AR for chronic pain included in the review, only 2 studies [10,11] expanded beyond a focus on pain intensity to measure functional outcomes. Both studies focused on chronic neck pain and demonstrated functional improvements on a standardized self-report measure of neck functioning during or immediately following the VR exposure, with 1 study [10] suggesting continued self-reported functional gains at a 3-month follow-up.

Trost et al [9] provided a timely overview of the existing research on VR applications for pain. The authors highlight the *3 pillars of VR*: presence, immersion, and interactivity, which vary in importance depending on the pain context (acute, experimental to examine mediators or moderators, or chronic). As noted by Trost et al [9], presence refers to the subjective experience of being in one environment while being physically situated in another. Immersion refers to the level of absorption a user experiences in the virtual world, and interactivity refers to the extent to which the user can manipulate the virtual environment. These authors provide a useful heuristic model that outlines technical VR configuration factors (eg, hepatic feedback), user experiential factors (eg, presence), and pain targets (eg, cognitive behavioral therapy skills) that converge to influence outcomes (eg, pain intensity) [9]. Importantly, these dimensions may vary based on the goals of the VR therapy context.

Many chronic pain studies have made the pillars of presence or embodiment and interactivity central to the target. Examples include studies of phantom limb pain [12,13] or spinal cord injury [14,15], with VR potentially amplifying the neuromodulatory effects of movement therapies. Less emphasized in the context of chronic pain is the pillar of immersion, given that distraction is less central in chronic pain management. For example, Villiger et al [16] used 16 to 20 sessions of VR to deliver intensive individual muscle training in patients undergoing neurorehabilitation for spinal cord injuries. The results showed both subjective and objective physical function improvements, with gains remaining stable at 12 and 16 weeks postintervention. Trost et al [17,18] pioneered the use of VR to deliver graded-exposure therapy targeting pain-related fear and disability in adults with chronic pain, recognizing the power of VR to facilitate pain-related movement in the presence of fear and behavioral avoidance. In addition to the recent work in this area specific to chronic pain, we can draw upon more robust literature on the use of VR for exposure-based treatments of other conditions. Several systematic reviews and meta-analyses of virtual reality–based exposure therapy (VRET) for anxiety disorders have shown that VRET is equal or superior to the gold standard of in vivo exposure for anxiety reduction [19-23].

Overall, there is support for using VR and AR as a tool to reduce perceptions of pain intensity in the context of procedural pain, including evidence of effects for children and adolescents. However, a recent review underscores the need for large, well-designed trials to fully evaluate the effects of VR on acute pain in children because of the variability and weaknesses in the study methodology to date [6]. There is growing evidence of the utility of VR and AR for reducing the intensity of chronic pain in the short term and emerging support for using VR in physical rehabilitation and to reduce the fear of pain through exposure-based paradigms in adult populations. The intersection of these areas—that is, the use of VR and AR technology to achieve multiple benefits (reduction of pain, disability, and fear or behavioral avoidance) over a longer period in the context of pediatric chronic pain rehabilitative treatment—is only emerging. To date, published work specifically focused on VR for pediatric chronic pain mainly includes small pilot studies, but these have demonstrated support for using VR to augment established treatments for pediatric chronic pain, including mirror visual feedback therapy for complex regional pain syndrome [24] and biofeedback for pediatric headache [25], with outcomes suggesting increased tolerance of rehabilitative therapies, reduced pain, and improved function and quality of life. Given the increasing accessibility of VR and AR interventions [26], their particular fit for pediatric populations, and their ability to complement and enhance standard approaches for the treatment of complex pediatric pain conditions [27], this is an important and timely area of innovation in our field. As new applications for VR and AR emerge, we need guidelines and best practices to inform the design and evaluation of new potential interventions.

Objectives

To review the current state of the field of VR for the treatment of chronic pediatric pain and to elucidate important directions for future research and innovation efforts, we convened a working group of experts across relevant domains to share lessons learned through their early work in this area and to generate consensus-backed recommendations for advancing the field. Herein, we provide guidance from the newly formed INOVATE-Pain collaborative (Interdisciplinary Network on Virtual and Augmented Technologies for Pain) for key domains: (1) describing models of academic-clinical-industry partnerships in the development and dissemination of immersive pain intervention approaches; (2) outlining current and future opportunities and challenges for evidence-based innovation, with an emphasis on collaboration across diverse sites, settings, and domains of expertise; and (3) identifying best practices in research on the use of VR and AR in children and adolescents with chronic pain, including recommendations for measuring meaningful outcomes of VR and AR-based interventions.

Methods

Participants

The INOVATE-Pain collaborative includes current contributors to science in the field of immersive interventions for pediatric pain rehabilitation, including clinicians, clinical researchers, neuroscientists, and VR software engineers. Potential participants were identified based on their involvement in ongoing work in the realm of VR for pediatric chronic pain treatment. Those first approached by the meeting organizer and chair (DL) were asked to suggest other participants who could represent different perspectives and experiences. Participants included all authors from the following institutions and organizations: Stanford Children's Health network, the Stanford Childhood Anxiety Reduction through Innovation and Technology (CHARIOT) program, Boston Children's Hospital (BCH), Cincinnati Children's Hospital Medical Center (CCHMC), The Hospital for Sick Children (SickKids) in Toronto, University of Southern California or Children's Hospital of Los Angeles (CHLA), Stanford Virtual Human Interaction Lab, and Mighty Immersion, Inc (a company focused on VR device management tools). This was the first meeting of this group. Follow-up meetings were planned but have not been executed because of the COVID-19 pandemic. The group continues to hold monthly Zoom meetings to continue the work that began at the initial meeting. This meeting was supported by The Mayday Fund. A representative from The Mayday Fund was invited to attend the meeting to provide perspective on the funding landscape and report to The Mayday Fund board on the proposed strategic directions of the INOVATE-Pain collaborative.

Setting

The meeting took place over the course of 2 days (January 22-23, 2020) in Palo Alto, California.

Procedures

The impetus for the INOVATE-Pain consensus meeting arose through The Mayday Fund's efforts to connect individuals engaged in funded research on VR for chronic pain with those seeking funding for proposed projects in this area in the hope of promoting greater collaboration and standardization in the

field. The meeting convened with a structured agenda (Multimedia Appendix 1) and planned deliverables for a consortium focused on VR and AR innovations in pediatric pain rehabilitation. Briefly, the meeting began with an overview of the state of the field and moved to reports from each participating academic medical center on their clinical and research-based uses of VR in pediatric chronic pain, followed by a discussion of new technological developments from our industry partner (LW) and his clinical collaborators. Group members representing the funding world and laboratories exploring the use of VR technology in adult populations shared relevant insights. This was followed by a discussion of best practices, with particular emphasis on what outcomes are most relevant to assess when evaluating pediatric chronic pain VR and AR interventions and what tools would be best for such assessments. The second day focused on arriving at a consensus on important new directions in the field and models of collaboration that bring clinicians, researchers, and industry partners together in ways that are mutually beneficial, nonexploitative, and hold patient care as a shared primary goal. Time was devoted to developing INOVATE-Pain's mission and vision statement, along with strategic goals focused on what our collaborative can offer the field. Finally, we outlined plans for moving forward with actionable, collaborative projects and outputs. Detailed notes were recorded throughout the meetings by the nonparticipants.

The meeting relied on consensus decision making in an open discussion format. To begin, we drew on case examples of current and potential projects overseen by group members to develop a shared understanding of where the field stands and to identify gaps. During discussions, the chair and cochair (LS) kept time limits and reflected themes and major points to the group to ensure that members were in agreement on how these were conceptualized. We then engaged in structured brainstorming sessions derived from ideation methods in design thinking, an approach now being applied to health care innovation and education [28]. We undertook this process for several of our key agenda topics, including identifying important outcome domains to assess in VR studies and developing our collaborative's mission, vision, and strategic goals. Given the group's relatively small size, discussions and brainstorming exercises were held with the full group. We adhered to design-thinking brainstorm rules (ie, time limit, stay on topic, defer judgment, encourage wild ideas, aim for quantity, build on each other's ideas, be visual, and one conversation at a time) utilizing a whiteboard and unlimited Post-its. Following the ideation phase, we grouped similar ideas and labeled these larger constructs, which ultimately became the major themes we discuss in our results (see Multimedia Appendix 2 for this exercise's visual depiction).

Results

Describing Models of Collaborative Partnerships to Advance VR Development, Implementation, and Evaluation

As a first step in identifying successful collaboration models, meeting attendees illustrated ways in which such partnerships have succeeded in their own settings to date.

The Stanford CHARIOT Program

The CHARIOT program has led the field in clinical applications and innovations in VR for pediatric procedural anxiety and pain. Having used VR in more than 5000 patients since 2017, the scope of impact and dissemination of VR software tools across 25 institutions worldwide reflects a motivation to rapidly equip hospitals with VR tools for patient care, particularly in the realms of procedural discomfort and anxiety. In addition to the direct distribution of content to these hospitals, the software developed by Stanford CHARIOT has been included on hospital VR platforms used by more than 200 hospitals and clinics in the United States.

Stanford Pediatric Pain Rehabilitation

Since 2018, the Stanford Children's Health Pediatric Rehabilitation Program (PReP) for youth with chronic pain has used VR interventions during physical therapy, occupational therapy, and individual psychology sessions. The program obtained a dedicated VR therapy room for use during the PReP treatment sessions. In collaboration with the Stanford CHARIOT program and through support from The Mayday Fund, a VR platform called Fruity Feet was developed with the PReP interdisciplinary team. This platform was created through an iterative process from PReP provider and patient feedback for improvements and modifications. The overall goal was to improve function and reduce the fear of pain. The initial implementation of Fruity Feet VR tested the acceptability and feasibility of facilitating increased upper and lower extremity engagement [29]. This platform was simultaneously tested with an inpatient population during physical therapy sessions with large effects on movement observed in VR compared with the standard of care physical therapy (Caruso et al, unpublished data, August 2019).

In response to the COVID-19 pandemic, this work involves pilot testing of at-home VR for pain rehabilitation. With PReP operating in a telehealth format for all treatment interventions, youth in PReP were provided with VR equipment for home use during telehealth sessions with providers and independently for their daily home exercise plan. Preliminary data for the at-home VR intervention are forthcoming, but the initial interview feedback is positive.

Cincinnati Children's Hospital Medical Center

Since 2018, the use of VR in patients with pain at CCHMC has followed a -pronged approach: a clinical research arm for managing acute postoperative pain and a clinical application arm for patients with chronic pain undergoing inpatient rehabilitation. Our team has conducted 2 pilot studies in children with moderate to severe pain after surgery, one of which used

distraction-based virtual reality (VR-D) and guided-relaxation virtual reality (VR-GR) using the Mindful Aurora app [30-32]. This pilot study demonstrated that a single, postoperative session of both VR-D and VR-GR was associated with small changes in pain and anxiety lasting up to 30 minutes. This pilot study supports the implementation of VR therapy in managing acute postoperative pain in children and the need for future studies. The CCHMC team worked with Stanford CHARIOT to use VR programs appropriate for pediatric patients. This partnership has afforded the clinical team access to VR content that is highly engaging and motivating for children and adolescents.

Going forward, the VR team continues to explore engaging and innovative ways of using VR for pain management. By adding VR to postoperative pain management, we hope to augment our primary strategy of multimodal analgesia by increasing patient motivation and engagement in alternative therapies (eg, distraction and relaxation). Plans are in place to continue the implementation of VR into chronic pain rehabilitation with an emphasis on increasing social interaction in group settings through cooperative VR activities and improving movement and body awareness by incorporating VR into physical and occupational therapy.

The Hospital for Sick Children

Clinicians and researchers have been implementing VR at SickKids over the past 8 years in diagnostic imaging and emergency departments for intravenous insertions [33], perioperative services to prepare children for anesthesia during the perioperative period, and for subcutaneous port-a-cath access in oncology (Aqua KindVR) [34,35]. In a single-site pilot randomized controlled trial comparing VR (peaceful underwater gamified environment) with iPad (Apple Inc; underwater video with headphones) for oncology procedures, nurses, parents, and children reported the interventions in both groups to be acceptable, with the VR participants reporting significantly higher immersion, an underassessed outcome metric in studies of VR for pediatric pain. In addition, there were trends toward reports of less pain and distress during procedures in the VR group compared with the iPad group [35].

More recently, the SickKids Chronic Pain Clinic rehabilitation team used the Fruity Feet program developed through collaboration with Stanford CHARIOT in a quality improvement (QI) project to implement and evaluate the hospital's rehabilitation department. The QI project involved interviews with 10 adolescents and their physical therapists (PT) and found that participants reported a high acceptance of the program, high immersion and high satisfaction, no adverse events, and lower pain scores after using VR. PTs also reported that VR was easy to use and feasible to implement in the pediatric rehabilitation setting. Given the success and clinical need, SickKids has successfully advocated for a dedicated child life specialist to help with the clinical implementation of VR coupled with a programmatic approach to rolling out new interventions using evidence-based methods.

Boston Children's Hospital

With support from The Mayday Fund, the BCH has played a central role in developing the INOVATE-Pain network. This partnership has afforded BCH with opportunities to gain VR expertise from initiatives undertaken by the leaders of the pediatric pain VR field. In addition, this collaboration has provided BCH with opportunities to creatively explore and expand the utilization of VR in the treatment of pediatric chronic pain and to plan research initiatives to evaluate these novel applications.

Since 2010, the BCH's intensive pain rehabilitation day program has used a basic interactive gaming platform, Xbox Kinect (Microsoft Corporation), to engage youth with chronic pain in their daily treatment. Given this technology's success and popularity, BCH is actively seeking the integration of newly released VR into their pain rehabilitation program. Initial efforts in this process focus on replicating the success established at Stanford, SickKids, and CCHMC in using VR-based physical therapy, occupational therapy, and psychological interventions in the context of our intensive pain rehabilitation day hospital program. In addition, the BCH team is leading the effort in the development of a novel, immersive VR-based intervention targeting successful school reentry in the context of intensive pain rehabilitation. These innovative efforts have successfully garnered the philanthropic support needed to bring them to fruition.

Children's Hospital of Los Angeles

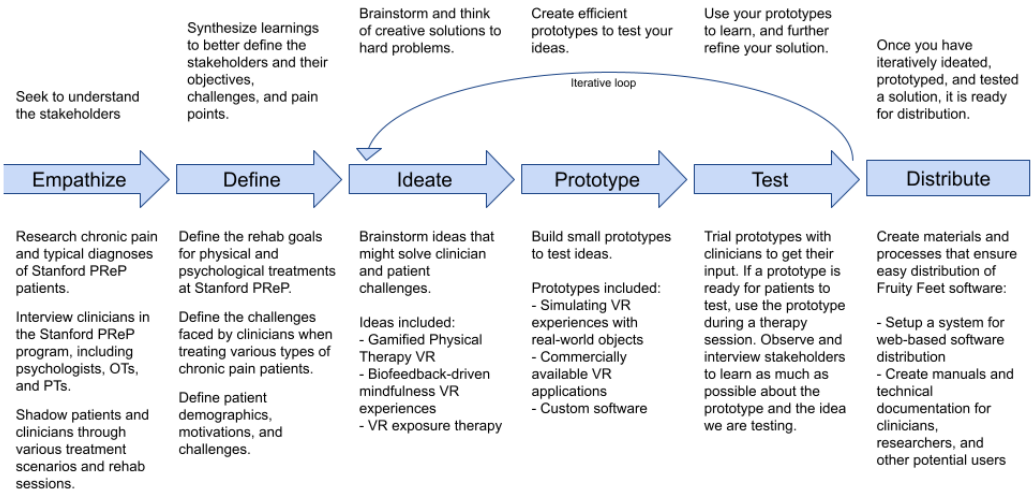
Clinician-scientists at CHLA have been exploring the use of VR for acute pain management for more than 20 years, pioneering its use with children for routine painful procedures [8,36-38]. Since its inception, the BioBehavioral Pain Lab at CHLA has partnered with academic institutions, technology companies, software developers, and other VR collaborators to maximally leverage content expertise in health care, technology advancements, and input from clinician-scientists to design and implement rigorous VR clinical trials to scientifically investigate the feasibility, usability, and efficacy of VR for managing pain with routine medical procedures. Early and recent efforts with technological advancements have fundamentally changed clinical service lines at CHLA in phlebotomy, where children coming for outpatient phlebotomy can now request VR as a standard of clinical care for blood draws. Recently, VR clinical research has focused on VR home-based systems. As virtual care has been catapulted by telehealth, home-based VR has become critical for ongoing VR investigations.

Partnerships in Action: The Fruity Feet Experience

Leveraging our collective experiences thus far, a key deliverable of the meeting was to build from these experiences to define optimal collaborative models to bring clinicians, researchers, industry partners, and funders together in ways that are mutually beneficial, nonexploitative, and hold patient care as a shared primary goal. The industry partner, Luke Wilson of Mighty Immersion Inc [39], provided an overview of the design-thinking framework used to build the VR program developed specifically for pediatric pain rehabilitation treatment centers, *Fruity Feet*, which is currently being implemented at Stanford, CCHMC, and SickKids (Figure 1). In addition to targeted software experiences, we identified additional tools crucial to the successful implementation of VR interventions in patient care settings. First, *device management tools* can facilitate updating

all of an institution's VR tools, track their location in busy clinical settings, and remotely manage devices as needed. Second, *companion applications* enable controlling the VR experience from a second device (eg, provider's phone), thus tweaking the therapy to fit the patient and therapeutic target. Third, *analytics capture tools* collect movement data, create playlists for VR protocols, and display real-time patient movement. Although seamless integration is the goal, having a technically knowledgeable team member is critical to reducing the clinician time burden and ease of implementation. Industry partners can provide valuable training to develop clinician champions who can oversee VR integration in clinical settings.

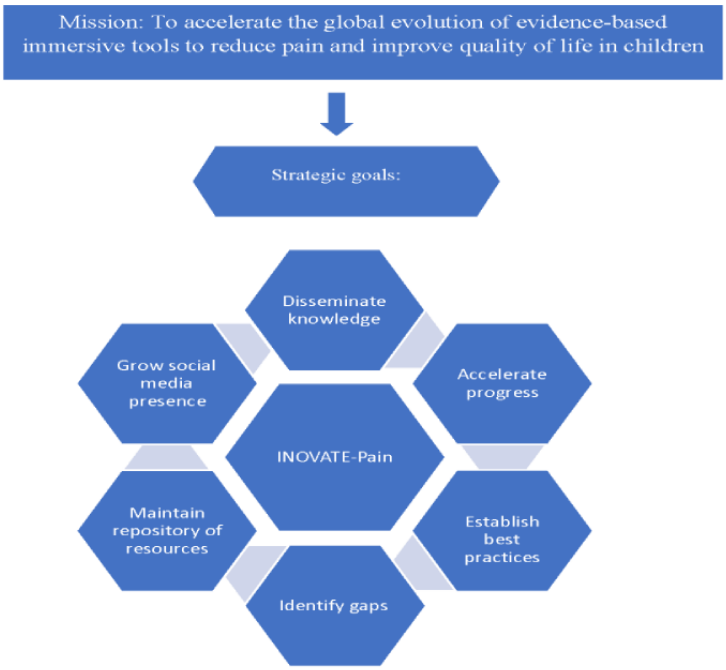
Figure 1. Fruity Feet/Design Thinking Development. PTs: physical therapists; OTs: occupational therapists; VR: virtual reality.



Defining a Mission and Vision for INOVATE-Pain

Building off this discussion of successful industry-academic partnership, the mission statement, vision, and strategic goals for the INOVATE-Pain collaborative were defined through design-thinking exercises and a consensus process. In formulating our mission, vision, and goals, we sought to differentiate our collaborative from existing programs by asking what we could add to the current efforts in the field. For example, how did we differ from the Stanford CHARIOT program, which uses VR in a broader range of populations and emphasizes the global dissemination of technology? Did we want INOVATE-Pain to be a marketplace for ideas, a repository of resources, and/or an established multisite consortium for new research projects? Through discussion, we identified a strong commitment to fostering and facilitating research and evaluation, given the importance of building an evidence base to support the use of VR interventions. As previously noted, a design-thinking process enabled us to identify the themes that were most widely endorsed by the group as important to our mission and vision, and further discussion of these themes led to full consensus. The mission and vision of accelerating the global evolution of evidence-based immersive tools to reduce pain, reduce disability, and improve children's quality of life are supported by our strategic goals (Figure 2).

Figure 2. Mission and strategic goals of the INOVATE-Pain (Interdisciplinary Network on Virtual and Augmented Technologies for Pain management) consortium.



Outlining Current and Future Challenges and Opportunities in the Field

A second key goal of the meeting was to identify both challenges and opportunities to move the field forward, along with ways that a collaborative network such as INOVATE-Pain could serve to capitalize on the opportunities and surmount the challenges. The 4 major factors were identified as follows: (1) industry versus academic approaches to the evaluation process, (2) discrepant resources and endpoints across academic, clinical, and industry collaborators, (3) proliferation of technology products and companies, and (4) adoption of VR in research and clinical applications.

Industry Versus Academic Approaches to the Evaluation Process

The importance of interdisciplinary, multi-institutional, and cross-contextual (industry, academic, and clinical) collaborations toward developing VR software and clinical investigations cannot be understated. However, there are challenges inherent in aligning approaches to the development and evaluation of products in each of these contexts. Navigating logistical, regulatory, and intellectual considerations is a challenge when collaborating with similar institutions (eg, academia), and they are amplified when hospitals and universities attempt to work with industry and commercial partners. Common hurdles that arise include the differing pace of development, the need to navigate multiple regulatory systems, and distinctions in the desired scope or target of the intervention. Start-ups and industries tend to move very quickly with innovation efforts and face fewer regulatory barriers than academic medicine. Large academic and clinical institutions have many layers of regulation, such as intellectual property (IP) considerations when developing products and licensing and billing issues when delivering these interventions in the clinical setting. This raises particular challenges in the realm of digital health and emerging technologies. After a rigorous randomized clinical trial is funded, institutional review is granted, and data are collected and analyzed (a course of action often measured in years), the technology under investigation may be rendered obsolete. However, opportunities exist within these challenges when these 2 approaches can work in a complementary fashion to pursue more nimble approaches to evaluation and dissemination. For example, clinical settings can provide real-world testing grounds and patient populations that are difficult for the industry to access alone. Meanwhile, performing some of the product development in the industry setting may allow the process to move more quickly than projects housed entirely within the academic environment.

In addition to working out issues of project pace and addressing regulatory requirements, partners may differ in their views of project scope. There are advantages and disadvantages to developing interventions tailored to a specific clinical population versus creating widely applicable tools, but potentially less targeted to a particular population (eg, disease condition and age group). This may be particularly true of VR, where there is a huge range of potential software applications and a variety of potential mechanisms of effectiveness that can be harnessed. There is tremendous opportunity to be leveraged when industry and academic partners come together early in the design process so that these advantages and disadvantages can be considered together and interventions can be designed to fit real-world clinical needs, rather than trying to retrofit existing products to use with specific patient populations. Fruity Feet is an excellent example of a collaboration that capitalized on the collaborative process to develop a project that held broad enough appeal to be useful in multiple contexts while also meeting specific needs of children with chronic extremity pain undergoing rehabilitative pain treatment.

Academic, Clinical, and Industry Collaborators May Have Different Resources and Endpoints

Related to, but in some ways separate from, the challenges around evaluation design, resources are a major point of negotiation in developing productive partnerships for VR innovation. Resource sharing between collaborators can offer huge benefits in evaluating new interventions, but resource sharing can also multiply hurdles. Given the obligations one assumes when undertaking this type of endeavor and the time and effort required to succeed, it is critical for academic partners to enter carefully into these partnerships to avoid becoming an open testing ground for too many industry products.

For academic and clinical researchers, opportunities lie in the fact that industry partners can bring specific financial benefits to fuel the research endeavor, with tech-savvy personnel and computer science skills exceeding those typically found within academia. In turn, academic partners bring expertise and access to some funding opportunities (eg, National Institutes of Health [NIH] Small Business Innovation Research and similar mechanisms, seed funding to pilot new ideas), along with the ability to gather data for extra- or intramural grant applications, culminating in peer-review publications contributing to the evidence base in VR. Other benefits to academic partners include the possibility of IP or equity in a start-up that could also contribute to academic success or contribute to building a financially secure lab for ongoing research and future collaborations. The industry tends to focus on validating their product through institutional acceptance and the association with large prestigious medical and/or university settings. Conversely, some industry partners want to engage with content expertise to iterate and improve their products to increase efficacy and impact. Ideally, similar-minded academic-industry collaborations focus on creating an ecologically sound product that delivers on the idea that technology can assist in solving complicated health care problems.

Proliferation of Technology Products and Companies

The major challenge in the vast immersive technology marketplace is finding effective products that arise from sound research-based development. Over time, the cost of VR hardware has significantly reduced. Once an experimental scientific *ivory tower* effort with limited clinical application, it has evolved into affordable, off-the-shelf products that operate with minimum components to increase ease of use. The accessibility of VR products provides new opportunities for integrating these interventions into clinical care. VR hardware has become highly sophisticated and affordable such that most clinician-scientists can now afford to add it to their toolkit or even work with equipment owned by patients. In addition, as the industry expanded, the inventory has grown from very few available virtual experiences (VEs) to hundreds. Even so, very few VEs have been scientifically well established as gold standard interventions for clinical problems.

Adoption of VR in Research and Clinical Applications

Although there are typical barriers to the adoption of new technologies in pediatric health care, VR research and adoption are particularly challenging. First, given the lack of VR safety research in pediatrics, most hardware manufacturers do not recommend VR for children before adolescence. This can further delay institutional review board approval and require additional safety monitoring that is not required with widely accepted hardware, such as tablets. Second, given the typical age of users, the headsets often require custom modifications to appropriately fit children's head circumference to facilitate such safety and efficacy research. Third, because VR is applied directly to the patient, near the nose and mouth, infection control practices require close attention. Many consumers facing VR products include cloth straps and face pads, which present challenges to sanitation among patients. Finally, although reduced costs have made VR headsets more affordable, they are still a relatively costly adjunct given the lack of reimbursement offered by insurance for their utilization. In the future, appropriate reimbursements will mitigate the cost of implementation.

Define and Refine Best Practices

The final major goal of our consensus meeting was to begin to develop a set of best practices for conducting methodologically sound research in VR in the context of pediatric chronic pain treatment. The best practices for VR and chronic pain management have not yet been established. Determining best practices is complex, as this academic-industry collaboration has many facets that include but are not limited to hardware products; software products; building an evidence base; and incorporating heterogeneous disease processes; and age, gender, linguistic, and cultural considerations. This section addresses 4 primary areas, recognizing that each area requires specific customizability for the targeted project: (1) assembling the right team, (2) developing or applying the best technology for the target project or population, (3) designing and executing a sound research design and methodology, and (4) disseminating the collaborative work process and study findings.

Assembling the Right Team

This is not an easy task, as industry start-ups are often quite eager to partner with academic VR leaders and to gain access to clinical populations to pilot and test their VR experiences. It is critical as a clinician-scientist to thoroughly vet potential partners. In these initial meetings, it is also critical to *right-size* the project and the timeline, that is, determine goals and benchmarks that are agreeable to all partners and appropriate to the desired outcomes. Aligning project scope, timeline, and financial concerns; assembling a team that includes all necessary domains of expertise; and clearly defining each team member's role are vital preliminary steps to determining the *match* between academia and industry (Textbox 1).

Textbox 1. Guidelines for establishing positive academic-industry partnerships in virtual reality innovation.

Partner assessment

- What is the reputation and track record of the industry partner?
- Are they a for-profit or nonprofit entity?
- What is their understanding of the research process?
- What are their expectations for what the academic or clinical partner(s) will provide?

Project validation

- What is the project scope?
- What is the expected timeline for deliverables?
- What are the deliverables or intended outcomes?

Understanding funding structure

- Who underwrites what aspects of the project, both in terms of money and effort?
- Is work done for compensation or in-kind arrangement?
- Discuss intellectual property arrangements—include academic or hospital legal representatives

Developing or Applying the Best Technology for the Targeted Project or Population

It is essential to carefully define the target population in the early phases of designing a VR and AR-based intervention. There are advantages and disadvantages to developing highly tailored products. On the one hand, clinical utility is paramount, and having an intervention that clearly targets a specific clinical problem increases the effectiveness of the intervention. On the other hand, the time and effort needed to create and evaluate such interventions steer away from creating products that appeal to a broader population in terms of clinical condition, age, and gender. A product that is not sufficiently specific in its intended application may be more challenging to validate through research trials. Ideally, the goal should be to create a suite of tools with options for customizing the experience to achieve a balance between specificity and broad application to a range of patients who can benefit from the intervention.

Designing and Executing the Right Research Design and Methodology

After establishing a partnership and aligning the direction and goals of the collaboration, a well-designed study to evaluate the project is vital. As with any clinical research, the goals, available sample, resources, and timeline should drive the study design. Studies to evaluate VR-based interventions can take a variety of scientifically rigorous forms before or in lieu of traditional clinical trials. Depending on the scope and goals, feasibility or usability studies, QI studies to evaluate clinical implementation, pilot studies to inform more definitive trials, and adaptive trial designs to reduce time to results may be appropriate. Ultimately, the use of rigorous design, methods, and standardized patient-reported outcomes will be critical to both the academic and the start-up and industry. The use of flexible and agnostic technology is critical for testing new software programs and moving toward disseminating new information and evidence-based results. It is necessary to set realistic shared visions, missions and objectives and to develop task-oriented timelines with deliverables. There is a need to move away from the traditional, cumbersome randomized controlled trial approach to evaluating VR interventions and toward more adaptive and efficient evaluation methods [40].

A critical element of research design is the thoughtful selection of measures to assess processes and outcomes. To date, there is no clear consensus on how to evaluate a VR experience appropriately or how to tailor the evaluation to the specific context of the intervention. As described earlier, immersion may be central in the context of acute pain distraction, whereas interactivity is paramount for pain rehabilitation and exposure-based VR protocols. Unfortunately, even in the VR field more broadly, there are no gold standard measures of embodiment, presence, and immersion, and more research is needed (see Multimedia Appendix 3 for an example measure of some of these constructs used in pediatric research). In clinical settings, it may also be important to assess provider satisfaction and feasibility in terms of how the intervention fits into the overall workload and workflow. Failure to understand and address these aspects can lead to lack of buy-in from clinical partners (see Multimedia Appendix 4 for an example measure of these constructs).

Although the factors that influence outcomes may vary, the outcomes of interest should remain uniform and consistent across studies and clinical contexts. On the basis of the discussion and consensus at our meeting, we present recommended domains of measurement to evaluate VR interventions for pediatric chronic pain (Textbox 2). Some of these domains have been deemed critical for pediatric chronic pain within the NIH common data elements (CDEs [41]). These CDEs include pain intensity, pain interference, functioning, pain catastrophizing, and treatment satisfaction [41]. Additional general domains considered particularly important for VR include affect and fear of pain or movement. Moreover, we highlight the VR-specific metrics to consider. These include physical movement, energy expenditure, physiology, and immersion. In the context of pain rehabilitation, increasing

movement is a highly relevant outcome that can be measured in real time [29]. An added consideration is the frequency of assessment, as it is likely that data collection may range from continual, session-contingent, daily, or milestone-based (eg, start of treatment and discharge). Ideally, a thorough measurement of an intervention will consist of a combination of these measurement timelines. For example, a study could include objective, continuously collected measures of physical activity and movement metrics cataloged during VR sessions, brief questionnaires deployed daily to capture gradual changes and enable single case experimental design analyses [42], and a longer battery of questionnaires completed at specified time points (eg, baseline and 3-month follow-up) to assess changes over time from repeated VR exposure.

Textbox 2. Recommended domains of measurement to evaluate virtual reality interventions for chronic pain.

Pediatric chronic pain

- Pain intensity (common data element for pediatric chronic pain from the National Institutes of Health recommendations [41]) and unpleasantness
  - Visual Analogue Scale [43]
  - Numerical Rating Scale [44]
- Pain interference (common data element for pediatric chronic pain from the National Institutes of Health recommendations [41])
  - Brief Pain Inventory [45]
  - PROMIS-Pain Interference [46]
- Functioning
  - Functional Disability Inventory [47]
  - Lower Extremity Function Scale [48]
  - Upper Extremity Functional Index [49]
  - Canadian Occupational Performance Measure [50]
- Fear of pain and movement
  - Fear of Pain Questionnaire-Short Form [51]
  - Tampa Scale of Kinesiophobia [52]
- Pain catastrophizing (common data element for pediatric chronic pain from the National Institutes of Health recommendations [41])
  - Pain Catastrophizing Scale [53]
- Affect
  - Positive and Negative Affect Schedule 10 item [54]
  - Childhood Anxiety Sensitivity Index [55]
- Satisfaction with treatment (common data element for pediatric chronic pain from the National Institutes of Health recommendations [41])
  - Patient Global Impression of Change [56]

Virtual reality specific

- Physical movement
  - Motion capture [57]
  - Actigraphy [58]
  - Wearables
- Energy expenditure
  - YUR Fit app
  - Wearables
- Physiology
  - Heart rate
  - Galvanic skin response
  - Respiration
  - Functional magnetic resonance imaging
- Immersion or presence
  - Child presence measure (Multimedia Appendix 2)

Dissemination of the Academic-Industry Collaborative Work Group and Study Findings

Not all collaborative efforts were the same. From the onset, it is critical to set mutually agreed-upon deliverables. As previously noted, academic goals are often quite different from industry objectives. Some of these discrepancies need to be addressed in the first phase of the academic-industry collaborative, establishing clear goals or deliverables. The framework (*for-profit* or *nonprofit*) can greatly influence the end goal. Ultimately, both the collaborative process and the findings derived from the academic-industry collaborative need to be published in peer-reviewed journals and disseminated widely to promote the innovation and proliferation of evidence-based technology in health care. To that end, healthy, transparent, well-communicated projects can lead to fruitful and rewarding collaborations for the academic and medical partners, industry, patient and their family, and ultimately, society. INOVATE-Pain is working to create a repository for protocols, products, resources, and recommendations to guide study design and clinical implementation that can be openly accessed in an effort to advance dissemination of the work in this field and increase opportunities for collaboration.

Discussion

Principal Findings and Next Steps

In an area as rapidly evolving and complex as digital health, there is a need for multisite efforts and cross-disciplinary collaboration to keep pace with emerging technology and develop sophisticated studies that build a sound and useful evidence base. Our consortium brought together expertise in software development, clinical applications, experimental work in VR, child psychology, physical or occupational therapy, experience in navigating IP issues and bringing industry partners into the hospital setting, and funders who provided insight into how projects can be competitive for financial support. This represents a diverse group that does not meet often to think of the challenges and opportunities in the field. Our guidance and recommendations are aimed primarily at academic and clinical partners, and we hope that further work by our group can also provide more guidance targeting best practices on the industry side of these partnerships. Furthermore, given the nascent nature of this area of innovation, our current focus is primarily on research and evaluation of new interventions. However, the ultimate goal is for VR interventions to become an evidence-based, widely adopted routine component of clinical care in pediatric chronic pain treatment.

Work to date highlights tremendous opportunities in this area of digital health innovation, with immense promise for improving the treatment of pediatric chronic pain. However, this remains a challenging field to navigate given the number of outstanding issues regarding how to identify and form productive collaborations across academic, clinical, and industry partners; how to design and obtain resources to support solid research protocols to evaluate potential interventions; and how to bring interventions from conceptualization into clinical use in large, complex institutional settings where they can be accessible to patients with the greatest needs.

We identified several important next steps to advance the field toward our mission of accelerating the global evolution of evidence-based immersive tools to reduce pain and improve the quality of life in children with pain. These include the following:

1. *Developing and maintaining a repository of resources.* We are working to collect and curate protocols, publications, available software products, information on funding mechanisms, and other resources to serve as a clearinghouse for researchers and academically oriented VR experience designers. Vetting information and opportunities and housing this information in a centralized, accessible, web-based location may help to lower the barrier to engaging in this field and better standardize the approach to evaluating new interventions. We plan to work synergistically with other like-minded groups in the field, such as the Invincikids nonprofit consortium [59].
2. *Continue our efforts to establish a gold standard set of outcomes to be measured in pediatric pain VR research and specific recommended measurement tools.* Well-validated measures exist in some of the recommended outcome assessment domains we describe but are notably lacking in domains including presence, immersion, interactivity, impact on clinical workload or workflow, and the subjective experience of both the clinician and patient users. Imminent steps toward this goal include undertaking a Delphi process to determine a minimal core data set for pediatric pain VR research and, where gaps are identified, working to develop tools to fill these gaps.
3. *Offer opportunities for education and connections in the field.* Through training opportunities and symposia, we hope our group can increase exposure to the work that has been done to date, disseminate current best practices, and facilitate connections among additional potential collaborators and industry partners who can bring new energy and ideas to advance the INOVATE-Pain mission.
4. *Work together to advance current projects and launch new interventions in a rigorous, appropriately resourced environment.* For example, we have begun planning a trial to develop and evaluate a VR intervention that exposes patients in pediatric intensive pain rehabilitation treatment to the challenges they face in returning to school settings. This intervention would incorporate physical therapy, occupational therapy, and psychological aspects and would be tailored to the specific fears and barriers each patient identifies, making returning to school such a challenging goal. We look forward to designing this project in the context of the INOVATE-Pain collaborative, where we can seamlessly access the full range of expertise needed to develop this type of patient experience and access to a large patient population by scaling the project up to multisite data collection. This is an example of the goals we can attain through the partnerships we have sought to create in this collaborative. Through specific projects, we also hope to evolve the approach to studying VR interventions in the pediatric pain environment, with the goal of balancing the rigor of traditional clinical trial design with the efficiency and creativity needed to deliver promising VR products and experiences to pediatric chronic pain patients in a

timeframe that keeps pace with digital health technology innovation.

Conclusions

In summary, VR is an exciting and promising digital health tool whose applications for reducing pediatric chronic pain are just emerging. To realize the promise of this realm of innovation, key ingredients for success include productive partnerships among industry, academic, and clinical stakeholders; a uniform set of outcome domains and measures for standardized evaluation; and easy, widespread access to the latest opportunities, tools, and resources. By exploring the current opportunities, challenges, best practices, and important next steps in VR for pediatric chronic pain, the INOVATE-Pain collaborative hopes to promote the creation, rigorous yet efficient evaluation, and dissemination of innovative VR-based interventions to reduce pain and improve quality of life for children.

Acknowledgments

The authors acknowledge funding from The Mayday Fund supporting the January 2020 planning meeting and some of the ongoing work of the INOVATE-Pain collaborative. The authors would like to thank Gillian Rush, Deborah Shear, and Marissa Heirich for taking detailed minutes during the summit meeting.

Conflicts of Interest

TC, SR, and EW are on the board of directors of Invincikids, a nonprofit company that seeks to distribute immersive technology to pediatric healthcare centers. They receive zero financial compensation for this role.

Abstract

Supportive couple relationships are associated with reduced risk of chronic illness development, such as cardiovascular disease, as well as improved secondary prevention. Healing Hearts Together (HHT) is an 8-week couples-based intervention designed to improve relationship quality, mental health, quality of life, and cardiovascular health among couples in which one partner has experienced a cardiac event. A randomized controlled trial began in October 2019 to test the efficacy of the in-person, group-based HHT program as compared to usual care. In March of 2020, all recruitment, assessments, and interventions halted due to the COVID-19 pandemic. Guided by optimal virtual care principles, as well as by Hom and colleagues' four-stage framework—consultation, adaptation, pilot-testing, and test launch—this paper is a tutorial for the step-by-step transition planning and implementation of a clinical research intervention from an in-person to a web-based format, using the HHT program as an example. Clinical and research considerations are reviewed, including (1) privacy, (2) therapeutic aspects of the intervention, (3) group cohesion, (4) research ethics, (5) participant recruitment, (6) assessment measures, (7) data collection, and (8) data analyses. This tutorial can assist clinical researchers in transitioning their research programs to a web-based format during the pandemic and beyond.

Introduction

This tutorial aims to help clinical researchers transition their in-person research programs to a web-based format during the pandemic and beyond. To our knowledge, no literature exists on how to navigate the steps required to transition a randomized controlled trial (RCT), designed for in-person delivery, to an online world. No one has outlined, for example, contacts with sponsors and research ethics boards, recruitment procedures, or informed consent changes. This paper expands the previous transitional work in a clinical-only environment by accounting for the unique demands of clinical research and RCTs. The Healing Hearts Together (HHT) RCT provides researchers a current example of this challenging transition. We begin by briefly describing the original in-person HHT intervention and research protocol. We then guide clinical researchers through five important stages of transition: (1) consultation and assessment of needs, (2) adaptation of procedures and materials

for web-based delivery, (3) adaptation of procedures and materials for the research protocol, (4) pilot sessions, and (5) the final launch of the web-based intervention and research protocol. We have also included a useful checklist of all the critical clinical and research elements that must be addressed so that the transition can be done in an efficient and ethical manner (see Multimedia Appendix 1 for checklist).

Original In-Person HHT Program

A healthy couple relationship (ie, one in which partners feel loved, emotionally supported, respected, and cared for) is a significant protective factor, particularly against cardiac disease incidence and outcomes [1-5]. Healthy relationships can influence positive cardiac outcomes in direct and indirect ways. Direct examples include improved high-frequency heart rate variability and decreased diastolic blood pressure in supportive relationships [6-8]. Indirect links to cardiovascular health include adaptive behavioral pathways, such as partners influencing health behaviors (eg, prepare low sodium meals), modeling healthy behavior (eg, exercise), or assisting in the management of disease (eg, medication management) [9-11]. In contrast to their more distressed peers, happily married cardiac patients demonstrate stronger adherence to blood pressure medication regimens and cardiac rehabilitation programs [12,13].

Unfortunately, the reverse is also true. Relationship distress can have a negative impact on heart disease. A recent meta-analysis showed that poor social relationships were associated with a 29% increase in risk of incident coronary artery disease [14]. Uchino and colleagues found that coronary artery calcification scores were higher for individuals who expressed ambivalence rather than positivity about their couple relationship [15]. Other researchers have highlighted the indirect pathways by which relationship distress influences cardiac outcomes, including smoking and alcohol use in response to relationship problems [16].

Despite burgeoning evidence indicating that healthy relationships are vital for reducing chronic disease incidence and management, current secondary prevention programming inadvertently neglects a crucial resource for disease management: the patient's partner. In order to address this gap in clinical care, the HHT program [17] was created with the aim of helping both cardiac patients and their partners better manage cardiac disease by strengthening the emotional bond between them. The goals of HHT are to help couples improve their relationship quality, mental health, quality of life, and cardiovascular health. The HHT couples-based intervention is adapted from the Hold Me Tight: Conversations for Connection (HMT) program [18], an intervention based on emotionally focused therapy (EFT) for couples, which is an empirically supported treatment for relationship distress [19,20]. EFT, HMT, and HHT are based on attachment theory, which states that humans have an innate need for close emotional bonds to significant others [10,11]. This need becomes especially pertinent when faced with a threat or stress (eg, a cardiac event); it triggers proximity seeking to "attachment figures" in order to regulate affect. EFT interventions help couples identify and articulate their vulnerability (eg, "I almost died/I almost lost you") and respond to these feelings in comforting ways, thereby solidifying their sense of security and emotional connection [19,21]. Couples who achieve this connection are happier in their relationships and are more effective problem solvers (eg, managing cardiovascular disease) [22-24]. Inspired by HMT, the HHT program guides couples through seven conversations, based on EFT principles, in which they learn to clearly communicate their need for connection and reassurance, with a focus on heart disease and healthy coping.

Preliminary results from a proof-of-concept study indicated that couples who participated in the HHT program reported significant improvements in relationship quality, mental health, and quality of life [25]. Based on these promising results and to assess the efficacy of the HHT program on a larger sample with additional cardiovascular outcomes, an RCT was initiated. Eligible patients and their partners who consent to participation undergo a baseline assessment and then are randomly assigned to either the HHT program or usual care at the hospital. Usual care participants are followed by their physician for clinical assessment and are referred to the standard programming at the center. All participants are reassessed at 8 and 24 weeks.

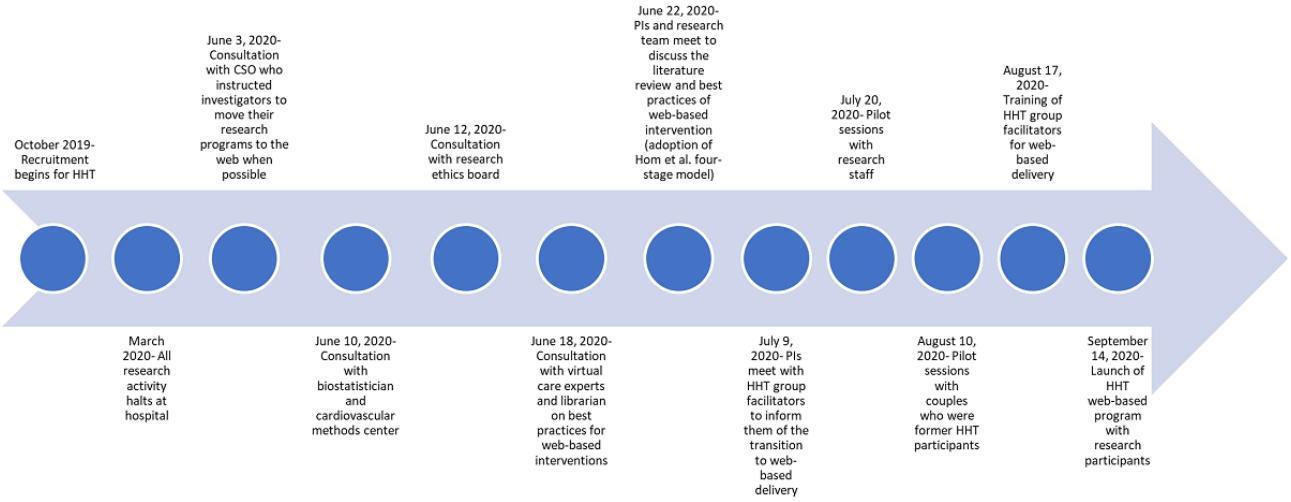
Prior to the COVID-19 pandemic, participants who were randomly assigned to the HHT group attended, in person, eight weekly 2-hour sessions led by two facilitators. The eight sessions focus on understanding love, attachment, and their relationship to heart health; provide an opportunity to share experiences related to cardiovascular disease with partners and peers; and assist in identifying and improving communication patterns that may inhibit positive interactions and healthy behaviors. Throughout each 2-hour session, participants are introduced to concepts through didactic presentations, videos, group and couple discussions, and homework exercises. Additional study procedures and intervention content will be reviewed below as the in-person and web-based HHT programs are compared.

Stage I: Consultation and Assessment of Needs for the Intervention and Research Protocol

Overview

During the first few months of the COVID-19 lockdown in March, April, and May of 2020, the chief scientific officer stopped all research in the hospital. At that time, it was not clear that HHT would have to transition to a web-based platform; many researchers were hoping that the situation with COVID-19 would stabilize within a few months. However, in June 2020, researchers at the hospital were asked to adapt their research protocols to allow for as much virtual care as possible. Following these directives, the HHT research team began to focus on how to do this while following best practices and preserving the integrity of the trial (see Figure 1 for a timeline of the transition to a web-based intervention during COVID-19).

Figure 1. Timeline of the transition to a web-based intervention during COVID-19. CSO: chief scientific officer; HHT: Healing Hearts Together; PI: principal investigator.



Literature Review

The principal investigators of HHT met at the beginning of June 2020 to outline a plan for transitioning to a web-based intervention as well as to review all study procedures to identify areas of required revision (eg, recruitment procedures and presentation of intervention content online). An examination of the current literature to aid in this transition was completed. We were able to identify best practices for virtual care (1) by seeking the help of a research librarian, who assisted with a literature review of resources on how to transition from an in-person psychological intervention to a web-based format, and (2) by consulting with internationally renowned experts in virtual care, who also directed our attention to pertinent literature.

The literature review yielded a small number of resources that provided a framework for the transition [26-33]. More specifically, these articles highlighted key areas of telehealth development, including patient involvement [29], technological support and training for the group facilitators [27], a strong working alliance during web-based therapy [33], ethical considerations [30], and the importance of comprehensive information technology (IT) training and support [28]. A systematic review of telehealth interventions delivering home-based support with group videoconferencing highlighted several benefits of web-based interventions, including improved accessibility, engagement with others facing similar challenges (eg, cardiovascular disease), development of health knowledge and skills, and improved mental health outcomes similar to face-to-face groups [28]. Finally, Hom and colleagues [26] provided a useful framework for modifying a clinical psychiatric program for a web-based platform using four stages: consultation, adaptation, pilot-testing, and test launch.

Research Staff Communication

Following the literature review and consultation with virtual care experts, a focus on ensuring open and clear communication among the members of the research team, who were all working from home, was needed. We chose a web-based collaborative workspace (eg, Trello and Slack) to streamline staff communication and to assign tasks and deadlines to research staff. This avoided the hassle and confusion of sending multiple emails regarding project updates. Instead, we simply log in to our web-based communication board to view the task list to be completed and by whom. Regular weekly lab meetings were also transitioned to a videoconferencing platform. These meetings assisted in the organization of deliverables and facilitated lab staff cohesion, morale, and motivation during these unprecedented times.

Updating the Funding Agency and Ethics Board

Shortly after research was halted at the hospital, the study's federal funding agency reached out to the nominated principal investigator proactively with an update reassuring all researchers that the funding window would be extended due to the COVID-19 crisis, and that no extra report or documentation would be required. The research coordinator updated the study registry, ClinicalTrials.gov, and the hospital's electronic medical record, noting that the study was no longer actively recruiting. Researchers may need to contact their sponsors or funding agencies to inquire about their specific requirements.

Consultation with our institutional ethics board regarding required study updates for the transition from a predominantly in-person-based study to one with virtual methods was then conducted. Within days of the shutdown, we informed the research ethics board of all changes in research activities (eg, phone contact to inform patients, no recruitment, and temporary follow-up by mail). Although the move to a web-based HHT program does lower the risk of COVID-19 transmission to our participants, there is also an increased risk of privacy breaches with an online format. In response to privacy concerns, a form outlining the changes to our methods and protocol, noting strategies to protect personal health information and privacy, was submitted to the research ethics board for approval. Once the approval was received, a form requesting permission to restart our research study was submitted to our research services department lead by the chief scientific officer of our institution. In this form, we outlined the safety protocols for the in-person baseline and follow-up assessments at the hospital, including appropriate personal protective equipment, cleaning the

workspace once participants have left, physical distancing when possible, and equipment changes to ensure that COVID-19 is not transmitted (eg, new valve in the carbon monoxide monitor). Our research staff attended a consenting and documentation seminar for studies conducting virtual recruitment, consent, and interventions at our facility. The principal investigator completed an online training seminar on how to use the hospital-approved secure videoconferencing platform linked with the hospital's secure electronic medical record software. This information was subsequently shared with staff.

Stage II: Adaptation of Procedures and Materials for Web-Based Delivery

Optimal Web-Based Care Principles

To ensure that we were following best practices in the provision of psychological services via telepsychology, we referred to the guidelines provided by the American Psychological Association [34], the Canadian Psychological Association, and the Ontario Psychological Association, in addition to the previously mentioned resources from the literature review [26-32]. For the purposes of this tutorial, we will highlight the best practices that were most relevant to our study and the adjustments that were required for the research protocol.

Provincial Jurisdiction of Psychological Services

Patients from the neighboring province of Quebec frequently seek services at our Ontario hospital. Because Quebec patients would no longer be able to come to the hospital to participate in the HHT program, the principal investigator contacted the Order of Psychologists of Quebec to obtain their permission to provide services to Quebec residents via a web-based platform. Due to the unusual pandemic circumstances, this permission was swiftly granted. It is recommended that clinician researchers ensure they have the appropriate credentials to provide care in the jurisdiction of the patient.

Security and Transmission of Data and Information

As per the directives at our institution, the hospital-approved videoconferencing platform was employed to run the HHT groups online. The principal investigators reviewed every session of the HHT program and determined that the intervention elements could be delivered securely via videoconferencing.

Appropriate Medium of Delivery

Another crucial factor in successful web-based therapy is the existence of adequate technology, equipment, and usability for research staff and participants. Previous research has shown that web-based interventions face common IT and visual issues, such as audio difficulties, delays, dropouts, background noise, difficulties downloading software, and poor lighting [28]. In response to these common challenges, a checklist for facilitators and potential participants was created to confirm that they had the necessary equipment, technology, and space to do HHT in a web-based format in a secure and private manner. It includes questions that assess whether they have (1) internet access (ie, Wi-Fi or ethernet) at home; (2) two devices that allow for videoconferencing (ie, camera and microphone), such as a desktop computer or laptop, a tablet or iPad, a Chromebook, or a smartphone; and (3) a quiet and private room in their residence.

Stage III: Adaptation of Procedures and Materials for the Research Protocol

Recruitment

Before the pandemic, recruitment was conducted in person at the hospital when patients came to see their cardiologists for follow-up appointments. Members of the research staff spoke with patients after their appointments and presented an overview of the HHT program. Interested patients agreed to be contacted by study staff, who described the study in greater detail and answered any questions. If still interested, an initial assessment appointment was scheduled. With the new COVID-19 restrictions, most clinical care is done virtually (ie, phone or video appointments). A new standard operating procedure for HHT recruitment was developed outlining the steps to call patients who have already given general consent to be contacted for research purposes at our center. With no in-person clinical visits, recruitment is now completed entirely over the phone. Members of the research staff call potential participants shortly after their phone consultation with their cardiologist and review the technology checklist before proceeding with the recruitment script. If patients do not have the necessary computer equipment, they are not eligible for the study at this time. As the pandemic restrictions ease, patients without the necessary technology will be provided the option to engage in person if randomized to the HHT condition.

Informed Consent

As our study is nonregulated and low risk, our institutional ethics review board informed us that we could adopt a well-documented verbal consent process that permits the research coordinator to read the full written informed consent form to potential participants via telephone. Participants can then ask the research coordinator any questions they have about the study before granting verbal consent. The research coordinator must document the consent process in the participant's research file and electronic medical record, with the help of a verbal consent checklist. If requested by the participant, the consent process may also be completed in person at the time of the assessment at the hospital. In this case, the in-person consent process will still be completed verbally with no transfer of paper between staff and participants.

Other secure methods of obtaining consent via electronic signature software and electronic consent platforms (eg, Research Electronic Data Capture [REDCap] e-consent framework, DocuSign, and Adobe Sign) may also be considered. The advantage of these systems is that they provide a user-friendly option for individuals to personally sign the consent form. However, there are potential disadvantages that include cost, the need for additional institutional approval, and complexity barriers for less tech-savvy individuals. Finally, there is the traditional method of obtaining informed consent by which the study team establishes a process, in alignment with research regulations, whereby the paper consent form is mailed to the participant and, following the consent discussion,

the participant signs the paper consent form and mails it back to the institution. Researchers who are working with external sponsors need to verify with their institution and their sponsor the appropriate informed consent process to use during the pandemic.

Assessment

In the original protocol, patients are asked to come to the hospital for a baseline assessment and two follow-up assessments. Physiological measurements are taken, including heart rate variability, blood pressure, height, weight, waist circumference, carbon monoxide concentration, and salivary samples. In addition, all the couples are asked to participate in a conflict resolution task (ie, a discussion of topics that engender conflict, such as finances, in-laws, or jealousy) that is video-recorded for analysis. The research team initially explored ways to complete these measures remotely, but realized it was not possible for many reasons (eg, cost, coordination of assessment, and variability in measurement). To facilitate coordination of staff on site, the hospital research support office implemented a shared calendar for staff to indicate when they would be on site so as to not exceed maximum pandemic capacity and to allow the coordination of clinical research activity among staff.

Stage IV: Pilot-Testing and Streamlining of Procedures

Pilot Tests

Once the HHT in-person intervention was adapted for web-based administration, the principal investigators (ie, trained group facilitators) ran pilot web-based HHT group sessions with volunteers from the research staff and their partners to identify any issues or problems. During these sessions, features of the videoconferencing platform were explored and problems addressed (eg, chat function and breakout rooms). During the traditional in-person format, the facilitators can quietly and respectfully check in with couples who are working privately on an in-class exercise together. The facilitators realized, however, that without the in-person visual cues, it would prove difficult to identify couples in need of assistance during the breakout sessions or to enter these sessions unannounced. Couples also have the option of notifying their hosts that they are in need of assistance. In addition, to prevent an intrusive interruption, facilitators now provide participants with a screen announcement—audio and video off—letting them know that a facilitator would like to join their breakout room. Next, permission to join is requested via audio, before their video image is shown. It is important to note that videoconferencing services now have excellent online support centers with helpful videos and tutorials where researchers can learn and explore the features and strategies that exist to enhance their web-based intervention. The lessons learned from the pilot tests were used to create separate tutorials for group facilitators and participants.

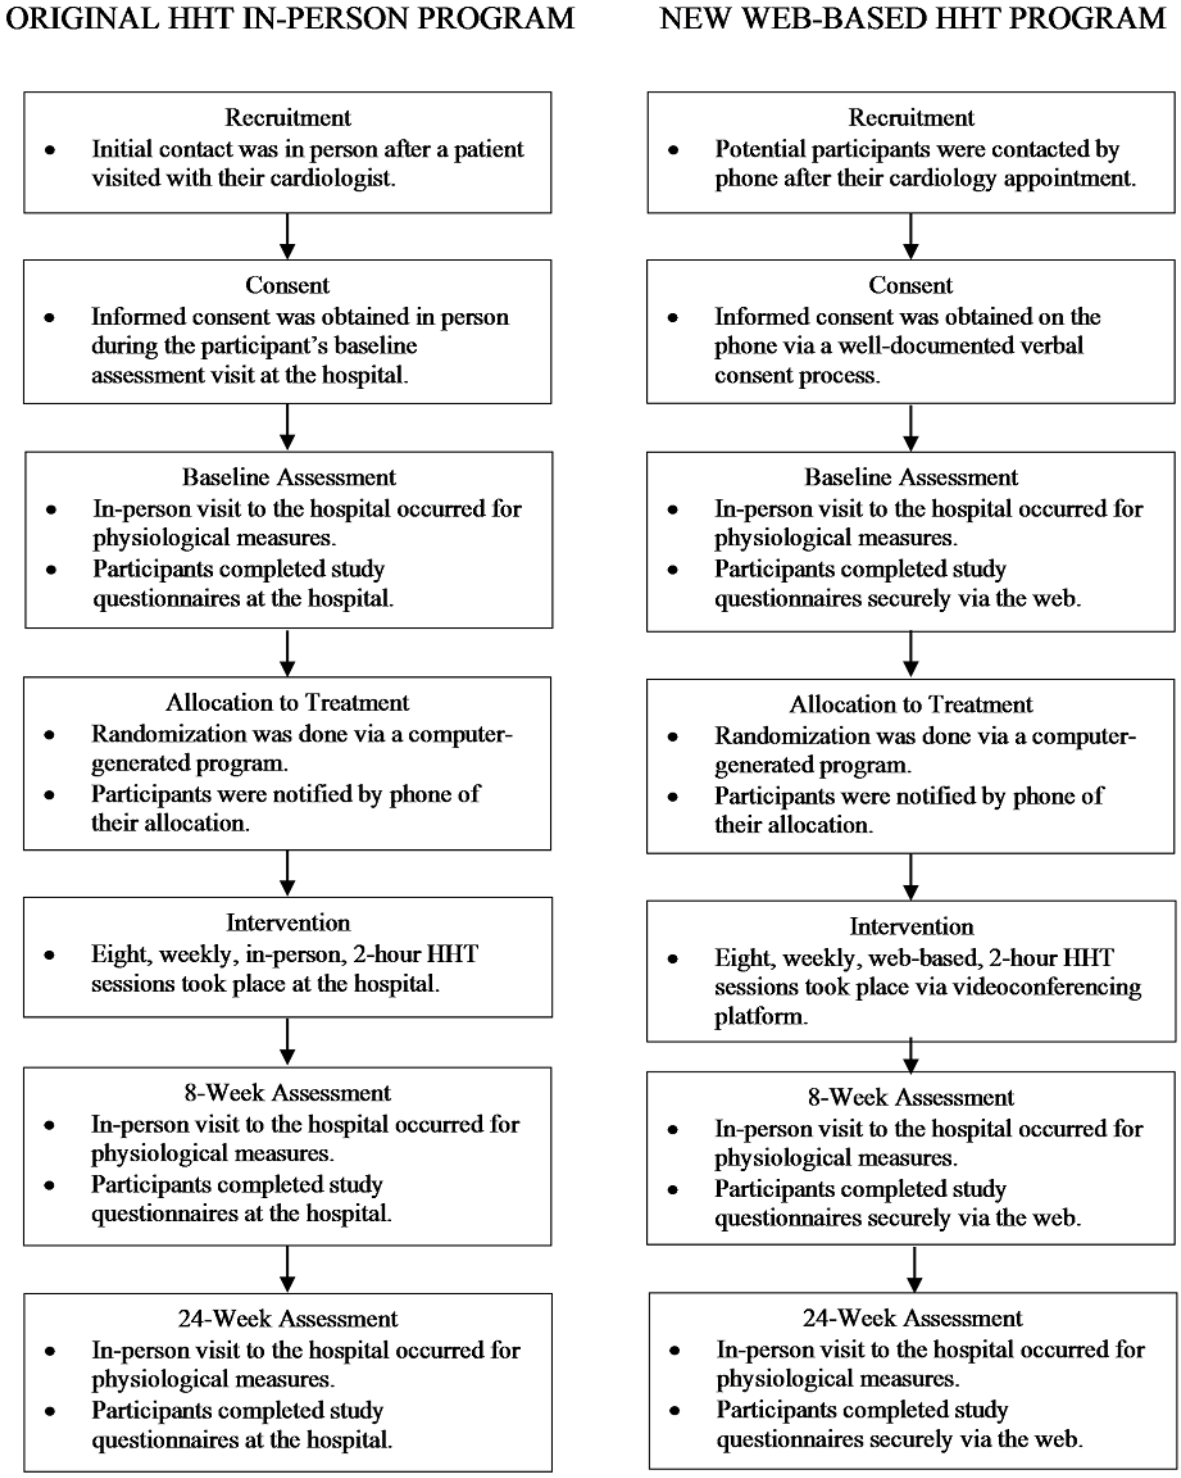
Test Launch With Previous HHT Participants

After running the pilot sessions with volunteer research staff and their partners, the principal investigators conducted a pilot HHT session with couples who were previous participants of the in-person HHT program. The research coordinator contacted these individuals in advance to review the technology checklist and to provide a brief tutorial on how to use the videoconferencing platform. By consulting previous participants of the traditional in-person HHT group, the facilitators gained instructive feedback that contributed to treatment fidelity and acceptability of the web-based format [29]. In an informal postsession feedback conversation, the couples provided suggestions, including (1) visual format changes (ie, reduce the slide size) in order to make the presenter's face more prominent to facilitate a personal connection, (2) offer participants a choice between receiving the printed session handouts by mail or digitally via email, and (3) purposefully enhance and monitor group cohesion. Methods to enhance group cohesion online have been suggested recently [35].

Lessons Learned From the Pilot Sessions

The most helpful step, of those outlined by Hom and colleagues [26], was pilot-testing the intervention to staff and previous HHT participants. Facilitators learned that to maximize group cohesion, maximize flow of conversation, and allow participants to contribute substantially to meaningful discussions, limiting the group to a maximum of 5 couples was required. During the sessions themselves, facilitators found it easier to manage the group dynamics by disabling the chat feature—except with the hosts—and by requesting that the participants use their mute function during the didactic and presentation portion of the session to minimize distraction and hearing difficulties. Finally, facilitators realized that it will be important to seek ongoing feedback from all the participants regarding IT issues or anything related to the web-based format; to that end, they employed a brief questionnaire for participants to fill out after the completion of the HHT program (see Multimedia Appendix 2 for the HHT Client Satisfaction Survey). With the pilot sessions completed, the new web-based HHT program was ready to launch (see Figure 2 for a comparison of the original in-person HHT program and the web-based HHT program).

Figure 2. A comparison of the original in-person Healing Hearts Together (HHT) program and the web-based HHT program.



Stage V: Launch of the Web-Based HHT Intervention and Research Protocol

Baseline Assessment

The baseline assessment visit is conducted at the hospital. Participants scheduled for the assessment are now screened for COVID-19 over the phone within 24 hours of their visit. Once they arrive at the hospital, they are rescreened at the hospital entrance and provided with a mask. Research staff wear appropriate personal protective equipment. Physical distancing regulations are respected, except when completing measurements such as heart rate variability, blood pressure, height, weight, waist circumference, carbon monoxide concentration, and saliva. Proper hygiene procedures are used at every stage of assessment. Questionnaires are completed by participants at home via a secure web application for building and managing web-based surveys and databases (eg, REDCap).

If participants decline an on-site appointment, questionnaires can still be completed online and physiological measures are not completed.

Allocation to Treatment

The randomization process has not changed with the new web-based format. Participants are randomized to the HHT program or to usual care using a computer-generated program at our cardiovascular methods center. Sequences are placed in sealed, numbered, opaque envelopes to ensure concealment of treatment allocation until after baseline data collection. The research coordinator allocates the next available number on study entry, logs all randomizations, and notifies participants of their allocated group immediately by phone. The research coordinator and participants are aware of group allocation. Research assistants, blinded to the participants' treatment allocation, conduct both follow-up assessments.

Intervention

The participants who are randomly assigned to the experimental intervention participate in the new web-based HHT group program. The research coordinator informs participants of their program start date, provides each couple with a brief tutorial of how to access the videoconferencing software, and sends them the intervention materials (eg, book and handouts) via email and/or post before the group start date. For extra technical support, participants receive an email with the prepared tip sheets to help them navigate the web-based format. The number (eight sessions) and duration (2 hours) of sessions remain the same in the web-based format. In this format, couples continue to benefit from the same didactic presentations, videos, and group and couple discussions that were offered in the traditional in-person format. After each web-based session, participants are asked to fill out a very brief feedback questionnaire.

End-of-Treatment and Follow-Up Assessment

As with the baseline assessment, participants will be permitted to go in person to the hospital for their 8-week follow-up assessments. Nevertheless, it was necessary to create a contingency plan that allows for a more flexible approach. Should more strict hospital restrictions emerge, the research staff has prepared alternative means of gathering assessment data, (eg, recording the conflict resolution task via the videoconferencing platform, using self-reported unstandardized height and weight readings, and using self-reported blood pressure readings).

CONSORT Reporting

The research coordinator updated the CONSORT data to include patients who were no longer eligible due to surpassing the eligibility window as well as patients who were unable to complete follow-up assessments due to the pandemic. In addition, revisions were made to the inclusion and exclusion criteria (eg, technology requirements and broader catchment area).

Data Management and Analysis

As COVID-19 restrictions lift, a choice for the in-person versus the web-based HHT program may be provided to participants. However, this creates a new and potentially confounding variable that will need to be included in the database and explored in statistical analyses. A dichotomous variable indicating participation in the web-based or in-person HHT program will then be used as a covariate to control for the mode of delivery. Exploratory analyses can be used to investigate whether the delivery mode made a difference by using an interaction term between delivery mode and the intervention. Advice from the study statistician regarding the above procedures was sought. Researchers should consult with appropriate statistics advisors when interim analyses are conducted and changes to the data analysis plan are considered.

Advantages of the New Web-Based Format

As we updated our protocol, several advantages of the web-based program became evident, both from a clinical and research perspective. These included the following:

1. Broader recruitment. With the necessity of weekly travel removed, the potential recruitment of patients living outside of a 1-hour radius from the hospital could now be included. Prior to the pandemic, participants who lived longer than an hour's drive from the hospital were excluded, as it was seldom feasible for couples to drive an hour or more for eight weekly group sessions, in addition to the three assessment appointments, especially in the winter months. However, with the web-based format, participants are required to attend only three assessments on site. As such, from a research perspective, it is important to note that the reduced travel burden permits potential recruitment from rural areas, which will enrich the diversity of our sample.
2. Flexible scheduling. Flexibility in scheduling both participants and facilitators for the group sessions and assessments emerged as another benefit of the HHT web-based intervention. With no need to reserve group rooms or to arrange for parking at our busy hospital, finding mutually convenient times for the web-based sessions and for the in-person assessments has been optimized. In addition, all group facilitators can be trained online at their convenience individually or as a group by the research coordinator, a process that allows for streamlined, efficient training and ongoing support for the HHT facilitators [27].
3. Flexible methodology. For several years, the gold standard for the informed consent process has involved face-to-face interactions with potential participants. With the recent increase in web-based surveys and interventions, there has been more openness to online consent forms. However, hospital-based clinical trials have always favored the traditional in-person model for obtaining consent. The COVID-19 pandemic has required hospitals and research institutions to adopt more flexible means to obtain informed consent, while assuring high ethical standards. This flexibility toward informed consent and other aspects of

methodology (eg, recruitment and web-based measures) will provide opportunities for researchers who would like to reach a broader population.

Conclusions

When the principal investigators conceptualized and created the HHT program, they envisioned an in-person group program that would help couples grow closer and work well together to improve cardiac health. The COVID-19 pandemic forced hospitals to rethink the mode of delivery for their services. While these drastic changes undoubtedly prompt stress and invoke challenges, there are opportunities for clinical research to extend the reach of recruitment to hard-to-access populations (eg, patients with chronic conditions or mobility issues and patients who have family and work obligations that do not allow them to leave their homes) and, ultimately, promote patient-centered care. It is understood that researchers around the world will also have to take into consideration the subject matter of their research, as well as the cultural, environmental, occupational, and economic factors in their home countries. Despite the diverse nature of global research, this tutorial aims to serve as a brief, yet comprehensive, framework for clinical researchers facing the challenge to offer flexible and innovative web-based interventions.

Acknowledgments

HT, PG, and SJ contributed to the development of the intervention. HT, PG, and KL coordinated the transition to a web-based intervention. KL and HT drafted the manuscript, and PG and KB critically revised the manuscript. All authors gave final approval and agree to be accountable for all aspects of the work, ensuring integrity and accuracy. This work was supported by an operating grant from the Canadian Institutes of Health Research. KB is supported by a Social Sciences and Humanities Research Council Postdoctoral Fellowship.

Conflicts of Interest

HT, SJ, and PG are coauthors of the Healing Hearts Together Relationship Program and receive royalties from its sales.

Abstract

Background: Many women experience urgency (UUI) and mixed (MUI) urinary incontinence but commonly hesitate to seek care. Treatment access and self-management for these conditions can be supported through eHealth approaches.

Objective: This study aimed to investigate the efficacy of the mobile app Tät II for self-management of UUI and MUI in women.

Methods: This randomized controlled trial included women ≥18 years old with UUI or MUI and ≥2 leakages per week. Those with red-flag symptoms were excluded. Participants were recruited via analog and digital advertisements and screened for initial selection through a web-based questionnaire. Data were collected using another questionnaire and a 2-day bladder diary. A telephone interview confirmed the symptom diagnosis. Participants were randomized (1:1) to receive access to a treatment app (including pelvic floor muscle training, bladder training, psychoeducation, lifestyle advice, tailored advice, exercise log, reinforcement messages, and reminders) or an information app (control group), with no external treatment guidance provided. The primary outcome was incontinence symptoms at the 15-week follow-up, measured using the International Consultation on Incontinence Questionnaire (ICIQ)−Urinary Incontinence Short Form (ICIQ-UI SF). Urgency symptoms were assessed using the ICIQ−Overactive Bladder Module (ICIQ-OAB) and quality of life using the ICIQ−Lower Urinary Tract Symptoms Quality of Life Module (ICIQ-LUTSqol). Incontinence episode frequency (IEF) was calculated per bladder diary entries. Improvement was measured using the Patient's Global Impression of Improvement. All outcomes were self-reported. Cure was defined as no leakages per the bladder diary. Intention-to-treat analysis was performed.

Results: Between April 2017 and March 2018, 123 women (mean age 58.3, SD 9.6 years) were randomized to the treatment (n=60, 2 lost to follow-up) or information (n=63) group. Of these, 35 (28%) women had UUI, and 88 (72%) had MUI. Mean ICIQ-UI SF score at follow-up was lower in the treatment group than in the information group (estimated difference −3.1, 95% CI −4.8 to −1.3). The estimated between-group difference was −1.8 (95% CI −2.8 to −0.99) for mean ICIQ-OAB score and −6.3 (95% CI −10.5 to −2.1) for the mean ICIQ-LUTSqol score at follow-up. IEF reduction from baseline to follow-up was greater in the treatment group (−10.5, IQR −17.5 to −3.5) than in the information group (P<.001). Improvement was reported by 87% (52/60) of treatment group participants and by 30% (19/63) of information group participants. The cure rate was 32% in the treatment group, and 6% in the information group (odds ratio 5.4, 95% CI 1.9-15.6; P=.002). About 67% (40/60) of the treatment group participants used the app more than thrice a week.

Conclusions: The treatment app was effective for improving urgency and mixed incontinence in women. When self-management is appropriate, this app may be a good alternative to pharmacological treatment or other conservative management, thus increasing access to care.

Trial Registration: ClinicalTrials.gov NCT03097549; https://clinicaltrials.gov/ct2/show/NCT03097549

KEYWORDS

eHealth; mHealth; urinary incontinence; urgency urinary incontinence; mixed urinary incontinence; self-management; mobile app; smartphone app; women

Introduction

Urinary incontinence is a common problem that affects many women at some time during their lives, with reported prevalence rates ranging between 25% and 45%, depending on the population and study design [1-4]. There are several types of urinary incontinence. Stress urinary incontinence (SUI) is defined as leakage upon exertion (eg, during coughing or jumping), urgency urinary incontinence (UUI) involves urinary leakage combined with an urge to void, and mixed urinary incontinence (MUI) manifests as a combination of SUI and UUI symptoms [5]. Prevalence rates vary from 1% to 11% for UUI and from 2% to 36% for MUI [1,4]. Overactive bladder is a broad term that includes UUI, and it is defined as the experience of a compelling urgency to void, often combined with more frequent voiding, and sometimes nocturia [5]. These conditions can lead to a sense of shame, social isolation, and lower self-esteem—with a significant impact on health-related quality of life [6-8].

For the three main types of urinary incontinence, the recommended first-line treatment includes pelvic floor muscle training (PFMT) and, where appropriate, lifestyle changes (eg, reduced caffeine intake, modified fluid intake, and weight reduction if overweight) [9,10]. Unsupervised PFMT has been recommended in cases wherein an underlying pathology is absent [9]. For women with urgency-predominant urinary incontinence and small micturition volumes, bladder training is recommended, with scheduled voiding or prolonged voiding intervals [3,9,10]. According to a recent review, PFMT might also be useful in overactive bladder treatment, but more evidence is needed in this regard [11]. As a second line of treatment, pharmacological therapy is recommended and widely used, but it often exhibits only modest effectiveness and commonly leads to side effects [3,10].

Although effective treatments for urinary incontinence are available, they do not cater to all individuals who may benefit from them [9,12]. Some studies describe patients' reluctance to seek help for urinary incontinence, sometimes explained by a sense of embarrassment or mistrust in health care [6,13]. Self-management or treatment options that do not require face-to-face contact might be suitable ways to provide care in some of these cases. Web-based platforms and smartphone apps represent an increasingly common way of supporting self-management or providing treatment for various conditions [14-16]. In the context of the current COVID-19 pandemic, the interest in these kinds of technical solutions has increased even further, and urology is one such field where technology-supported treatment or self-management might be useful [17,18]. However, among the currently available treatment apps related to urinary incontinence, only few have been evaluated with regard to their efficacy [19].

As part of the current research project, we examined the effects of an internet-based treatment program and a smartphone app designed for women with SUI. Both programs were found to be effective treatment options with regard to short-term and long-term improvement of clinically relevant symptoms as well as cost-effectiveness [20-24]. However, evidence regarding app-based treatment for women with UUI or MUI remains scarce. Since urgency-predominant urinary incontinence may be associated with an underlying disease, physical examination is recommended before treatment. An algorithm comprising structured questions combined with dipstick urinalysis has been found to be useful in identifying women who may benefit from management in ways other than the usual care provided [25]. Along with other innovative options for providing non−face-to-face diagnosis and treatment for UUI and MUI, this approach might facilitate patients to seek help regarding urinary incontinence and enable increased access to treatment.

We have developed a new smartphone app featuring a complex, individually tailored treatment program designed to help patients self-manage UUI and MUI. In this study, we aimed to evaluate whether this app was effective for improvement and cure of UUI and MUI in women.

Methods

Study Design and Participants

This 1:1 randomized, controlled, parallel-arm trial was performed in Sweden between April 2017 and September 2018. Community-dwelling adult women were recruited via information broadcasted on TV, radio, and newspapers in Sweden, and via targeted Facebook advertisements. The inclusion criteria were as follows: female sex, age ≥18 years, experiencing UUI or MUI with ≥2 leakages/week and symptoms lasting for ≥12 months, access to a smartphone (at least iOS 8.0 or Android 4.0.3), and the ability to send and receive email. The exclusion criteria were as follows: pregnancy, use of another PFMT app, use of mirabegron or antimuscarinic drugs, and incontinence surgery within the last 5 years. Additional exclusion criteria related to red-flag symptoms and certain medical conditions were also considered, namely, painful urgency; previous pyelonephritis; ≥3 urinary tract infections in the last 12 months; dysuria (burning sensation when voiding); visible hematuria; noninvestigated bladder-emptying difficulties;

metrorrhagia; cancer in the pelvic area, bladder, or bowels; decreased mobility or sensitivity in the legs or pelvic area; history of stroke; neurological disease; or diabetes.

Initial selection was performed using a web-based screening questionnaire that included questions regarding education level, postal code, and inclusion and exclusion criteria, which was available on the eContinence project website. To distinguish sex from gender, the question "Are you a woman?" was followed by the question "Were you assigned female sex at birth?" To identify red flags, an algorithm containing structured questions about the presence of relevant symptoms was integrated into the questionnaire (Multimedia Appendix 1). This algorithm was developed through several workshops with researchers and clinicians, and it was based on the best available evidence and clinical experience. Respondents presenting any red flags or other exclusion criteria were not allowed to proceed with the questionnaire, and they were automatically recommended to seek usual care (ie, contact their ordinary health care provider). After completing the full questionnaire and submitting their email address, eligible respondents received an email with an informed consent form and a printable 2-day bladder diary. Respondents with a maximum voided volume of ≤150 mL were deemed ineligible and were contacted by a physician (ES) who redirected them to their usual health care provider as a precautionary measure. The remaining respondents completed a web-based inclusion questionnaire comprising items regarding background information, medical history and lifestyle, more detailed symptom questions, as well as forms related to the outcome measures. In all web-based questionnaires, respondents were required to answer each question in order to proceed to the next. Nonrespondents who did not submit their informed consent and bladder diary, or those who did not answer the inclusion questionnaire, were sent two reminders via email.

Finally, each respondent was contacted via telephone by a specialist incontinence nurse or general practitioner (ES). A telephone interview was conducted with the objectives of confirming the symptom diagnosis (ie, UUI or MUI), reconfirming the absence of exclusion criteria, and ensuring that the participant was fully informed about the study.

This study was approved by the regional ethical review board of Umeå, Sweden (registry number 2016/523-31) and registered at Clinicaltrials.gov (NCT03097549). Before and during the study, and after completion, on-site monitoring was conducted by an independent monitor. The monitor ensured study performance according to the protocol, and the collection, documentation, and reporting of data following good clinical practice and applicable ethical and regulatory requirements.

Randomization and Blinding

The participants included in the study were randomized to one of two study groups: the treatment group or the information group. An independent administrator generated the allocation sequence and prepared 130 numbered, opaque, sealed envelopes, with assignments equally distributed between the two study groups. The study coordinator opened one envelope for each participant, in the order in which they received an email from the interviewer indicating that they were ready for randomization. The participants were not blinded to their allocation. Each participant received an email informing them of their assigned group and providing instructions on how to access the relevant app. Participants randomized to the information group were notified that they would gain access to the intervention once of their follow-up data for the trial was complete.

Intervention and Procedures

The Tät II mobile app was designed for both Android and iOS devices. The contents of the app were developed based on research and clinical experience and were discussed in 2015-2016 with a multi-professional group comprising researchers and clinicians with expertise in family medicine, urogynecology, urology, specialized incontinence care, and psychology. The app was developed during 2016-2018 by ES and TW, in collaboration with other researchers involved in the project and the technical development division at Umeå University. The development process also incorporated user feedback—both from users of the previous app developed within this research project and from a test group of women outside the medical professions. The Tät II app is focused on four themes: PFMT, bladder training, psychoeducation, and lifestyle advice. It also contains automatic reinforcement messages and an exercise log. Tailored advice, based on information from the user's bladder diary and responses to the inclusion questionnaire, was designed to guide the user to the features of the app that would be most relevant to her symptoms and lifestyle (eg, bladder training was recommended if the user had small micturition portions, or weight reduction was recommended if the user was overweight). The different components of the Tät II app are detailed below (Figure 1, Table 1, and Multimedia Appendices 2 and 3). The PFMT treatment program in the app has been previously described and evaluated as part of a smartphone app developed earlier [20].

Figure 1. Screenshots from the treatment app (Tät II). Upper-left corner: main (home) screen; upper-right corner: active view of an exercise in the bladder training program; lower-left corner: textual description of another bladder training exercise; lower-right corner: information from the lifestyle section. Text has been translated from Swedish to English for illustration purposes.

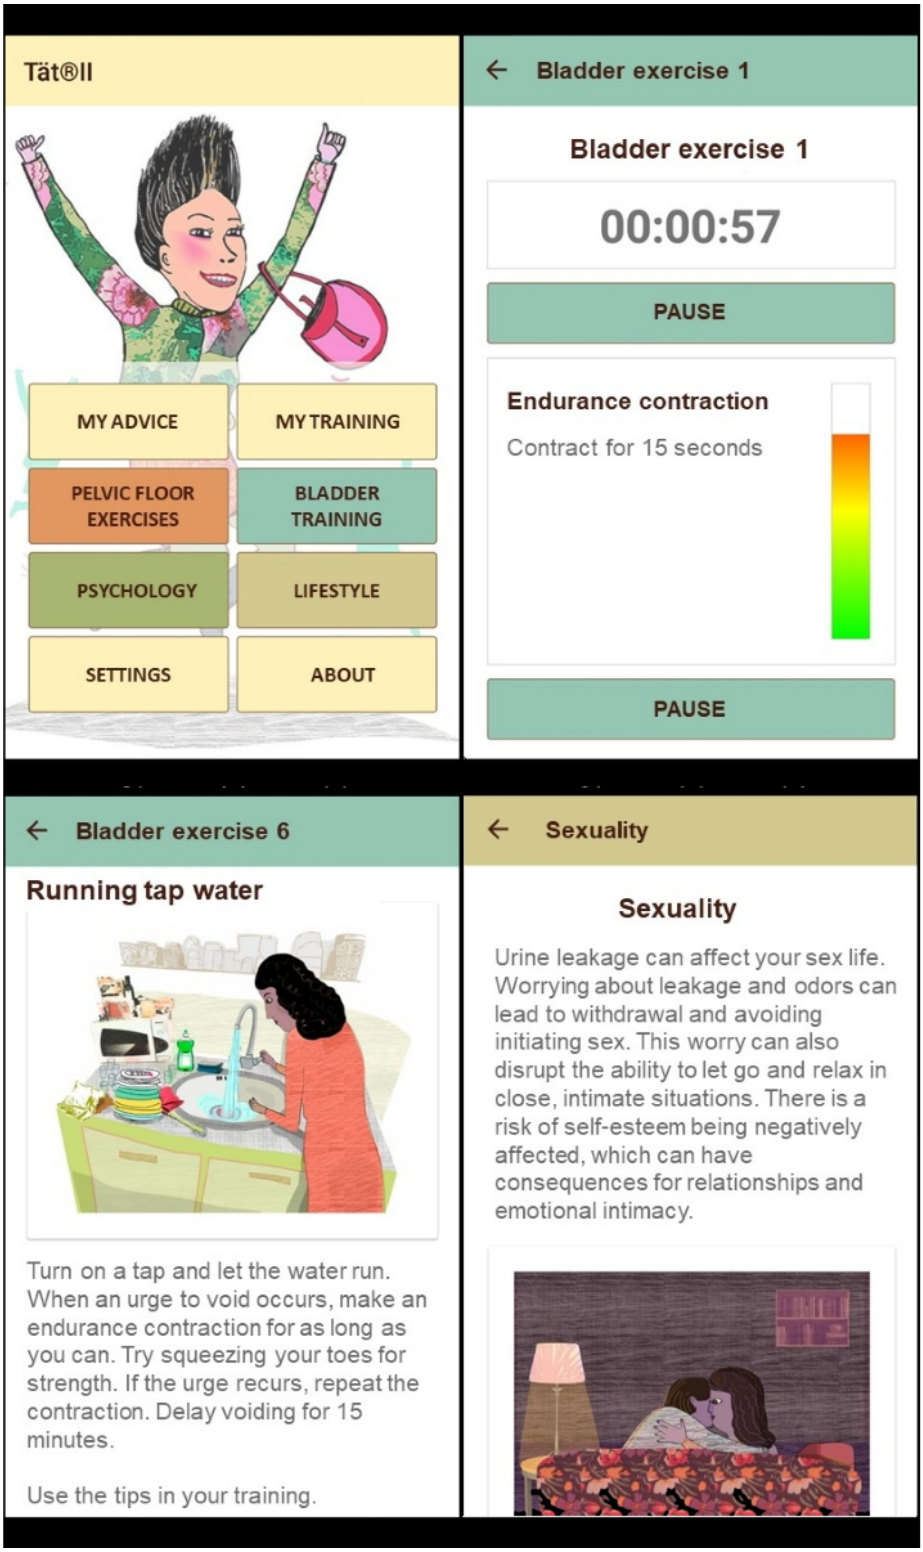

Table 1. Contents of the Tät II treatment app and information app.

Topic	Treatment app	Information app
Pelvic floor muscle training	• Extensive information on anatomy and pelvic floor muscle training • A pelvic floor muscle training program in 11 steps	• Very brief information on pelvic floor muscle training
Bladder training	• Extensive information on bladder physiology and bladder training • A bladder training program in 7 steps[a]	• Very brief information on bladder training
Psychological education	• Extensive information on psychological topics related to urgency symptoms • Three tasks based on cognitive behavioral therapy theory	• Very brief information on psychological topics related to urgency symptoms
Lifestyle advice	• Information on topics of estrogen, fluid intake, physical activity, overweight, smoking, sexuality, constipation, foods, and incontinence aids	• Summarized information on lifestyle advice
Reinforcement	• Recurring questions on degree of bother[b] • Automatic reinforcement messages based on progress • Three customizable notifications for daily reminders	N/A[c]
Other functions	• Exercise log • Tailored advice on what areas to focus on in the app, based on information from bladder diary and questionnaire[d] • Optional 4-digit password protection	N/A

[a]The bladder training program featured exercises for enduring urgency to achieve longer voiding intervals. It did not feature scheduled voiding.

[b]In-app questions about the degree of bother from leakage, urgency, and worry about leaking. The user is asked these questions directly after installing and activating the treatment app, and after 4, 8, and 12 weeks of intervention.

[c]Not applicable.

[d]User is provided 4-10 advices, as relevant, on the following topics: pelvic floor muscle training, bladder training, fluid intake, psychoeducation, local estrogen treatment, obesity, smoking, and constipation.

Activation of the treatment app enabled complete access to all components of the Tät II app. For activation, participants randomized to the treatment group were registered in a database stored on a secure server. A unique one-time activation code was generated and used as a password along with the user ID. The tailored advice was automatically downloaded from the database into the app during the activation process. If the app was not activated within 2 weeks, an email reminder was sent to the participant, and if it was not activated within another week, the participant was contacted via telephone and offered technical guidance. Apart from this, the participants received no guidance from the researchers during the study.

The information app is a limited version of Tät II, which is freely downloadable from app stores. It includes a short summary of lifestyle advice and brief information about the various app components (Table 1).

At the 15-week follow-up, participants were asked to complete a web-based questionnaire and a new 2-day bladder diary. The follow-up questionnaire also included the possibility to add qualitative user feedback. After collection of the follow-up data for the trial, participants in the information group received access to the full treatment app, and participants in the treatment group received information on maintenance training. The different data collection time points of the trial are detailed in Multimedia Appendix 4.

No data were transmitted from the app apart from the voluntary submission of user statistics at follow-up. Participants were encouraged to report any potential side-effects to the research team via email or telephone. Participants were also instructed to seek usual care if any red-flag symptoms appeared.

Outcomes

The primary outcome was the between-group difference in incontinence symptom severity at follow-up, as measured using the Swedish version of a validated questionnaire: the International Consultation on Incontinence Questionnaire−Urinary Incontinence Short Form (ICIQ-UI SF) [26]. The ICIQ-UI SF includes 3 questions about the frequency and amount of urinary leakage and its effect on everyday life. The responses are summed to obtain a total score ranging from 0 to 21 points. The severity of incontinence symptoms was categorized as slight (1-5 points), moderate (6-12 points), severe (13-18 points), or very severe (19-21 points) [27].

Secondary outcomes included urgency symptoms, quality of life, and catastrophizing. The International Consultation on Incontinence Questionnaire−Overactive Bladder Module (ICIQ-OAB) includes 4 items on the frequency of day and night

micturition, urgency, and urgency leakage, and the responses are summed to obtain a total score ranging from 0 to 16 points [28]. The International Consultation on Incontinence Questionnaire−Lower Urinary Tract Symptoms Quality of Life Module (ICIQ-LUTSqol) includes 19 items regarding the impact of urinary leakage on the quality of life, and the responses are summed to obtain an overall score ranging from 19 to 76 points [28]. We also used a nonvalidated score, the Incontinence Catastrophizing (IC) Scale, which was adapted from a short version of the validated Pain Catastrophizing Scale [29]. This scale was translated to Swedish by the research group by using a structured procedure. The IC Scale comprises 7 items regarding fear of leakage and urgency, and the responses are summed to obtain a total score ranging from 0 to 21 points. For all the above-mentioned scores, a reduction in the score indicates an improvement of the symptoms.

Other secondary outcomes included the number of leakages, use of incontinence aids, impression of improvement, and patient satisfaction. Incontinence episode frequency (IEF) was calculated as the number of leakages reported in a 2-day bladder diary multiplied by 3.5 to generate the weekly number of incontinence episodes. Participants were asked about their use of incontinence aids over the last 4 weeks, and they were provided 6 response options ranging from “No, never” to “Yes, more than 1 pad per day.” The Patient Global Impression of Improvement (PGI-I) is a validated questionnaire evaluating improvement, which was only used at follow-up. Participants rated their follow-up condition as compared with their pretreatment condition, using a 7-item scale with answer options ranging from “Very much better” to “Very much worse” [30]. Patient satisfaction was evaluated only in the treatment group at follow-up. This item asked whether the current treatment was perceived as sufficient, with 3 response options regarding satisfaction and intention to seek further care.

We used information from the bladder diary and follow-up questionnaire to assess cure and improvement. *Cure* was defined as no leakage episodes recorded in the bladder diary at follow-up, and *improvement* was defined as any improvement on the PGI-I.

Performance and Adherence

At both the baseline and follow-up, participants were asked whether they perceived themselves as able to correctly perform pelvic floor contractions. At the follow-up, they were also asked to appraise their current ability to contract their pelvic floor muscles as compared with before they had access to the assigned treatment or information app, with responses ranging from “Much better” to “Much worse,” and to appraise the ability to resist urgency through a corresponding question, with similar response options.

Furthermore, the follow-up questionnaire included a question on how often the participants had used their assigned app during the study period. Response options ranged from “Never” to “Daily, three times a day, or more often.” There was also a question on whether the participant had used another incontinence app or participated in another incontinence treatment program during the study period.

Technical Issues and User Feedback

Participants were informed that they could contact the researchers via email in case of technical problems with the app. The follow-up questionnaire allowed participants to provide qualitative feedback via nonmandatory open-ended questions about how they perceived the assigned app, in general, and the specific contents of the app. Participants in the treatment app group were also asked to rank the 6 treatment app components (tailored advice, exercise log, PFMT, bladder training, psychoeducation, and lifestyle advice) from most useful to least useful.

Sample Size

The expected response was based on results from our previous smartphone study, and the findings of Albers-Heitner et al [20,31]. We anticipated ICIQ-UI SF improvements of 2.5 points in the treatment group and 0.9 points in the information group. This level of change has also been found to reflect a clinically important difference in women with stress urinary incontinence after treatment via eHealth [22]. Detecting this difference with 80% power, a two-sided test, and a significance level of $P<.05$ would require a sample size of 49 in each group. With an expected drop-out rate of 20%, we needed approximately 60 participants in each group. Thus, we aimed to recruit 120 women for this study.

Statistical Analysis

For all outcome measures, we performed an intention-to-treat analysis. To analyze the ICIQ-UI SF, ICIQ-LUTSqol, ICIQ-OAB, and IC scale, we used analytical methods that accounted for all available data. We used the last observation carried forward method for IEF and incontinence aid usage, and we applied imputation of values corresponding to no change in the PGI-I.

Baseline data were described in terms of age, BMI, educational level, medication use, and all primary and secondary outcomes that were measured at the baseline. For the primary outcome, we examined the between-group difference in the mean ICIQ-UI SF score at the 15-week follow-up using a linear mixed-model analysis incorporating baseline data. For the secondary outcomes, between-group comparisons were made using a linear mixed-model analysis for the difference in mean values for continuous variables, and the Mann-Whitney *U* test for the distribution of categorical variables and for the difference in median for nonnormally distributed continuous variables. For within-group comparisons (ie, between baseline and follow-up), we used a paired *t* test for continuous variables and a Wilcoxon signed-rank test for nonnormally distributed continuous variables. For IEF, we calculated the difference between baseline and follow-up scores for each individual, presented as median and IQR values. Since IEF data were not normally distributed, they were analyzed using the Wilcoxon signed-rank test. We used a chi-square test with continuity correction to calculate the odds ratios (ORs) for cure and improvement.

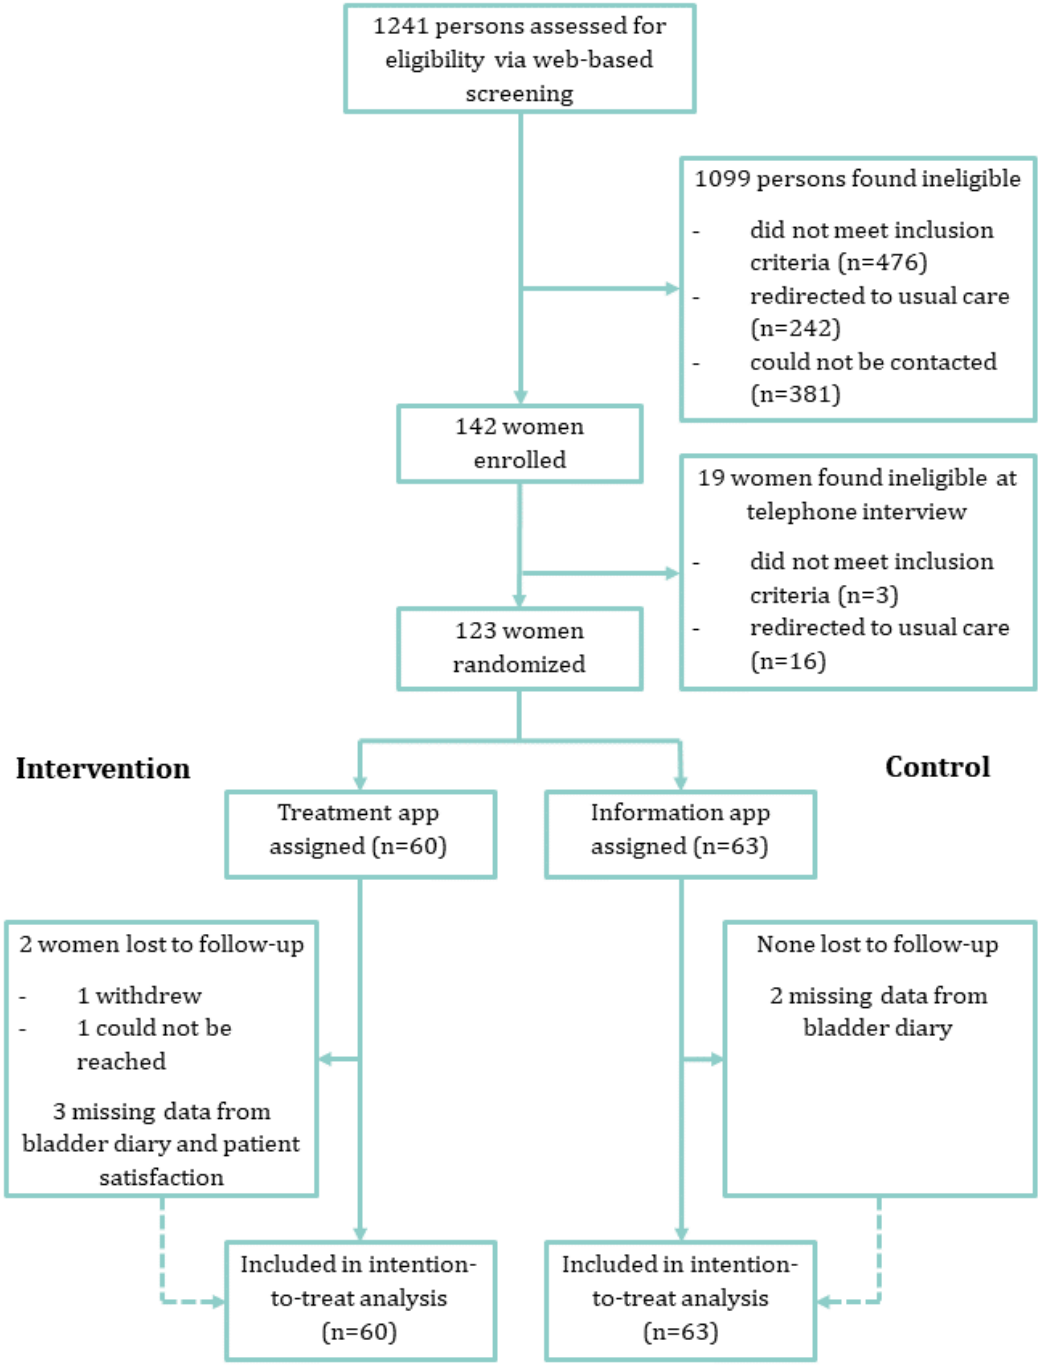
All statistical analyses were performed using SPSS (version 25; IBM Corp).

Results

Study Flow and Participant Characteristics

The web-based screening questionnaire was initiated by 1241 individuals, of whom 1099 were ineligible. A total of 142 women were interviewed, of which 123 were included in the study and randomized to receive either the treatment app (n=60) or the information app (n=63). Two women (both in the treatment group) were lost to follow-up. Five women submitted incomplete follow-up data regarding two secondary outcomes (Figure 2). The median time from randomization to follow-up was 16.1 (IQR 15.0-18.1) weeks in the treatment group and 15.5 (IQR 14.6-17.6) weeks in the information group (*P*=.14).

Figure 2. Trial profile.



Baseline characteristics did not differ between the two groups. The mean age of women included was 58 (range 31-77) years. Half of the women (64/123, 52%) were overweight or obese. The majority of participants had received university-level education, and 95% (117/123) of them classified themselves as being quite or very knowledgeable in using computers or tablets.

Three-quarters of the participants (88/123, 72%) were diagnosed with MUI, and 69% (85/123) had not previously sought care for their incontinence (Table 2). Severe or very severe incontinence was reported by 38% (47/123) of the participants, and the mean symptom severity score was 11.6 (SD 3.3).

Table 2. Baseline characteristics of study participants.

Characteristic	Treatment group (n=60)	Information group (n=63)
General information		
Age in years, mean (SD)	58.9 (9.2)	57.7 (9.9)
BMI in kg/m^2, mean (SD)	26.5 (3.6)	25.9 (5.2)
University education ≥3 years, n (%)	44 (73.3)	35 (55.6)
Self-rated knowledge in using computers or tablets (1-4 points[a]), mean (SD)	3.5 (0.6)	3.4 (0.6)
eHEALS[b] score, mean (SD)	32.9 (5.6)	33.8 (4.5)
Lifestyle		
Physical activity >3 hours/week, n (%)	33 (55.0)	40 (63.5)
Smoker[c], n (%)	1 (1.7)	2 (3.2)

Urinary incontinence		
Symptom diagnosis, n (%)		
Mixed urinary incontinence	45 (75)	43 (68.3)
Urgency urinary incontinence	15 (25)	20 (31.7)
Duration of symptoms >5 years, n (%)	37 (61.7)	38 (60.3)
Previous health care contact for incontinence symptoms, n (%)	19 (31.7)	19 (30.2)
ICIQ-UI SF[e] score, mean (SD)	11.7 (3.5)	11.4 (3.2)
IEF[f] per week, mean (SD)[g]	21.8 (16.8)	21.1 (13.7)

[a]A higher score indicates higher self-perceived knowledge.

[b]eHEALS: eHealth Literacy Scale, a self-reported 8-item scale assessing an individual's ability to identify, evaluate, and use eHealth resources.

[c]No daily smokers, only weekly smokers, participated in the study.

[d]Participants who had undergone incontinence surgery in the last 5 years were not included in the study.

[e]ICIQ-UI SF: International Consultation on Incontinence Questionnaire−Urinary Incontinence Short Form.

[f]IEF: incontinence episode frequency.

[g]Mean (SD) values presented to facilitate comparison with other populations.

Outcomes

At the 15-week follow-up, women in the treatment group had significantly lower incontinence symptom scores than those in the information group. The estimated between-group difference in mean in the primary outcome, the ICIQ-UI SF score, was −3.1 (95% CI −4.8 to −1.3). Both groups showed an improvement from the baseline but a larger improvement was noted in the treatment group (Table 3).

Table 3. Continuous outcomes compared between the treatment group (n=60) and information group (n=63) at follow-up.

Outcome measure and group allocation	Baseline, mean (SD)	Follow-up, mean (SD)	Between-group comparison at follow-up	
			Estimated difference (95% CI)[a]	*P* value
Primary outcome				
ICIQ-UI SF[b]			−3.1 (−4.8 to −1.3)	.001
Treatment group (n=60)	11.7 (3.5)	7.0 (3.7)[c]		
Information group (n=63)	11.4 (3.2)	9.8 (3.5)		
Secondary outcomes				
ICIQ-OAB[d]			−1.8 (−2.8 to −0.9)	<.001
Treatment group (n=60)	6.8 (1.8)	4.7 (2.0) [c]		
Information group (n=63)	6.7 (1.8)	6.4 (2.0)		
ICIQ-LUTSqol[e,f]			−6.3 (−10.5 to −2.1)	.004
Treatment group (n=60)	37.6 (8.3)	29.8 (7.8)[c]		
Information group (n=63)	38.0 (8.1)	36.5 (9.0)		
Incontinence Catastrophizing Scale			−1.6 (−2.8 to −0.3)	.016
Treatment group (n=60)	4.4 (2.8)	2.3 (2.1)[c]		
Information group (n=63)	4.7 (2.5)	4.1 (2.5)		

[a]Comparison of mean scores using a linear mixed model.

[b]ICIQ-UI SF: International Consultation on Incontinence Questionnaire−Urinary Incontinence Short Form.

[c]Mean values based on the scores of the 58 treatment app users who completed the follow-up questionnaire.

[d]ICIQ-OAB: International Consultation on Incontinence Questionnaire−Overactive Bladder Module.

[e]ICIQ-LUTSqol: International Consultation on Incontinence Questionnaire−Lower Urinary Tract Symptoms Quality of Life Module.

[f]Three of the items in the ICIQ-LUTSqol included an additional response option, “Not applicable” (these questions concerned partner relations, sex life, and family life). For this study, we set this response option as equal to 1 point, corresponding to the response option “Not at all” (ie, no impact).

Compared with those in the information group, participants in the treatment group also showed significantly greater improvements in the secondary outcomes, with lower scores for urgency symptoms, condition-specific quality of life, and catastrophizing at follow-up. Within-group comparisons revealed statistically significant improvements from baseline to follow-up in all outcomes, except urgency symptoms in the information group (Table 3 and Multimedia Appendix 5).

Participants in both the treatment and information groups exhibited a significant reduction in the number of incontinence episodes (IEF) from the baseline to follow-up. This improvement was greater in the treatment group than in the information group (Table 4). The number of incontinence episodes was reduced by 50% or more in 68% (41/60) of the participants in the treatment group and 30% (19/63) of the participants in the information group. Incontinence aids were used less than once a week at follow-up by the majority of participants (38/60, 63%) in the treatment group compared with those (25/60, 40%) in the information group (Table 5).

Table 4. Differences in incontinence episode frequency from the baseline to follow-up compared between the treatment group (n=60) and the information group (n=63).

Group allocation	Baseline, median (IQR)	Follow-up, median (IQR)	Within-group comparison[a]		Between-group comparison at follow-up[b]
			Difference[c], median (IQR)	*P* value	*P* value
Treatment app	17.5 (10.5 to 27.1)	3.5 (0.0 to 10.5)	−10.5 (−17.5 to −3.5)	<.001	<.001
Information app	21.0 (7.0 to 31.5)	10.5 (7.0 to 21.0)	−3.5 (−14.0 to 3.5)	.003	

[a]For within-group comparisons, we calculated the difference from baseline to follow-up for each individual and performed analyses using a Wilcoxon signed-rank test.

[b]Mann-Whitney *U* test.

[c]5 participants in the treatment group and 2 participants in the information group had a missing value at follow-up, and for those, the difference was set to 0 (ie, no change).

Table 5. Incontinence aid usage by participants in the treatment group (n=60) and information group (n=63), reported at baseline and at follow-up.

Allocation and incontinence aid usage	Participants, n (%)		*P* value	
	Baseline	Follow-up	Within-group comparison[a]	Between-group comparison at follow-up[b]
Treatment app			<.001	.01
Never	11 (18.3)	26 (43.3)[c]		
<1/week	10 (16.7)	12 (20)		
1-3/week	12 (20)	4 (6.7)		
>3/week, not daily	4 (6.7)	2 (3.3)		
1/day	12 (20.0)	10 (16.7)		
>1/day	11 (18.3)	6 (10)[c]		
Information app			.15	
Never	14 (22.2)	14 (22.2)		
<1/week	11 (17.5)	11 (17.5)		
1-3/week	7 (11.1)	8 (12.7)		
>3/week, not daily	4 (6.3)	6 (9.5)		
1/day	11 (17.5)	13 (20.6)		
>1/day	16 (25.4)	11 (17.5)		

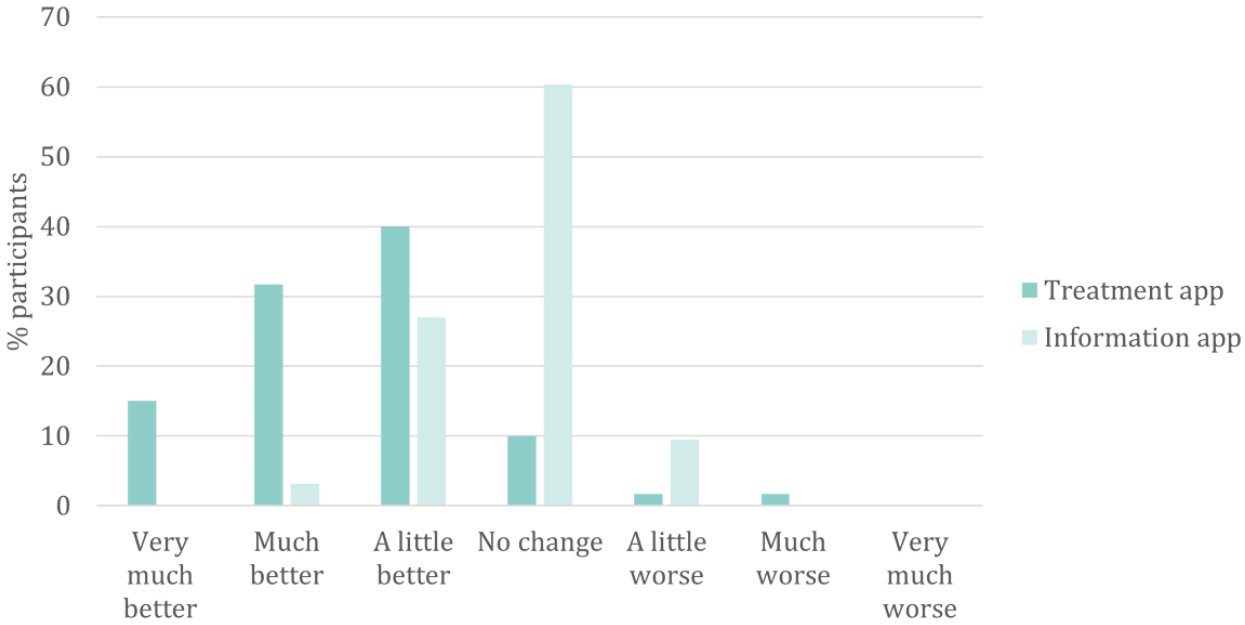
[a]Wilcoxon signed-rank test.

[b]Mann-Whitney *U* test.

[c]Imputed baseline value for 1 participant lost to follow-up.

PGI-I scores indicated that 87% (52/60) of the participants in the treatment group reported an improvement as compared with 30% (19/63) in the information group. Figure 3 details the distribution of the responses. Cure was reported by 32% (19/60) of the participants in the treatment group and by 8% (5/63) of the participants in the information group. The OR for cure was 5.4 (95% CI 1.9-15.6, *P*=.002) for the treatment group with the information group as reference. Moreover, the OR for improvement was 15.1 (95% CI 6.0-37.7, *P*<.001) for the treatment group with the information group as reference.

Figure 3. Patient's Global Impression of Improvement responses reported by the participants at follow-up. Comparison between the treatment group (n=60) and the information group (n=63). *P<.001 (Mann-Whitney U test). Two participants were lost to follow-up in the treatment group and imputed as "no change" for this analysis.



In the treatment group, 7% (4/60) of the participants reported their current satisfaction with the treatment and that they were completely free from urinary leakage and urgency symptoms, whereas 52% (31/60) of the women reported their satisfaction with the treatment despite some remaining symptoms. The remaining 33% (20/60) of the participants reported that they were not satisfied with the treatment, but only 7 of these 20 considered seeking additional care.

Performance and Adherence

At baseline, 40% (49/123) of the participants were confident that they correctly performed pelvic floor contractions, with no between-group difference. At follow-up, this rate was increased to 62% (37/60) of the participants in the treatment group, and 52% (33/63) of the participants in the information group (P=.39). At follow-up, 85% (51/60) of the participants in the treatment group stated that their ability to contract their pelvic floor muscles was slightly or much improved, compared with 16% (10/63) of the participants in the information group (P<.001). Similarly, the ability to resist an urge to void was slightly or much improved for 80% (48/60) of the participants in the treatment group, compared with 27% (17/63) of the participants in the information group (P<.001).

During the 15-week treatment period, 40 (67%) of the 60 participants in the treatment group used the app more than three times per week, and 6 (10%) participants used it at least three times per day. None of the treatment group participants used other incontinence apps or treatment programs during the study period. In the information group, 2 of the 63 (3%) participants used another PFMT app, and 1 (2%) participant practiced PFMT and tried to resist urgency. Moreover, 1 (2%) participant in the information group sought help from usual care for incontinence-related symptoms during the study period and received incontinence aids, advice on PFMT, and treatment with intravesical hyaluronic acid-chondroitin sulphate. The adherence to the tailored advice is described in Multimedia Appendix 3.

Technical Issues and User Feedback

No participants reported technical problems with the apps, and no privacy breaches occurred. Many participants in the information group thought that the information was too brief and, therefore, they rarely used the app. Most participants in the treatment group were satisfied with their experience of the app in terms of contents and usability. The users ranked the various treatment app components, with the PFMT portion deemed most useful (ranked 1, 2, or 3 by 95% of all users), followed by the exercise log (ranked 1, 2, or 3 by 80% of all users) and tailored advice (ranked 1, 2, or 3 by 66% of all users).

Adverse Events

Two participants (both in the treatment group) reported potential adverse events: one of them reported the development of an inguinal hernia during the treatment period, which later required surgery. Discussion of this case with the specialists in the research group, an independent specialist in hernia surgery, and an official at Medical Products Agency, Sweden, led to the conclusion that the hernia was likely not related with the use of the treatment app. The other participant reported altered incontinence symptoms, with decreased urgency but increased episodes of spontaneous urinary leakage.

Discussion

Principal Results

In the present randomized controlled trial among women with mixed and urgency urinary incontinence, we found that the treatment app was effective in reducing incontinence symptoms (our primary outcome), with lower scores observed at the 15-week follow-up in the treatment group compared with those in the information group. We also found that treatment app users

showed greater improvements regarding quality of life, urgency symptoms, number of incontinence episodes, use of incontinence aids, and catastrophizing, compared with the information app users.

Clinical Relevance

About 87% (52/60) of the treatment app users reported an improvement, and half of them (28/60, 47%) reported *much* or *very much* improvement. A 50% reduction in the frequency of incontinence episodes is considered clinically relevant, and this degree of reduction was observed for the majority of the treatment app users in our study [32]. For women with SUI, reductions of 2.5 points in the ICIQ-UI SF score and 3.7 points in the ICIQ-LUTSqol score has been considered to reflect clinically relevant improvement after pelvic floor muscle training via an eHealth approach [22]. The within-group reductions observed in our study were larger than these thresholds and also larger than the 4- and 6-point reduction in the ICIQ-UI SF and ICIQ-LUTSqol scores established by Lim et al as minimum important differences for other conservative management [33]. To our knowledge, there are no similar studies of women with UUI and MUI, but minimum important differences are likely to be at a similar level compared with the studies mentioned above. The PGI-I and comparison with minimum important differences indicate that the changes in symptoms and quality of life for the treatment group observed in our study are clinically relevant.

Strengths and Limitations

One of the strengths of our study was that we used clinically relevant outcomes that were carefully selected to cover different aspects of UUI and MUI, including symptoms, quantification, quality of life, and subjective improvement. The three ICIQ scores, including the one used as the primary outcome (ICIQ-UI SF), are all Grade A or A+ recommended outcome measures according to the International Continence Society [3]. These questionnaires are also validated for electronic use [34,35]. Additionally, our study was adequately sized and conducted with external monitoring, as a mark of quality. There were very small losses to follow-up and no internal losses, except for the secondary outcome of IEF. We developed and utilized an algorithm to identify suitable participants, and all participants experienced extensive incontinence symptoms at the baseline, strengthening the need for treatment. Another strength of our study was that the app was thoroughly designed and stable and required no updates during the study period. No users experienced technical issues. The treatment app included a patient-centered design, such that the user herself decided which parts of the app to use. Tailored advice, based on information about the user's lifestyle and incontinence symptoms, offered guidance on what might be the most beneficial component or feature of the app for her to focus on. All participants in the treatment group downloaded and activated the app, and most of them regularly used the app. The risk for contamination between the two groups was negligible since activation of the treatment app required a unique one-time authorization code. The treatment app featured information and exercises covering multiple topics related to UUI and MUI, resembling a clinical reality with a multi-faceted intervention. Therefore, this study cannot discriminate how different parts of the app contributed to the various effects.

A potential limitation of this study is that we cannot yet assess the long-term effects of the app. However, we previously reported that our smartphone app targeted at women with SUI had a long-lasting effect at the 2-year follow-up [21]. Similar to most other investigations of eHealth or behavioral therapy interventions, another limitation of our study was that the participants could not be blinded to their group allocation. Our choice to not use care-as-usual as a control group could also be viewed as a limitation. However, seeking care-as-usual was not a likely option for most of our intended target population; thus, we argue that the information app was the most comparable control. Another potential concern is the lack of face-to-face contact with a health care provider and that there was no professional assessment of the participants' ability to perform correct PFMT contractions. However, in a JAMA review from 2017, unsupervised PFMT is recommended as a first-line treatment after exclusion of serious underlying pathologies [9]. The treatment app included information on how to correctly perform contractions, and it recommended women who were uncertain of their contraction technique to contact their ordinary health care provider for advice. At follow-up, no treatment app users had sought help from usual care, and the majority stated that their ability to perform PFMT contractions had improved. Most of the women in the treatment group were satisfied with the treatment, and of those who were not satisfied, only a few intended to seek care elsewhere. However, since the qualitative feedback was optional, we do not know the reason behind their decision not to seek further care despite not being satisfied. Furthermore, this study focused on the presentation of quantitative data, and while this is a strength when investigating efficacy, a deeper analysis of the qualitative data collected might provide valuable information about the experiences of the participants in the trial. A common issue in research, and particularly in studies of eHealth interventions, is that the participants' education level is often higher than that of the general population. The average education level of people in Sweden is higher than that of people in many other countries; nonetheless, women with a university-level education were over-represented among our participants, which may potentially affect the generalizability of our results.

Comparison With Prior Work

Several systematic reviews report that antimuscarinic drugs and mirabegron yield a mean reduction corresponding to half a leakage per 24 hours at the 3-month follow-up when compared with the placebo [36-39]. The median reduction for the treatment group in our study was twice as large as this. Moreover, antimuscarinic medication is commonly associated with side-effects, such as dry mouth and constipation. Mirabegron is better tolerated but has side-effects, such as urinary tract infections, irregular heartrate, and palpitations [3,36,37]. In contrast, behavioral treatment and lifestyle advice carry no known side-effects. Women with urgency urinary incontinence are more likely to achieve improvement, cure, and satisfaction with behavioral therapy than with anticholinergics [40]. The cure and improvement rates in our treatment app group were in line with the findings from other studies. A systematic review

update from 2018 reported a 25%-30% cure rate of urgency urinary incontinence with neuromodulation, behavioral therapy, or combined anticholinergic and behavioral therapy. The OR for cure of urgency incontinence with behavioral therapy was 2.75 (95% CI 1.53-4.92) compared with the placebo, sham, or no treatment [40].

Conclusions and Outlook

UUI and MUI affect many women and can have a potentially large impact on their quality of life. Thus, it is important to offer effective treatment options that can reach many patients, and eHealth methods are a new potential means of supporting self-management. Providing treatment that does not require face-to-face contact with the health care service provider might facilitate increased care-seeking among these women. Additionally, eHealth tools (eg, smartphone apps) provide possibilities for adherence-promotion, such as reminder notifications, and can be tailored for the specific user, such as through the tailored advice provided in our presently tested treatment app. Concerns have recently been raised about a digital divide such that some groups might be less able to use these digital health aids [41-43]. Future research is needed to identify ways to improve the interventions, or the development process, to make eHealth treatment options more accessible or relevant for new user groups. Further investigations are also needed to evaluate the use of algorithms to select patients for self-management of these conditions, with regard to medical safety. For populations similar to the participants in our present study, our results indicate that the treatment app is already an effective treatment option. There remains a need to study the long-term effects, and to decide how to make this app available to patients—that is, whether the app can be offered as a stand-alone, first-line intervention for women with an uncomplicated medical history, or whether it should be regulated and prescribed only by health care professionals.

To our knowledge, this is the first study to demonstrate the potential to provide an effective, tailored, app-based treatment to women with urgency or mixed urinary incontinence suited for self-management. Our results show an efficacy that is comparable to other first-line treatments available. Therefore, we propose that this app could be added to the treatment options offered as part of usual care for women presenting with these conditions.

Acknowledgments

The authors would like to thank the following individuals: Susanne Johansson, for coordinating the study; Agneta Jervhed, for conducting telephone interviews and reminder phone calls to the participants; Johanna Ekdahl, for assisting the development of the psycho-educative component of the Tät II app and compiling the Incontinence Catastrophizing Scale; Karin Stenzelius, for participating in the planning for this study, developing the foundation of the bladder training program, creating some of the lifestyle advice contents available on the app, and participating in the translation and adaptation of some of the questionnaires used; the statisticians Lars Söderström and Hans Stenlund, for their involvement in developing the statistical plan, sample size calculations, and initial analyses; and Lars Malmberg, for participating in the early stages of planning for this study. We also want to thank all the women who participated in the study. Our study was funded by the Kamprad Family Foundation; the Swedish Research Council for Health, Working, and Welfare; and the Region Jämtland Härjedalen. These organizations provided grants but had no role in the study design, data collection, data analysis, data interpretation, or writing of the manuscript.

Authors' Contributions

ES conceptualized the study, was the principal investigator, and led the study at all stages. ES, EN, and TW designed the study with input from KF and EW. The statistical plan and protocol for the study were written by ES with support from TW, EN, and Lars Söderström (statistician). TW and EN performed the statistical analyses of the trial data, and ES and AL participated in the analyses. All authors had full access to all study data and participated in the interpretation of the data and statistical analyses. TW wrote the manuscript draft, with substantial input from ES and EN, and all authors critically reviewed successive drafts of the report and approved the final version of the manuscript before publication.

Abstract

Background: Web-based interventions are a promising approach to support youth at risk of suicide, and those incorporating peer-to-peer social networking may have the added potential to target interpersonal states of perceived burdensomeness and thwarted belongingness. Owing to feasibility and safety concerns, including fear of contagion, this had not been tested until recently. In 2018, we conducted a pilot evaluation to test the feasibility, safety, and acceptability of a Moderated Online Social Therapy intervention, called Affinity, with a sample of young people with active suicidal ideation.

Objective: The aim of this study is to report qualitative data collected from study participants regarding their experience of the web-based social network and the consequent safety features.

Methods: Affinity is a closed website incorporating 3 key components: therapeutic content delivered via comics, peer-to-peer social networking, and moderation by peers and clinicians. Semistructured interviews were conducted with 17 young people who participated in the pilot study after 8 weeks of exposure to the intervention. Interview data from 2 young people who did not use Affinity were excluded from the analysis. The interviews were analyzed using thematic analysis, with the frequency of responses characterized using the consensual qualitative research method. The results are reported in accordance with the Consolidated Criteria for Reporting Qualitative Research checklist.

Results: A total of 4 overarching themes were identified: a safe and supportive environment, the importance of mutual experiences, difficulty engaging and connecting, and the pros and cons of banning discussions about suicide. Interestingly, although Affinity was perceived to be safe and free of judgment, concerns about negative evaluation and triggering others were significant barriers to posting on the social network. Participants generally supported the banning of conversations about suicide, although for some this was perceived to reinforce stigma or was associated with frustration and distress.

Conclusions: The results not only support the safety and potential therapeutic benefit of the social networking aspect of Affinity but also highlight several implementation challenges. There is a need to carefully balance the need for stringent safety and design features while ensuring that the potential for therapeutic benefit is maximized.

KEYWORDS

suicide; youth; social media; internet-based intervention

Introduction

Background

Globally, suicide is the second-leading cause of mortality in young people, defined as those aged between 15 and 24 years [1,2]. In Australia, it is the leading cause of death in youth, accounting for more than one-third of all deaths in this age group [3]. Suicidal ideation and behavior, including self-harm, are relatively common in young people, with approximately 10.6% and 1.2% of young people reporting past 12-month suicidal ideation and suicide attempts, respectively [4]. Suicidal ideation and behavior are risk factors for future suicidal behavior and suicide [5], along with mental disorders including, most significantly, a diagnosis of depression [6]. Moreover, interpersonal states, including perceived burdensomeness (feeling as though one is a burden on others) and thwarted belongingness (lacking a sense of belonging to any particular group) may also confer risk, as articulated by the Interpersonal Theory of Suicide [7,8]. Despite extensive investment and research into youth suicide prevention, the rates of suicide and suicide-related behavior in young people are rising both in Australia and internationally [3,9,10]. The reasons for this are complex, as such there is unlikely to be a single causal factor or solution. However, youth consultations suggest that there is a need to develop and evaluate new and innovative interventions that are theoretically based, target known risk factors for suicide, and are acceptable and relevant for young people [1,11].

The internet has increasingly received attention as a potential platform for the delivery of suicide prevention interventions for young people because of its reach, accessibility, acceptability, and cost-effectiveness [12-14]. Although several systematic reviews and meta-analyses have shown that digital interventions can reduce suicidal ideation and/or behavior in adults [15-18], far fewer studies have focused on developing and testing digital suicide prevention interventions for youth [12,19]. In addition, although the integration of digital interventions with existing mental health services may have several benefits, including improved treatment engagement and outcomes [20,21], to date there have been limited efforts to integrate web-based and face-to-face treatments for young people with suicidal thoughts or behaviors [22]. Finally, the internet has the capacity to facilitate mutual peer-to-peer support, which may in turn have the potential to target interpersonal risk factors for suicide (perceived burdensomeness and thwarted belongingness) [23]; however, no professionally developed intervention has included such a component. This may be in part because of concerns regarding the possible contagion of suicidal behavior, cyberbullying, and trolls [14,23].

Objectives

To address these gaps while also mitigating the potential risks, researchers at Orygen in Melbourne, Australia, developed and pilot tested *Affinity*, a Moderated Online Social Therapy (MOST) [24-26] intervention designed as an adjunct to face-to-face treatment for young people with active suicidal ideation. Quantitative data, reported elsewhere [27], revealed Affinity to be safe, feasible, and acceptable, with exploratory correlations indicating associations between clinical improvement and key aspects of Affinity usage. Given the novel nature of the Affinity intervention, particularly its inclusion of a web-based social network, quantitative data alone are insufficient to understand important aspects of the user experience of the platform. Thus, the aim of this study is to qualitatively explore the views and experiences of young people who participated in the Affinity pilot study. Qualitative outcomes focused on the social networking aspect of the intervention, including moderation and safety features.

Methods

Design

This study reports qualitative interview data collected from young people who took part in a single-arm, pre-post test pilot study of the Affinity intervention conducted in 2018.

Participants

Participants were current clients of a youth mental health clinic in Melbourne, Australia (the Youth Mood Clinic), that specializes in the treatment of young people with severe mood disorders [28]. The Youth Mood Clinic clients were referred to the study by their treating clinicians based on the clinician's perception of their suitability. They were eligible to participate in the trial if they had experienced suicidal ideation within the past 4 weeks (screened for by the lead author using the question, "Have you had any thoughts of suicide in the past four weeks?"), had regular and ongoing internet and telephone access, and were able to give informed consent and comply with study procedures. Additional inclusion criteria to ensure participants' safety and enable execution of safety protocols (if required) were as follows: well engaged with treatment and not approaching discharge in the next 4 weeks; familiar with, and willing to use, crisis supports; and willing and able to nominate 2 emergency contacts. There were no specific exclusion criteria related to the level of suicide risk, although clinicians were consulted on a case-by-case basis regarding participant suitability.

Of the 20 young people who participated in the pilot study, 17 (85%) completed a qualitative interview at follow-up. Of the 3 who did not complete a qualitative interview, 2 were not responsive to the research team's contact attempts at follow-up (but remained engaged in their treatment at the clinical service) and 1 moved overseas before the qualitative interview could be completed. A total of 2 participants did not use the social network during the intervention period, engaging only with the therapeutic comic component of Affinity; therefore, their interview transcripts were excluded from the analysis.

The 15 remaining participants had a mean age of 21.3 years (SD 2.7; range 17-24), with 9 identifying as female, 5 as male, and 1 as transgender. At baseline, 93% (14/15) participants had suicidal ideation scores above the clinical cutoff on the Adult Suicidal Ideation Questionnaire [29] and 73% (11/15) reported at least one previous suicide attempt. On the Patient Health Questionnaire-9 [30], 80% (12/15) participants were in the *severe* or *moderately severe* range for depressive symptoms.

Intervention

The Affinity intervention is described in detail elsewhere [23,27]. Affinity is a closed website that consists of 3 main components: (1) therapeutic content delivered in the form of illustrated comics; (2) peer-to-peer social networking; (3) moderation by clinical experts and young people with lived experience of mental ill health. Users create a profile using either their own first name or a pseudonym, with 67% (10/15) participants in this study choosing to use their real first name. Users can access Affinity 24 hours a day, as often or little as they like, and can use any or all of the components. Clinical and peer moderators promote engagement with the social network and therapeutic content and provide guidance, information, and emotional support to users. Although both clinical and peer moderators post publicly on Affinity and communicate with users via private message, only the clinical moderators are responsible for monitoring and managing clinical risk. Moderators checked Affinity for posts potentially indicative of clinical risk twice daily on weekdays and once daily on weekend days.

In addition to clinical moderation, the Affinity intervention and research design incorporated a number of safety features. First, posts containing keywords related to suicide risk (eg, suicide, suicidal, die) were automatically detected and blocked by the system, which would then trigger a notification to the lead author's business mobile phone. Participants were made aware that this was accessed only during business hours. If notified, the lead author would immediately review the post in question and, if concerned about risk, respond according to the approved study safety protocol (see the following paragraph). Affinity also includes a vent post function, which allows users to select "I'm just venting" before making a post. When selected, the post appears masked by a warning to other users about the potentially inflammatory nature of the post, and users can then elect to view the post's content. The vent post function is primarily designed to protect users from unwillingly viewing posts with swear words. Importantly, vent posts are not immune to the automatic detecting and blocking safety function; as such, posts expressing suicide risk could still be blocked even if "I'm just venting" is selected. Throughout the trial, 3 participants had at least one post that was automatically blocked. One of these posts communicated current suicidal ideation but not imminent risk, and the remainder of the blocked posts were not related to suicide risk but to other violent or aggressive behaviors that participants had experienced. Although the automatic blocking system used simple string matching and could not detect alternatives of keywords, such as sui*c*de, no participants in this study attempted to bypass the system.

A comprehensive safety protocol was in place outlining risk assessment and management procedures, including provisions for telephoning participants' emergency contacts and/or emergency services, if risk was assessed to be high. All information about clinical risk identified during participation in the trial was communicated to the participants' treating clinicians. Participants were also required to agree to a *terms of use* before being given access to Affinity, which included a request not to share personal or contact information with other users via the website to prevent conversations about suicide happening externally. These measures were in place to mitigate the risk of distress to participants or the contagion of suicidal behavior [23]. Accordingly, although participants were aware that the purpose of Affinity was to support young people who experience suicidal thoughts, they were actively discouraged from talking about suicide in the social network.

Procedure

Participants were referred to the study by their treating clinicians between April and August 2018 and were given access to Affinity from the point of entry into the study until the intervention was closed (October 31, 2018). Semistructured interviews were conducted with each participant approximately 8 weeks after they were given access to Affinity by the lead author (EB), an experienced research assistant and a PhD candidate. EB had an established relationship with the participants in that she had also conducted the baseline assessments but was not involved in the delivery of the intervention itself (ie, did not post on Affinity or use it to communicate with users). The interviews were conducted either in a private room at the mental health service or in participants' homes, with only the interviewer and interviewee present. The interview length ranged from 26 minutes to 75 minutes, with a mean duration of 48.3 (SD 16.4) minutes. Table 1 displays each participant's study ID, age, interview length, severity of depression symptoms at baseline, and suicidal ideation score at baseline. To protect the identity of the transgender participant, participants' genders are not provided. Participants were informed that the purpose of the interview was to explore positive, negative, and neutral feedback about Affinity, and were encouraged to be as open and honest as possible. As the purpose was to obtain feedback from as many participants as possible regarding their experience, data saturation was not assessed.

The interview schedule was designed to obtain participants' views and experiences about Affinity, with prompts included if answers were vague. For the purpose of this paper, only responses related to the social network, safety features, and peer and clinical moderation were analyzed. The full interview schedule is provided in Multimedia Appendix 1. All interviews were audio recorded and transcribed verbatim, and potentially identifiable information was removed. Brief field notes were recorded during interviews.

This study was approved by the Melbourne Health Human Research Ethics Committee (ID 2017.187). All participants provided written informed consent. Participants under the age of 18 years were required to provide consent from their parents or guardians.

Table 1. Participant ID, age, interview length, and clinical characteristics at baseline (N=15).

ID	Age (years)	Interview length (min)	Baseline depression category (Patient Health Questionnaire-9)	Baseline suicidal ideation score (ASIQ)[a]
2	20	48	Severe	130
3	23	68	Moderate	42
5	22	50	Moderately severe	61
6	24	70	Moderately severe	24
7	23	71	Severe	130
8	23	32	Moderately severe	120
10	21	48	Severe	79
11	18	53	Moderately severe	119
12	24	46	Moderate	78
13	17	26	Severe	132
15	17	26	Moderately severe	69
16	17	34	Severe	136
17	24	75	Severe	78
18	23	39	Moderate	74
19	23	39	Severe	79

[a]ASIQ: The Adult Suicidal Ideation Questionnaire. The scale has a possible score range of 0-150; scores of 31 or more are considered to be in the clinical range.

Data Reporting and Analysis

Data were reported in accordance with the Consolidated Criteria for Reporting Qualitative Research [31]. The checklist is provided in Multimedia Appendix 2. Only interview data pertaining to the social network, moderation, and safety features were analyzed for the purpose of this paper. Data were analyzed using inductive thematic analysis following 6 steps by Braun and Clarke [32]: (1) familiarizing with data, (2) generating an initial coding frame, (3) searching for themes, (4) reviewing themes, (5) defining and naming themes, and (6) reporting. The lead author (EB) read and reread the interview transcripts to immerse herself in the data, and based on this, an initial coding frame was generated. A coauthor (LV) checked the coding frame against a 10% subset of the data (ie, 2 interviews) and then discussed this with EB to refine the coding frame. The coding frame was then applied to the data provided by the lead author. Codes were then grouped into initial themes, which were reviewed and refined, with some combined and grouped into minor themes as necessary. SR, MN, and JR were regularly consulted regarding the codes and themes developed. The data were coded, and codes were grouped into themes by hand and then transferred to a web-based whiteboard platform (Miro) to produce hierarchical thematic maps, where they were organized, reviewed, and refined.

Data were reported according to the consensual qualitative research method [28], using the labels *few* (rare support; endorsed by 10%-20% of the respondents), *some* (variant support; endorsed by 21%-50% of the respondents), *many* (typical support; endorsed by 51%-90% of the respondents), or *most* (general support; endorsed by 91%-100% of the respondents).

Results

Overview

A total of 4 key themes were identified: (1) a safe and supportive environment, (2) the importance of mutual experiences, (3) difficulties in connecting and engaging, and (4) the pros and cons of banning discussions about suicide. These themes are outlined later and illustrated with exemplar quotes. Study ID and age are provided alongside quotes. The hierarchical thematic maps are available in Multimedia Appendix 3, and a table of themes, subthemes and/or codes, endorsement percentages, and exemplar quotes are available in Multimedia Appendix 4.

Theme 1: A Safe and Supportive Environment

The first theme describes participants experiencing Affinity as a positive environment, wherein they felt both safe and supported. Indeed, many participants (11/15, 73%) specifically discussed feeling safe on Affinity. This sense of safety was discussed both in terms of being shielded from negative content and feeling safe from ridicule or judgment. A few participants (2/15, 13%) also referred to feeling safe because they knew their privacy was protected.

Some participants (6/15, 40%) specifically referred to the presence of clinical moderators as contributing to the sense of safety, in that users knew "if something did happen that there were people there that could step in" (ID 08, aged 22 years). A few participants (3/15, 20%) also reported feeling safe because they knew that all users were well-intentioned, with one stating they knew other users "weren't there to harm me or affect me negatively in any way. They were just there to better themselves" (ID 02, aged 20 years). This belief in the good intentions of other users was partly attributed to their mutual

experiences, although this was identified as a distinct theme and is therefore elaborated separately later.

Some (6/15, 40%) specifically labeled Affinity as a *friendly* and/or *supportive* space. Many (8/15, 53%) participants said that they had provided support to other people on Affinity; 6 of these said this was a positive experience, with 1 participant noting "…it feels good to know you've helped someone" (ID 05, aged 22 years). Two of these participants noted negative impacts in addition to discussing positive outcomes of supporting others, with one stating "it can be frustrating when people don't want to listen to what you've got to say" (ID 07, aged 23 years), and another referring to their tendency to worry about other people at the expense of "fully looking after myself" (ID 17, aged 23 years).

Participants also expressed appreciation for the way the peer and clinical moderators connected with them and the social network. Many (8/15, 53%) valued when moderators reached out with personalized messages to check on them or suggest particular therapeutic components to try within Affinity:

> *[The moderators] sent us really big paragraphs which I really liked. I don't care how long they are, but the fact that they took time to write that and it was meaningful, it was really supportive.* [ID 16, aged 16 years]

Although many participants (9/15, 60%) also appreciated the effort the moderators put into facilitating group conversations and welcoming new users, some participants (4/15, 27%) felt they were overly enthusiastic in their attempts to promote connections within the network:

> *They were good. For one thing, it made it so that there was no post that was really ignored...But I will say that there were points where it felt a bit artificial to an extent.* [ID 11, aged 18 years]

Some participants (6/15, 40%) specifically drew comparisons between Affinity and other mainstream social networking sites, such as Facebook, stating that Affinity felt safer and more supportive:

> *People feel more secure being open in that area, as opposed to other social media. They could be attacked or feel triggered. But in Affinity, we're all here to support each other.* [ID 03, aged 22 years]

> *When I'm in a good mood Facebook was great. But when I'm in a bad mood or have anxiety, I'm not sure, something about it upsets me. I never got that from Affinity, I'm not sure if it's because I didn't know the people, or it's because the posts were positive, or because I knew they were going through the same thing I was going through. Whatever it was, I never felt upset.* [ID 12, aged 23 years]

For some (7/15, 47%), Affinity was therefore perceived to provide a way for safely and easily interacting, or connecting, with others, which was particularly helpful in periods of low mood or isolation when any form of interaction was difficult:

> *I mean, for me I feel very disconnected from the world, so I feel a little bit more connected when I'm on Affinity. Just a little bit more. It's not fixing anything per se but I do feel a little better using it.* [ID 06, aged 24 years]

> *Previous, what I would normally do is just cut contact off completely. This gave me one thing that I could stay on.* [ID 12, aged 23 years]

Theme 2: The Importance of Mutual Experiences

Many participants (13/15, 87%) specifically spoke about valuing participation in a network of other people with similar lived experiences (namely, depression and suicidal thoughts). Many (8/15, 53%) specifically spoke about how this helped them to feel less alone or *crazy* with regard to these experiences:

> *You read posts and it would be something, you'd be like oh I've had that thought or that's how I feel. Then in your head you're like oh, this person's feeling that way too. [...] You read that post and think oh okay I'm not crazy, I'm not the only person that thinks that.* [ID 08, aged 22 years]

> *Talking to other people that actually feel what I do is - I mean yeah, it's pretty good. I think the most terrible thing about depression is it makes me feel like I'm the only person in the world who feels that and it makes me feel lonely.* [ID 10, aged 21 years]

Some (7/15, 47%) also discussed how this led to them feeling particularly validated and understood by the other users, with one stating:

> *That was something I could talk about on Affinity, and be candid about on Affinity and not - I could tell my friends, but there was - it was - there was something about saying it in front of other people who understood about this.* [ID 11, aged 18 years]

Some participants (4/15, 27%) also reported that they were able to learn from other users, because they either provided relevant advice or a new perspective or posted about how they had dealt with their own problems. For example, one participant reflected that suggestions from other users were "more useful than people that haven't been through this kind of thing, purely because they themselves know more or less what helps and what doesn't" (ID 05, aged 22 years). Another user discussed how responses to a different user's post about a "problem that was similar to mine...helped me see things from the other person's side of view and look at their problem in a different way" (ID 02, aged 20 years). A few participants (3/15, 20%) said that hearing about the experiences of others was encouraging in terms of their own ability to "get through this." One participant said that knowing the peer moderators had lived experience of mental ill health and that they were in recovery "gives a little bit of hope" (ID 02, aged 20 years).

Finally, some participants (4/15, 27%) specifically stated that they experienced many of the benefits related to mutual experiences even though they did not actively engage in social networking; in other words, just reading posts was beneficial. One participant said that even though they did not post, "it helped to just read someone else's post about how they were feeling" (ID 17, aged 23 years).

Theme 3: Difficulties in Engaging and Connecting

Participants also reported that they encountered barriers to engaging with the affinity social network and/or connecting with other users. These barriers have been categorized into subthemes of internal barriers (related to feelings of anxiety or apprehension) and external barriers (attributes specific to Affinity).

Internal Barriers to Engaging and Connecting

Many participants (12/15, 80%) discussed feelings of anxiety or apprehension related to posting on the network and/or replying to posts made by others. A total of 2 subthemes related to the source of this anxiety were identified: fear of negative evaluation and fear of causing harm.

Fear of Negative Evaluation

Many (8/15, 53%) participants discussed feelings of anxiety related to posting or replying to posts on Affinity, often related to concerns that other users would not care about their post or that no one would respond to their disclosure or comment. For example, one participant (ID 18, aged 23 years) discussed not wanting to be "the first one to comment," for fear that other users "won't react to it and you'd just be sitting there and no-one will give a shit about what you said." Some participants (4/15, 27%) said this uncertainty manifested as "overthinking," with one participant stating, "I just kept second guessing whatever I would write whenever I wanted to make a post" (ID 02, aged 20 years).

One participant (ID 17, aged 23 years) likened this to anxiety associated with posting on other forms of social media, stating "social media has ruined people, and they're like, ah, is this going to get likes, or are people going to comment back to this?" Indeed, some (5/15, 33%) specifically stated that these thoughts and feelings were typical for them and extended to all social media and did not attribute them to Affinity specifically.

Some participants (4/15, 27%) expressed confusion about the fact that they felt anxious despite the supportive nature of the social network, with one saying, "It's weird because we know that it's a safe place, and yet we still get very anxious about those things" (ID 19, aged 23 years). Another said, "I don't know why I was being super scared, because I have all this proof that everybody on there is actually really supportive and nice and nothing that I'm posting is too bad or controversial" (ID 02, aged 20 years).

Fear of Causing Harm

Some participants (6/15, 40%) reported that they held back from posting or replying to posts because they were worried about causing distress or being unhelpful to others, with 2 users expressing uncertainty regarding permitted posts:

> *I guess I didn't even post things, like thoughts that I might be having, no one likes me or I'm just a complete failure or life's not worth living, I feel so hopeless, I feel like I don't have a future. I wouldn't say stuff like that, because I thought it would be too triggering for other people.* [ID 07, aged 23 years]

> *I felt even if I had something to say, I didn't feel comfortable saying it. I wasn't sure if I wrote something if it'd make it worse, or I'm not sure how to feel about giving other people advice. So, I kind of deliberately took a - even if I thought I had advice, I wouldn't give it, because I'm not sure how the reaction would be.* [ID 12, aged 23 years]

One participant suggested that this uncertainty could have been better managed if Affinity had contained a list of topics or phrases that were permitted and not permitted or if moderators had initiated group discussions around sensitive issues.

External Barriers to Engaging and Connecting

In total, 2 external barriers were identified: the small user base and the impersonal nature of the interactions with other users.

Small, Inactive User Base

Many participants (9/15, 60%) stated that there were too few users on Affinity and/or that the user base was too inactive. A few participants (2/15, 13%) specifically said that this reduced their motivation to log in altogether because "there isn't much happening" (ID 06, aged 24 years). A few (3/15, 20%) stated this hindered willingness to post because they anticipated a delayed response, and 2 participants reported that a lack of timely or prompt acknowledgment or validation from the network in relation to comments or disclosures made on Affinity had a negative impact:

> *You can post something and go unnoticed for two days. So, in that aspect, it [...] felt almost a little counterproductive [...]it just didn't necessarily help with the isolation.* [ID 05, aged 22 years]

> *Just say I type something, and no one responded within a day, I'm like, oh, they don't care about me. Oh, they don't want to listen. I made them feel shit, or something. Those thoughts keep going around in my head, and I'm like, oh, I shouldn't have said that.* [ID 16, aged 16 years]

Impersonal Interactions

Some participants (7/15, 47%) expressed dissatisfaction with their inability to interact more closely or on a long-term basis with other users. Specifically, the prohibition of sharing personal or contact information, the lack of a private user-to-user chat function, and the temporary nature of Affinity were perceived to have contributed to difficulties establishing meaningful connections with other users:

> *It probably helped a little bit and made me feel connected and heard, but not like - it didn't, you know, completely erase my feeling of isolation and loneliness because at the end of the day, it's a temporary thing, it's not permanent, I don't know who anyone is on there.* [ID 07, aged 23 years]

Theme 4: Pros and Cons of Banning Discussions About Suicide

The fourth general theme was related to the fact that both positive and negative feedback was received regarding the banning of suicide-related posts on Affinity. A total of 11 participants specifically discussed this policy; of these, 7 (64%) generally supported it, 2 (18%) did not, and 2 (18%) mentioned

both positive and negative impacts. Participants in support of prohibiting suicide-related posts stated that they felt conversations about suicide could be harmful or *triggering* for themselves or other users, with one stating:

> *For me, it would be very triggering if I were to see anything about suicidal thoughts. But that depends on the person I guess because I think I'm just very emotional, and very easily influenced.* [ID 19, aged 23 years]

Some participants (3/11, 27%) specifically stated that they valued the *vent post* function of Affinity.

One participant with mixed views about these terms of use stated:

> *It's definitely a little bit weird that [Affinity] is for people who are feeling suicidal but you can't really talk about it or - definitely seems like it had sort of a stigma as well. But I feel like it was good that you didn't let us talk about it like that because I feel like if I saw somebody talking about suicide, then it would get me thinking. Or I'd be super worried about them and I don't think either of those are helpful for me or anybody else on the website.* [ID 02, aged 20 years]

Another participant suggested that banning discussions about suicide could be challenging for people who *need to talk about* their suicidality. Indeed, some participants (3/11, 27%) spoke about needing to vent without necessarily needing a crisis intervention, for example, one said:

> *I know for myself sometimes when you want to - you just need to say something and to some people it's going to sound really bad but you're genuinely like I just need to get this out of my head.* [ID 08, aged 22 years]

One participant said it would have been helpful for them if they had been able to engage in discussions openly about suicide on Affinity:

> *So when I was alone and I was able to be on my phone and look through, it just would have helped [...] to have other people share their actual experiences.* [ID 17, aged 23 years]

A few participants (2/11, 18%) described the experience of having a post automatically blocked by the system and both found it a negative experience, mostly because of confusion about why it was blocked in the first place:

> *It was just like annoying. I was just like, really? Especially [because] there was no real obvious reason as to why it got blocked. I feel like for me if it was an obvious reason I'd be like okay, I can change that, but I'm looking at it going I can't actually change anything in this to make it any less - different to what it is.* [ID 08, aged 22 years]

> *I thought somebody took time out of their life to block my - or report me. I was like, are you serious? [...] Yeah, just seems like nothing now, but at the time I got really upset. Other people were using swearing and stuff. How can F-U-C-K be involved but not death? That's what I didn't understand, but yeah, I get it now.* [ID 16, aged 16 years]

Discussion

Principal Findings

This study used thematic analysis to examine the experiences of 15 young people who used the therapeutic web-based social networking platform, Affinity. We found that participants experienced Affinity as a safe and supportive environment where they felt less alone and understood by others, yet also experienced barriers to fully engaging and connecting. We also found that although participants generally supported banning discussions about suicide, some potential adverse effects were noted.

Positive Appraisals of the Affinity Social Network

The finding that Affinity was perceived to be supportive and safe and that participants valued being surrounded by others with similar experiences aligns with the quantitative results we have reported elsewhere supporting the acceptability and safety of Affinity [27]. The importance of mutual experiences has also been identified as a theme in other studies using the MOST platform [33,34] and the literature on online support groups for suicidal people [35,36]. The positive impact of providing support to others was also raised by some participants and has been identified in the broader online support group literature [36], although it is acknowledged that 2 participants in this study also reported negative aspects of supporting others, which are important and worthy of further exploration. For example, phenomena such as compassion fatigue or burnout may impact young people supporting other young people on Affinity; this has been hypothesized to occur in trained volunteers from at least one anonymous online forum for suicidal people [37].

Previously, we theorized that the peer-to-peer support facilitated by Affinity could mitigate the key risk factors described in the Interpersonal Theory of Suicide [7,8] of thwarted belongingness (via immersion in a network of similar others) and perceived burdensomeness (by enabling users to help others in need) [23]. The feeling of being less alone reported by participants suggests that they may have experienced an increased sense of belongingness; this aligns with our quantitative results showing a significant and large effect size (Cohen d=−0.96; P=.006) improvement in thwarted belongingness [27]. Regarding the possible influence of Affinity on perceived burdensomeness, as noted earlier, several participants reported that providing support to others was a positive experience. Although limited data preclude a deeper exploration of this, it is possible that helping others may effectively lessen the sense of burdensomeness [23]. Conversely, however, it may also be that fear of causing harm to others, either by triggering them or by providing advice perceived to be *bad* in response to a post, may also serve to increase burdensomeness. Therefore, further studies are warranted. Overall, these findings attest to the significance of the social networking component of Affinity and that it may have therapeutic benefits in and of itself. Moreover, some participants reported experiencing these benefits just by reading other users' posts, suggesting that the positive impact of mutual experiences may occur even without active participation. The

ability of participants to experience therapeutic benefit from passively participating in web-based peer support networks has also been found in previous studies using the MOST model [33,38] and in studies of online health-related support groups more broadly [39,40].

Barriers to Engaging and Connecting

Despite positive appraisals, participants also reflected on experiencing barriers to engaging and connecting in the trial. Perhaps unsurprisingly, given that most participants had depression symptoms in the severe or moderately severe range, fear of negative evaluation was a key barrier to engaging with the social network. Research has shown a link between symptoms of depression and a tendency to participate passively (or *lurk*) in web-based social networks [41-44]; indeed, participants in this study likened their apprehension about posting or commenting on Affinity to how they feel about social media more generally. Despite Affinity's vent post feature, which 3 participants specifically discussed in positive terms, a key barrier to engaging with the social network was fear of causing harm or triggering others. Participants also reported an inability to properly connect with other users, attributed to the finite period of access to Affinity as well as the lack of one-to-one chat and ban on sharing contact details. Building presence in a social network can be a significant investment of an individual's effort and time, and this was likely negated in this study, given the short intervention period and lack of opportunity to connect with users beyond the intervention. Although these safety and design choices were deliberately made because of the novel nature of the intervention and the high-risk nature of the sample, these will likely be carefully relaxed in future iterations of Affinity.

Balancing Risks and Benefits of Talking About Suicide

The finding that many participants supported the prohibition of suicide-related posts is somewhat surprising; we expected participants may have experienced this feature as authoritarian based on research suggesting that young people want to talk about suicide with one another and with adults [45]. This previous research, however, was conducted with young people who were not currently at risk. It is possible that young people with active suicidal ideation are more likely than those who have recovered to find open discussions about suicide distressing, particularly where suicidal cognitions are experienced as intrusive and involuntary. Indeed, concerns about becoming distressed or suicidal themselves were cited as key reasons for supporting the prohibition of discussions about suicide. Despite this, several adverse effects associated with banning discussions about suicide have also been raised by the participants. For example, one participant suggested that this may serve to perpetuate stigma. Given that openly talking about suicide to alleviate stigma and encourage help seeking is the rationale underpinning suicide prevention media campaigns [46], the potentially stigmatizing nature of prohibiting conversations about suicide on Affinity is worthy of consideration. Participants also suggested that talking about suicidal thoughts may be helpful for some people, and one participant said it would have been helpful to see how other people on Affinity deal with their suicidal thoughts; possibly, the benefits associated with mutual experiences would be heightened if these discussions were permitted. In addition, the participants who experienced having a post automatically blocked by the system reflected that this was a negative and confusing experience for them. This way, the automatic blocking system used in the Affinity pilot may actually be counterproductive and lead to increased distress, particularly for users who are already in a distressed state when posting. In the pilot, the list of risk words that would trigger a post to be blocked was not disclosed to participants nor were they informed which words had triggered the blocking after the fact. It is therefore possible that communicating this information to participants would have reduced their distress and frustration in response to having a post blocked. Given the mixed responses to the banning of discussions about suicide, more research is required to determine under what circumstances, by what mechanisms, and for whom, talking about suicide on platforms such as Affinity may be helpful or harmful. One possibility is that young people actively trying to suppress or avoid their suicidal thoughts as a coping strategy might experience anxiety or distress when encouraged to discuss them [47].

Implementation Challenges and Future Directions

Although the first 2 themes are indeed encouraging and provide further support for the acceptability, safety, and potential therapeutic benefit of Affinity, the barriers to engaging and connecting and mixed views on banning discussions about suicide pose a number of implementation challenges. First, there is a question of how to promote active participation in the social network to a population of users who may be particularly sensitive to judgment from others and who may perceive social media as being *unsafe*. Indeed, previous research has identified that adolescents tend to view social media as judgmental and threatening, particularly where they may be affected by mental illness, making them more susceptible to these cognitions [48,49]. Other challenges relate to how to allow users to connect more personally with each other and how to allow discussions about suicide to occur while maintaining adequate safety standards. There is clearly a careful balance to be struck so that the potential benefits of Affinity, particularly those related to mutual experiences, can be maximized while still protecting users who may be more susceptible to feeling distressed or triggered. This tension, associated with balancing safety features and ensuring potential benefits are maximized, is common to internet-based suicide prevention intervention research more broadly [50]. Given the quantitative [27] and qualitative findings of this study supporting the safety of Affinity, there is an opportunity to carefully relax some of the safety features used in the pilot study in the future. The inclusion criterion related to participants being sufficiently engaged with the clinical service, which in this study was implemented to ensure safety protocols could be appropriately executed, could potentially be relaxed in future iterations so that young people who are less well engaged in treatment could provide access to this potentially helpful intervention. Other options for consideration in future iterations of Affinity could include scheduled, moderator-facilitated discussions about suicidal thoughts focusing on helpful strategies and stories of hope and the promotion of guidelines about how to safely talk about suicide

[51], including specific advice about unacceptable content (eg, threatening suicide, inciting suicide in others). Importantly, users should be able to avoid discussions about suicide altogether on Affinity, without fear of judgment. In the absence of evidence-based guidelines for implementing digital interventions for this population, decisions regarding these features should be theoretically and empirically driven, consumer led, and carefully evaluated in an ongoing way regarding their acceptability and safety.

Limitations

Several limitations should be considered when interpreting the findings of this study. First, the interviews focused on breadth, rather than depth of data; as such, we were unable to explore in great detail the themes and subthemes that were identified. Future research is warranted to explore some ideas in detail; for example, understanding moderators of engagement and different engagement profiles would be important for the development of targeted consumer-informed web-based interventions for this population. Second, the sample size of 15, which is typical for qualitative research, prevents generalization of these findings beyond this study. Third, it is acknowledged that qualitative methods bring a degree of researcher subjectivity, which may have influenced the analysis and interpretation of results. To address this, regular discussions between members of the research team were held throughout the analysis process. Fourth, participants were not asked to review the transcripts or the study findings; however, as the transcripts were recorded and transcribed verbatim, the likelihood of error was minimal. Moreover, given the difficulty associated with contacting participants in this study, it was not appropriate or feasible to request that they provide feedback on the findings. Fifth, we did not analyze relationships between the themes, for example, whether participants who thought they benefited from passive participation were also those who experienced fear of negative evaluation in relation to posting; this should be a priority for future research. Finally, we did not include a measure of social anxiety, which would have shed more light on participants' experience of barriers to posting; this should be a focus of future evaluations of Affinity.

Conclusions

This study provides important preliminary data on the user experience of a web-based intervention for young people at risk of suicide, incorporating a social networking component and strict safety features. The findings suggest that the social networking component of Affinity is both safe and may possibly have therapeutic benefit, although participants experienced barriers to engaging and connecting related to their underlying feelings of anxiety as well as to design and the safety features of Affinity. Therefore, there is a need to carefully balance ensuring participants' safety with maximizing the potential for therapeutic benefit. That participants experienced benefit despite the ban on conversations about suicide and that passive participation was reported to be beneficial suggest that just knowing one part of a network of similar others may be in and of itself therapeutic for young people at risk of suicide. Future iterations of Affinity should consider carefully relaxing the safety features while continually monitoring and evaluating their acceptability and safety; these decisions should be based on the theoretical and empirical literature and made collaboratively with consumers.

Abstract

Background: Caregiving for a family member can result in reduced well-being for the caregiver. Internet-delivered cognitive behavioral therapy (ICBT) may be one way to support this population. This is especially the case for caregivers in countries with limited resources, but high demand for psychological services.

Objective: In this study we evaluated the effects of a therapist-guided 8-week-long ICBT intervention for informal caregivers.

Methods: In total, 63 participants were recruited online and randomized either to the intervention or to the wait-list control group. The main study outcome was the Caregiver Burden Inventory (CBI). Secondary outcomes included measures of caregiver depression, anxiety, stress, and quality of life.

Results: Moderate between-group effect sizes were observed for the CBI measure, in favor of the intervention group, with a Cohen *d*=–0.70 for the intention-to-treat analysis. Analyses of the subscales of the CBI showed significant reductions on the subscales of Development and Physical Health. Moderate reductions were found for depression and anxiety scores as indicated by the Patient Health Questionnaire-9 (PHQ-9) and Generalized Anxiety Disorder-7 (GAD-7) scores. Large between-group effects were observed for reduction in stress and increase in quality of life as indicated by the Perceived Stress Scale-14 (PSS-14), The Brunnsviken Brief Quality of Life Scale (BBQ), and The World Health Organization-Five Well-Being Index (WHO-5). In addition, participants experienced little to no difficulty in using the program and were mostly satisfied with the intervention's platform and the choice of content.

Conclusions: This is the first internet intervention study for informal caregivers in Lithuania. The results suggest that therapist-guided ICBT can be effective in reducing caregiver burden, anxiety, depression, stress, and improving quality of life.

Introduction

Because of an increase in longevity and a decrease in fertility, it has been suggested that in the future more individuals will be involved in taking care of the elderly than raising children [1]. Approximately one-third of the population could be described as informal caregivers as they look after someone in their close environment: individual(s) who are either physically or mentally ill, or experience difficulties due to old age [2]. Over the course of the history, women were more often expected to take up caregiving tasks within the family context [3]. Today, caregiving is still more prevalent among women [2]. Across Europe, informal caregiving is also more common among those aged between 50 and 59 as well as among non-employed or religious individuals [2]. Informal caregivers are becoming increasingly relied on for managing health care and societal costs for the elderly and chronically ill [4]. Yet, caregivers themselves are often faced with many challenges which puts them at risk for their own well-being.

Caregiving tasks and intensity vary greatly based on the condition of care recipients, available resources, and a combination of many other factors. Accordingly, caregiving might affect individuals differently too. For example, it has been shown that informal caregiving can bring satisfaction and fulfilment [5], especially if appraised positively [6]. However, this is only one side of the coin. It has been previously found that caregivers, in comparison to noncarers, experience reduced mental well-being [7], chronic stress, and increase in depressive symptoms [8]. Such a combination of physical, psychological, financial, and social demands of caregiving can be overall referred to as caregiver burden [3]. According to this definition, caregiver burden is viewed as a multidimensional experience that affects several aspects of caregiver's life. Hence, despite the positive consequences, informal caregiving can also have a negative effect on the informal caregiver's physical and emotional well-being.

Intercultural differences exist in the type of support that informal caregivers receive across Europe [9]. For example, caregivers in the Northern countries, such as Sweden or Denmark, tend to receive tax-funded professional help, and therefore spend on average less time for caregiving duties (approximately 2-3 hours per week) [10]. Contrary to this, caregivers in Southern European countries might be required to provide 24-hour support [10]. These are rather drastic cross-country differences that might in turn have a different effect on caregiver's overall well-being and experience of burden. Apart from availability of formal support, countries differ in other factors such as traditions and societal expectations toward care provision [3]. It is therefore important to consider specific cultural context when developing support services, and in the present context psychological services delivered via the internet.

Because of the increasing numbers of informal caregivers and evidence of their experienced burden, recent years have seen a rise in research studies investigating ways to improve their well-being. Different types of support interventions could be distinguished: interventions providing education and information, interventions providing practical support via respite services for the caregiver, and interventions providing psychological support [3]. Interventions in the latter group are of particular interest because they target informal caregiver well-being. Specifically, these interventions aim at supporting caregivers in their emotion management as well as problem-solving skills, and hence improving their overall quality of life.

Apart from the traditional, face-to-face format, psychological support interventions are being increasingly offered online. One of the benefits of internet interventions is that it can reach a wide range of individuals, even in remote places [11]. This is a very important benefit as opposed to the face-to-face format, especially in the context of the current COVID-19 pandemic, which is having an impact not only on individual mobility, but also on accessibility of various support services. Regarding internet intervention programs for informal caregivers, differences can be observed in both the mode of delivery and the content of programs [12]. To give an example, some programs provide video materials, whereas others mainly rely on text. In addition, some programs offer human support via professional feedback, whereas others offer opportunities for peer support. Despite differing formats of such interventions, based on the current findings there is some evidence that internet interventions for informal caregivers can be effective in improving their well-being [13]. At the same time, despite the emergence of internet intervention studies for informal caregivers, further high-quality research is encouraged [14].

Internet-delivered cognitive behavioral therapy (ICBT) is one of the treatment formats that now has been tested in various populations with success rate similar to that of face-to-face therapy [15]. Few attempts have been previously made to implement ICBT for informal caregivers (eg, [16]). However, in most cases treatments were targeted to a specific group of caregivers. For example, caregivers of individuals with dementia, cancer, or other disorders. Hence, there is little existing knowledge about the effectiveness of transdiagnostic ICBT for informal caregivers. Transdiagnostic treatments target common mechanisms observed in various psychiatric disorders, instead of focusing on one specific disorder. Such treatments are especially useful in addressing comorbidity. To give an example, the same intervention program could be used by individuals with stress and anxiety as well as depression symptoms. Therefore, if effective, transdiagnostic ICBT could be applied for a wide range of informal caregivers.

Considering the need for further research studies, the growing number of caregivers, and the need for accessible interventions, the aim of this study was to develop and evaluate the effectiveness of an internet-based, therapist-guided ICBT intervention in reducing caregiver burden. Caregiver burden was chosen as a focus for the intervention because current research findings regarding the effectiveness of internet intervention in reducing caregiver burden are inconclusive [6]. The intervention was targeted at informal caregivers in Lithuania and was a set up as a pilot randomized controlled trial. A decrease in the caregiver burden was defined as the primary goal with reduction in depression, anxiety, and stress as well as increase in quality of life as secondary goals. Results of this study will provide information about the acceptability and

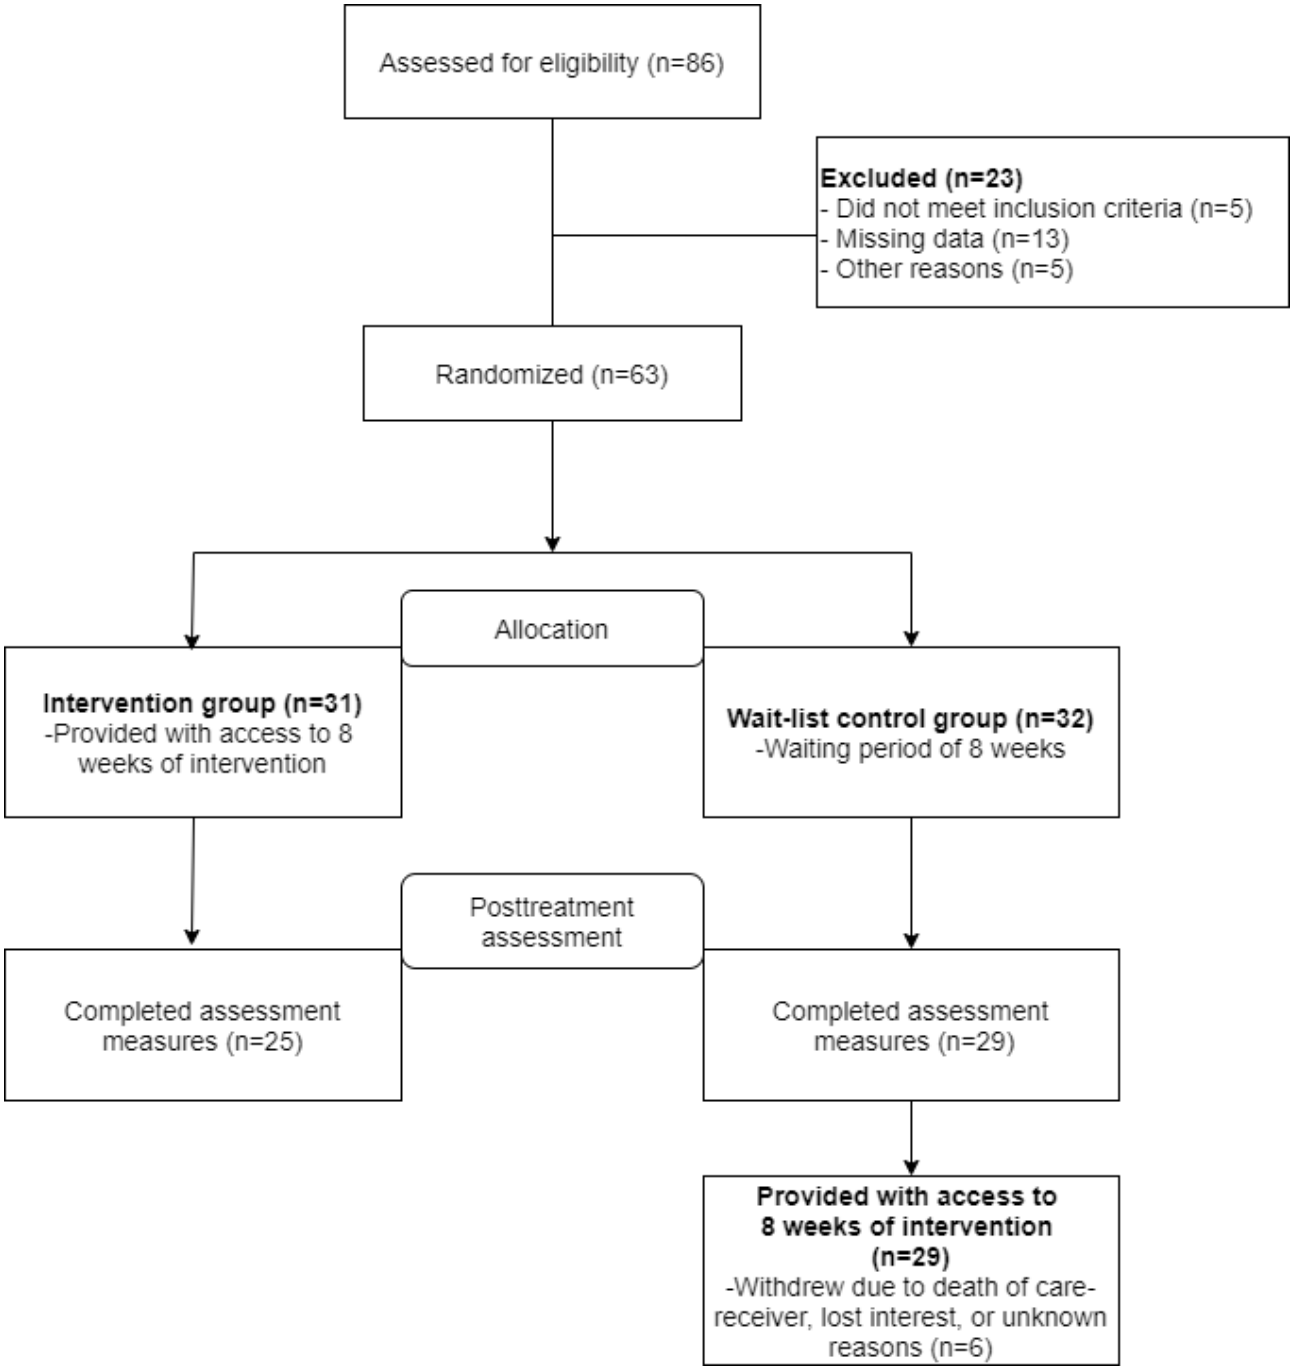
effectiveness of such interventions in a unique population where the demand for such services is high [17].

Methods

Design

A 2-armed randomized controlled trial was conducted online in Lithuania with participants recruited from the general population. Participants were randomly allocated to either an 8-week internet treatment or a wait-list control condition. Measures were collected online and administered at 2 points in time: at the start of the treatment (pretreatment) and at the end of the treatment (posttreatment). In addition, 4 weeks after the start of the intervention, participants were contacted for a short telephone interview. The main purpose of this conversation was to provide participants with an opportunity to ask questions about the use of the treatment as well as to raise any related concerns. Control group participants received the same treatment once the initial treatment phase had finished (posttreatment). A flowchart representation of the study is presented in Figure 1. Ethical approval for this study was received from the Vilnius University Psychology Research Ethics Committee (08-07-2019 No. 26). The trial was registered in ClinicalTrials.gov (registration number NCT04052724) and reported in accordance with the CONSORT-EHEALTH checklist (Multimedia Appendix 1).

Figure 1. Flowchart of the participant recruitment to the randomized controlled pilot trial.



Participants

Eligible participants were able to register from September 2019 to October 2019. Recruitment was conducted in various forms. The study was announced by the Vilnius University press release and posted on the Vilnius University website, Facebook, and other social media. Additionally, invitation to participate in the study was disseminated among the health care institutions, social services, and patient organizations targeted to reach informal caregivers. The study publicity campaign reached national media, and the study was covered by national TV and radio programs. In addition, information about the study was posted in national and regional press. After registration, individuals who filled in all the required measures online were contacted for a structured interview over telephone, after which eligibility to participate in the study was finalized.

To participate in the study, individuals had to have access to the internet via a computer or any other compatible device (eg, smartphone or tablet) as well as the ability to use it throughout the duration of the intervention. Eligible participants had to have a score of 24 or more on the Caregiver Burden Inventory (CBI) [18], be 18 years old or over, and be fluent in comprehending, writing, and reading Lithuanian language. The intervention was not tailored to any specific group of caregivers (eg, those caring for patients with dementia). Individuals were not eligible to participate in the study if they were experiencing severe physical or mental health problems, alcohol addiction, other severe traumatic events, suicide risk, severe interpersonal violence, or their care receiver had a life expectancy below or approximately around 6 months.

Overall, 86 individuals expressed interest to participate and provided informed written consent. Of these, 13 did not fill in all the required questionnaires. One participant was excluded as we were not able to reach the person for screening. Eligibility of the remaining 72 participants was assessed via phone interviews. Mini International Neuropsychiatric Interview Version 5 [19] was translated into Lithuanian language by the research group and was used in phone interviews for additional assessment of inclusion criteria. Following interviews, 9 participants were excluded due to either not meeting inclusion criteria (n=5) or losing interest in participation (n=3). One remaining application was removed, because the participant had registered twice. We have made an exception regarding cut-off scores for CBI: 1 participant with a score of 21 was included in the study because the individual expressed feeling burdened as well as wished for support during the phone interview. Hence, 63 participants were randomized to either the intervention (n=31) or the wait-list control group (n=32). Randomization was conducted by an independent researcher not involved in the trial and performed according to a 1:1 ratio. The website for generation of random numbers [20] was used. Randomization procedure was also used for randomly allocating therapists to participants.

All the included participants were requested about the condition of their care receiver. As there would be several small groups among our sample regarding different medical conditions of the care receivers, we chose not to further categorize these data. Moreover, many caregivers indicated that their care receiver experiences several comorbidities, which would make it difficult to categorize the data. Nevertheless, some of the more common health conditions of the care receivers were dementia and frailty due to old age.

Measures

Primary Outcome Measure

Caregiver Burden Inventory

The CBI [18] was chosen as it views caregiver burden as a multidimensional experience. The CBI comprises 24 items that are distributed within 5 areas: development, physical health, time dependency, emotional health, and social relationships. Response options are presented on a 5-item Likert scale ranging from 0 (Never) to 4 (Nearly always). All areas have 5 questions dedicated to them with the exception of physical health, which has 4. The total score of the CBI is summed up and ranges from 0 to 96, with higher scores indicating higher levels of burden. Reliability coefficients for each of the subscales of the CBI were previously shown to be high: development (α=.87), physical health (α=.86), time dependency (α=.85), emotional health (α=.81), and social relationships (α=.69) [21]. In this sample, Cronbach α for each of the subscales was high: development (α=.85), physical health (α=.80), time dependency (α=.89), emotional health (α=.83), and social relationships (α=.81). Cronbach α for CBI altogether in this sample was also high (α=.87). The CBI has been translated and previously applied in research studies in several different countries (eg, [22,23]) as well as for specific caregiver groups. In our study, the CBI was translated into Lithuanian language by the research group.

Secondary Outcome Measures

For these measures existing official Lithuanian language translations were used.

Patient Health Questionnaire-9

The Patient Health Questionnaire-9 (PHQ-9) [24] comprises 9 questions aimed at evaluating depressive symptoms. Response options are presented on a 4-item Likert scale ranging from 0 (Not at all) to 3 (Nearly every day). Higher scores indicate higher symptom severity. This questionnaire is widely used in research studies, due to easy administration and very good psychometric properties (α=.89) [24]. In this sample, Cronbach α for PHQ-9 was high (α=.82).

Generalized Anxiety Disorder-7

The Generalized Anxiety Disorder-7 (GAD-7) questionnaire [25] is used for evaluating symptoms of generalized anxiety disorder. This questionnaire consists of 7 questions. As with PHQ-9, answers for this questionnaire are distributed on a 4-item Likert scale ranging from 0 (Not at all) to 3 (Nearly every day). Higher score indicates higher levels of anxiety. This measure displays very good psychometric properties (α=.92) [25]. In this sample, Cronbach α for GAD-7 was high (α=.87).

Perceived Stress Scale-14

The Perceived Stress Scale-14 (PSS-14) [26] is a 14-item questionnaire that contains questions measuring stress on a 5-point Likert scale ranging from 0 (‘Never’) to 4 (‘Very Often’) [26]. Items on the PSS-14 touch upon aspects such as feeling

of nervousness and ability to cope as experienced over the last 4 weeks. Higher scores on PSS-14 indicate higher levels of stress. This measure has previously shown good psychometric properties with Cronbach α ranging from .75 to .89 [27]. In this sample, Cronbach α was found to be high (α=.85).

Brunnsviken Brief Quality of Life Scale (BBQ)

The Brunnsviken Brief Quality of Life Scale (BBQ) [28] is a questionnaire developed for evaluating quality of life for both clinical and nonclinical samples. It contains 12 statements that cover topics such as creativity, leisure time, and view on oneself. Responses are distributed on a 5-point Likert scale ranging from 0 (Strongly disagree) to 4 (Strongly agree). Higher scores on this measure indicate higher quality of life. Psychometric properties of BBQ are good (α=.76) [28]. The BBQ in our sample showed good internal consistency (α=.87).

The World Health Organization-Five Well-Being Index

The World Health Organization-Five Well-Being Index (WHO-5) [29] is a widely used short questionnaire that was developed by the World Health Organization [30] and has shown to be a valid and reliable measure of overall well-being (α=.88) [29]. This questionnaire contains 5 statements regarding an individual's well-being over the last 2 weeks. Each of the statements is evaluated using a 6-item Likert scale ranging from 0 (At no time) to 5 (All the time). Higher scores indicate higher well-being. The internal consistency for WHO-5 in our sample was acceptable (α=.76).

Baseline Measures

Life Events Checklist

The Life Events Checklist (LEC) [31] was developed at the National Center for Post-Traumatic Stress Disorder to screen for potentially traumatic events in a respondent's lifetime. In this study, we used 19-item version that has been adapted to the Lithuanian cultural context [32]. This questionnaire has acceptable psychometric properties (κ=0.61) [33]. In our sample, the internal consistency for LEC was acceptable (α=.78).

The Alcohol Use Disorders Identification Test (AUDIT)

The Alcohol Use Disorders Identification Test (AUDIT) [34] is a 10-item instrument for assessing alcohol consumption and indicating its consequences on the well-being of an individual. Each statement is evaluated by choosing an answer from either 5 or 3 different response options. This instrument has been a subject of extensive evaluation and has consistently displayed good psychometric properties with a median reliability value of 0.82 for non-English versions [35]. The AUDIT in our sample displayed acceptable internal consistency (α=.73).

Intervention

The intervention was an ICBT program consisting of 8 modules, each dedicated to 1 theme. The themes were (chronologically): introduction, thoughts, stress, and relaxation, problem solving, communication, anxiety, behavioral activation, and maintenance. The content was mainly presented in the form of written text with the exception of relaxation instructions, which participants could choose to either read or listen to. See Figure 2 for a screenshot of the 8 modules in the program provided to participants after logging in. In Lithuanian language, the name of the program was *Slaugau artimą*, which if translated literally means, "I take care of my close one." The intervention content was partly adapted from materials previously used in other ICBT studies (eg, [36-38]). The choice of content, examples, and exercises of the intervention were carefully selected and adopted for the target population grounded on the practices and guidelines in the field of informal caregiving (eg, [3]). A short description of the 8 modules as well as a list of exercises for each module is presented in Table 1.

Figure 2. Screenshot of the eight intervention modules as presented to participants after logging in.

Participants were provided access to 1 new module every week over the 8 weeks of intervention, starting from module 1. Once accessible, modules remained available throughout the duration of the treatment. The basic structure of the modules is very similar throughout the intervention: each module starts with psychoeducation, followed by one or few case examples which are then followed by several exercises. At the end of each module, participants were provided with suggestions about which exercises they should practice further that week. In this way participants were encouraged to learn and apply gained knowledge in managing maladaptive thoughts or behaviors in their own situation. In cases of lack of clarity, participants were able to contact their assigned therapist via a secure internal messaging function on the platform. Therapists monitored participants' questions and provided feedback on completed exercises daily via the intervention's platform.

Table 1. Description of intervention content.

Module (length)	Goals of the module	Exercises
Introduction (1089 words)	• Instruct about how to use the intervention • Introduce main principles of cognitive behavioral therapy • Inform about what participants can expect throughout the treatment • Encourage to formulate individual goals for the duration of the program	• Writing exercise I—Describing emotionally difficult caregiving-related situation and further reflecting on thoughts, behavior, and short- and long-term consequences. • Writing exercise II—Setting goals for the treatment
Thoughts (1682 words)	• Discuss how thoughts impact on one's well-being • Introduce the concept of automatic thoughts • Instruct about how to practice recognizing automatic thoughts • Introduce the most common cognitive distortions	• Thinking of own thought patterns and cognitive distortions • Thought Change Record—participants use a predefined structure to evaluate their situation, automatic thoughts, emotions, rational response, and outcome
Stress and relaxation (2426 words)	• Define stress • Discuss what effect stress can have on well-being • Discuss how one can reduce stress in daily life • Familiarize with relaxation methods	• Writing exercise—Thinking and describing which caregiving-related situation(s) causes most stress • Thinking of ways to increase inner resources and lower mental or physical load • Planning when to engage in pleasurable activities • Listening and practicing short meditations
Problem solving (1524 words)	• Encourage to reflect on own problem-solving strategies • Familiarize with different coping strategies • Emphasize helpful and harmful coping strategies • Learn about factors that interfere with problem solving	• Writing exercise—Thinking and describing strategies that an individual uses to deal with problems • Based on provided theory and examples, reflecting once more on problem-solving strategies • Solving own problem(s) a using step-by-step approach
Communication (2635 words)	• Discuss possible changes in communication after one becomes a caregiver • Discuss possible ways of maintaining or improving communication with people in a close environment	• Reflecting on changes in communication after becoming a caregiver • Step-by-step structure from previous module for solving communication problems • Perspective taking exercise—Evaluating difficulties in communication from a different point of view • Writing exercise—Using writing to express own emotions
Anxiety (2090 words)	• Discuss what anxiety is and what effect it can have on well-being • Discuss ways in which anxiety could be reduced	• Reflecting on sources of worry in own situation • Exercise "Balcony"—Evaluating a worrisome situation by observing it from the distance • Listening and practicing short meditations
Behavioral activation (1338 words)	• Emphasize the importance of personal time and small rewards • Encourage to spend time for own needs	• Reflecting on behavior and activities that are not useful • Thinking of how one can find more time and opportunities for pleasant activities
Maintenance (906 words)	• Summarize most important points • Provide with tips for maintaining gained knowledge • Encourage to reflect on previously formed goals and goals for the future • Farewell	• Reflecting on what was the most useful throughout the program and which knowledge or exercises one can also apply in the future • Reflecting on initial goal and progress throughout the program

Therapists

Three Master's in Clinical Psychology program students trained to deliver this intervention under supervision and 3 clinical psychologists were involved as therapists in the study. The main role of the therapists was to answer participant questions as well as to provide feedback on completed modules via a secure messaging system in the intervention's platform [39]. Weekly scheduled and on-demand supervision meetings for therapists were conducted and lead by one of the experienced clinical psychologists (AD) in the study. These supervision meetings varied in length between 1 and 2 hours.

Procedure

Upon opening the study website, participants were provided with information regarding inclusion and exclusion criteria as

well as the registration process, management, and research team. After participants provided informed consent on a secure study website, they were asked to fill in the screening questionnaires. Participants were then invited for a phone interview. Following phone interviews, the final decision about participation in the study was jointly discussed and agreed upon by the 3 coauthors (IB, IT-K, and AD). Decision about exclusion or inclusion in the study was communicated to the participants in a span of a few days. After randomization, participants in the intervention and wait-list control group were provided with information about the start of the intervention. Participants in the waiting-list control group were also explained that they will be able to receive access to the same treatment after the intervention group is finished.

A secure online platform (*Iterapi* [40]) was used for communication between therapists and participants, distribution of program materials, and collection of assessments. Participants' personal information was anonymized by assigning each participant a code, which participants then used for logging into the program. Included participants were also able to extend their data security by receiving a code (one-time password) to their phone number, which had to be entered upon every logging in, after entering their self-generated password.

At the start of the intervention, all participants received an email containing their username as well as personalized link for creating their own password. Throughout the duration of the program, every Thursday, participants received an email stating availability of the new material. Participants who did not view a particular week's materials or have not conducted exercises were sent 1 weekly reminder. Reminder contained a predefined short encouraging message and was sent on Mondays, by therapists to participants in own groups.

Statistical Analysis

Analysis was performed using IBM SPSS Statistics (version 25). The significance level was set at .05. Independent samples *t* test and Fisher exact test were used for investigating possible differences among participants in the 2 groups at baseline. Data collected at posttreatment were treated according to the intention-to-treat (ITT) principle. Following ITT all participants were analyzed according to their treatment assignment included in the analysis [41]. This method was chosen as it preserves the integrity of the randomization and minimizes the risks of bias that could occur due to the differences in groups following attrition or nonadherence [42]. For this purpose, a multiple imputation procedure was chosen considering that data were missing at random (MAR) [43]. According to MAR, missingness depends on the observed data, where incomplete values are replaced by values that are based on the complete data [44]. In our study MAR was considered, as no clear patterns in the missing data regarding pretreatment scores or demographic variables were identified. During the multiple imputation procedure, 20 simulations were imputed in a sequence. Because it is practically difficult to be fully confident that data are missing at random, complete case analyses were also performed.

Descriptive statistics were used for evaluating attrition and overall satisfaction with the program. Regarding main outcomes, effect sizes and confidence intervals were calculated for within and between groups. Analysis of covariance (ANCOVA) was conducted to investigate treatment effects at posttreatment for primary and all secondary measures with baseline scores entered as covariates [45].

The Jacobson and Truax [46] method was used for calculating Reliable Change Index (RCI) and investigating clinical significance of change in primary outcome at posttreatment. Because population norms were not available, criteria *a* was calculated, resulting in a cut-off point of 28.8. According to this, individuals who scored below 28.8 points at posttreatment should fall outside of the dysfunctional population and be considered recovered [46]. As for reliability of the scores, RCI values were calculated. In cases where a positive reliable change was achieved, participants were deemed improved. In turn, negative reliable change scores were used to determine deterioration. In the current sample, participants had to obtain a reduction of 8.8 scores on CBI at postassessment for a positive reliable change to be achieved.

Results

Participants

Most of the recruited participants were female (57/63, 90%) caring for either their elderly mother or father (44/63, 70%). Most participants had provided care for either 1-4 years (28/63, 44%) or more than 4 years (25/63, 40%). Most caregivers were spending 5-7 days per week (54/63, 86%), and either 3-7 (24/63, 38%) or 12 or more hours (23/63, 37%) per day providing care. In this respect, the sample could be described as consisting of high-intensity, long-term carers. Demographic characteristics of the sample are presented in Table 2. No pretreatment differences regarding demographic or outcome measures between participants randomized to treatment and wait-list control group were detected.

Table 2. Sociodemographic characteristics of the sample at baseline.

Participant characteristics	Overall (n=63)	Intervention group (n=31)	Wait-list control group (n=32)
Age caregiver (year), mean (SD)	52 (8.4)	54 (7.9)	50 (8.57)
Age recipient (year), mean (SD)	71 (21.1)	70 (23.13)	72 (19.28)
Gender (female) caregiver, n (%)	57 (90)	28 (90)	29 (91)
Gender (female) recipient, n (%)	44 (70)	20 (65)	24 (75)
Relation receiver, n (%)			
Husband/wife/partner	8 (13)	5 (16)	3 (9)
Father/mother	44 (70)	20 (65)	24 (75)
Other	11 (17)	6 (19)	5 (16)
Time caring (months), n (%)			
<12	10 (16)	6 (19)	4 (13)

Single	12 (19)	7 (23)	5 (16)
Married/partner	39 (62)	18 (58)	21 (66)
Divorced/widowed or other	12 (19)	6 (19)	6 (19)

Attrition

Participants were regarded as dropouts if the posttreatment measures were missing. Independent samples *t* test and Fisher exact test were performed for investigating differences between dropouts and completers. No differences were detected between the groups regrading demographic characteristics or scores on outcome measures.

At posttreatment, out of 31 participants in the intervention group, 25 have filled in the measures (81%), yielding a dropout rate of approximately 19%. At the same time, 29 out of 32 participants have filled in the measures in the wait-list control group (91%). Overall, posttreatment measures were collected from 54 participants (86%), which indicated a dropout rate of 14%. Following the intervention, out of 32 participants in the wait-list control group, 23 had filled in the measures (72%), showing a dropout rate of approximately 28%. In total, the overall dropout rate (ie, both groups combined) after the intervention period ended was 24% (15/63).

We were not able to reach all the participants who did not fill in the posttreatment measures. From participants that we did manage to reach, there were 2 main reasons for ceased participation: losing interest in participation (n=3) or death of care receiver (n=3).

Main Outcomes

Within- and between-group effect sizes were calculated for both completers and ITT sample. We found moderate within- and between-group effect sizes for the CBI measure (Table 3). Besides, moderate to large between- and small to large within-group effect sizes for secondary outcome measures were observed. Effect sizes for the completers were higher than those for ITT, indicating that the ITT result should be the one to consider. Further, only the ITT results will be reported. Completer results are provided in Multimedia Appendix 2.

The ANCOVAs were performed to determine differences between the control and intervention group on the posttreatment scores when controlling for the pretreatment scores. For primary and all secondary measures, significant effects of group on posttreatment scores were found in the ITT sample—CBI: $F_{1,60}$=5.39, P=.02; PHQ-9: $F_{1,60}$=6.12, P=.01; GAD-7: $F_{1,60}$=8.24, P=.004; PSS-14: $F_{1,60}$=13.56, P<.001; BBQ: $F_{1,60}$=10.88, P=.001; and WHO-5: $F_{1,60}$=10.7, P=.001. The ANCOVAs were also conducted to investigate changes over 5 subscales of the CBI separately at posttreatment. In the ITT sample significant changes have been detected for the reduction in postassessment scores in the subscales of Development and Physical Health, $F_{1,60}$=6.99, P=.008 and $F_{1,60}$=5.5, P=.02, respectively. No significant changes were observed for the remaining 3 subscales—Time Dependency: $F_{1,60}$=0.25, P=.62; Emotional Health: $F_{1,60}$=2.05, P=.15; and Social Relationships: $F_{1,60}$=2.67, P=.10.

Table 3. Means, standard deviations, and effect sizes (Cohen *d*) with confidence intervals.

Measures and condition	Intention to treat, mean (SD)		Completers, mean (SD)		Effect size (95% CI)	
	Pretreatment (n=63)	Posttreatment (n=63)	Pretreatment (n=63)	Posttreatment (n=54)	Within-group prepost	Between-group post-treatment

[f]WHO-5: The World Health Organization-Five Well-Being Index.

Clinically Significant Change and RCI of Caregiver Burden

Results regarding RCI for the ITT sample are presented in Table 4. McNemar test was performed to test whether the difference between participants in the 2 groups regarding positive reliable change is significant. An exact McNemar test result indicated that significantly more participants in the intervention group as opposed to the wait-list control group have achieved a positive reliable change for CBI scores at postassessment (P<.001). Regarding clinical significance, 2 (6%) participants in the intervention group scored below the cut-off score of 28.8. These

participants were deemed as recovered because they achieved a clinically significant change. In the control group, 1 (3%) participant was found to achieve a clinically significant change.

Table 4. RCI of participants in the ITT sample.

Group	RCI[a] for CBI[b] scores		
	Positive RCI	No change	Negative RCI
Intervention (n=31), n (%)	14 (45)	13 (42)	4 (13)
Wait-list (control; n=32), n (%)	3 (9)	23 (72)	6 (19)

[a]RCI: Reliable Change Index.

[b]CBI: Caregiver Burden Inventory.

Participant Evaluation of the Intervention

Overall, 56% (14/25) of participants who filled in posttreatment measures in the intervention group indicated that throughout the program their well-being had improved. Most participants also indicated that using the program was either easy (13/25, 52%) or very easy (6/25, 24%) and was either useful (12/25, 48%) or very useful (7/25, 28%). Participants were also positive about the opportunity to contact and receive feedback from a therapist, with 44% (11/25) indicating that this opportunity was useful, while 28% (7/25) of participants rated it as very useful. Lastly, information and tasks in the program were mostly rated as useful (10/25, 40%) or very useful (9/25, 36%).

Almost half of the participants (12/25, 48%) indicated that all the modules in the program were useful and none (0/25, 0%) noted that modules were not useful. The highest ranking in terms of usefulness was module 7 (“behavioral activation”; 16/25, 64%). The second most useful was module 6 (“anxiety”; 14/25, 56%). The modules “stress and relaxation” and “problem solving” were also rated as very useful by more than half of the participants (13/25, 52%). Module 1 ("introduction") was rated as the least useful (5/25, 20%).

Discussion

Principal Findings

The aim of this study was to evaluate the effectiveness of an internet-based therapist-guided program for reducing caregiver burden. Moderate between- and within-group effect sizes were found in reducing caregiver burden in the intervention group. This is a promising finding keeping in mind that previous face-to-face studies have achieved small to moderate between-group effect sizes (d=0.09-0.23) [47]. Our results also revealed that out of 5 caregiver-burden components, significant posttreatment reductions were observed for the subscales of Physical Health and Development. The latter subscale consists of items regarding missing out on life, emotional tiredness, and limited social life. In turn, the Physical Health subscale questions sleep disturbances, worsened health, and tiredness. It could be argued that behavioral and cognitive components of the intervention, such as time scheduling, thought diary, stress management exercises, and relaxation methods, helped participants to address these areas the most. To our knowledge, there is only 1 previous study that has reported improvement in these subscales of caregiver burden [48]. This is a study by Spatuzzi and colleagues [48], in which caregivers (of patients with cancer) with low spiritual well-being were compared with those with high spiritual well-being, with the latter found to be experiencing significantly less burden in the Development and Physical Health subscales of CBI. In their study, spiritual well-being was described as one of the core domains in quality of life that also helps in dealing with caregiving tasks. Improvements in quality of life ratings in our sample come in hand with this explanation. However, further investigation is warranted before any conclusions can be drawn.

Moderate to high between-group effect sizes were found on measures of anxiety, depression, and stress as well as increase in quality of life scores with only slight differences between ITT and completer analysis. These findings are in line with existing evidence of internet intervention potential in improving caregiver well-being [14]. We consider this finding of great importance because participants in our sample were found to be highly invested in caregiving: caring on average 5-7 days per week, between 3 and 7 or more than 12 hours per day. The latter could also explain the finding that only 2 participants had clinically recovered and slightly less than half had achieved a positive reliable change in relation to their burden. Caregiver burden, as described by Novak and Guest [18], is a complex experience that compromises emotional, physical, developmental, social, and time-dependency factors. Although our intervention provided participants with tools to deal with negative automatic thoughts, manage stress and anxiety, improve communication, and be attentive to their own needs, it could not change caregiving tasks or the amount of time required for supporting the care receiver. Nevertheless, moderate to high effect sizes found for the primary and secondary measures indicate that internet-delivered CBT (ICBT) can be effective in improving caregiver well-being in Lithuania. This argument is further supported by participant evaluations: more than half of the participants indicated that their well-being improved throughout the duration of the program and almost half noted that all modules were useful and the program was easy to use.

Limitations and Strengths

One of the main limitations in this study is that we did not control for external help that caregivers were receiving. Although all participants in the study identified themselves as primary caregivers, they could have been receiving various levels of support from other family members or professional workers such as nurses. A second limitation concerns the implementation of the CBI measure and The Mini International Neuropsychiatric Interview (MINI) that were used for the

screening purposes. This was the first time both instruments were translated and used in Lithuanian language which could bias the validity and reliability of these measures. Importantly, forward and backward translations were performed independently by the 2 bilingual members (IB and AD) of the research team. Independent versions were then compared and finalized following discussion among the research group members. In addition, translations were presented to a small convenience sample for evaluation of the comprehension of the items. By following such a procedure, we wanted to make sure that translated versions are as accurate as possible while culturally appropriate. We have chosen such an approach due to the pilot nature of the study. We aim to further investigate psychometric properties of these instruments before their implementation in subsequent trials.

Few other limitations must be mentioned. One is that all participants in the study were self-referred which limits the generalizability of our findings and presents the risk of the volunteer bias. Another important limitation is lack of information regarding the long-term effects of the intervention. In addition to the postintervention assessment, follow-up with the participants is highly desirable for investigating if the effects of the intervention were maintained long term. Consequently, it is important to mention that we included 1 participant with a score few points below the initial cut-off point for the CBI. One approach could have been to exclude this individual, but taking into account the pilot nature of the study, we have decided to include the participant and to further reflect on this decision when reviewing inclusion criteria for a prospective larger trial in the future. Lastly, even though positive changes in caregiver well-being were identified, at this point it is not possible to determine which components of the intervention were responsible for this improvement. We aim to further investigate this in the future.

Informal caregivers supporting individuals with a range of support needs were included in this study. For example, there were individuals who were caring for a sibling with a mental disorder as well as their own underage children or elderly parents diagnosed with dementia. For this reason, it could be argued that the intervention did not equally suit everyone's need. However, our initial idea was to create an intervention that would be suitable to a wide group of caregivers. In that way, independent of the care receiver's condition, everyone would find something that is applicable to one's own situation. The fact that we managed to detect improvement in caregiver well-being indicates that such transdiagnostic interventions can be effective. As another strength, we would like to outline the relatively low drop-out rates in our study. We consider the therapist support, weekly reminders, and feedback that participants received from the therapist as possibly the most effective factors in keeping participants engaged with the intervention. Lastly, there were no technical problems with the intervention that could have impacted participant's overall experience. A full-time IT technician was responsible for managing the technical aspects of the intervention's platform and thus possible problems would have been handled rapidly.

Clinical Implications

As briefly outlined previously, informal caregivers represent an increasing part of the society. Their task, even though rewarding, is still demanding. As our results indicate, ICBT can be effective in reducing caregiver burden as well as other negative states such as stress. In turn, it can also be effective in improving the overall quality of life. Importantly, it can reach a wide range of individuals, even the ones in remote locations. Internet interventions as opposed to face-to-face interventions are most likely even of a greater importance currently, considering the COVID-19 pandemic. In addition, for many individuals such a solution could be much more affordable not only time wise, but also financially. As for our target group, informal caregivers in Lithuania, such solutions are of even higher importance considering that psychological support services in general are very limited and not always accessible for all [17]. At this point, we must stress the pilot nature of the study and that our results should be interpreted with caution. Yet, we encourage additional research to further build on this idea and extend our findings in larger randomized trials. Because the numbers of informal caregivers is increasing worldwide and is only considered to further grow in the future, researchers are encouraged to further pursue these ideas in diverse cultural backgrounds, possibly with additional emphasis on the countries in which strong familial norms and little formal support are available to support informal caregivers.

Conclusion

This study is the first internet intervention study aimed at informal caregivers in Lithuania. The internet-based therapist-guided intervention based on CBT principles was found to be moderately effective in reducing caregiver burden, anxiety, and depressive symptoms. It was also found to be highly effective in reducing stress and improving quality of life for informal caregivers supporting individuals with various care needs. Such an intervention could be of special importance for caregivers who due to time-constraints, geographical, medical, or other reasons are not able to attend face-to-face therapy. Because of close cultural and historical aspects, this experience could further extend to neighboring Baltic countries in the region such as Latvia, where the need for psychological services for the informal caregivers is also high.

Acknowledgments

This project has received funding from the European Union's Horizon 2020 Research and Innovation Programme under the Marie Skłodowska-Curie grant agreement number 814072 and is part of The European Training Network on Informal Care (ENTWINE). This work was highly supported by George Vlaescu. We also thank Vaiva Milasiunaite, Julija Mingaudaite, and Irma Sabonyte for their assistance.

Authors' Contributions

IB contributed to the study conception, design, coordination, data collection, data analysis, and drafting of the manuscript. EK, IT-K, and AD and contributed to the study design, coordination, data collection, and data analysis. RS contributed to the design of the study and data analysis. GA contributed to the study conception, design, coordination, data collection, and data analysis. All authors were involved in revising the manuscript. Final approval was obtained from all the authors for the publication of the manuscript.

Abstract

Background: Chronic health conditions are affecting an increasing number of individuals, who experience various symptoms that decrease their quality of life. Digital communication interventions that enable patients to report their symptoms have been shown to positively impact chronic disease management by improving access to care, patient-provider communication, clinical outcomes, and health-related quality of life. These interventions have the potential to prepare patients and health care providers (HCPs) before visits and improve patient-provider communication. Despite the recent rapid development and increasing number of digital communication interventions that have shown positive research results, barriers to realizing the benefits offered through these types of interventions still exist.

Objective: The aim of this study is to prepare for the implementation of a digital patient-provider communication intervention in the daily workflow at 2 outpatient clinics by identifying potential determinants of implementation using the Consolidated Framework for Implementation Research (CFIR) to tailor the use of digital communication intervention to the intended context and identify key aspects for an implementation plan.

Methods: A combination of focus groups, workshops, and project steering committee meetings was conducted with HCPs (n=14) and patients (n=2) from 2 outpatient clinics at a university hospital. The CFIR was used to guide data collection and analysis. Transcripts, written minutes, and notes were analyzed and coded into 5 CFIR domains using thematic analysis.

Results: Data were examined and analyzed into 18 CFIR constructs relevant to the study purpose. On the basis of the identified determinants, important intervention tailoring includes adjustments to the digital features and adjustments to fit the clinical workflow and a decision to conduct a future pilot study. Furthermore, it was decided to provide the intervention to patients as early as possible in their disease trajectory, with tailored information about its use. Key aspects for the implementation plan encompassed maintaining the identified engagement and positive attitude, involving key stakeholders in the implementation process, and providing the needed support and training.

Conclusions: This study offers insight into the involvement of stakeholders in the tailoring and implementation planning of a digital communication intervention in clinical practice. Stakeholder involvement in the identification of implementation facilitators and barriers can contribute to the tailoring of digital communication interventions and how they are used and can also inform systematic and targeted implementation planning.

Introduction

Background

Living with a chronic health condition causes symptoms that negatively affect health-related quality of life (HRQoL) [1-4]. Symptom recognition may be challenging for patients and, by extension, for health care providers (HCPs) [5,6]. This can relate to patients' poor understanding of disease mechanisms and progression, lack of knowledge, and low levels of health literacy [5,7] and to practical barriers to inform HCPs about symptoms [6]. Experiences of difficulties in communication and interaction between patients and HCPs are common, including poor timing of information and challenging symptom recognition, which are factors that may interfere with symptom management and help seeking [5,7]. eHealth communication interventions may offer the potential to alleviate such difficulties.

Studies of eHealth communication interventions have reported benefits in terms of patient-provider communication [8-14], patient-provider relationship [15], patient self-management [16], symptom management [11,17,18], preparation before hospital visits [9,10,18,19], and HRQoL [8,17,20] in chronic health care settings. Despite these benefits, barriers to benefit realization still exist [21], including staff familiarity with technology [22,23], level of patient education [20,23], and issues with user-friendliness [22,24].

Although the positive effects of eHealth interventions on patient-provider communication and patient outcomes are known, HCPs report concerns regarding the integration of eHealth interventions into daily workflow [25,26] and concerns about increased workload [27-29]. In addition, the use of eHealth interventions can challenge HCPs' competence [25,26]. Such challenges may act as barriers to implementation and actual use, which could be another barrier for use. Successful implementation of such eHealth interventions requires attention to the development and evaluation of strategies to implement the interventions [30-32]. An important factor for the acceptance and success of eHealth implementation is the tailoring of the interventions to suit the local context [33]. Stakeholders representing the target group and the actual context can provide important input to reduce system complexity, increase system acceptability, and make systems as user-friendly as possible [33,34]. To increase the likelihood of implementation success, there is also a need to examine intervention characteristics from the end-user perspective in order to inform the tailoring of the intervention to suit contextual needs.

Implementation refers to the systematic uptake of research into HCP practice to improve the quality of health care services [35]. Implementation strategies can be explained as methods or techniques used to enhance the adoption, implementation, and sustainability of HCP clinical practice [36]. However, there is limited guidance regarding the types of implementation strategies that may be effective when implementing eHealth interventions to practice [30]. Nevertheless, it has been suggested that implementation strategies should be selected and tailored to address the unique contextual needs based on an identification of determinants (ie, factors that act as facilitators or barriers) that may influence the implementation process [32]. The identification of determinants can be used to address barriers and leverage facilitators [32,37].

Implementation frameworks can guide the identification of determinants that might influence the implementation, its effectiveness, and the implementation process [32,35]. The Consolidated Framework for Implementation Research (CFIR) is a widely used framework to identify facilitators and barriers [38-40]. The CFIR was developed from a synthesis of 20 existing theories and frameworks and consists of 5 overarching domains, including 39 specific constructs within these 5 domains [38]. The first domain of the CFIR is the *Intervention Characteristics* and includes constructs such as the adaptability of the intervention, the perceived relative advantage, and the complexity and cost of the intervention [38]. The *Outer Setting* domain includes constructs such as the patient's needs and resources related to the intervention, whereas the *Inner Setting* domain includes constructs such as implementation climate and readiness for implementation, the organization's culture, and leadership engagement. The fourth domain is the *Characteristics of Individuals* involved in the intervention or implementation process; it relates to personal attributes, including personal traits such as motivation, values, and competence. The last domain relates to the *Process* and includes planning, execution, and evaluation of the implementation process [38].

Objectives

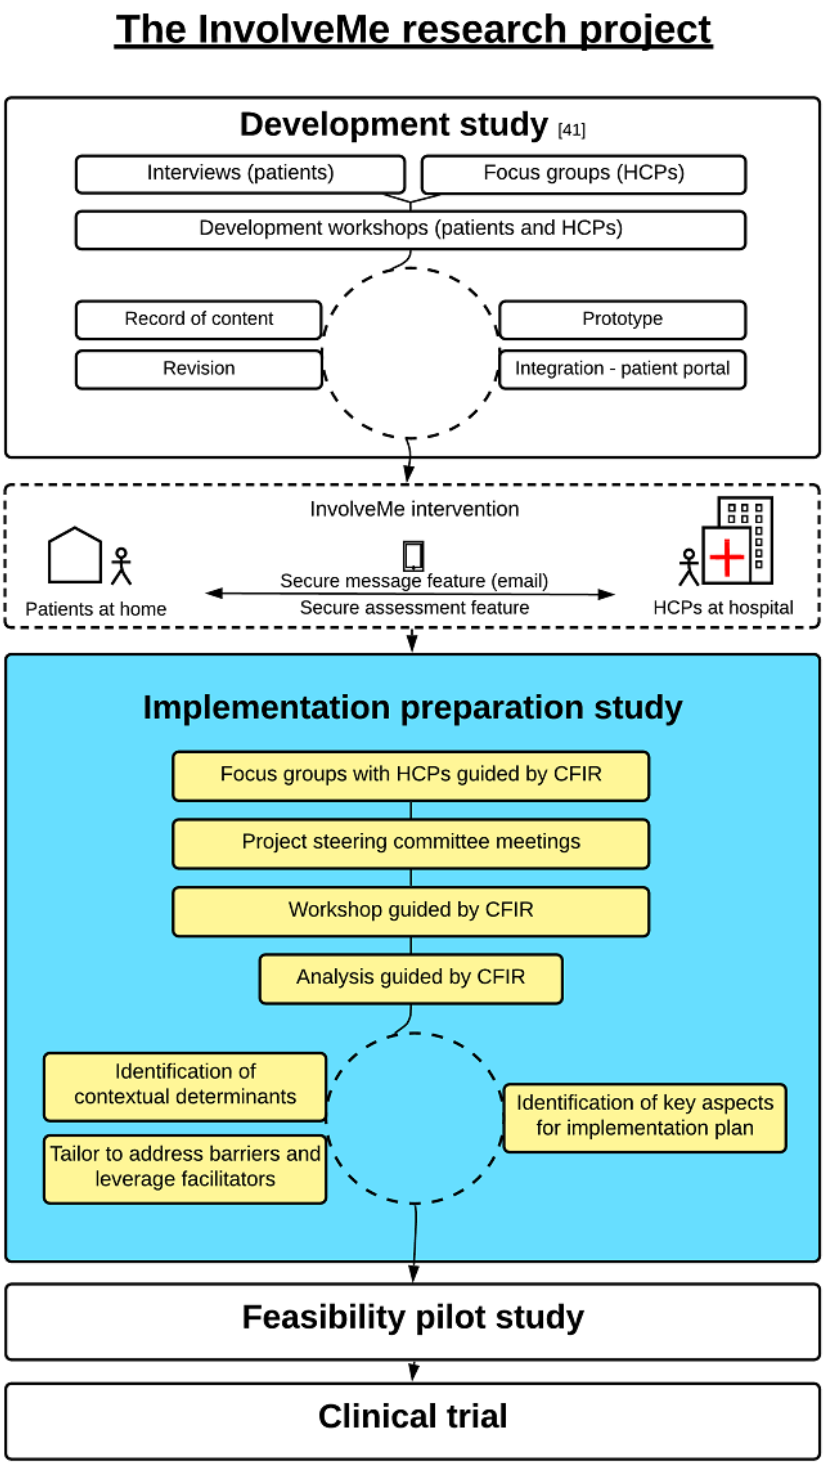
The aim of this study is to prepare the implementation of a digital patient-provider communication intervention, *InvolveMe*, into the daily workflow at 2 outpatient clinics where patients with chronic health conditions are treated by identifying potential facilitators and barriers to implementation using CFIR as the conceptual framework to (1) tailor the *InvolveMe* intervention to the intended context and (2) identify key aspects for an implementation plan.

Methods

Overview

This study is part of the *InvolveMe* research project, which includes the development, implementation, and evaluation of a digital intervention (Figure 1). The *InvolveMe* research project is a collaboration between 2 outpatient clinics and 1 research department at a large university hospital in Norway. The *InvolveMe* intervention will be implemented in 2 outpatient clinics and tested in a future clinical trial (Figure 1).

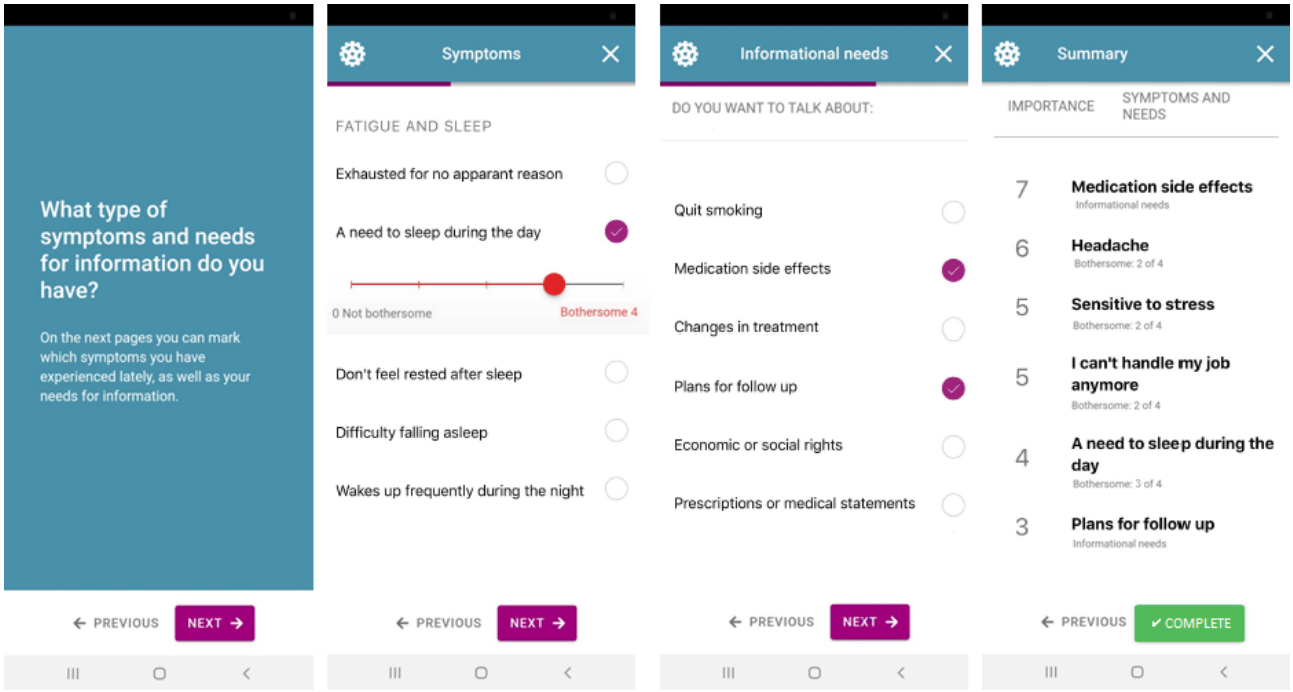
Figure 1. Overview of the InvolveMe research project. CFIR: Consolidated Framework for Implementation Research; HCP: health care providers.



Description of the InvolveMe Intervention

InvolveMe was developed at the initiative of HCPs aiming to improve follow-up for two specific categories of patients: renal transplant recipients and patients with nonfunctioning pituitary adenomas [41]. *InvolveMe* was internally developed at the hospital in close cooperation with registered nurses, physicians, health support personnel, patients, researchers, and system developers (Figure 1). A detailed description of the content and system development of *InvolveMe* is provided elsewhere [41]. The *InvolveMe* intervention contains two features: (1) a secure message feature and (2) a secure assessment feature (ie, predefined list) where patients can prioritize their need for symptom management, information, and preferences for care from home and on a scale from 0 to 10 (Figure 2).

Figure 2. Screenshots of InvolveMe.



Patients and HCPs can use the secure message feature to interact with each other between or after outpatient visits [41]. Completion of the secure assessment feature generates a summary that is sent to the patients' HCPs for use in upcoming consultations. The secure message(s) and the assessment(s) are integrated into an existing patient portal that allows patients to read their electronic patient record (EPR). However, the opposite is not possible (ie, the EPR cannot receive data from the patient portal) owing to information safety regulations.

Design

This study used a participatory and iterative design approach [42] using qualitative methods for data collection. The data collection period was November 2017 to December 2018 and proceeded through focus groups, project steering committee meetings, and a workshop (Figure 1). Data collection from focus groups and workshops was guided by CFIR [38] (Multimedia Appendices 1 and 2). The variety of data collection activities and diverse data collection approaches allowed for mutual stakeholder learning and comprehension of all stakeholder perspectives involved [43]. As part of the main focus of this study is to identify local determinants to tailor the intervention into the intended context (ie, HCPs' practice) and identify key aspects for an implementation plan, most study participants represented the HCP perspective. However, to ensure that the patient perspective was also continuously involved, 2 patients with experience from the *InvolveMe* development study [41] were included in the steering committees to ensure knowledge, inclusion, and prioritization of the patient perspective(s).

The determinants identified from data collection and analysis informed the tailoring of the *InvolveMe* intervention to suit workflow at the 2 participating outpatient clinics and aided in the identification of key aspects to include in an implementation plan. Tailoring, as described in this study, refers to addressing intervention barriers and leveraging facilitators as key aspects of the implementation planning process.

Data Collection Guided by CFIR

CFIR allows researchers to select constructs that they perceive as most relevant and use them to guide the assessment of determinants in the implementation context [38]. The operationalization of CFIR domains in this study was based on discussion and consensus in the research team, where all 5 domains of CFIR were explored for the development of focus group and workshop guides (Multimedia Appendices 1 and 2). Significant themes were to be discussed for determinants important for tailoring the intervention and providing input for the implementation plan (ie, key aspects). By asking about themes to discuss within each domain, rather than questions for each construct, several CFIR constructs would most likely not be covered by the focus group and workshop guides.

Focus Groups

The focus group guide centered around HCPs' experiences from previous successful implementation projects, their perception

of possible advantages and challenges of using a digital patient-provider communication intervention, and how to successfully implement the *InvolveMe* intervention (Multimedia Appendix 1).

Workshop

The workshop guide consisted of the 5 operationalized domains of CFIR (Multimedia Appendix 2): (1) the *InvolveMe* intervention (*Intervention Characteristics*); (2) the patients who will be offered the *InvolveMe* intervention (*Outer Setting*); (3) the 2 outpatient clinics where the patients are being treated (*Inner Setting*); (4) the HCPs (*Characteristics of Individuals*); and (5) the preparation for implementation of the *InvolveMe* intervention (*Process*).

Settings, Participants, and Recruitment

Participants were HCPs and patients. HCPs were purposely selected and recruited from an outpatient nephrology clinic and an outpatient endocrine clinic at a large university hospital in Norway. They were registered nurses, physicians, and health support personnel responsible for the treatment and care of patients with renal transplants or nonfunctioning pituitary adenomas. HCPs were provided with written information about the study and those willing to participate were included. The patients were participants in the development study [41] (Figure 1). They were asked to participate in the project steering committees, representing each of the 2 categories of patients. This was based on detailed knowledge about the *InvolveMe* research project [41], in addition to their own experience of being a patient. The patients were contacted by HCPs at the clinics and asked to participate before being contacted by the first author (BS), who described study participation in detail before the final study participation agreement was received.

HCPs had 2 to 38 years of clinical experience from specialist health care, with a median of 49.5 years (range 28-63 years), and most were female (10/14, 71%). Some HCPs participated in all data collection activities, whereas others participated in 1 or 2 activities (Table 1). The patient participants were female.

Table 1. Overview of participants in the focus groups, project steering committees, and workshop.

Data Collection

Focus Groups

HCPs were invited to participate in focus groups, a method suitable for exploring attitudes and experiences, and to encourage group discussion [44]. The HCPs from the nephrology (n=6) and endocrine (n=5) clinics participated in separate groups to explore context-related determinants and key aspects of an implementation plan (Table 1). The focus groups were facilitated by the first (BS) and last (EB) authors. Both focus group sessions lasted approximately 50 minutes and were recorded with a digital voice recorder and transcribed verbatim.

Project Steering Committee Meetings

A total of 2 project steering committees were established, one for each participating clinic, to promote leadership and stakeholder engagement in the intervention and to ensure input on the process of tailoring the intervention to fit contextual needs. Participants in each of the 2 project steering committees represented either nephrology (n=3) or endocrine (n=3) outpatient clinics (Table 1). The first (BS) and last (EB) authors facilitated the committee meetings. Each group met twice in the preimplementation phase of the study, which lasted for 1 year. All committee meetings lasted approximately 60 minutes and had a set agenda with topics to discuss (eg, workshop preparation and integration of the intervention into practice). Data collection from committee meetings was based on written minutes made by the last author (EB) during meetings. Each participant received and approved the minutes before the analysis.

Workshop

On the basis of the project steering committee meeting discussions and decisions, a joint workshop (n=7) for both participating clinics was considered expedient to share insights and experiences and to identify determinants for tailoring and key aspects for implementation (Table 1). A workshop with HCPs from both clinics was therefore conducted to gain further insight into participants' reflections and expectations about the *InvolveMe* intervention and elaborate on how to implement the intervention in the 2 clinics [45]. Workshop participants were invited to share their reflections through an exercise in which they were presented with the 5 operationalized domains of CFIR to facilitate narration (Multimedia Appendix 2). The presentation of each domain was followed by group discussions on potential facilitators and barriers. Thereafter, Post-it notes were used to present group reflections and encourage discussions between participants from the 2 clinics. The workshop was facilitated by the first (BS) and last (EB) authors and lasted 180 minutes, including a 15-minute break. Data collection from the workshop resulted in a report based on written notes made by the last author (EB) and pictures of the written Post-it notes made and shared by workshop participants.

Analysis

Transcripts, meeting minutes, and notes from the 3 data collection activities were deductively analyzed as one data set, based on thematic analysis by Braun and Clarke [46,47], and into the 5 domains of CFIR (ie, themes). The first author (BS) led the analysis process, which involved 2 coauthors (EB and CV). The first step was to read through and become familiar with the transcripts, meeting minutes, and notes. Early impressions were captured during the writing process. Next, the data were coded (ie, coding by CFIR constructs) using an Excel spreadsheet. Quotes from the focus group transcripts were copied and pasted into the spreadsheet along with text sections from meeting minutes and notes. Colors were used to mark data based on sources. The codes were then resorted and re-evaluated based on the CFIR domains and constructs. Through regular coauthor meetings (BS, EB, and CV), codes were discussed and revised to reach a consensus. Codes that did not appear to fit any of the CFIR constructs were also re-evaluated. The analysis was then refined, and the results were written and reviewed. In the final step, quotes were chosen for representation.

Ethics

The study was performed in accordance with the Helsinki Declaration and approved by the Department for Data Protection and Information Security (equivalent to an institutional review board) at Oslo University Hospital (20178/9223). Written informed consent was obtained from all participants (ie, HCPs and patient representatives). To guarantee confidentiality, the transcripts were coded with project ID numbers and stored on a secure server for sensitive research data, as required by the Department for Data Protection and Information Security at Oslo University Hospital. Only the first author and project administrator (BS) and last author and principal investigator (EB) had access to the code connecting the project ID numbers and the actual participant's name. Owing to the design and implementation emphasis of the study, the need for study approval was waived by the Regional Committee for Medical and Health Research Ethics for South East Norway, which is in line with the Norwegian legislation [48].

Results

Overview

Data were examined and analyzed into 18 CFIR constructs relevant to the study purpose. The constructs are presented by the domains of CFIR, which include description and considerations regarding tailoring of the *InvolveMe* intervention to the intended context (Tables 2-5) and identification of key aspects for the implementation plan (Table 6). A brief description of the relevant CFIR construct is provided to support the interpretation of the results.

Table 2. Intervention Characteristics: determinants, tailoring, and identification of key aspects for implementation planning.

Construct and study results	Considerations regarding determinants	Tailoring and key aspects
Intervention Source: intervention considered as internally developed	Facilitator: the involvement in the development study [41] and this study may promote ownership to the intervention, which may support intervention implementation.	Key aspect: ownership
Relative Advantage: the intervention as an advantage to current practice	Facilitator: HCPs[a] pointed to aspects perceived to be advantages of the intervention. This may be considered as a positive attitude to what is being implemented.	Key aspect: a positive attitude to implement the intervention
Adaptability: use of existing system	Facilitator: participants perceived the previous integration of *InvolveMe* in a patient portal to be beneficial. This may support acceptance and adoption	Key aspect: system acceptance and adoption
Adaptability: a new work task; the secure assessment feature	Barrier: The assessment was a new work task for HCPs, which caused a concern for increased workload and potentially increased time pressure on consultations.	Tailoring: the assessment feature was condensed to a brief list and refinement was made to the summary
Trialability: a need to test before the clinical trial	Barrier: HCPs highlighted that a pilot study would be important to test the intervention and the implementation strategies. A test of the intervention would also inform HCPs that were not formerly involved in the research project and potentially address concerns in advance.	Tailoring: decision, agreed upon by all parties involved, to conduct a pilot study
Complexity: lack of integration between EPR[b] and patient portal	Barrier: it was recognized as important to improve accessibility and avoid paper printouts of the assessment summary.	Tailoring: the summary was created in a format that could be copied and pasted from the patient portal and into the EPR
Complexity: messages sent directly to the physicians	Barrier: it was considered important to tailor the intervention to suit the physician's clinical workflow to succeed with intervention implementation.	Tailoring: a shared email inbox with a dedicated triage moderator was established

[a]HCP: health care provider.

[b]EPR: electronic patient record.

Table 3. Outer Setting: determinants, tailoring, and identification of key aspects for implementation planning.

Construct and study results	Considerations regarding determinants	Tailoring and key aspects
Patient Needs and Resources: *InvolveMe* could potentially contribute to less anxiety	Facilitator: HCPs[a] described patients being worried and anxious early in the disease trajectory. *InvolveMe* could be beneficial to patients in terms of increased information and thereby potentially help patients avoid or experience less anxiety.	Tailoring: to provide the intervention as early as possible to patients
Patient Needs and Resources: patient's motivation to use *InvolveMe*	Facilitator: it can be difficult to reach HCPs on the telephone. *InvolveMe* may have the potential to represent a place where patients can get in contact with HCPs.	Key aspect: motivated patients could contribute to HCPs implementing *InvolveMe*
Patient Needs and Resources: patient acceptance—use of a patient portal	Facilitator: the potential for intervention integration into a patient portal seemed acceptable. This supports findings from the development study [41].	Key aspect: intervention acceptance and adoption
Patient Needs and Resources: patient acceptance—use of a digital health service	Barrier: HCPs described being concerned that *InvolveMe* might be technically demanding for some patients. Therefore, *InvolveMe* was designed to be a voluntary supplement to standard care, not a replacement. The assessment in *InvolveMe* can act as preparation before consultations. To make this clear to all patients, relevant information should be provided.	Tailoring: provide patients with tailored information about the intervention

[a]HCP: health care provider.

Table 4. Inner Setting: determinants, tailoring, and identification of key aspects for implementation planning.

Construct and study results	Considerations regarding determinants	Tailoring and key aspects
Structural Characteristics: 2 outpatient clinics organized differently from each other	Facilitator: knowledge about the different organization and staffing may be of importance for tailoring the intervention to fit each outpatient clinics (ie, the moderator functioning).	Tailoring: one clinic designated a nurse to be the moderator, and the other clinic designated health support personnel
Network and Communication: weekly meetings for activity planning	Facilitator: existing meetings were considered appropriate and feasible to discuss and evaluate the implementation process in the research project.	Key aspect: use of existing weekly meetings to monitor implementation process
Culture: interest in innovations	Facilitator: an interest in innovations may provide opportunities to interact with end users (here HCPs[a]) regarding the intervention. This has the potential to support a collaborative relationship between researchers and HCPs.	Key aspect: a collaborative relationship
Tension for Change: improve patient follow-up	Facilitator: HCPs perceived the current situation as demanding, which could contribute to strengthened motivation to change practice (ie, intervention implementation).	Key aspect: monitoring the number of phone calls and the measurement of HRQoL[b] before and after intervention to visualize change
Leadership Engagement: the heads of the clinics were engaged and active	Facilitator: by their participation in the research project, the heads of the clinics display their commitment and accountability, which may contribute to staff engagement and support a culture for change.	Key aspect: providing anchoring and acceptance for the intervention and a change of practice

[a]HCP: health care provider.

[b]HRQoL: health-related quality of life.

Table 5. Characteristics of Individuals: determinants, tailoring, and identification of key aspects for implementation planning.

Construct and study results	Considerations regarding determinants	Tailoring and key aspects
Knowledge and Beliefs: a positive attitude about using a digital intervention such as *InvolveMe*	Facilitator: a positive attitude may act as a facilitator for the implementation process. Reflection on how to maintain a positive attitude throughout the implementation process should be done to establish a close researcher-clinician relationship. The provision of positive feedback along the implementation process might contribute to maintenance of use and collaboration.	Key aspect: maintaining the positive attitude

Table 6. Process: determinants and identification of key aspects for implementation planning.

Construct and study results	Considerations regarding determinants	Key aspects
Planning: lack of information and assignment of responsibility may reduce the motivation of HCPs[a]	Barrier: providing information and intervention guidance to staff involved in intervention implementation could include providing project information at meetings and brief updates via email or other information channels to all staff members. Meetings and updates could also allow for information exchange on implementation strategies. Easy access to researchers and technical support in case of questions may be of importance.	Providing: • Timely information • Someone to call on a specific number • Technical training and support • Joint project steering committee meetings for mutual exchange of experiences
Engagement: attracting and involving HCPs	Facilitator: some participants initiated writing abstracts to present study details at local and national conferences.	• Maintaining engagement
Opinion Leaders	Facilitator: physicians (and head of clinics) were described by some of the nurses as filling an Opinion Leader role.	• Involving Opinion Leaders in implementation
Implementation Leaders	Facilitator: participants of the project steering committee were suggested as filling the positions as Implementation Leaders.	• Involving members of steering committees in implementation
Champions	Facilitator: registered nurses with a responsibility for the project were seen as potential Champions and drivers of the implementation, inspiring, motivating, and helping other staff members.	• Involving registered nurses in implementation
External Change Agents: provide support to clinics	Facilitator: the clinics wanted a designated external facilitator from the research team to provide support for staff members in implementation.	• First author (BS) designated as External Change Agent in this study

[a]HCP: health care provider.

Intervention Characteristics

Intervention Source is defined as the key stakeholders' perception of whether the intervention is externally or internally developed [38]. Most participants were involved in activities to prepare the content and development of the system underlying *InvolveMe*, as described elsewhere [41]. The *InvolveMe* intervention was collaboratively developed within the hospital, and the participating HCPs expressed a perception of *InvolveMe* ownership.

Relative Advantage refers to the stakeholder's perception of the advantage of implementing the intervention rather than an alternative solution [38]. Although symptom assessments were a part of routine consultations, they were performed based on the preference and prioritization of the HCP and the history of the patients. Most participants perceived that the *InvolveMe* intervention could be an advantage compared with current practice where there is no digital communication between patients and HCPs. The participants reported that such a digital intervention could increase patient safety; raise awareness about the patient's perspective (ie, symptoms and informational needs); and improve patient-provider communication, patient satisfaction, and HRQoL. An intervention that could document contact between patient and provider and reduce the number of phone calls from patients was seen as warranted. One participant stated:

> *An email is much less disruptive than a phone call. An email I open when I have some spare time, while the phone call I have to answer while in the middle of something, while doing something else.* [HCP 10, focus group]

Adaptability refers to the degree to which an intervention can be adapted, tailored, and refined to meet local needs [38]. The participants shared their opinions on how they thought *InvolveMe* could fit into existing workflows in the clinics. The use of an already existing system was perceived as positive. Participants perceived that there were "already too many digital clinical systems" and that it was beneficial for *InvolveMe* to be integrated into an excising system (ie, patient portal) [41]. Some HCPs expressed concern that the intervention would introduce additional work tasks in an already hectic work environment. These concerns were raised surrounding worries that patients might complete extensive assessments, expecting everything to be addressed in the consultation. One participant stated:

> *If it becomes one more thing I have to deal with when meeting a patient for half an hour, we'll have to start considering extending the consultation time.* [HCP 6, focus group]

Trialability relates to the ability to test the intervention on a small scale in the organization and be able to reverse course if warranted [38]. Participants were positive for participating in

a clinical trial to test *InvolveMe*. However, HCPs raised concerns about carrying out the planned trial without them being able to test the intervention in advance.

Complexity is defined as the perceived difficulty of implementation, reflected by duration, scope, radicalness, disruptiveness, centrality, intricacy, and the number of steps required for implementation [38]. The participants stated that the digital communication tool must be intuitive and easy for them to use. As expressed by one participant:

> *It has to be something that is intuitive and easy to answer and...something you don't spend a lot of extra time on.* [HCP 9, focus group]

Although *InvolveMe* could be integrated into a patient portal, the participants expressed concern that the intervention, because of data protection and privacy regulations, likely would not be allowed to communicate directly with the hospital EPR. If current regulations would require that paper printouts from *InvolveMe* had to be manually scanned into the EPR, rather than received directly from the patient portal, participants were concerned that this would add to their workload. The participating physicians also raised concerns about receiving secure messages directly to an individual mailbox, without some form of triage. There were also some concerns that the message functionality might become more like a chat, with messages going back and forth between patients and HCPs, potentially increasing the time HCPs spend communicating with each other for management of the patients' many questions.

Outer Setting

The construct of *Patient Needs and Resources* concerns the extent to which patients' needs and facilitators and barriers to meeting these needs are accurately known and prioritized by the organization [38]. The participating HCPs explained that they, based on their own experience, perceived patients as the most worried and anxious early in the disease trajectory. They described a structured follow-up for the 2 categories of patients, with room for improvement. As expressed by one participant:

> *That's also what we, me too, have been thinking about for many years when it comes to our patients, that they come to the 3-month check-up and they have questions that we could have answered for them [before the time of check-up], but they've had no place to pose their questions before consultation.* [HCP 2, focus group]

HCPs described that they thought most patients would be motivated to use *InvolveMe* and that the intervention could improve patient-provider communication related to symptoms, needs, and preferences, but also serve as a secure digital channel where patients knew that they could get in touch with their HCPs between consultations. This aspect was also discussed in the workshop. One participant described the following:

> *Satisfied patients, they will feel more seen and heard.* [Post-it note, workshop]

The use of the existing system was considered positive for patient use. However, the HCPs were concerned about various aspects of patient acceptance. They expressed thoughts that some patients might be afraid of losing in-person contact with their HCPs and that digital communication might not suit all patients. This issue was particularly raised as a digital intervention could potentially require a level of digital competence that some patients might not have. One participant stated:

> *Some patients might be afraid to use technology.* [Post-it note, workshop]

Adding to the HCP input, the patient participants in this study supplemented patient input from the development study [41] and strengthened the patient's voice by providing direct input on the *InvolveMe* intervention. They were very positive toward the use of *InvolveMe* and expressed their view that digital patient-provider communication would strengthen patient follow-up.

Inner Setting

The construct of *Structural Characteristics* is explained as the social architecture, age, maturity, and size of an organization [38]. The 2 included outpatient clinics were organized differently from each other, although both clinics described staff stability. One clinic was larger than the other and included 2 registered nurses and several physicians. This clinic also had several health support personnel who organized much of the patient-administrative work for registered nurses and physicians. The other clinic included registered nurses and physicians in a relatively small HCP group, which was perceived as an advantage by the HCPs in question in terms of implementation. One participant stated:

> *It is probably an advantage that we are a small group, and not thousands of people.* [HCP 5, focus group]

The construct of *Network and Communication* involves the nature and quality of social networks and the nature and quality of formal and informal communication in an organization [38]. Both clinics had weekly meetings for activity planning, where research projects, including this study, were discussed.

Culture, as a construct, includes the norms, values, and basic assumptions of a given organization [38]. The HCPs reported that they were generally interested in innovations. This interest was also displayed in attendance and discussions at presentations and meetings about *InvolveMe*. Most of the participating HCPs also pointed to the potential for improved symptom management through interventions such as *InvolveMe*. One participant stated:

> *It's the issue of identifying the patient's problem...that we sometimes struggle to capture.* [HCP 4, focus group]

Tension for Change is the degree to which HCPs perceive the current situation as intolerable or needing change [38]. With regard to digital patient-provider communication, there was a general tension for change among all groups of HCPs in this study. All participants described receiving many phone calls from patients, and that they needed and wanted an easier method for patient follow-up than what current practice allowed, suggesting that digital communication could be one way to improve this issue. One participant stated:

> *There will be less "noise" if we have one of those electronic communication channels...then we would have the opportunity to convey something, and at the same time reduce the patient's level of anxiety.* [HCP 4, focus group]

Leadership Engagement refers to the commitment, involvement, and accountability of leaders regarding implementation [38]. The heads of the participating clinics were positive and engaged members of the project steering committee. They were also supportive and involved in the research project, facilitating and participating in research activities and allocating clinic personnel to participate in research project activities and meetings.

Characteristics of Individuals

The construct of *Knowledge and Beliefs* about the intervention involves individuals' attitudes and the value placed on the intervention and familiarity with facts, truths, and principles related to the intervention [38]. The participants expressed, for the most part, a positive attitude toward using *InvolveMe* and stated that they believed the use of such an intervention could improve clinical practice through highlighting the importance of good patient-provider communication related to symptom management. One participant stated:

> *Being able to clarify some expectations makes it easier to...the patient is better prepared for consultation, they understand what they are struggling with and why they come in for consultation...it will potentially make it easier to talk to them when some things are clarified in advance...* [HCP 4, focus group]

Participating HCPs expressed that digital interventions, such as *InvolveMe*, should be a part of modern practice. The positive attitude toward an intervention such as *InvolveMe* was also expressed in other ways, for example, written on a Post-it note:

> *Will provide structure to the workday.* [Post-it note, workshop]

HCPs also stated that they believed that such an intervention could make patients feel safe and cared for. One participant said:

> *Possibly an increased level of security [for the patient] provided by a communication channel that is not filtered through a switchboard...* [HCP 5, focus group]

Process

The construct of *Planning* is explained as the degree to which a scheme or method of behavior, and tasks for implementing an intervention in advance, corresponds with the consideration of the quality of those schemes or methods [38]. The participants in this study stated that a lack of information and assignment of responsibility could potentially reduce HCP motivation. The importance of providing information and guidance for use to everyone involved at the clinics was highlighted:

> *When switching to new systems, it is always important to have an easily accessible support person who can help solve issues right away.* [HCP 5, focus group]

The heads of the participating clinics suggested joint project steering committee meetings to exchange information on implementation strategies in the implementation process. In addition, availability from someone from the research team, including the possibility to call if the HCPs had any questions, was suggested. The need for technical support and training was also suggested:

> *Some training in the use of the software maybe...*
>
> *Yes, but I often think we get too much of that...*
>
> *Agreed, but not too long in advance then, as it is so easy to forget. But you could get help with specific things that you wonder about, and then you learn and acquire knowledge, while if you're sitting in a classroom, learning about a lot of things that you can't really easily relate to...* [Discussion between HCP 6 and 9, focus group]

The construct of *Engagement* involves attracting and involving appropriate individuals in the implementation and use of the intervention through a combined strategy of social marketing, education, role modeling, training, or similar activities [38]. There was definite engagement in the planned intervention in this study. For example, some participants initiated writing abstracts to present study details at local and national conferences. This initiation was discussed in project steering committees, and the research team allocated responsibility for the writing process. Abstracts written for the part of the process also received two Best Poster Awards and a Meritorious Abstract Award [49] and contributed to maintaining engagement.

Opinion Leaders are individuals in an organization who have formal or informal influence on the attitudes and beliefs of their colleagues regarding the implementation of the intervention [38]. Physicians (and head of clinics) were described by some of the nurses as filling an *Opinion Leader* role. Participants of the project steering committee were suggested to fill the positions as *Implementation Leaders*. Registered nurses who were responsible for the project were seen as potential *Champions* and drivers of the implementation.

External Change Agents are individuals who are affiliated with an outside entity and who formally influence and facilitate interventions in a desirable direction [38]. By facilitating the project steering committee meetings, the first (BS) and last (EB) authors potentially influenced and facilitated the intervention as *External Change Agents*. In addition, the participants suggested a facilitator from the research team to be available to the clinic staff members for support during the implementation process.

Discussion

Principal Findings

This study identifies the determinants using the CFIR framework [38] to inform tailoring of the *InvolveMe* intervention and to identify key aspects for implementation planning based on context.

The identification of determinants in this study supports findings from existing literature [23,33,50]. However, the influence of

context on implementation outcomes must be considered to understand the need to tailor interventions [51]. To the best of the authors' knowledge, descriptions of how identified determinants can be used to tailor interventions to context are largely lacking. The HCPs participating in this study were mostly positive toward implementing the digital communication intervention *InvolveMe* and perceived the intervention as having the potential to improve patient-provider communication. This is in line with existing research showing that improvements in communication can act as facilitators in eHealth implementation [24,50].

In the development study [41] preceding this study, the participants voiced a concern about lack of integration with existing systems, which corresponds with findings from other studies where lack of accessibility and fit into organizational structures have been identified as barriers to implementation of eHealth interventions [23,33,50]. Therefore, the *InvolveMe* intervention was integrated into a patient portal already in use by patients and HCPs. What was initially perceived as a barrier in the development study [41] was hence turned into something, perceived by participants, beneficial in this study. This confirmed the decision made in the development study [41], acting as a potential facilitator for intervention implementation and potentially improving acceptance and adoption [33].

The HCPs in this study voiced some concerns regarding the assessment feature in terms of being a new work task that could potentially increase the workload. The assessment feature was therefore condensed to a brief list and refinements were made to the assessment summary by conducting several user tests in close collaboration with HCPs, patient participants, and the research team. This strategy is supported by the literature, showing user-friendliness and integration into care as known facilitators for the implementation of eHealth interventions [22,50,52]. In addition, this strategy can prevent the need for intervention redesign, which is likely to delay use and increase costs, which are known barriers to eHealth interventions [33].

The involvement of relevant stakeholders is a known facilitator of implementation [50,53]. Although stakeholders were involved in the development [41] of the *InvolveMe* intervention, the participants in this study provided valuable additional information for the tailoring of the intervention, including the need to test the intervention before any upcoming clinical trial. Participants in this study raised concerns about potential implications for clinical workflow and workload when using a digital communication intervention. Concerns about increased workload are a well-known barrier to the implementation of eHealth interventions [28,50]. A growing point of importance is also to tailor eHealth interventions to existing clinical workflows, minimizing potential burdens [30]. A moderator function for triaging secure messages should therefore be organized in a flexible way, depending on the clinic organization and available HCPs. Such tailoring to the local context may facilitate intervention integration into clinical workflow, a known facilitator for implementation of eHealth interventions in practice [22,50].

In this study, HCPs also expressed concerns about patient acceptance of a digital communication intervention, described as a lack of digital competence among some patients. This concern is supported by patient education literature [20,24,54]. However, there are some indications that it is feasible to deliver eHealth interventions to improve eHealth and health literacy skills among patients with chronic health conditions [22,54]. To be able to offer interventions, such as *InvolveMe* to patients, regardless of digital competence, studies have suggested employing blended care models, involving a mixture of in-person, technology, or telephone contact as a way to help facilitate use [23,55,56]. Furthermore, alternating health care delivery between digital communication and in-person meetings has been described as a way to avoid losing in-person contact with patients [23].

To ensure successful implementation of an eHealth intervention in a certain context, the need to develop and follow an implementation plan is widely recognized [36] and the lack of such a plan is considered a barrier to implementation [33]. In this study, results from the CFIR *Planning* construct provided insight into the participants' thoughts on how to involve key stakeholders, secure leadership support, and how to provide information training and coaching. These factors have previously been described as important for incorporation into an implementation plan [32,37]. In addition, several facilitators (eg, ownership, positive attitude, and system acceptance) identified in the other CFIR domains were considered important to build on (ie, leverage facilitators) when planning for implementation. HCPs struggling with the use of technology are a known barrier in the implementation of eHealth interventions [23]. Training of HCPs is therefore a preferred and widely used implementation strategy [53], and a combination of software training and training in how to incorporate the intervention into daily clinical workflow may be required [30,31]. In this study, it was hence considered an important aspect to include training and follow-up of HCPs in the implementation plan. Training of designated clinicians who would subsequently train others to use *InvolveMe* was planned [32]. External support (ie, provided by a member of the research team) was also identified as a key aspect of the implementation plan.

The heads of both clinics participating in this study were involved in the development study [41] and in the tailoring and implementation planning. Several studies have shown that implementation strategies that encourage leadership support and engagement are crucial to implementation success [30]. Leaders are often seen as providers of new knowledge and as key influencers related to implementation initiatives, including facilitating effective teamwork and cultivating a culture of learning [57]. In addition, leaders can assign dedicated staff to perform the required change, which may ease workload and the concern for increased work [57]. Therefore, strategies targeting leaders, such as continuing the project steering committee meetings, should be considered key aspects to include in the implementation plan of interventions, such as *InvolveMe*, into outpatient clinics. In addition, carrying out implementation preparation workshops (Multimedia Appendix 2), as in this study, might also capture local knowledge of what works and not, knowledge that can be shared between implementation sites [32].

In this study, the project steering committee meetings were also intended to build a coalition between patient participants, HCPs, and the research team to cultivate a good relationship in the implementation effort, another described implementation strategy [32,37,53], and thus a key aspect to include in an implementation plan. Collaborative relationships are crucial for implementing plans and, through a social exchange communicating the potential impact of innovations, for the implementation of interventions, such as *InvolveMe*, into clinical practice may be facilitated [57].

Strengths and Limitations

This study has some limitations that need to be addressed. *First*, the study was conducted at a single university hospital. This might limit transferability to other settings. However, the inclusion of 2 outpatient clinics, following up 2 different patient categories, might increase transferability to other settings. *Second*, the study had a relatively small sample size, a factor potentially limiting transferability. A small sample size may limit the ability of data to describe the entire local context at the clinics involved. However, the study was performed in outpatient clinics where the implementation of the intervention is planned to take place, thus enabling identification of local determinants and key aspects that may be crucial for an implementation plan. *Third*, there was an imbalance in the number of HCPs compared with patients in this study. Traditionally, implementation involves the improvement of HCP practices [35]. CFIR does not differ from this tradition, as CFIR places patients under the *Outer Setting* domain, where only one single construct is intended to capture patients' needs and resources [38]. As such, patients are considered to have a peripheral role in their implementation. However, this study examined all perspectives and interplay of all stakeholders involved, including patient participants, which helped to illuminate stakeholder aspects and may help increase the likelihood of successful implementation to practice [33]. In addition, even with a limited number of patient participants, patient participants' experience from the development study [41] and subsequent direct input on various topics in this study may have ensured relevance and reliability from the patient perspective. *Fourth*, the perceived facilitators and barriers of participants in this study might not necessarily correspond to facilitators and barriers experienced in clinical practice in general. However, recent evidence indicates that the limited use of tailoring to context could explain the limited implementation success [30]. Knowledge generated during preparation for implementation can contribute to intervention tailoring and context-specific individualization, which implies that stakeholders' needs are more likely met, and hence intervention design and implementation preparation are improved [58].

This study has some strengths. Applying a structured and comprehensive framework such as CFIR within the field of implementation is considered to be a strength guiding data collection and analysis [59]. Identifying and describing determinants that affect implementation, as well as identifying key aspects for implementation planning, are also strengths [59]. Furthermore, the use of CFIR in this study provided a common language through the use of constructs and definitions for the analysis of data and thus may provide comparable results that may make it easier to assess why and how certain elements work. However, it should be noted that the strength of CFIR as a comprehensive framework may also be a weakness. CFIR does not distinguish between the relative importance of all of its constructs, which may imply that the details necessary for implementation success could be lost if trying to capture as many constructs as possible. In this study, a number of CFIR constructs were not covered by the data collection, as only discrete but significant themes and questions were targeted (Multimedia Appendices 1 and 2). Another challenge using CFIR is that some constructs are broad and difficult to capture and some may overlap with other constructs. Further descriptions and explanations related to constructs could enhance the CFIR and thus make the framework more intuitive to use when planning for implementation.

Future Directions

The ongoing COVID-19 pandemic has triggered a significant need for a wide range of digital communication services between patients and HCPs and has led to increased demand for digital intervention from within the health care services themselves. As such, and with the tremendous challenges posed by this significant health challenge, the pandemic might turn out to be a powerful facilitator for the implementation of digital interventions in health care services.

This study revealed some specific aspects that need to be investigated in future research. In particular, the results show that a pilot study may contribute to identify gaps and inform further necessary tailoring of the intervention and an implementation plan (ie, strategies) before clinical trials. This emphasizes that, regardless of stakeholder involvement in intervention development, a pilot test should always be considered.

Future studies should also aim to better understand how the CFIR framework can inform an implementation planning process in terms of tailoring interventions before implementation and the selection of implementation strategies based on identified determinants. In addition, refinements of the CFIR to strengthen the patient-related constructs and make the framework easier to apply would be beneficial for researchers and for HCPs conducting implementation in clinical practice.

Conclusions

This study contributes to the field of implementation science by using identified determinants to inform the tailoring of a digital communication intervention (ie, *InvolveMe*) and to identify key aspects of an implementation plan to context. Important intervention tailoring aspects identified were adjustments to the digital features and adjustments to fit the clinical workflow as well as recommendations to conduct a future pilot study before testing in larger clinical trials. Future research into the implementation of digital communication interventions should focus on the early identification of determinants and attention to tailoring to address barriers and leverage facilitators. In addition, key aspects of implementation planning should be identified, raising the probability of implementation success.

Acknowledgments

This study was funded by the Norwegian Nurses Organization grant 847382 (principal investigator: EB). The authors would like to thank the patient participants and HCPs who participated in this study. The authors would also like to thank all collaborating project team partners, including the editorial group and software team in the Department of Digital Health Research at Oslo University Hospital.

Abstract

Background: Health information technology (IT) interventions to decrease readmissions for cirrhosis may be limited by patient-associated factors.

Objective: The aim of this study was to determine perspectives regarding adoption versus refusal of health IT interventions among patient-caregiver dyads.

Methods: Inpatients with cirrhosis and their caregivers were approached to participate in a randomized health IT intervention trial requiring daily contact with research teams via the Patient Buddy app. This app focuses on ascites, medications, and hepatic encephalopathy over 30 days. Regression analyses for characteristics associated with acceptance were performed. For those who declined, a semistructured interview was performed with themes focused on caregivers, protocol, transport/logistics, technology demands, and privacy.

Results: A total of 349 patient-caregiver dyads were approached (191 from Virginia Commonwealth University, 56 from Richmond Veterans Affairs Medical Center, and 102 from Mayo Clinic), 87 of which (25%) agreed to participate. On regression, dyads agreeing included a male patient (odds ratio [OR] 2.08, *P*=.01), gastrointestinal bleeding (OR 2.3, *P*=.006), or hepatic encephalopathy admission (OR 2.0, *P*=.01), whereas opioid use (OR 0.46, *P*=.03) and alcohol-related etiology (OR 0.54, *P*=.02) were associated with refusal. Race, study site, and other admission reasons did not contribute to refusing participation. Among the 262 dyads who declined randomization, caregiver reluctance (43%), perceived burden (31%), technology-related issues (14%), transportation/logistics (10%), and others (4%), but not privacy, were highlighted as major concerns.

Conclusions: Patients with cirrhosis admitted with hepatic encephalopathy and gastrointestinal bleeding without opioid use or alcohol-related etiologies were more likely to participate in a health IT intervention focused on preventing readmissions. Caregiver and study burden but not privacy were major reasons to decline participation. Reducing perceived patient-caregiver burden and improving communication may improve participation.

hepatic encephalopathy; cirrhosis; outcomes; acceptance; PatientBuddy; ascites; readmissions; hepatic; encephalopathy

Introduction

Patients with cirrhosis often require expensive inpatient and outpatient care, mainly centered around complications related to hepatic encephalopathy, variceal bleeding, ascites, and medication management [1]. A critical component of optimal care is the education of patients and their caregivers, and communication with the clinical team [2]. Educational strategies for and involvement of caregivers in care processes are often neglected in favor of dispensing medications and scheduling appointments at the time of discharge [3,4]. Tools that could enhance delivery of care and maintain a link between health care providers and patients/caregivers are needed to improve clinical management and outcomes. In a prior single-center study, we evaluated the acceptability and performance of the Patient Buddy app for preventing readmissions in patients with cirrhosis [5]. The app involves two components recorded by patients and their caregivers on EncephalApp, a separate app designed to assess cognitive function in patients with cirrhosis: (1) daily postdischarge smartphone entry for 30 days of weight, abdominal girth, temperature, and medication adherence; and (2) weekly results of responses to questions related to orientation in time, place, and person [6,7]. The data are transmitted via a Health Insurance Portability and Accountability Act (HIPAA)-compliant server to central iPads, which the study team then review for assessment of alarm values that are used for communication with patients and caregivers and to determine if action is required. The central iPads are reviewed multiple times a day. In our single-center study, we found that use of the app alerted health care providers to early evolution of hepatic encephalopathy, and was largely favorably received by the patients and caregivers using the app [5].

We are currently performing a multicenter randomized trial of the Patient Buddy app at three clinical sites in patients with cirrhosis and their caregivers. The purpose of this study was to examine the perspectives of both patients and caregivers when considering use of this intensive daily health information technology (IT). Their willingness to use the app has direct bearing on patient participation in this and other multisite trials, and ultimately on the health care team's ability to monitor clinical status, reduce readmissions, and improve outcomes in cirrhosis.

Methods

We designed this study to assess the reasons for potential refusal to better inform recruitment approaches. We performed semistructured interviews in patient-caregiver dyads in the ongoing multicenter randomized study of cirrhosis inpatients and their caregivers on use of the Patient Buddy app to prevent 30-day readmissions. The randomized study is being performed in tertiary-care hospitals serving three different populations: veterans at Veterans Affairs (VA) Medical Center (Richmond, VA), uninsured/underinsured patients at a state safety net institution (Virginia Commonwealth University [VCU], Richmond, VA), and insured patients receiving care at a private group practice (Mayo Clinic, Rochester, MN). Regardless of the setting, the standard of care for all three hospitals requires setting up a postdischarge follow-up appointment within 1 month and a phone call within 1 week.

We screened for inpatients who met the following eligibility criteria: (1) diagnosis of cirrhosis as defined by liver biopsy, overt hepatic decompensation (hepatic encephalopathy, ascites, variceal bleeding, or jaundice), or radiological features of cirrhosis and endoscopic features of varices in patients with chronic liver disease; and (2) those who were admitted nonelectively and had adult cohabitating caregivers. Patients excluded for screening were those with an active alcohol use disorder, without caregivers or a stable home, on hemodialysis, discharged to a facility or hospice, inadequate internet connection at home, or an unclear diagnosis of cirrhosis. For patients who met the eligibility criteria, a member of the study team approached the patient and caregiver in person or via telephone while the patient was still hospitalized and explained the study in detail. This explanation included a discussion with the patient-caregiver dyad that emphasized the necessity of being in contact with the study team after discharge, and the potential educational value of the app and its implications for communication with the team on clinical issues. Another aspect of the discussion involved a demonstration of the app and the need for data entry of critical medications (ie, hepatic encephalopathy medications, antibiotics, beta blockers, diuretics, and other cirrhosis-related medications), weight and abdominal girth, and orientation with EncephalApp.

The intervention consisted of the Patient Buddy app coupled with EncephalApp. For the dyad to participate in the multisite randomized trial postdischarge, they had to agree to be trained individually while the patient was hospitalized, including instructions for data entry in the app; measuring body weight, temperature, and girth (using scales, measuring tapes, and thermometers provided by the study team, respectively); assessing orientation; and training to caregivers in administration of EncephalApp. If the dyad consented to participate, they were randomly assigned to one of three groups (standard of care, health IT intervention with as-needed follow-up, or health IT intervention with scheduled outpatient visits and calls within 30 days of discharge). If assigned to either of the health IT groups, the app was activated upon discharge on a smartphone provided as part of the study.

In the randomized study, we collect data from all dyads who are approached for participation, including demographic and clinical characteristics, reasons for admission, and current patient medications. Dyads indicating that they did not want to be randomized were then asked if they would participate in a semistructured qualitative interview that was designed and supervised by an expert (DM) to explore reasons for deciding not to participate and to help ascertain issues related to use of health IT as opposed to research as a whole that could guide future similar studies.

The patients and caregivers were asked about their reasons for unwillingness divided into five categories (demands related to technology, caregiver reluctance, perceived burden of the study, transport and logistics, privacy-related, or other) and other reasons through the interview questions prompted by the coordinators with qualitative responses allowed. All potential

inpatients were approached in person. The study coordinators carried out the interview, and every effort was made to perform these analyses within 1 day for both potential caregivers and patients. The responses were transcribed on an interview form by the study coordinator explaining the study, which also had space for expressing other potential reasons that informed their decision not to participate further. The other reasons included refusal to participate in studies of any kind regardless of the health IT intervention, unspecified, or unwillingness to elaborate further.

In the analysis, we compared the demographic and clinical variables such as cirrhosis characteristics, especially hepatic encephalopathy, current medications, and reasons for admission, in dyads who agreed to participate with those of dyads who did not agree to participate using unpaired *t* tests or χ^2 tests as appropriate. Finally, a logistic regression analysis was performed with agreement to participate in the randomization process as the dependent variable and disease characteristics as independent variables.

Results

A total of 349 patient-caregiver dyads were approached at the three sites (191 at VCU, 56 at VA, and 102 at Mayo Clinic), 87 of which (24.9%) agreed to participate. Table 1 shows the characteristics of these dyads and indicates the significantly different variables between those who agreed and declined participation.

Table 1. Demographic and clinical characteristics of patients who agreed and did not agree to randomization for the health information technology intervention study.

Characteristics	Agreed to randomization (n=87)	Did not agree to randomization (n=262)	*P* value

[a]HCV: hepatitis C virus.

[b]NAFLD: nonalcoholic fatty liver disease.

[c]HE: hepatic encephalopathy.

[d]MELD: Model for End-stage Liver Disease.

Of these 87 dyads, 40 were from VCU, 22 from VA, and 25 from Mayo Clinic. The 262 dyads (75.1%) who decided not to move forward to the randomization process all agreed to participate in the semistructured interview. Of this group, 151

were from VCU, 34 from VA, and 77 from Mayo Clinic. Results from the semistructured interview revealed that 206 dyads had only one reason for not participating, 50 had two reasons, and 6 had three or more reasons. Of these, the majority of the dyads (198/262, 75.6%) agreed to having the interviews performed in person, while the remaining 8 (3.1%) had the potential caregiver interviewed on the phone within 1 day of initial in-person contact with the patient. The most common reason was caregiver reluctance (114/262, 43.5%), followed by perceived study burden (n=82, 31.3%), technology-related issues (n=36, 13.7%), transportation and logistics (n=26, 9.9%), and no specific reason (n=11, 4.2%). Importantly, none of the dyads listed privacy as a concern for their refusal.

Logistic regression was performed using dyads that said "yes" to being randomized and therefore were included in the multisite trial. The significant factors associated with dyads saying yes (Table 1) included male gender (odds ratio [OR] 2.08, *P*=.01), admission for gastrointestinal bleeding (OR 2.3, *P*=.006), or hepatic encephalopathy (OR 2.0, *P*=.01), whereas opioids (OR 0.46, *P*=.03) and alcohol-related etiology (OR 0.54, *P*=.02) showed the reverse pattern. Race, site of recruitment, other reasons for admission, whether or not the potential caregiver was a spouse, education, and use of other medications were not significantly associated with saying "yes" to be randomized.

In the 262 dyads who declined to be randomized, we compared characteristics of patients who refused for specific reasons (Tables 2 and 3). We did not compare those who had some part of this interview performed in person versus telephone due to the small number (n=8) of those interviewed solely by telephone. Of the potential caregivers, the majority were wives (n=90, 34.4%), followed by husbands (n=55, 21.0%), children (n=30, 11.5%), significant others (n=8, 3.1%), parents (n=18, 6.9%), siblings (n=16, 6.1%), and other people (n=45, 17.2%). Of the 262 patients who did not want to participate, 116 (44.3%) had an education below or at high school level, 113 (43.1%) patients had completed undergraduate college education, and 50 (19.1%) patients had masters or higher degrees.

For analyses, we combined spouse/significant others (n=153, 58.4%) and those with high school education or below for comparison with the others. Apart from technology-related demands, there were no significant differences in the demographic variables, cirrhosis severity or etiology, medication use, hepatic encephalopathy status, or reason for admission among patients who refused compared to the rest. Dyads who refused for technology-related reasons were more likely to be older, with lower education in the patient, had a higher Model for End-stage Liver Disease (MELD) score on admission, higher frequency of hepatic encephalopathy, and were less likely to be admitted for gastrointestinal bleeding or liver-unrelated (other) reasons compared with those who did not refuse for technology-related reasons (Table 2). Caregiver reluctance was lower when the potential caregiver was a spouse, but the reverse was found for perceived study burden. Very few dyads expressed that they were refusing randomization because they were not interested in research, which was included in the "no reason" category.

Table 2. Reasons for refusal to participate in relation to patient characteristics (N=262).

Characteristic	Caregiver reluctance		Perceived study burden		Technology demands	
	Yes (n=114)	No (n=148)	Yes (n=82)	No (n=180)	Yes (n=36)	No (n=226)

[a]MELD: Model for End-stage Liver Disease.

[b]HE: hepatic encephalopathy.

[c]Significant difference for transport/logistics (*P*=.002).

As shown in Table 4, there were some differences detected between the patients across the three sites with respect to demographic characteristics, whereas MELD score and prior hepatic encephalopathy rates were similar. Veterans were older, likely to be men, and more likely to be on rifaximin, whereas the VCU cohort was more likely to be on psychoactive medications and to be admitted for infection or renal/metabolic reasons. Mayo Clinic patients were more likely to be Caucasian and to be admitted for gastrointestinal bleeding. Although there were differences in the reason for admission of patients at each site, differences between sites were ultimately not significant in the multivariable logistic regression analysis.

Table 4. Differences in patient characteristics among the three sites.

Discussion

Our results demonstrate that agreeing to participate in an intensive health IT regimen aimed at preventing 30-day readmissions for inpatients with cirrhosis and their caregivers may depend in part on the cirrhosis etiology and reasons for inpatient admission. However, the major reasons cited by dyads for not participating appeared to focus on caregivers, study burden, and technological demands rather than on privacy issues. The goal of this multisite trial is to reduce readmissions in cirrhosis, an intractable issue that has medical, psychosocial, and financial consequences [2,8,9]. Our preliminary study demonstrated reductions in hepatic encephalopathy–related readmissions at 30 days when using an intensive health IT intervention that focused on daily communications among patients, family caregivers, and the clinical team [5]. However, given that this previously tested intervention involved several steps in the daily recording of data that could potentially become onerous for the respondents, we included this semistructured interview study within the multisite trial to examine dyads' perspectives on the use of health IT interventions to better streamline our approach.

Only 25% of the patient-caregiver dyads who were approached in the hospital agreed to be randomly assigned to standard care or to one of the two health IT interventions. This rate is relatively lower than that of individuals who ultimately decided to download another app, EncephalApp, but was similar to the rate of individuals that ultimately used the technology in a recent study of outpatients with cirrhosis [10]. Unlike EncephalApp, which links to the Patient Buddy app, the regimen tested in our

multisite trial involves daily entry of data related to medication adherence, weight, and a multipronged approach to orientation that unfolds over 30 days and includes an educational component. This time frame requires a much longer commitment from patient-caregiver dyads along with training from health care providers at the time of discharge. Nevertheless, the intervention includes valuable educational material and offers the potential to continue communication with the treating teams after discharge for most of the clinical issues that underlie readmission, such as hepatic encephalopathy, gastrointestinal bleeding, ascites, and medication management [3,9]. This approach was tested by Bloom et al [11] in a cross-sectional survey where theoretical acceptance of an app that would require similar communications as currently being tested with Patient Buddy was considered to be acceptable to most patients. This finding is in contrast to the results of this study, likely because unlike the theoretical constructs in the prior study, the dyads had to agree to be randomized for a 30-day trial in real life in our study.

The fact that patients admitted with hepatic encephalopathy and gastrointestinal bleeding were more likely to agree to participate in randomization may be related to the patient-caregiver dyad wanting to avoid such occurrences in the future. By contrast, patients with alcohol-related liver disease etiology and opioid use, which often coexist with lower socioeconomic and education status (and potentially unfamiliarity with apps), were less likely to participate [12]. The burden of cirrhosis, and especially hepatic encephalopathy, is shared by patients and their caregivers [13]. Since the most important reasons behind patient-caregiver dyads not agreeing to proceed further were related to caregiver reluctance, perceived burden of the study, and issues involving transport and logistics, the design and components of the health IT intervention may need reconsideration.

The findings of this study are instructive. Although the overall goal of the study team and the multisite trial is to reduce burden for both patients and their families by preventing readmission, the amount of time and effort required to participate in this study may have mitigated the dyads' desire or willingness to engage in the activities needed to keep up with data entry in the app [14]. The Patient Buddy app being tested in the multisite trial was streamlined from the version tested in our preliminary work based on patient and caregiver responses (specifically items designed to reduce gait issues, fall risk, and sodium content of the diet, and the complexity of the questions asked). However, given the multiple demands on the patient-caregiver dyads' time during hospitalization and just prior to discharge, and the complexities of the current Patient Buddy app (even with its improvements), it appears that a better balance between gaining the information required and minimizing the burden on patient-caregiver dyads is warranted.

Apart from the barriers mentioned above, reasons for not wanting to be randomized to using a health IT intervention could also be centered around privacy and technological demands. However, of interest, privacy issues were not cited as a reason for the decision not to undergo randomization, which might signify trust in the HIPAA compliance of these apps or the presence of other more pervasive issues.

With respect to refusals on technological grounds, we found that patients admitted with hepatic encephalopathy and those who were older, less educated, and with higher MELD scores were more likely to refuse participation. Similar results have been shown in prior studies in patients with and without cirrhosis, and may represent a lack of individual or family capability to perform the tasks [15]. Given that we anticipated enrolling patient-caregiver dyads from a lower socioeconomic status in the multisite trial, we specifically designed a study protocol that provided smartphones individually to patients and their caregivers. However, it is still possible that unfamiliarity with a smartphone, including the use of apps, remains a barrier to engagement in health IT interventions in patients with liver disease. Although the potential issues with use of one-time apps, particularly in the outpatient setting, may be overcome with teaching, it is possible that sustained use over 30 days for the Patient Buddy app could have been construed as too demanding for older patients with hepatic encephalopathy and more advanced cirrhosis.

Finally, an important area for discussion is that perspectives of the study team and patient-caregiver dyads may have influenced our results. Although some studies focus on specific areas of cirrhosis case management postdischarge, the Patient Buddy app incorporates a more customized approach to cirrhosis and is also more broadly focused. For instance, factors such as hepatic encephalopathy, ascites, renal and metabolic issues, and gastrointestinal bleeding could all potentially influence readmission risk. Therefore, the comprehensive nature of this app could have resulted in the perception that it was more difficult to use compared to other apps focused on a single complication. Nonetheless, a broadly focused and well-rounded app addressing the impact of all complications of cirrhosis is needed to better educate patients and their family members about the disease and ultimately reduce readmission rates.

Our work with the Patient Buddy app and its impact on readmissions is continuing in the multisite trial, but this interim exploration of reasons for why dyads declined randomization in the trial has provided information to further refine our understanding on how to better address barriers to using health IT interventions. This will result in streamlining our approach toward the dyads and focusing on the time spent and potential benefits as we approach them. The rate of participation was lower compared with that reported in some other app-based trials in gastroenterology that focused on patients undergoing colonoscopy and those with inflammatory bowel disease [16,17]. These differences could be due to the inpatient setting, which selects for advanced disease and cognitive demands of the cirrhosis disease process, likely being greater than those involved for other diseases studied. Moreover, we interviewed patients and caregivers together, which makes it difficult to evaluate individual responses, and we did not specifically evaluate socioeconomic factors. We asked questions regarding technological familiarity rather than providing dedicated questionnaires since the dyads were not interested in performing further study-related work apart from a brief interview.

In conclusion, the reasons for patients with cirrhosis and their caregivers declining to participate in a trial using an intensive app that requires 30 days of feedback regardless of

demographics and clinical settings were mainly related to caregiver and study demands, but importantly not to privacy concerns. Those admitted with hepatic encephalopathy and gastrointestinal bleeding issues were more likely to agree to participate, whereas those with alcohol etiology and opioid use were less likely to participate in the health IT study. Further research should address the careful balance of patient and caregiver burdens with clinicians' needs for accurate and timely information that enables good disease management.

Abstract

Background: Obesity is a known risk factor for cardiovascular disease risk factors, including hypertension and type II diabetes. Although numerous weight loss interventions have demonstrated efficacy, there is considerably less evidence about the theoretical mechanisms through which they work. Delivering lifestyle behavior change interventions via social media provides unique opportunities for understanding mechanisms of intervention effects. Server data collected directly from web-based platforms can provide detailed, real-time behavioral information over the course of intervention programs that can be used to understand how interventions work.

Objective: The objective of this study was to demonstrate how social network analysis can facilitate our understanding of the mechanisms underlying a social media–based weight loss intervention.

Methods: We performed secondary analysis by using data from a pilot study that delivered a dietary and physical activity intervention to a group of participants via Facebook. We mapped out participants' interaction networks over the 12-week intervention period and linked participants' network characteristics (eg, in-degree, out-degree, network constraint) to participants' changes in theoretical mediators (ie, dietary knowledge, perceived social support, self-efficacy) and weight loss by using regression analysis. We also performed mediation analyses to explore how the effects of social network measures on weight loss could be mediated by the aforementioned theoretical mediators.

Results: In this analysis, 47 participants from 2 waves completed the study and were included. We found that increases in the number of posts, comments, and reactions significantly predicted weight loss (β=–.94, *P*=.04); receiving comments positively predicted changes in self-efficacy (β=7.81, *P*=.009), and the degree to which one's network neighbors are tightly connected with each other weakly predicted changes in perceived social support (β=7.70, *P*=.08). In addition, change in self-efficacy mediated the relationship between receiving comments and weight loss (β=–.89, *P*=.02).

Conclusions: Our analyses using data from this pilot study linked participants' network characteristics with changes in several important study outcomes of interest such as self-efficacy, social support, and weight. Our results point to the potential of using social network analysis to understand the social processes and mechanisms through which web-based behavioral interventions affect participants' psychological and behavioral outcomes. Future studies are warranted to validate our results and to further explore the relationship between network dynamics and study outcomes in similar and larger trials.

Introduction

Obesity is a common disease with a high economic burden, and it is a known risk factor for several chronic diseases, including cancer, cardiovascular diseases, and diabetes [1]. Individuals with low socioeconomic status (SES) are disproportionately more likely to be obese and develop related diseases [2,3]. While there are a vast number of behavioral weight loss interventions established in previous literature [4], relatively few studies of high quality have targeted participants of low SES. There is some evidence that groups with low SES experience lower efficacy in weight loss interventions, especially those that focus only on individual-level determinants [5-7]. This highlights the need for the development of effective behavioral weight loss strategies for individuals with low SES.

A potentially effective way of delivering behavioral weight loss interventions to participants of low SES is the use of social media platforms (eg, Facebook, Twitter). Social media is widely used by internet users of low SES [8]. Compared with face-to-face interventions, web-based delivery of social media offers advantages such as continuous availability and remote access, which could reduce barriers to intervention use among participants of low SES, such as limited time or inadequate transportation [9,10]. In addition, social media users are accustomed to sharing information about their health experiences and opinions [11,12]. This sharing may be enhanced by the communication features of social media websites, which can facilitate sharing and communication among users about weight loss behaviors, goals, and experiences [13,14]. These features make social media platforms particularly attractive for delivering behavioral weight loss interventions. Indeed, some preliminary evidence suggests that social media–based interventions can be efficacious in producing weight loss and increasing the frequency of social interaction and social support [15]. Results from a handful of social media–based behavioral weight loss interventions targeting participants of low SES show that participants have similar receptiveness to the intervention format and weight loss outcome when comparing in-person and social media intervention delivery [16,17]. However, as the evidence of the efficacy of social media–based weight loss intervention accumulates, our understanding of the mechanisms underlying social media–based weight loss interventions is still somewhat limited. Previous literature suggests that constructs such as social support and social comparison are important weight loss predictors. Some studies have linked social media–based intervention components with increased social support, positive behavior change, and health outcomes [18,19]. Studies have also reported greater weight loss for participants in teams or those reporting greater social influence [20]. This evidence, however, is scattered in the context of social media–based weight loss interventions and is largely based on cross-sectional or post-hoc studies. The mechanisms through which social media–based weight loss interventions change participants' interactions, theoretical mediators (eg, knowledge, social support, self-efficacy), and subsequent weight loss behavior and outcomes are still largely unclear.

A promising approach to increase our understanding of the mechanisms underlying social media–based weight loss interventions is to study the user-generated content and interactions during the intervention by using social network analysis. Previous research has shown that interactions generated through social networks serve as important sources for information and knowledge [21-23], social and physical resources [24,25], and social support [26,27]. In addition, social networks influence individual behavior and perception through various mechanisms such as sensemaking, norms, and learning [28,29]. Thus, it is possible to leverage social network analysis to better understand users' position and role in the interaction networks and how that affects the theoretical mediators and subsequent weight loss behavior and outcomes.

In this study, using data from a 12-week pilot behavioral intervention that assessed the feasibility of a weight loss program delivered via social media to adults of low SES [30], we mapped out participants' interaction networks and conducted social network analysis to assess how participants' network characteristics were associated with various psychological and behavioral study outcomes, as well as the possible mediating mechanisms that lead to participants' weight loss.

Methods

Design

We conducted secondary analysis of data from the INSHAPE CLE study. INSHAPE CLE was a single-arm, pre-post intervention trial designed to assess the feasibility of delivering a social media–based weight loss intervention to low-income residents of a large midwestern urban area of the United States of America. INSHAPE CLE delivered a 12-week behavioral weight loss intervention that included goal setting and self-monitoring using Fitbit devices and the Fitbit self-monitoring platform. Participants were also enrolled in a private Facebook group moderated by study personnel (Moderator), who posted planned communications to the group that delivered nutrition and physical activity education and encouraged participants to exchange social support and model desired behaviors. Moderators also responded to participant questions and monitored the group for inappropriate communications. All procedures performed in this study involving human participants were in accordance with the ethical standards of the institutional and national research committee and were approved by the Case Western Reserve University Institutional Review Board and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards [31-34]. This paper does not contain any studies with animals performed by any of the authors.

Participants

INSHAPE CLE participants were recruited using social media advertisements, flyers posted in strategic locations, and in-person recruitment events at federally sponsored nutrition education events. Primary inclusion criteria were age of 35-65 years, regular internet use, BMI of 25-40, less than 30 minutes per day of moderate or vigorous physical activity, residence in the target metropolitan area, income less than 185% of the federal poverty based on family size, and no affirmative answers on the Physical Activity Readiness Questionnaire [35] or written clearance by a physician. Participants were recruited in 2 waves

and enrolled in 2 separate Facebook groups with largely identical moderator content.

Study Procedures

Participants were screened online. Eligible participants were provided a web-based consent form and those who accepted were provided a web-based baseline questionnaire and invited to an in-person orientation meeting where study instructions were provided and anthropometric measures were collected. Participants attending an orientation meeting were considered enrolled in the study. Enrollees were provided a web-based follow-up questionnaire at the end of the 12-week intervention and invited to a meeting where follow-up anthropometric measures were taken. Additional details of the INSHAPE CLE intervention and study procedures can be found elsewhere [30].

Measures

Demographics

As a part of the baseline questionnaire, participants were asked to report their birth year, gender, race, ethnicity, educational status, and employment status.

Anthropometrics

All anthropometrics were collected by study staff who attended a 1-hour training session. We measured height by using a stadiometer (Detecto PHR Portable Mechanical Height Rod for DR400C) and weight by using a floor scale (Detecto DR550C) calibrated using a 10-kg weight (Ohaus 80850302). Measurement procedures were based on the National Health and Nutrition Examination Survey Anthropometry Procedures Manual.

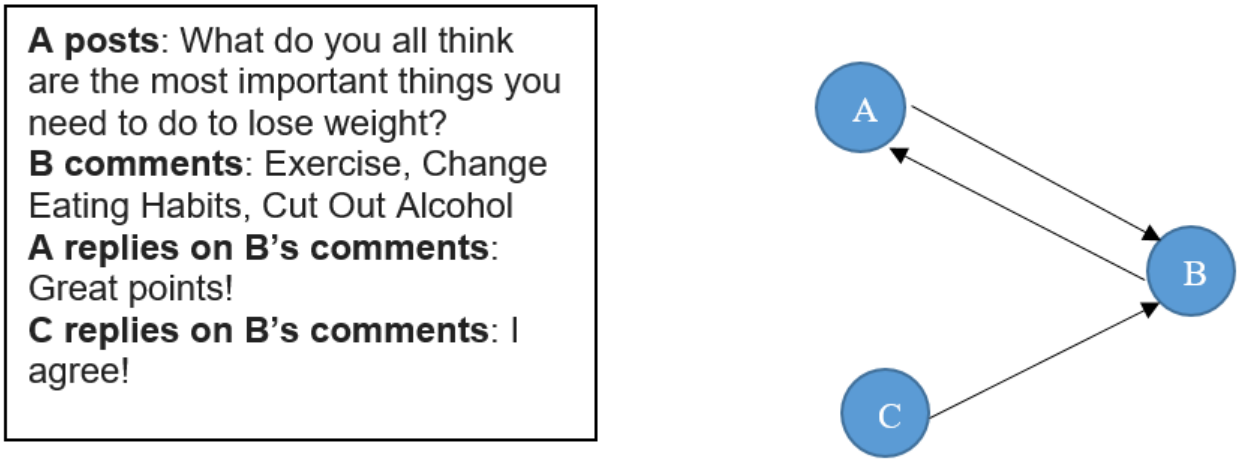
Theoretical Mediators

Several psychological and behavioral constructs were theorized to be important determinants of the weight loss outcome. Specifically, dietary knowledge was assessed by the sum of correct answers from a 36-item questionnaire adapted from a validated nutrition knowledge questionnaire and was scored as the percentage of questions answered correctly. The questionnaire assessed several domains of nutrition knowledge, including national dietary recommendations, the nutrient content of foods, and the relationship between dietary behavior and chronic disease. Perceived social support was measured using the 5-item Friend Social Support and Eating Habits Scale that asks participants to indicate how often their friends (1=never, 5=very often) communicated positive messages about dietary behavior (eg, discussed my eating habit changes with me [asked me how I'm doing with my eating changes]). Self-efficacy was assessed using a validated 4-item scale measure. This scale asked participants "How confident are you that you can lose weight?" with a series of conditional statements (eg, Even if you have to try several times until it works) rated on a sliding scale from 0% (not at all confident) to 100% (completely confident).

Social Network/Engagement Measures

Each post, comment, and reaction (eg, emojis) on the Facebook group during the intervention was recorded. Two data collection methods were used to obtain Facebook data. The Grytics analytical platform [36] provided data directly from the Facebook application programming interface. We also collected select data manually by reviewing and logging information directly from the Facebook group. This was required due to changes to Facebook's privacy policy that occurred during the second group's intervention that deidentified individual Facebook user data. However, the Grytics platform did not provide data on the reactions for comments with the exception of likes. Data were collected in both ways and validated by comparing aggregate data provided by Grytics, where available, to the totals from the manual data collection. In cases where totals did not agree, Facebook was manually checked a second time to ensure that the data collection methods produce consistent data across the entire intervention period. To obtain a more nuanced understanding of subjects' different levels/types of participation and engagement in the intervention, a social network was constructed using the comment relationship. A network tie from i to j represents i has sent out a comment/reply to j's post or comment, with the weight representing the number of comments across the whole intervention. To further illustrate this, in the simple example shown in Figure 1, the communication stream on the left can be represented as the network on the right.

Figure 1. A simple example illustrating the network construction process, wherein the link represents the comment/reply relationship.



We derived several centrality measures from the social network to indicate the type or level of treatment an individual received during the intervention. Specifically, in-degree was calculated as the total number of comments each individual received during the intervention. Network constraint was calculated to represent the degree to which one's interaction partners also interact with each other. Previous studies have linked network constraint to individual's social capital, social support, and access to diverse information [24]. The interaction partners/network neighbors of an individual with higher network constraint are more tightly connected with each other, while the interaction partners/network neighbors of an individual with lower network constraint are more disconnected from each other. Finally, we calculated out-degree to represent participants' engagement. As the network constructed excluded posts and reactions that one created, instead of out-degree based on the constructed network, we calculated out-degree as the sum of posts, reactions, and comments for each individual. As out-degree and in-degree are highly skewed, we used the log-transformed variables in the final analysis.

Data Analyses

Data analyses were completed using STATA 16.0 (StataCorp). Data were screened for deviations from assumptions required for the statistical analyses used. Analyses were performed on participants who completed baseline and follow-up measures on variables used in the analysis (ie, study completers). There were no significant differences in the demographic characteristics between completers (N=47) and those lost to follow-up (n=8). We calculated descriptive statistics for baseline characteristics, outcome, and theoretical mediator measures, as well as social network measures. To examine how social network measures were associated with the change in outcome and theoretical mediators, we used multivariate regression analysis with the change in weight, dietary knowledge, social support, and self-efficacy as the outcome (ie, difference between the outcome after the intervention and at baseline) and each aforementioned social network measure as the predictor in separate regression models. In each regression analysis, we controlled for the baseline value of the outcome, the treatment group indicator (group 1 or group 2) as well as other baseline characteristics such as age, race, education status, and BMI. We reported robust standard error to account for possible heteroscedasticity. In addition, to rule out the possible bias of network construction in our results, we also performed 2 sensitivity analyses: (1) we calculated out-degree as the total number of comments each individual made during the intervention and reran the aforementioned analyses and (2) we constructed the comment networks and associated network measures by excluding moderator-related interactions (ie, participant-only network) and reran the aforementioned analysis. Detailed results are reported in Multimedia Appendix 1. Furthermore, while the original intervention was not powered for the mediation analysis, to explore the possible mediating roles of changes in dietary knowledge, social support, and self-efficacy on the effect of social network measures on weight change, we conducted separate mediation analyses by using structural equation modeling, with changes in each of the theoretical mediators as the mediator and each social network measure as the predictor. In each structural equation modeling model, we controlled for the same covariates as previously mentioned.

Results

Participants' Demographics and Intervention Outcomes

Table 1 presents the baseline characteristics of the participants (N=47) included in the analysis (n=34 for wave I [group 1], n=13 for wave II [group 2]). The mean age of the participants was 46 years with mean baseline BMI of 34.09 kg/m^2. Participants were predominantly female (44/47, 94%) and mostly African American (32/47, 68%). Almost half (22/47, 47%) reported completing college or graduate school. The baseline characteristics of the participants in the 2 waves/groups were similar and we did not observe noticeable differences in these variables between the waves/groups.

Table 2 reports the change in the main study outcomes during the intervention. Compared with the baseline values, participants experienced an average weight loss of 1.25 kg (P=.049), significant increases in dietary knowledge of 2.28 (P=.02), and positive dietary social support of 2.87 (P<.001), but a nonsignificant decrease in average self-efficacy of 3.07 (P=.28).

Table 1. Demographics of INSHAPE CLE participants who completed the study.

Characteristics	Group 1 (n=34)	Group 2 (n=13)	Total (N=47)
Age (years), mean (SD)	45.59 (8.91)	48.38 (10.52)	46.36 (9.35)
Gender, n (%)			
Female	31 (91)	13 (100)	44 (94)
Male	2 (6)	0 (0)	2 (4)
Transgender	1 (3)	0 (0)	1 (2)
Race, n (%)			
White	9 (27)	3 (23)	12 (26)
Black or African American	23 (68)	9 (69)	32 (68)
More than one race	2 (6)	1 (8)	3 (6)
Education, n (%)			
College graduate or more	19 (56)	3 (23)	22 (47)
Some college	13 (38)	7 (54)	20 (43)
High school graduate	2 (6)	3 (23)	5 (11)
BMI, mean (SD)	33.79 (3.88)	34.87 (3.86)	34.09 (3.86)

Table 2. Study outcomes of INSHAPE CLE participants who completed the study.

Outcome	Baseline values, mean (SD)	Follow-up values, mean (SD)	Mean change (95% CI)	*P* value
Weight (kg)	94.63 (12.85)	93.38 (13.76)	–1.25[a] (–2.51 to 0.00)	.049
Dietary knowledge (scale 0-100)	27.64 (7.57)	30.08 (8.19)	2.28[a] (0.44 to 4.13)	.02
Positive dietary social support (scale 5-25)	10.48 (5.27)	13.26 (4.83)	2.87[b] (1.25 to 4.49)	<.001

Social Network Measures and Association With Changes in the Study Outcome

Social network was constructed based on participants' comment relationships during the intervention. Figure 2A and Figure 2B present the comment network among participants in group 1 and group 2, respectively. A link from node 1 to node 2 represents that node 1 has made comments to node 2, with thickness representing frequency. Node color represents the number of comments one made to others, with darker color indicating more comments. Node size represents the number of posts one created, with larger size indicating more posts. Nodes were laid out by a multilevel force-directed algorithm [37]. The network graph intuitively shows there are different levels of engagement among participants—some participants were positioned at the center of the network with many posts or comments, while many participants were positioned at the periphery of the network with very few comments or posts. The structure is more evident in group 1 (where the group size is larger), where k-core analysis [38] showed 14 people formed a core—each person in the core received comments from at least 10 other people in the core. This figure also shows there are different types of engagement among participants—some participants had few original posts but commented on others frequently, some participants did not make many comments to others but received many comments, and some participants were more embedded in the network with their network neighbors tightly connecting to each other. This observation is evident in Table 3, which shows there were large variations in both out-degree (mean 186.32, SD 178.24) and in-degree (mean 25.42, SD 30.83) among the participants. Table 3 also reports the results from regression analyses on how different types of engagement (indicated by social network measures) were associated with changes in study outcomes. Among them, increases in the number of posts, comments, and reactions made (out-degree) significantly predicted weight loss (β=–.94, $P=.04$)—1% increase in the number of posts, comments, and reactions made was associated with 0.0094 kg in weight loss. Increase in the number of comments received (in-degree) significantly predicted increase in self-efficacy (β=7.81, $P=.009$)—1% increase in the number of comments received was associated with 0.0781 units increase in positive self-efficacy change (self-efficacy was measured on a 0-100 scale). In addition, while not significant at .05 level, out-degree was also likely to be positively associated with changes in self-efficacy (β=3.44, $P=.08$), and the degree to which one's network neighbors are tightly connected with each other (network constraint) was likely to be positively associated with changes in positive dietary social support (β=7.70, $P=.08$).

Sensitivity analyses reported in Multimedia Appendix 1 (Table S1 and Table S2) showed that the network structures and the regression results related to in-degree and out-degree were consistent and robust with different ways of constructing networks.

Figure 2. Comment network during the intervention in group 1 (A) and group 2 (B). Link from node 1 to node 2 represents node 1 has made comments to node 2, with thickness representing frequency. Node color represents the number of comments one made to others, with darker color indicating more comments. Node size represents the number of posts one created, with larger size indicating more posts.

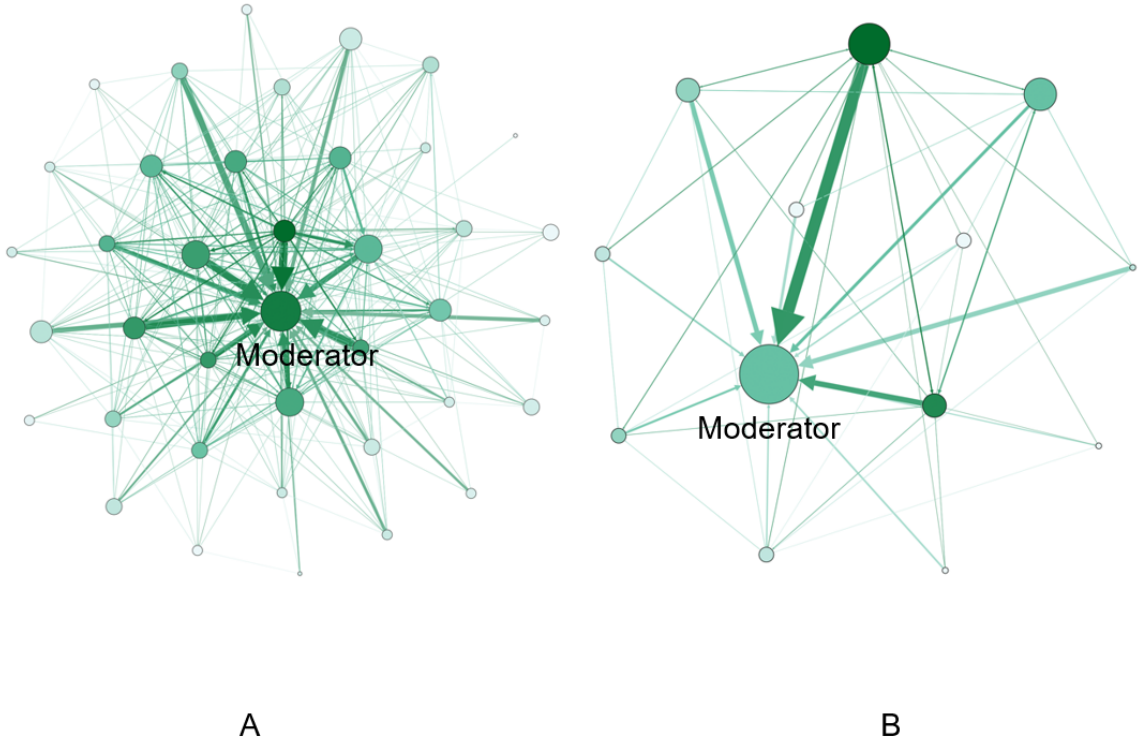

Table 3. Associations between social network measures and change in study outcomes for INSHAPE CLE participants.[a]

Predictors/outcome	Mean (SD)	Median (IQR)	Min-Max	Weight change		Dietary knowledge change		Social support change		Self-efficacy change	
				β (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value
Out-degree	186.32 (178.24)	127 (238)	1-643	–.94[b] (–1.85 to –.04)	.04	.06 (–1.13 to 1.24)	.93	.69 (–.37 to 1.75)	.20	3.44[c] (–.38 to 7.26)	.08
In-degree	25.42 (30.83)	15 (29)	0-174	–.72 (–2.08 to .64)	.29	.94 (–.57 to 2.46)	.21	–.22 (–1.58 to 1.12)	.73	7.81[d] (2.06 to 13.57)	.009
Network constraint	0.62 (0.24)	0.52 (0.46)	0.23-1.05	–6.16 (–15.99 to 3.66)	.21	–7.78 (–18.36 to 2.79)	.14	7.70[c] (–.98 to 16.39)	.08	–21.96 (–63.12 to 19.20)	.29

[a]In the analysis, out-degree and in-degree were log-transformed. All models controlled for the outcome before the intervention, the treatment group indicator, age, race, education status, and BMI.

[d]Significant at *P*<.01.

Mediation Analysis

As an exploratory step, we also investigated the possible mediating effects of the theoretical mediators on the effects of social network measures on weight loss, which is presented in Table 4. Structural equation modeling results show that there was a significant indirect effect from in-degree to weight loss that went through a change in self-efficacy (β=–.89, *P*=.02). Figure 3 shows that receiving more comments was positively associated with changes in one's self-efficacy during the intervention (β=7.81, *P*<.001), which was subsequently associated with more weight loss (β=–.11, *P*=.001).

Table 4. Mediation analysis from social network measures to changes in theoretical mediators to weight change for INSHAPE CLE participants.[a]

Predictors/mediators	Dietary knowledge change		Social support change		Self-efficacy change	
	β (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value
Out-degree	–.01 (–.06 to .05)	.83	–.09 (–.32 to .14)	.43	–.29 (–.64 to .06)	.11
In-degree	–.03 (–.37 to .31)	.88	.04 (–.20 to .29)	.73	–.89[b] (–1.62 to –.16)	.02
Network constraint	1.22 (–1.52 to 3.95)	.38	–1.21 (–3.84 to 1.40)	.36	2.43 (–1.99 to 6.86)	.28

[a]In the analysis, out-degree and in-degree were log-transformed. All models controlled for the outcome before the intervention, the treatment group indicator, age, race, education status, and BMI.

[b]Significant at $P<.05$.

Discussion

Principal Results

In this study, we used social network analysis to analyze the interaction data from a pilot study that delivered a dietary and physical activity intervention to a group of participants of low SES via Facebook. We mapped out participants' interaction networks over the 12-week intervention period and linked participants' network characteristics to their behavioral and psychological outcomes such as weight change, self-efficacy, dietary knowledge, as well as perceived social support. Our findings suggest that there is great heterogeneity in the ways and degree to which participants engage in the intervention. Participants engaged at different levels—some participants posted and commented much more than other participants during the intervention, creating a core-periphery structure in the interaction network. Participants also engaged in different ways—some participants had few original posts but commented on others frequently, some participants did not make many comments to others but received many comments, and some participants were more embedded in the network with their network neighbors tightly connecting to each other. Individuals' network characteristics in the interaction network are predictive of their various study outcomes. Specifically, we found that the number of posts, comments, and reactions one made was directly associated with weight loss, the number of comments one received significantly predicted change in self-efficacy, and the degree to which one's network neighbors are tightly connected with each other also weakly predicted change in perceived social support. The interactions generated through the intervention may change participants' weight loss outcomes by affecting their psychological mediators. One mechanism we found was that receiving comments/replies is associated with weight loss through increase in a participant's self-efficacy.

Implications

Here, we demonstrate the potential of using social network analysis to understand the social processes of behavior change within the web-based weight loss intervention. Our findings shed light on the social processes participants experienced during the web-based weight loss intervention and how these processes might affect their psychological and behavioral outcomes, which can inform the design of future interventions to achieve better outcomes. For example, the interventionist can monitor the interaction network throughout the intervention

and deliberately reach out to those who are less likely to engage. The interventionist could also encourage participants to comment and reply to others more often to boost other participants' self-efficacy. Moreover, the interventionist could focus on design features to facilitate the formation of cohesive groups, which might increase perceived social support. Finally, the interventionist could train actively engaging participants to be a peer leader who can help with engaging other participants.

Comparison With Prior Work

While there are ample studies applying the concept of social network analysis in health and health care settings [39-42], not many have been used in the context of web-based behavioral interventions and fewer have specifically focused on weight loss interventions. Our study contributes to this body of literature by improving our understanding of the mechanisms through which social processes generated through intervention affect participants' psychological and behavioral outcomes. While participant engagement in the Facebook group used in this study exceeded that in previous studies using similar formats targeting diet or physical activity [43,44], similar to previous studies and social media research in other domains, we found great heterogeneity in ways and levels that participants engage in Facebook discussions [45-48]. Consistent with previous studies, we also found that engagement during the intervention was positively associated with weight loss [49,50]. Furthermore, we found that an individual's various network characteristics are associated with other important psychological outcomes—receiving comments is positively associated with participants' changes in self-efficacy, and embedding in a more cohesive network (one's network neighbors more tightly connected with each other) is likely to have a positive association with changes in perceived social support. While not studied in the web-based behavioral intervention context, this is consistent with social network literature from other fields [51,52]. Finally, our mediation analysis shows an interesting path explaining how the intervention might affect participants' weight loss outcome—receiving comments (in-degree) during the intervention is likely to boost one's self-efficacy, which resulted in greater weight loss. While the separate links from in-degree to self-efficacy or from self-efficacy to weight loss have been established and validated in other contexts [53,54], to our knowledge, this is the first study to establish this path in web-based behavioral weight loss intervention, which further points to the potential of using social network analysis to understand the mechanisms through which web-based behavioral weight loss intervention affect participants' psychological and behavioral outcomes.

Limitations and Future Work

This study has several limitations that point to avenues for future research. First, our sample size was small (N=47) and our participants were predominantly female (44/47, 94%). This limits the statistical power to detect the intervention effects as well as the generalizability of our results to a larger or more gender-balanced population, following a longstanding pattern in weight loss studies of difficulty recruiting male participants [55]. Similarly, we used income as a proxy measure for SES in the inclusion criteria. Given that 47% (22/47) of our participants reported attaining a college degree or advanced degree, we cannot generalize our results to individuals with low levels of education. Future studies should include more male participants and participants with low levels of education to further explore the efficacy of the intervention and how subjects may respond differently. Second, this study did not fully tease out all possible confounding factors and thus cannot establish causality. For instance, participants with higher baseline levels of motivation may be more successful at losing weight and more likely to post comments. Future studies may include more baseline characteristics and utilize randomized controlled designs to better establish causality. Third, in our analysis, the interaction network and associated network measures were aggregated over a 12-week intervention period; thus, we did not fully explore the interaction dynamics during the intervention. Future studies could study how networks change over time and unpack the temporal dynamics between networks and the study outcomes. Fourth, the network in our analysis is primarily constructed from posts and comments and we did not fully explore other relationships such as reactions and views (ie, we did not consider the number of reactions or views one received). While comments and posts have been considered more valuable than other engagement (eg, likes and "lurking") as they are more cognitively demanding [30], other engagements potentially comprise a substantial proportion of social media use and thus warrant more careful consideration in future studies [56]. Finally, when constructing the interaction network, we did not consider the content of the conversation, which is hypothesized to have different effects on the participants (eg, informational conversation may increase dietary knowledge while emotional support conversation may increase perceived social support). Future studies may employ qualitative analysis and natural language processing to further distinguish the network ties with different content.

Conclusions

In this pilot study, we constructed participants' interaction networks by using data from a feasibility trial of a web-based weight loss intervention delivered via Facebook and linked their network characteristics with changes in several important study outcomes of interest such as self-efficacy, social support, and weight. Our results point to the potential of using social network analysis to understand the social processes and mechanisms through which web-based behavioral interventions affect participants' psychological and behavioral outcomes. Future studies are warranted to validate our results and further explore the relationship between network dynamics and study outcomes in similar and larger trials.

Abstract

Background: Depression is one of the leading causes of illness and disability in young people, with approximately 20% having experienced a depressive episode by the age of 18 years. Behavioral activation (BA), a National Institute for Health and Care Excellence–recommended treatment for adults with depression, has shown preliminary support for its use with young people. BA may have the potential to be adapted and delivered in a computerized format to address the barriers often associated with young people accessing support. Despite the benefits of adopting computerized therapy delivery, the limited effectiveness of some programs has been attributed to a failure to tailor interventions to patients and practices. Therefore, while developing new treatments, it is important that target users be involved in the intervention design.

Objective: This qualitative study aims to explore the views and preferences of young people and health care professionals regarding the development of a new computerized BA therapy for young people with low mood or depression, to ensure that the therapy was suitable for the target user.

Methods: Semistructured focus groups and individual interviews were conducted with young people (those with experience in accessing support and those without) and health care professionals regarding the development of a new computerized BA therapy for young people with low mood or depression. The data were analyzed using thematic analysis.

Results: A total of 27 individuals, comprising both health care professionals and young people, participated in this study. Vital information pertaining to the important components of a new therapy, including its presentation, delivery, and content, was collected.

Conclusions: Variations in perspectives highlighted the need to adopt a systemic approach in therapy development by considering the opinions of young people with and without experience in accessing mental health support and health care professionals.

Introduction

Background

Approximately 20% of young people experience at least one depressive episode by the age of 18 years [1], making depression one of the leading causes of illness and disability in this group [2]. Despite this, help-seeking is limited only to approximately 35% of young people [1] because of factors including stigma [3,4], negative attitudes about help-seeking [4], accessibility [3], and reluctance to engage one-to-one with a therapist [5]. Much attention has been placed on computerized delivery of

therapy, in particular cognitive behavioral therapy (CBT) [6-8], which removes some of these barriers. One alternative to CBT is behavioral activation (BA), which encourages increased engagement in adaptive activities and decreased engagement in activities that might maintain or increase depression risk [9]. Owing to its empirical support [10-13], BA is a National Institute for Health and Care Excellence–recommended treatment for adults with depression [14]. Given its demonstrated effectiveness and simple delivery, BA may have the potential to be adapted for use with young people and delivered in a computerized format.

Despite the evident benefits of adopting a computerized approach to therapy delivery, including increasing therapy accessibility, availability [15], and anonymity [16]; reducing stigmatization [17]; and providing those reluctant to engage one-to-one with a therapist with access to care [18], the limited effectiveness of some programs has been attributed to a failure to tailor interventions to patients and practices [19,20]. Therefore, in the development of new treatments, it is important that those for whom an intervention is being designed are involved in its development [21,22], and qualitative research is particularly useful in this context.

When designing a computerized BA program, those deemed the best to inform the development include not only those who may use such a program but also those involved in treatment delivery. Research suggests that one important process that may enhance treatment effectiveness is the incorporation of young people's views in treatment design to ensure that the developmental needs of the users are considered [23]. However, some depression and anxiety treatments for young people are simply downward extensions of adult therapies, as reflected in both their design and delivery [24,25]. Therefore, the needs and capacities of young people are not always considered when such information is being collected from adults, including parents and pediatric health care professionals [26]. This omission to collect information firsthand may result in the misinterpretation of young peoples' needs and a focus on the needs of adult representatives instead [27], highlighting the need to include young people when developing interventions designed for them.

In research that has incorporated the views of young people, differences have been evident between their perceptions and those of health care providers. When reviewing research related to the experiences of care systems, health care professionals' priorities contrasted with the key points highlighted by young people [27]. Furthermore, an examination of illness experiences through interviews with 7 children who had been hospitalized showed that illnesses had different meanings for young people compared with those for professional caregivers [28]. Here, both the illnesses and the mechanisms of recovery were seen in very different ways. Although young people had subjective and personal knowledge of illnesses derived from their own experiences, health care professionals based their knowledge on easily measured objective symptoms. Therefore, there is a need to encapsulate the perspectives of both health care professionals and young people in the development of a computerized BA program.

Objectives

This qualitative study explores the views and preferences of young people and health care professionals regarding the development of a new computerized BA therapy for young people with low mood or depression. The information gathered about the treatment components that such a therapy should include and how it should be presented and delivered inform the development of the new treatment.

Methods

Overview

This research adopted an exploratory, qualitative design using a critical realist approach [29] and was conducted within 4 UK National Health Service (NHS) trusts. Ethical approval was granted by the Health Research Authority (reference: 16/EM/0420) and the Department of Health Sciences Research Ethics Committee at the University of York.

Participants, Sampling, and Recruitment

In total, 3 groups of individuals participated: young people from a community sample, young people from a service user sample, and health care professionals with experience of working with young people with low mood or depression. Participants were identified using a combination of purposive and snowball sampling approaches.

Young People

As many young people experiencing a depressive disorder do not seek help [1], a community sample of young people from a local school within the remits of one of the participating NHS trusts was invited to a focus group. A purposive sampling approach was used, stratifying those identified by age and gender to increase the representativeness of the participants. In addition, a sample of young people receiving support for depression within 3 local child and adolescent mental health services (CAMHS) were identified by health care professionals and invited to attend face-to-face, semistructured interviews with the researcher. Recruiting young people from both a community and a health care sample allowed maximum variation in the views collected. The recruited participants were males and females aged between 11 and 16 years. This ensured that those recruited represented a sample similar to the target group that the eventual program was to be designed for.

All prospective participants received information about the study, with those expressing interest providing written assent alongside consent from a parent or guardian.

Health Care Professionals

A sample of health care professionals with experience of working with young people with low mood or depression from 2 CAMHS was invited to a focus group or an individual interview if more convenient. Anyone expressing interest provided written consent for participation.

Data Collection

All focus groups and interviews were conducted by the lead researcher within the schools and CAMHS sites where recruitment occurred. Before all interviews and focus groups,

attendees completed a short questionnaire—young people were asked to supply basic demographic information and health care professionals provided information about their clinical practice.

The interviews and focus groups closely followed 1 of 2 interview schedules (one for young people and one for health care professionals; Multimedia Appendix 1), comprising semistructured, open-ended questions. The interview schedules for young people were based on collecting information pertaining to 4 different domains: previous experiences of web-based help and opinions regarding the new program development, the content and treatment-related activities to be considered for inclusion in the new program, delivery-specific information (eg, the number and structure of sessions, access, and program presentation), and parental involvement. Although a similar structure was adopted in the interview schedules for health care professionals, they were also asked questions related to the new program's positioning in the care pathway and about perceived support requirements for program completion. With permission, all interviews and focus groups were audio recorded digitally and transcribed verbatim.

During the focus groups and interviews, participants completed 2 bespoke activities specifically developed for the research. The first activity, which was completed by all, was used to elicit further information regarding the content to be considered for inclusion in the new program, with individuals asked to indicate what they deemed to be important from a list of potential options (eg, activity scheduling, activity monitoring, and relapse prevention). Definitions of terms were provided as part of this activity to aid in participants' understanding. This list was generated from a review of the treatment components often included in BA [30] and the findings from a previous systematic review and meta-analysis of BA used in young people [31]. The second activity, which was completed by young people only, was used as an additional tool to collect delivery-specific information. This involved young people ranking 10 factors that they felt would make the program more attractive to young people (interactivity, colorfulness, etc) in order of importance. The activities allowed for methodological triangulation [32], made participation more enjoyable, and allowed individuals to provide information in various ways.

Data Analysis

Data were analyzed using thematic analysis, which was selected to provide rich and detailed insights about a given topic [33]. The analysis was both inductive and deductive, with themes or subthemes generated from both the raw data provided by participants and from theory and previous research. Thematic analysis comprises 6 phases: familiarization with the data, generating initial codes, searching for themes, reviewing themes, defining and naming themes, and reporting production [33]. By closely following these phases, themes were identified from what participants perceived to be the important components of a computerized BA program for use with young people experiencing low mood or depression. All analyses were completed by hand using Microsoft Word, and no specific qualitative software packages were used.

Results

Overview

In total, 27 individuals comprising young people from a community sample, young people from a service user sample, and health care professionals attended interviews and focus groups with the lead researcher. Participant demographic information is presented in Table 1, whereas the themes identified in the thematic analysis and their interrelations across groups are presented in Figure 1.

Table 1. Participant sample characteristics (N=27).

Participant characteristics	Young person: community sample (n=9)	Young person: service use sample (n=9)	Health care professional sample (n=9)
Gender, n (%)

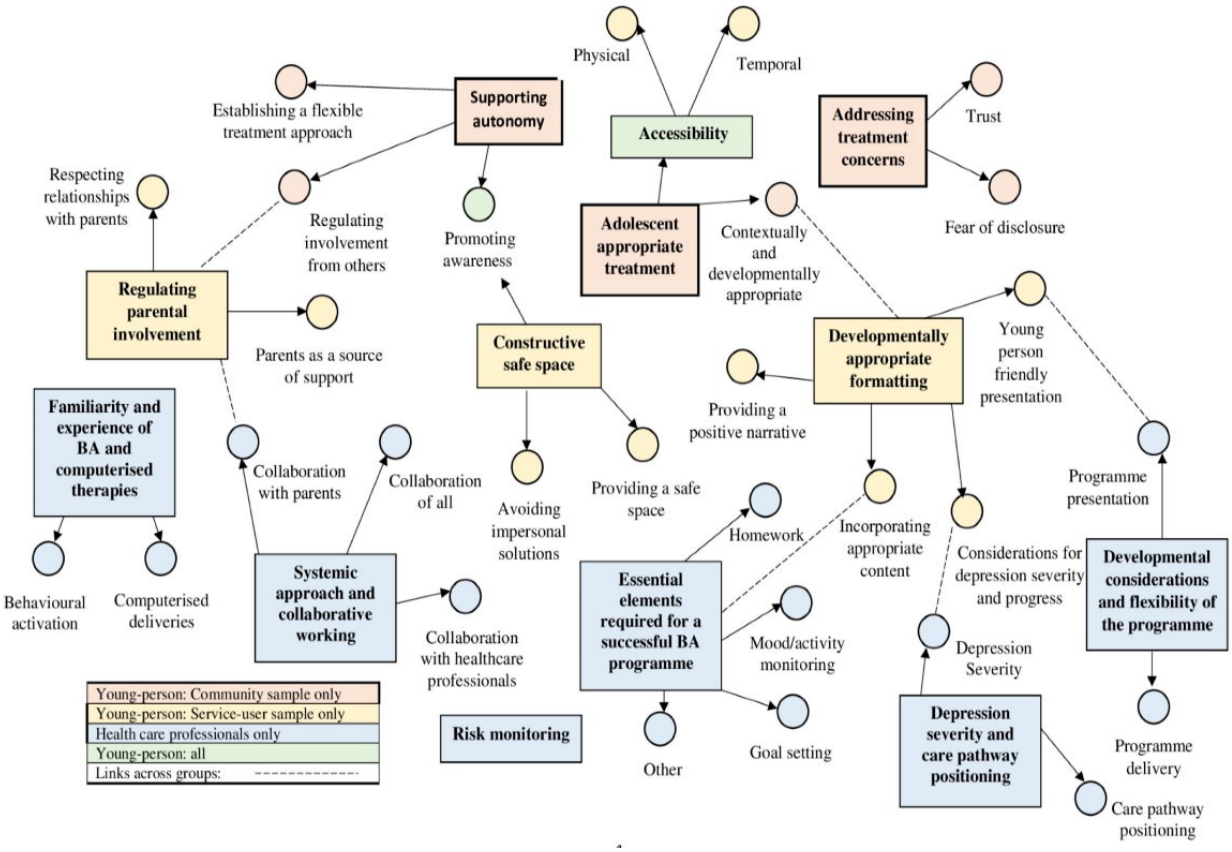
Figure 1. Thematic map of young person participants and health care professionals' perspectives. BA: behavioral activation.



Young People: Community Sample

In total, 3 main themes were identified: supporting autonomy, addressing treatment concerns, and adolescent-appropriate treatment.

Supporting Autonomy

Most young people in the community sample were unsure of how to access support if required, with only 2 having ever received any support—one for bullying support and another for dealing with their parents' divorce. Most assumed that, if they needed any support, their parents would access it on their behalf. None of the users had ever accessed any web-based support, with the majority unaware of its existence, thus highlighting the need for increased awareness of its availability:

> *I think that's why a lot of kids nowadays are feeling more pressured into committing suicide and things like that because it's like "oh I can't get any help" because they don't know what to do.* [Male, community, aged 13 years]

Young people wanted the opportunity for autonomy if using the new program, highlighting the need for flexibility and wanting to make treatment decisions. Therefore, they wanted much of the program to be optional, with users choosing what to view and when. Examples included deciding whether to disclose information about experiences of low mood or depression, selecting which activities to participate in, and deciding whether to complete additional follow-up sessions if available. They also wanted to decide how long they spent on sessions and the frequency of logging on. However, if flexibility with session length was not possible, approximately 30 minutes per session was regarded as reasonable.

Wanting to be independent and able to make treatment-related decisions, many young people did not want parents to be involved, reporting that such involvement could be detrimental to improving mood. Particular concerns included feeling that parents would not understand young person–specific issues:

> *I'm not being disrespectful to them, but they'll think they know everything about kids and stuff, but they really like, they don't.* [Male, community, aged 13 years]

Friends were suggested as an alternative support to parents, but shortcomings of this approach were identified, including concerns that this could place great pressure on friends who might worry too much, who may not take things seriously, or who could be patronizing. Therefore, if any risk was presumed, young people felt that parents needed to be informed. Consequently, they contended that the new program should include some information for parents but that this should be both minimal and optional, so young people could retain autonomy.

Addressing Treatment Concerns

Concerns were raised about how young people would be treated if they accessed support. In particular, they worried that information disclosed would be reported back to parents who may then treat their child differently and place restrictions on them that could worsen their low mood:

> *...your mum and dad would be like "right I'm not letting you out the house, I'm not letting you do this, I'm not letting you do that" because that kind of puts you down more.* [Male, community, aged 13 years]

Such concerns were not limited to parents, with some worried about what would happen if they were to report low mood to health care professionals, particularly general practitioners. For most participants, the prospect of computerized therapy delivery allayed some of these concerns. However, for one individual, even accessing therapy in a computerized format could lead to others finding out about their low mood and treating them differently. Specifically, this individual was worried that if they felt particularly low and accessed computerized therapy, people might arrive at their house to tell them "don't kill yourself."

Young people wanted assurance that, if accessing computerized therapy, confidentiality would be maintained. They suggested having good security with individual usernames and passwords required for access, incorporating automatic log-offs after short periods of inactivity, and ensuring no personal information requests were made. They also wanted the program's name to be discrete and not indicative of its purpose.

A consensus emerged that young people would only disclose information about how they were feeling to another person if trust was both established and retained. One young person had concerns about trust if therapy was delivered in a computerized format, stating that "anyone can set up a website." This was different for others, with one individual highlighting that if therapy was set up by a reputable source, trust could be gained. Second, the anonymity of a computerized approach meant that establishing trust was not an issue.

Adolescent-Appropriate Treatment

The community sample felt that the adolescent period was where computerized therapy could be of most importance, particularly for those already experiencing low mood or depression. They outlined specific stressors, including the transition to secondary school, changes to curriculum and workload, and working toward and completing the General Certificate of Secondary Education.

Overall, they felt that 2 or 3 different presentations were needed to suit the target age range, with developmental level guiding the program presentation and chronological age guiding the content (ie, to ensure the therapy did not place greater pressure on young people at already stressful times, such as during examination periods):

> *A low level sixteen-year-old might have the same ability as a high level twelve-year-old.* [Female, community, aged 14 years]

The community sample identified communication, goal setting, activity scheduling, and identifying barriers as the most important components for inclusion. In particular, they felt that communication would help users to develop their social skills and described how the inclusion of links to clubs would aid activity scheduling. Additional content for consideration included games or puzzles, if these were not *childish*, and videos, if these were nonpatronizing, modern, showed depression in a "serious way," and included actors that users could identify with. Several young people wanted homework to be included but only if it were called something else and minimal, thus considering other demands on users' time. If information about depression was included, young people wanted this to incorporate depression statistics, information about coping strategies, and current treatments. Advice from health care professionals was requested as part of any problem solving. Although recording activities and moods was the least favored component for inclusion (with some participants concerned that this could lead to information disclosure), others wanted this to be included to allow connections to be made between periods and moods.

The colorfulness of the new program, including information about depression and having additional follow-up sessions, was regarded as the most important component in making the new program attractive to users, whereas having printable handouts and homework activities was considered less important. Participants also wanted the program to be sensitive, fun, and relaxed and to provide adequate information—not too much so that users would be overwhelmed or too little so that they would not take it seriously.

Concerns were expressed that not all young people would be able to access a computerized program with proposals made to place it in accessible locations (eg, general practice [GP] surgeries) to ensure equal access. Furthermore, young people wanted the program to be available at all times and therefore accessible not only when most convenient but also when most required. Consequently, young people wanted the program content to be downloadable to ensure it could be viewed even if an internet connection was unavailable. Program access also had to be simple, with no requirements for young people to trawl through terms or conditions or have to "sign up now," which they described would dissuade them from using the program.

Young People: Service User Sample

A total of 4 main themes were identified: constructive safe space, developmentally appropriate formatting, accessibility, and regulation of parental involvement.

Constructive Safe Space

In total, 4 service users had accessed web-based support, searching the internet and browsing websites, generally when they felt particularly low and when alternative support was unavailable. Although 2 users had found web-based help useful, shortcomings of the approach were described, including a lack of personal rapport, automated responses described as "robotic," and a feeling that information was more directed at parents:

> *I found the [name of website] one to be a lot of phone numbers and it was a lot more directed towards parents than the child.* [Female, service user, aged 16 years]

All the service users had received face-to-face support for low mood or depression, with the majority describing how hard they had found this, particularly talking with another person about their feelings. Similar to the community sample, their main concern related to how they would be perceived, with several reporting feelings of embarrassment or worry that others would

not understand. Consequently, they felt that a computerized treatment approach addressed some of these difficulties, providing young people with anonymity that allowed them to talk freely without judgment, in a format that they were both familiar with and comfortable using:

> *...our safe space is talking through a phone, through a screen because that seems easier than talking to people.* [Female, service user, aged 15 years]

Other perceived benefits included enabling young people to access support without having to ask for it and the opportunity to receive it within their own surroundings where they felt most comfortable.

None of the service users had ever had any web-based therapies recommended to them or been directed to it as part of therapy. They were therefore keen to ensure that young people were aware of its availability and suggested advertising the new program in health care settings and schools and via social media.

Developmentally Appropriate Formatting

The consensus was that 2 versions of the new program were needed. A simpler version was proposed for younger users aged 11-13 years, with more in-depth information presented for older individuals aged 14-16 years.

The service users wanted the new program to be fun, relaxed, and nonpatronizing while being simple, so that young people would not disengage:

> *If an eleven-year-old who is anxious, low mood, stressing out about themselves is answering questions or reading words that they don't understand, it is only going to make it worse for them.* [Female, service user, aged 15 years]

Furthermore, it was highlighted that many young people, especially those with low mood or depression, tend to procrastinate; therefore, the simpler and more focused the new program, the more likely young people would be to use it.

The activities considered most important for inclusion included learning about coping, playing games or puzzles, practicing new skills, and having information about relapse prevention. Several service users had previously used mood monitoring, finding it useful in allowing them to monitor their feelings over time; therefore, this was suggested for inclusion by some users. Additional components identified included information about exercise and other conditions (eg, eating disorders), a chat option so that users could communicate with similar others, useful telephone numbers, and satisfying videos (videos designed to reduce anxiety and aid relaxation). Homework was considered the least important for inclusion, with the requisite that, if included, it had to be minimal to increase adherence and avoid people *getting bored*.

Some users wanted notifications included to remind users to complete sessions and the option to print content. However, these were not favored by all. Some users felt that as long as program content was downloadable, printable content was not required, and it would be easier to keep all information in one place, that is, on the computer. Although some users could see the benefits of notifications, they felt that these needed to be optional, with users controlling how and when to receive them.

To make the program more attractive to users, its interactivity and its availability for completion were considered the most important components, whereas homework and having printable handouts were considered less important.

Although the majority of service users wanted information about depression presented in the new program, several concerns were raised. Some worried that information of this type could make some people feel worse, and therefore, this needed to be optional. Similar concerns were also discussed regarding the recording of activities and moods and watching videos:

> *I know the videos are to show that people have overcome it, but the only other thing I would say is that I remember looking at people and stuff like that and then I'd feel bad because I'd feel like "well they've got it worse than me, so I'm just being dramatic for no reason.*" [Female, service user, aged 16 years]

The service users felt that the program length—both its session number and the time needed to complete them—required flexibility. Although they had made suggestions about this, they felt that more or less time could be spent on the program relative to how users were feeling and how they were progressing through it. Therefore, anyone noticing positive changes and feeling better would cease program use, whereas those who did not would use it for longer. They also proposed that anyone experiencing a relapse should be offered a follow-up session or be able to repeat the new program in its entirety.

Accessibility

The service users felt that through computerized therapy delivery, more young people would be aware of and more likely to access support. They reported that "nowadays everyone has access to the internet" and therefore wanted the new program to be widely available and not restricted to specific locations (eg, GP surgeries or CAMHS sites). This was deemed especially important for those who might struggle to access face-to-face support (eg, those who are too anxious or have transportation issues) and would help to address lengthy waiting lists in CAMHS:

> *The process of getting into CAMHS is like a bit of a pain with waiting lists and then maybe not having enough sessions and getting discharged before you're ready and stuff because the fact that there are so many people that need to use the service, but if it's internet, like, as many people can use it as they need I'm guessing.* [Female, service user, aged 15 years]

Although the service users felt that internet access would not be a problem for most young people, they did however recommend that all program content should be downloadable so that individuals could ensure program access even without an internet connection.

Although some users felt that it should be available to all, others felt that, to monitor risk, only those given access by a clinician should be able to use it. One individual suggested that clinicians

could send program log-in details to anyone they deemed suitable or their parents.

Although variation in the number of sessions was proposed, the consensus was that this should be dependent on the level of support required. Furthermore, some form of follow-up, to review progress and ensure therapy did not simply stop, was regarded as important. There was variation in how this could be incorporated, with some users suggesting a single session after therapy completion to be sufficient and others wanting monthly follow-ups for up to 6 months. One individual suggested making follow-ups optional and aimed at those who might not have processed all of the program content.

The service users felt that the program length needed to consider the attention spans of young people, with most deeming between 30 and 45 minutes per session as sufficient. They felt that young people might *lose focus* if sessions were too long and proposed that larger topics could be covered in multiple sessions to keep session lengths shorter.

Some users felt that weekly sessions with time to practice skills would be appropriate, with concern that users may forget what they had done in a session if longer than a week was left until the next. Others wanted a higher frequency of sessions, with both completing 2 sessions per week and completing sessions on alternate days. It was also suggested that program content should remain accessible following completion so that it could be repeated if needed.

Regulating Parental Involvement

Several service users felt that there should be no parental involvement in the new program with concerns that those not having a close relationship with their parents would not engage with a parent present. Some felt that parental involvement should be decided by the user, whereas one service user felt that parents should be informed if their child was using the program simply to show them that they were using the computer in an appropriate way.

In contrast, parental involvement was regarded positively by some users who felt that the program could be completed more successfully if parents were involved. These individuals described how this could result in parents gaining a better understanding of how their child was feeling and how parents could learn techniques to be able to provide more suitable support:

> *If parents have techniques for the child, they could then show them techniques, you know that could help them, or maybe learn not to maybe act a certain way with them and stuff.* [Male, service user, aged 16 years]

Handouts providing information about low mood or depression and coping techniques were suggested as a way of implementing parental involvement. There were also suggestions about including parents in some sessions with variations, including young people completing sessions together with parents, having parent-only and young person-only sessions completed separately, or combining these approaches with parents attending sessions at various points.

Health Care Professionals

In total, 6 main themes were identified: familiarity and experience of BA and computerized therapies, essential elements required for a successful BA program, developmental considerations and flexibility of the program, depression severity and care pathway positioning, risk monitoring and systemic approach, and collaborative working.

Familiarity and Experience of BA and Computerized Therapies

Most health care professionals were familiar with the components of BA, having used some of them—mainly mood and activity monitoring—in therapy. However, most health care professionals, unaware of the term, did not refer to this as BA. Those who were familiar with BA described how their knowledge of the treatment was derived from an adult model. Therefore, if they had applied BA principles to young people, this was through them adapting their knowledge of BA with adults and creating a bespoke treatment approach.

All health care professionals were familiar with, and valued, the increased use of computerized therapies, with some having referred young people to web-based resources while awaiting face-to-face therapy. Despite this, limitations of the approach were discussed, particularly the lack of therapist presence during therapy delivery:

> *Instilling the hope, the computer cannot instill hope.* [Health care professional, male]

Furthermore, they felt that computerized therapy delivery was not suitable for all, especially in high-risk situations, and expressed concern about what would happen to young people if they felt particularly low following completion of computerized treatment sessions.

Essential Elements Required for a Successful BA Program

Goal setting, activity scheduling, coping skills, mood or activity recording, and monitoring feelings were deemed the most important criteria for inclusion in the new program. Although goal setting was regarded as a *vital* component in assisting therapists to gauge treatment direction, health care professionals also felt it was important for young people to monitor their mood regularly and identify factors affecting it. Most users also wanted to see information about depression, problem solving, and quizzes included. However, there was concern about how components such as goal setting and problem solving could be implemented in a computerized format, given that they are person-centered and individualized approaches. Some users wanted homework to be included, but they stipulated that this needed to be presented under a different name and monitored with reminders sent to support engagement.

To increase inclusivity, health care professionals suggested presenting information in different modes and allowing users to adjust program settings to enhance ease of use. They also wanted users to be able to ask questions about anything they did not understand and have key points revisited in each session to assist understanding.

Developmental Considerations and Flexibility of the Program

It was felt that more than one presentation of the new program, based on developmental level, was needed. There was concern that some young people would not understand particular words and others, especially those with low mood or depression and lacking energy, would struggle if presented with a lot of text. Therefore, breaking words down to aid understanding, using combinations of words and pictures in the program, and embedding an audio option so that content could be read aloud were suggested.

The health care professionals wanted both session frequency and length to be tailored to each user with consideration given to energy levels, depression severity, developmental level, and the number of questions a young person had. One individual, highlighting that those with low moods might have shorter attention spans, proposed basing sessions upon graded exposure. Overall, the consensus was that approximately 8-12 sessions, delivered weekly and lasting between 30 and 45 minutes, would be optimal.

Depression Severity and Care Pathway Positioning

It was felt that those with severe low mood or depression might have difficulties using a computerized program; therefore, it would be most suited to those experiencing mild-to-moderate low mood or depression. Aligning to this, tiers 2 (early help and targeted services) and 3 (specialized services) of CAMHS and step 2 of the children and young people's improving access to psychological therapy stepped care model (low-intensity services) were suggested as areas where the new program would be best placed.

Health care professionals felt that the new program could be positioned anywhere in the care pathway. First, it could be used by young people awaiting treatment, thus reducing the number of subsequent face-to-face appointments and allowing more time to be allocated to those with more severe depression. Another recommendation was for the program to be used alongside usual care, either between or during face-to-face sessions with the therapist present. Particular benefits of this included providing young people with a new medium within their care and providing therapists with an additional tool to monitor progress. Finally, it was proposed that the new program could be offered as a *further treatment* and used before discharge from CAMHS.

Risk Monitoring

Several recommendations were made about how to identify anyone deemed at risk following computerized therapy and how to manage this situation. These included incorporating live chat or crisis numbers into the new program, allowing young people to request a call back from a health care professional if they were feeling at risk and encouraging users to take control and agree to seek additional support if required. To implement this, one health care professional suggested using contracts:

> *You could have it in the contract...so just something that they signed to say that "if you do feel at risk or you feel that you need to talk to someone that you are willing to contact the crisis team and speak to someone," even the Samaritans.* [Health care professional, female]

Systemic Approach and Collaborative Working

Therapeutic alliance was particularly important to health care professionals. They felt that during the treatment process, clinicians were required to instill hope and monitor both progress and deterioration with individual clients, providing support accordingly. They were therefore concerned about the lack of human contact inherent to computerized therapy delivery and, although supportive of the new program, wanted treatment delivery to incorporate a balance between the computer and therapist:

> *I think for me though there is nothing more powerful that the connection between the therapist and the client, you know.* [Health care professional, female]

Health care professionals felt that parental involvement was also essential, particularly regarding risk monitoring, and reported that therapies were often more successful if parents were included. However, they acknowledged that relationships with parents can be difficult, and therefore, parental support within the new program would need to be adapted based on user-parent relationships.

Finally, it was highlighted that, for treatment success, a systemic approach to therapy delivery was required with the cooperation of multiple agencies. They contended that everyone had a role during therapy delivery, and therefore, it was important to be flexible and ensure roles were clearly defined:

> *Everybody has a role to play from the preventative early intervention, the mild end, the moderate end, the severe end so it will be quite clear who does what, when, and how, and then that maxes our public money, so we're not stop starting.* [Health care professional, male]

Through collaboration, it was felt that multilevel monitoring would be in place throughout treatment completion, with young people having a variety of support contacts when required, something especially important if the risk was presumed.

Discussion

Principal Findings

This study allowed vital information to be collected from various perspectives to inform the development of a new computerized BA program for young people. Previous research suggests that differences exist between the views of young people and health care professionals [27,28], with the limited effectiveness of some programs attributed to a failure to tailor interventions to patients and practices [19,20]. Therefore, the views of both young people and health care professionals were collected and incorporated into the development of the new intervention.

The findings from this qualitative work demonstrated that both young people and health care professionals endorsed the use of computerized therapy delivery, and the advantages of the approach were identified. These included enhanced anonymity, treatment accessibility, and awareness; these findings were

concordant with previous research in the area [15,16,18]. Through the focus group and interview discussions and the associated activities completed, the contention that BA may be an acceptable treatment for delivery in this context was supported, as was support for future clinical effectiveness research. When presented with potential content for inclusion in the new intervention, based on techniques commonly delivered within BA, all content was selected by at least one-third of participants in each group. Furthermore, two of the main approaches consistently delivered within the BA, activity scheduling and activity monitoring [30], were selected for inclusion by most participants.

Apart from providing support for the development of a new computerized therapy program based on BA, this qualitative work also provided vital information regarding the presentation, delivery, and content of the new program to ensure that it meets the needs of the target user.

Although there were individual differences across the 3 participant groups, with novel themes emerging from each (Figure 1), agreements were evident about several issues pertaining to the presentation and delivery of the program, which were used to inform its development. For example, all groups felt that more than one presentation was required to suit the target age range, and it was generally felt that program sessions should last approximately 30-45 minutes with appropriate time in between sessions, and all groups wanted the program to be easily accessible.

However, opinions regarding some of the program content were more complex to reconcile, both in incorporating the views of the 3 participant groups where differences were apparent and also being mindful of the need to include evidence-based components of therapy.

Across all groups, concern was expressed about the inclusion of homework, with this component regarded as less important than others. Despite these concerns, research has demonstrated correlations between homework compliance and clinical improvements when delivered within CBT [34]. Including homework in the new program was therefore important, despite being unpopular. To ensure a balance between incorporating evidence-based components within therapy but being sensitive to the opinions of the target users, both were considered. Although they would generally have preferred homework to be omitted from the new program, the participants stipulated that, if included, it required a different name and had to be minimal. Therefore, in the development of the new program, these stipulations guided the inclusion of a homework component.

Discussions also occurred regarding the involvement of others in the completion of a computerized therapy, particularly parents. As reported elsewhere in a systematic review of young people's experiences of using technology-assisted CBT [17], both positive and negative opinions regarding parental involvement were expressed. Although the community sample would have preferred no involvement from others, they agreed that in instances of risk, parents needed to be notified; the service users were generally more positive and identified how treatment effectiveness could be enhanced if parents were involved. In contrast, health care professionals regarded the involvement of others, both parents and health care professionals, as essential, contending that both needed to take an active role in the new program. Research has highlighted that the need for autonomy among young people can be a barrier to seeking mental health support [35]. Therefore, this clearly needs to be addressed in the development of the new program while considering the important perspectives captured within this study. Researchers argue that interventions need to address the autonomous needs of young people to increase their likelihood of seeking help and suggest helping young people to know how and when to seek support from others [35]. Therefore, in the new program, development focus needed to be placed upon supporting help-seeking while remaining sensitive to young people's need for autonomy.

The needs of young people can be better met if there is knowledge about where they seek help when they are distressed [36]. Despite different experiences, the young-person participants expressed concerns related to accessing support, particularly concerning information disclosure and how they would be treated and perceived as a result. They felt that a computerized therapy would allay some of these concerns while allowing them to access therapy at times when most needed and in their own surroundings where they feel most comfortable. Similar findings have been reported in previous research [37,38], which highlights the benefits of adopting a computerized therapy delivery approach in ameliorating some of the barriers faced by young people in accessing services. However, although the health care professionals in this study were familiar with the availability of computerized therapies, few young people were, as none were directed to any resources in the past. This is represented in Figure 1, which shows that although familiarity with computerized therapies emerged as the main theme for health care professionals, this was not the case for young-person participants who instead discussed the requirement of promoting awareness. This demonstrates the need to sufficiently promote the support available to young people.

Similar to previous research [27,28] and as presented in Figure 1, the differences in the experiences, opinions, and priorities across the participant groups in this work highlight the need to incorporate different stakeholders in the development of new therapies. Although it is clear that the opinions of young people need to be considered within their own care, the views of health care professionals also need acknowledgment, as those who participated in this study provided salient information from a clinical perspective. Furthermore, the opinions of those who do not routinely access services but for whom a treatment may be useful need to be considered in therapy design. All young-person participants were from similar age ranges and ethnic groups and lived within relative geographical proximity. Despite this, clear differences in opinion were evident based on whether they had previously accessed support. As discussed, 65% of young people with low mood or depression do not access care [1] because of factors including stigma [3,4], negative attitudes about help-seeking [4], accessibility [3], and reluctance to engage one-to-one with a therapist [5]. Thus, although it is undoubtedly important to tailor treatments to target users [39], the views of those with limited experience of CAMHS also need to be considered.

Therefore, a systemic approach to the development of new interventions needs to be adopted to ensure that they meet the needs of the target user. Such an approach should incorporate the views of those with treatment experience, who are experts on what works and what does not; those who have not accessed treatment, who are the experts on the barriers and how these may be overcome; and health care professionals, who are experts on the practical application of therapy and its integration into services.

Limitations

Owing to several limitations of this study, the results need to be interpreted with caution. To ensure that rich and trustworthy information was collected as part of this study, 3 different participant groups were recruited. Despite this, several factors may have affected the transferability of the findings. As an opt-in method was used, the young-person participants were more likely to be those motivated to engage and thus might not have expressed views demonstrative of the general age range population. Only one service user participant was male, which, although unsurprising with research suggesting that males are less likely to access mental health services [40], meant that the views of males were underrepresented within this sample. Furthermore, although recruitment occurred within 4 NHS trusts, these were all located in close proximity to each other and were culturally similar, with little ethnic diversity in the overall sample. Therefore, the views expressed might not be typical of health care professionals based within the NHS trusts or young people receiving support from other NHS trusts.

Conclusions

Vital information was collected to inform the development of a new computerized therapy. Although similarities in the opinions of the participant groups were evident, differences highlighted the need to adopt a systemic approach in therapy development. In the context of young-person therapy, the opinions of young people with and without experience in accessing mental health support and health care professionals need to be incorporated.

Acknowledgments

This work was supported by the Economic and Social Research Council (grant number: 1500498). The authors would like to thank the young people and health care professionals who participated in this research.

Abstract

Background: Globally, there is an increasing prevalence of excessive screen time exposure among young children, including in Malaysia. Parents are advised to limit this exposure, but there are barriers for many of them to follow this recommendation. To date, there is a lack of research on the factors that cause these parental barriers.

Objective: This study aimed to determine the parental barrier toward the reduction of excessive child screen time and its predictors among parents of children aged younger than 5 years in the Petaling District, Selangor, Malaysia.

Methods: A cross-sectional study was conducted from April 2019 to June 2020 among 789 parent-child dyads attending child health clinics in the Petaling District. Validated self-administered questionnaires were used to capture information on sociodemographic, parental, child-related, and environmental factors and parental barriers. Stratified sampling with probability proportionate to size was employed. Data were analyzed using SPSS Statistics version 25 (IBM Corp). Descriptive analysis and bivariable analysis were performed before multiple linear regression was used to identify predictors of parental barriers.

Results: The overall mean score of parental barriers was 3.51 (SD 0.83), indicating that the average numbers of barriers experienced by parents were more than 3. The multivariable analysis showed that the predictors of parental barriers included monthly household income (adjusted β=–.03, 95% CI –0.05 to –0.02), parents who worked in public sectors (adjusted β=.18, 95% CI 0.06 to 0.29), positive parental attitude on screens (adjusted β=.68, 95% CI 0.58 to 0.79), low parent self-efficacy to influence child's physical activity (adjusted β=–.32, 95% CI –0.43 to –0.20), and child screen time (adjusted β=.04, 95% CI 0.02 to 0.06).

Conclusions: The strongest predictor of parental barriers to reduce excessive child screen time was the positive parental attitude on screen time which could contribute to their abilities to limit child screen time. Thus, future intervention strategies should aim to foster correct parental attitudes toward screen time activities among young children.

Introduction

Screen time refers to the total amount of time a person spends passively on any screen-based technology such as smartphone, tablet, video game, computer, television, or any wearable device [1,2]. The World Health Organization recommends that children aged younger than 2 years should have no access to screen time whereas for those aged 2 to 5 years, sedentary screen time should not exceed 1 hour per day, and less is better [1]. In recent years, the increasing prevalence of excessive screen time among children has become a public health issue of global importance [1,2]. Research studies showed a high percentage of children and youth who exceeded the recommended screen time worldwide [3-5]. For example, a study in the United States reported that on average, children aged 8 months to 8 years were exposed up to 4 hours of background television in a day [6]. Likewise, a study in the United Kingdom reported a high proportion of children aged 6 to 36 months were using screen media, and their screen time increased significantly with age [7]. In addition, studies from two developed countries in Asia (ie, Singapore and Japan) also reported that children aged younger than 5 years were exposed to both television and other devices an average of 4 hours per day [8,9]. Locally, two Malaysian surveys found that 27% to 52% of children aged younger than 6 years were exposed to television and other devices (computers, tablets, and smartphones) for more than 2 hours per day [10,11]. Furthermore, about 68% of older Malaysian children (aged 7 to 12 years) spent an average of 3 hours on screen time daily [12]. Even more worrying is the fact that as high as 74% of Malaysian children aged younger than 2 years have been exposed to screen time, in contrast to the World Health Organization recommendation [11].

Multiple studies have highlighted the undesirable effects of excessive screen time on the developmental, psychosocial, and physical health of children. Among these negative effects were visual symptoms after prolonged screen use [13]; speech delay; and unfavorable development of physical, cognitive, and academic abilities of children [14-18]. Moreover, studies also report increased body fat and obesity as a result of increased food consumption and exposure to unhealthy food advertisements during screen viewing [19]. In view of these adverse effects, parents were advised to limit the screen time of their children based on the appropriate duration recommended for the child's age [1,2].

During childhood and adolescence periods, parents play a crucial role in preventing the development of sedentary behavior [20]. Several studies have demonstrated the role of parental influences on a child's screen time behavior [21,22]. However, it was also reported that parents could be facing various barriers in the efforts to reduce excessive child screen time [23-26]. Among these barriers were the lack of affordable alternative activities and poor accessibility to them secondary to weather conditions and transportation issues [23,24,26]. Additionally, parental issues such as parental fatigue, time constraints, and a desire to have time away from children to complete personal tasks also hinder the participation of children in physical activities [24,25,27]. Available studies suggested it is vital to identify such barriers experienced by parents for the establishment of effective intervention in promoting healthy behaviors among children [28]. However, a limited number of studies report on factors associated with parental barriers to reduce a child's screen time in Malaysia. This study aimed to investigate parental barriers toward the reduction of a child's screen time and relevant predictors from the aspect of sociodemographic, parental, child-related, and environmental factors among parents of children aged younger than 5 years who attended child health clinics in the Petaling District, Selangor, Malaysia.

Methods

Study Design and Location

A cross-sectional study was conducted in 9 health clinics located in the Petaling District from April 2019 to June 2020. This study was conducted in health clinics because all government health clinics in Malaysia offer free child health services such as health screening, developmental and nutritional status assessment, immunizations, and dental health services that are accessible for all local citizens [29,30]. Due to this fact, Malaysian parents, especially those of middle and lower income groups, predominantly used these health clinics. Petaling District was selected as the study site was because it is the most populated district in Selangor, Malaysia, with a high number of young children [31]. Petaling District is urbanized with one of the highest median household incomes [32].

Study Participants

The study population was Malaysian parents of children aged younger than 5 years attending the child health clinics in the Petaling District. Parents who were illiterate or whose children had physical or mental disabilities or chronic diseases such as heart disease and asthma were excluded. These exclusion criteria ensured that we recruited parents with healthy children whose access to screen media was not influenced by their health condition.

Sample Size and Sampling Method

The sample size was calculated using the correlation coefficient formula based on the inputs from a previous study of a similar topic [33]. Based on a 95% confidence level, 80% power, and 20% nonresponse rate, a minimum sample size of 737 participants were required. To achieve the sample size, stratified sampling with probability proportionate to sample size was adopted. The sample size for the parent-child dyad in each clinic was made to be proportionate to the average number of children attending the 9 child health clinics in the Petaling District in 2017, totaling approximately 7270. We used the attendance record from each clinic as the sampling frame, and each respondent was selected using a systematic sampling method whereby the k interval obtained was 14. The first parent-child dyad (a parent attending the clinic with a child aged younger than 5 years) was selected using a random number generator that gave all respondents an equal chance of being chosen. By repeating the same method in each clinic, a total of 789 participants were recruited for the study.

Study Instruments

The study employed a validated study instrument adapted from various studies with a good to excellent level of 1-week test-retest reliability (intraclass correlation coefficient 0.64-0.98). The original English version of the questionnaire consisted of 8 sections and was translated into the Malay language by experts from the Editing and Translation Service, Centre for the Advancement of Language Competence, at University Putra Malaysia. See Multimedia Appendix 1 for questionnaire.

Sociodemographic Factors

Information regarding age, gender, ethnicity, education level, household income, employment status, and marital status of respondents was collected. The household income in Malaysia is categorized into 3 income groups based on the median monthly household income reported by Department of Statistics Malaysia: namely, the upper 20% (T20), the middle 40% (M40), and the lower 40% (B40) [32]. These income group definitions are not fixed depending on the Malaysia's gross domestic product.

Parental Factors

Parental attitude toward screen time was evaluated based on parent opinions of statements related to screen time benefits. The scores were then categorized [34,35], and parents who scored above 32 were rated as having a positive attitude. Next, parent perceptions were evaluated regarding the influence of screen time on their child's physical, cognitive, and social well-being [36]. Higher scores represent a greater perception of positive influence of screen time toward the specific aspect of well-being. In addition, the parent's self-efficacy in influencing the child's physical activity reflected the confidence level of the parent in situations related to a child's physical activity. This variable was classified into 3 groups based on the percentile of the score [26].

Last, parenting style was categorized into 4 groups according to the median split in the Baumrind classification of parent involvement and strictness toward their child [37]. Parental restrictive practices on screen time were assessed based on their sedentary-related restrictive practices in which higher scores reflected more restrictive practices [38]. Parental screen time was defined as the average number of hours a parent spent on television, computers, cell phones, and other electronic devices for leisure purposes excluding work or school use during weekdays and weekends.

Child-Related Factors

Data on sociodemographic characteristics (age, gender, and numbers of siblings) of the child were obtained from the parents. The child's screen time was taken as the average time spent by the child on each media device per weekday and weekend [8]. Child care settings were categorized into home care by parents, home care by other than parents, and childcare center [39].

Environmental Factors

Environmental factors refer to the conditions of both the household and neighborhood. Questions on the household environment captured information on the number and type of screen devices in the home including those in the child's bedroom,, and outdoor play equipment at home. Questions on the neighborhood environment asked about the availability of physical activity facilities in the public areas and perceived safety with regard to the likelihood of criminal activities [40].

Parental Barriers to Reduce Excessive Child Screen Time

The outcome of this study was assessed based on 6 statements [34]: (1) there is pressure from society to purchase and use media-related equipment, (2) my neighborhood is not safe for my child to play outdoors, (3) poor weather limits my child's opportunities to go outside, (4) I need a coping tool to meet the demands of a busy day at work or raising multiple children, (5) I need time to do household chores, and (6) my child really enjoys screen time activities. All items were rated on a 5-point Likert scale ranging from strongly disagree to strongly agree. The mean scores of the responses represented an overall score with regard to parental barriers. The maximum score was 6, with higher scores indicated that parents were facing more barriers.

Data Collection

A validated self-administered questionnaire was distributed to all respondents. Selected parents were approached during their visits to the child health clinics in the Petaling District.

Statistical Analysis

Data entry and analysis were performed using SPSS Statistics version 25.0 (IBM Corp). Prior to the analysis, data cleaning was done. Skewness, kurtosis, and histogram were part of the normality testing conducted on continuous data. Following that, descriptive analysis was performed for all variables. Categorical data were described in frequency and percentage, whereas continuous data were shown in mean and standard deviation or median and interquartile range depending on normality test results.

In the next step, bivariable analysis was performed using simple linear regression to determine the association between parental barriers in reducing excessive child screen time and all independent variables. Dummy variables were created for all categorical variables prior to bivariable analysis. Based on the findings from simple linear regression, any variables with $P<.25$ were included in the subsequent multiple linear regression analysis to identify the predictors of parental barriers in reducing excessive child screen time [41]. All variables in the model were tested for interaction and multicollinearity to fulfill the assumption for multiple linear regression analysis. Final findings were presented as adjusted β with 95% confidence intervals with the level of significance set at $P<.05$.

Ethics

Ethical approval was obtained from the medical research and ethics committee of the Ministry of Health Malaysia (NMRR-19-41-45681 [Investigator-Initiated Research]). All participants provided written informed consent. They were notified that their information would be kept confidential and they could withdraw from the study at any time.

Results

Sociodemographic Characteristics of Participants

The majority of the 789 participants were women (662/789, 83.9%), Malays (684/789, 86.7%), and married (781/789, 99.0%). The mean age of the respondents was 31.6 (SD 4.81) years, and 70.6% (557/789) had tertiary education. The median income of parents in this study was MYR 5000 (interquartile range 3000); half (403/789, 51.1%) of the parents belonged to the B40 income group based on the categorization of the Malaysia household income groups [32]. Among the 77.7% (613/789) of parents who were employed, the proportion of parents working in the private and public sectors was similar (Table 1).

Parental Barriers to Reduce Excessive Child Screen Time

The mean score of each barrier reported by parents toward the reduction of excessive screen time as outlined in Table 2 was 3.51 (SD 0.83), and a higher mean score represented a more commonly encountered barrier among the parents. Most parents attributed the need to spend time on household chores, unpredictable weather, and lack of a safe neighborhood that restricted outdoor play as barriers for them to limit screen time exposure in their children. Table 2 shows the distribution of the

different barriers experienced by parents in the efforts to reduce screen time among children.

Table 2. Distribution of parental barriers to reduce excessive child screen time (n=789).

Bivariable Analysis of Parental Barriers to Reduce Excessive Child Screen Time

Table 3 shows all the factors studied that were significantly associated with parental barriers including sociodemographic, parental, child-related, and environmental factors. For sociodemographic factors, parents of Malay (β=–.29, 95% CI –0.56 to –0.01; *P*=.04), Chinese (β=–.49, 95% CI –0.88 to –0.09; *P*=.02), and Indian (β=–.40, 95% CI –0.78 to –0.02; *P*=.04) ethnicity; combined monthly household income (β=–.04, 95% CI –0.06 to –0.02, *P*<.001), and employment status in terms of parents who worked in the public sector (β=.16, 95% CI 0.00 to 0.32, *P*=.045) or were unemployed/housewife (β=.18, 95% CI 0.01 to 0.34, *P*=.04) were among the factors that were significantly associated with parental barriers.

Parental factors found to be positively associated with parental barriers included parental attitude on child screen time (β=.78, 95% CI 0.66 to 0.89; *P*<.001), perception on the influence of screen time on cognitive well-being (β=.04, 95% CI 0.02 to 0.06; *P*=.001) and social well-being (β=.05, 95% CI 0.02 to 0.08; *P*=.001), as well as parental screen time (β=.18, 95% CI 0.06 to 0.31; *P*=.003). On the contrary, a neglectful type of parenting style (β=.15, 95% CI 0.01 to 0.28; *P*=.03) and low self-efficacy to influence child's physical activity (β=–.43 95% CI –0.58 to –0.28; *P*<.001) were negatively associated with parental barriers.

In addition, 3 of the 5 child-related factors were significantly associated with parental barriers in reducing a child's screen time. The significant factors included number of children (β=.18, 95% CI 0.06 to 0.30; *P*=.003), child's age (β=.01, 95% CI 0.00 to 0.01; *P*=.001), and child's screen time (β=.07, 95% CI 0.05 to 0.09; *P*<.001).

Environmental factors significantly associated with parental barriers included the presence of screen devices in child's bedroom (β=–.19, 95% CI –0.35 to –0.03; *P*=.02) and parental perceived safety related to crime (β=.27, 95% CI 0.21 to 0.34; *P*<.001).

Predictors of Parental Barriers to Reduce Excessive Child Screen Time

A total of 16 factors with $P<.25$ in the simple linear regression were included in the preliminary model. One of the factors, parental perception of safety related to crime, was removed from the model due to its interaction with 2 other factors (public sector employment and monthly household income). The remaining 15 variables showed no multicollinearity and interaction. Hence, all assumptions for multiple linear regression were fulfilled. Forward variable selection method was applied in the final model. The model fits reasonably well with adjusted $R^2=.26$ and F test<0.001.

Table 4 shows that among parents of children aged younger than 5 years, those with low monthly household income encountered more barriers in the efforts to reduce their child's screen time (adjusted β=–.03, 95% CI –0.05 to –0.02). Furthermore, parents who worked in the public sector were more likely to have a higher parental barrier score when

compared with those in the private sector (adjusted β=.18, 95% CI 0.06 to –0.29). Moreover, parents with a positive attitude toward child screen time recorded a higher score of parental barriers than those with a negative attitude (adjusted β=.68, 95% CI 0.58 to 0.79). Parents with low self-efficacy to influence their child's physical activity also displayed a higher parental barrier score as compared with their counterparts (adjusted β=–.32, 95% CI –0.43 to –0.20). Last, parents whose children spent more hours on screen were expected to face more barriers in the efforts to reduce excessive child screen time (adjusted β=.04, 95% CI 0.02 to 0.06).

Discussion

Principal Findings

The majority of parents who participated in this study were Malay, females, and married. More than half of them were aged older than 30 years. This finding highlighted the fact that mothers frequently dealt with all matters related to a child's health, including routine clinic appointments [42]. Moreover, a profile of the respondents also reflected most Malaysian adults, who married in their mid to late 20s [43] and would only bear a child after that age. The high numbers of Malay respondents mirrored the attendees of primary health care facilities in Malaysia, who were mostly Malays with less than one-third being Chinese and Indians [44]. Even though most parents in this study attained preuniversity and higher levels of education, the majority of them belonged to the B40 or M40 group. Furthermore, two-thirds of parents were employed, and the number of parents who worked in the private and public sectors was nearly equivalent. The remaining 22% was self-employed. This finding showed that adults living in urban areas such as the Petaling District have access to various employment sectors in Malaysia.

To the best of our knowledge, no previous studies in Malaysia have reported the barriers experienced by parents in limiting screen time among children aged younger than 5 years. From the analysis, most of the parents experienced an average of more than 3 barriers. This differed significantly from the findings of Jarvis and colleagues [45], whereby parents experienced only one type of barrier. The differences could be due to the different types of barriers presented to the respondents in the studies. Jarvis et al [45] explored barriers that were self-reported by parents through open-ended questions, whereas specific barriers were presented in a self-administered questionnaire to parents in this study. Common barriers encountered by parents in this study (ie, time needed for household chores, weather factor, and coping tools to meet the demand of a busy day) were consistent with previous research findings [23,24,27]. We have found it is a common occurrence among current generations of modern parents to provide screen devices to their young ones as an easy way out [27,46].

In this study, the strongest predictor for parental barriers was the parents' positive attitude on child screen time. A previous study showed that parents' positive attitude toward screen behavior could contribute to internal conflict and thus reduce their abilities to limit child screen time [47]. A similar finding was noted in this study. When parents displayed supportive behavior toward screen time and perceived screen time to be beneficial to their child or themselves, it became a barrier for them to place the necessary restriction on screen time activity. This is not surprising because parents' attitudes toward technology use cast a big influence on how they perceive and value screen time at home [48]. Therefore, our study findings suggested that parents with a more positive attitude toward screen behavior could be subconsciously establishing a home environment that facilitated screen-based activities for their children. Subsequently, this might become a routine habit, leading to early overexposure of children to screen time [5,49]. Eventually, parents would face an uphill battle with the worsening level of barriers toward the reduction of excessive screen time in their children [23].

Furthermore, our study reported that parents with low self-efficacy to influence child's physical activity encountered more barriers to reduce child screen time when compared with parents with high self-efficacy, as highlighted in a previous study [50]. Parents with low confidence to motivate children in engaging in physical activity might also be less likely to initiate screen time reduction in children. In other words, it would not be convincing for the children to follow the restriction if the parents failed to be the role models in supporting healthy behavior among the children [51].

Apart from that, monthly household income was also a predictor of parental barriers in our study. Parents were likely to have an 0.03 increase in the score of the parental barrier for every 1000 MYR decrement in monthly household income. Lower family income could be linked to certain cost issues and, subsequently, restrict access to healthier choices and substitute activities for screen time, thus constituting a common barrier to support healthy behavior [23,25]. In other words, this could explain why lower income families encounter more barriers: they lack the resources to substitute screen-based activities with other activities as compared with higher income families that can afford to provide alternative activities and facilities for their children to substitute screen time [52,53].

Besides family income, parents' employment status was another determinant of parental barriers toward the support of active lifestyles in children, based on a systematic review [23]. Our findings were similar in which working parents encountered more barriers to reduce excessive screen time. However, the difference in the challenges encountered by parents working in the public and private sectors needs to be explored further. A recent study showed that workers in the Malaysian public sector frequently experienced work-life conflict as they had difficulty in coping with the pressures of integrating their work and personal lives as a result of the long and inconsistent working hours [54]. This could in turn lead to parenting stress that acts as a potential parental barrier in the reduction of screen time exposure in children [45,55].

Last, previous studies have reported that children's screen times rose substantially when more barriers were reported by parents [26,34]. This was echoed by our results that demonstrated child screen time as a predictor of parental barriers in the reduction of screen time. The potential reason behind this could be the addictive nature of screen behavior that was integrated into every day routine, thus making it extremely difficult to minimize children's time spent on screen [5,56].

Limitations and Strengths

To the best of our knowledge, this is among the first quantitative studies in the local setting that tried to determine parental barriers toward the reduction of screen time in children. The data were collected with a self-administered validated questionnaire using the probability sampling method and examined the association between a dependent variable with many factors. However, this study is not without limitations. Potential recall bias could have occurred during data collection as many factors were only evaluated from the perspective of a single respondent. Furthermore, the samples were only recruited among parents attending the child health clinics in one district. Thus, the study findings should be interpreted with caution in view of the limited generalizability to other populations.

Future Direction

To overcome barriers encountered by parents, it is essential to enhance parental awareness by providing valuable information through a well-designed health education program. These efforts can help parents overcome the challenges and difficulties of screen time restriction. Health education should consist of information on the recommended screen time behavior for young children. Apart from that, the program should also aim to establish the correct parental attitude on the children's screen time behavior and provide the relevant skills to improve parental self-efficacy in supporting screen time reduction in children. Importantly, the health education program should target families with low income and parents working in the public sector. Future studies should consider intervention research that pinpoints effective strategies for targeted parental barriers.

Conclusion

In summary, this study identified 5 predictors of parental barriers to reducing excessive screen time among children, the strongest one being the positive parental attitude toward child screen time. The majority of parents with children aged younger than 5 years experienced more than 3 barriers in their efforts to reduce screen time.

Acknowledgments

We would like to thank the Director General of Health Malaysia for his permission to publish this article. We also want to acknowledge the Petaling District Health Office and all the participating health clinics under them as well as parents who participated in this study for their extraordinary cooperation and support especially during data collection. Our research has been funded by grant GP-IPM/2018/9640700 from Inisiatif Putra Muda, University Putra Malaysia. However, the execution of this research is the sole responsibility of the authors, and the content of this manuscript does not reflect the official views of the funder.

Authors' Contributions

EM was the principal researcher responsible for the study design and performing the data analysis. DR contributed to the design of this study and the collection of data. NA, NAMZ, and ZMS supervised the execution of this study and contributed to the study design. NA guided, advised, and supervised the analyses and edited the manuscript. All authors were involved in writing and authorized the submitted and published version of this manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Effective help for depression and anxiety reaches a small proportion of people who might benefit from it. The scale of the problem suggests the need for effective, safe web-based public health services delivered directly to the public. One model, the Big White Wall (BWW), offers peer support at low cost. As these interventions are delivered digitally, we tested whether a randomized controlled trial (RCT) intervention could also be fully delivered and evaluated digitally.

Objective: This study aims to determine the reach, feasibility, acceptability, baseline costs, and outcomes of a public health campaign for an automated RCT of the BWW, providing digital peer support and information, compared with a standard website used by the National Health Service Moodzone (MZ), to people with probable mild-to-moderate depression and anxiety disorder. The primary outcome was the change in self-rated well-being at 6 weeks, measured using the Warwick-Edinburgh Mental Well-Being Scale.

Methods: An 18-month campaign was conducted across Nottinghamshire, the United Kingdom (target population 914,000) to advertise the trial directly to the public through general marketing, web-based and social media sources, health services, other public services, and third-sector groups. The population reach of this campaign was examined by the number of people accessing the study website and self-registering to the study. A pragmatic, parallel-group, single-blind RCT was then conducted using a fully automated trial website in which eligible participants were randomized to receive either 6 months of access to BWW or signposted to MZ. Those eligible for participation were aged >16 years with probable mild-to-moderate depression or anxiety disorders.

Results: Of 6483 visitors to the study website, 1510 (23.29%) were eligible. Overall, 790 of 1510 (52.32%) visitors participated. Of 790 visitors, 397 (50.3%) were randomized to BWW and 393 (49.7%) to MZ. Their mean age was 38 (SD 13.8) years, 81.0% (640/790) were female, 93.4% (738/790) were White, and 47.4% (271/572) had no contact with health services in the previous 3 months. We estimated 3-month productivity losses of £1001.01 (95% CI 868.75-1133.27; US $1380.79; 95% CI 1198.35-1563.23) per person for those employed. Only 16.6% (131/790) participants completed the primary outcome assessment. There were no differences in the primary or secondary outcomes between the 2 groups.

Conclusions: Most participants reached and those eligible for this trial of digital interventions were White women not in recent contact with health services and whose productivity losses represent a significant annual societal burden. A fully automated RCT recruiting directly from the public failed to recruit and retain sufficient participants to test the clinical effectiveness of this digital intervention, primarily because it did not personally engage participants and explain how these unfamiliar interventions might benefit them.

Introduction

Background

Depression and anxiety are, respectively, the first and sixth leading causes of years lived with disability globally among all health problems [1]. In the United Kingdom in 2014, 15% of the general population of adults aged >18 years had depression or anxiety, but only 1 in 3 sought help for these conditions in the preceding 12-month period [2]. In principle, the internet backed by a public health campaign might be a useful platform for reaching people with depression or anxiety who do not or are unable to access face-to-face health care. However, the use of the internet as a potential therapeutic platform raises a series of important concerns about data safety and privacy, effectiveness, user experience and adherence, exclusion of people without access to the internet, and data integration with care [3,4]. It is important to establish who might be reached by such an approach, whether they are already accessing mental health or general health services, and which recruitment approaches and interventions are most effective [5].

In this study, we explored the reach of a recruitment strategy for internet-based therapy directed at the public in one English county (Nottinghamshire, estimated population size of 914,000; aged >16 years in 2017, with 145,000 people with case-level depression and anxiety [6,7]). We used traditional and internet media and contacts through health, social care, and third-sector organizations for a randomized controlled trial (RCT) of 2 well-established digital services: the Big White Wall (BWW, now known as Togetherall) and Moodzone (MZ). BWW [8] offers (1) web-based assessment to assess common mental health problems and comorbid physical conditions; (2) moderated web-based peer support network: a community of peers, professionally staffed at all times, enabling safe support where individuals can choose if they wish to remain anonymous; and (3) guided support: a range of self-managed and facilitated programs for depression and anxiety based on cognitive behavioral therapy and social support principles. It was founded by a service user because existing services did not provide support when it was needed and was first developed as a collaboration among service users, digital experts, and a National Health Service (NHS) organization providing mental health services in London. Although BWW is widely available in many parts of England, there was little uptake of this intervention in Nottinghamshire before 2017. In England, the NHS provides its own free website with general information and contact details of local and national resources to help people with common mental health problems. It is known as NHS Mental Health and Well-being, previously called NHS Choices Moodzone [9].

To date, BWW and other web-based peer support for depression or anxiety have only been evaluated in RCTs conducted through primary or specialist mental health services rather than directly to the public [10-13]. There is uncertainty about how to conduct fully automated RCTs of digital mental health interventions directly targeted at the public [14]. In principle, fully automated RCTs without human contact are less prone to bias and can better elucidate actual treatment effects attributable to the digital intervention than those conducted with human conduct, where human contact may contribute to part of the treatment effect [15]. They can also be relatively inexpensive to run on a large scale [16]. However, it is unclear if and under what circumstances they would be feasible or acceptable to participants [17]. Automated trials have sometimes failed to engage some populations [18,19], whereas others offering otherwise difficult to obtain structured psychological treatments have been more successful [20-22].

Objectives

This study has two main aims: (1) to investigate the reach, feasibility, and acceptability of a public health recruitment campaign using general media, digital media, health, third sector, and social services for a trial in people with probable mild-to-moderate depression or anxiety and (2) to test the feasibility, acceptability, baseline costs to society, and outcomes of conducting a fully automated RCT of 2 established digital

interventions providing moderated web-based peer support and information (BWW) versus web-based information only (MZ).

Methods

Design

The Lived Experience Advisory Panel (LEAP) of patients and public representatives with personal experience of depression and anxiety that was formed for the study advised us on the best approaches to recruit people with depression and anxiety in the community. They recommended using the terms *low in mood* for depression and *stressed* for anxiety. We ran a public health campaign using these terms and offered the opportunity to take part in a study free of charge by comparing an information-giving website (MZ), which is a standard designed with and used within the NHS in the United Kingdom, with a web-based peer support site (BWW). We used a mix of traditional health research recruitment strategies, such as general practitioner (GP) endorsement, outpatient clinics, and support groups, as well as less traditional advertising, such as on buses and trams and via letter box leafleting. Special efforts were made to reach groups regarded as higher risk and harder to reach, such as the farming community. Reach was defined as the absolute number, proportion, and representativeness of individuals willing to participate in a given initiative [23].

The second stage of the study was a single-blind RCT using a fully automated bespoke study website. A member of the public could participate in the trial as they might do with other web-based applications, including consenting to the trial and all decision making, only seeking technical support if and when they need it. Full details are available in the published protocol [24]. Eligible participants self-referred and were recruited through the study website following a public health campaign. Consenting participants were randomly allocated to receive either 6 months of free access to BWW or signposted to the NHS MZ website.

Ethical approval was granted by the Local Research Ethics Committee (REC 16/EM/0204), and the final approval was received from the UK Health Research Authority.

Public Health Campaign

The research team worked closely with a research delivery and support service (the National Institute of Health Research [NIHR] Clinical Research Network East Midlands), a professional marketing business (The Dairy), the study LEAP (18 people aged 25-65 years, 12 females), and the web developer (Ayup). The aim was to establish a brand for the study that was considered by the LEAP and study team to appeal to people who may be affected by low mood and/or stress in line with marketing materials but that would also instill professionalism and confidence with respect to the research project.

Trifold leaflets (Figure S1 in Multimedia Appendix 1), posters, bus and tram adverts, and business cards with quick response codes were subsequently developed, and a marketing plan for distribution and dissemination across Nottinghamshire was created for the duration of the study. We targeted tram routes across central Nottingham and bus routes that were purposefully targeted at the more deprived regions of the county. We took out newspaper and magazine advertisements and also spoke on local radio programs dedicated to health matters. We used a digital marketing agency (Nativve) to develop and implement a targeted local Facebook campaign and employed other social media, such as Twitter, to disseminate the study through appropriate networks.

In addition to the blanket approach that was adopted for the general public, the recruitment team also targeted particular groups, such as those in areas of greater deprivation, through door drops. Other targeted approaches involved asking organizations and health professionals to hand out leaflets or spread the word to their community to patients in their preferred method. For example, health visitors were asked to hand out leaflets to young parents, and Black and minority ethnic (BAME) groups were targeted through a third-sector organization, Awaaz. Places where the internet was accessed for free, such as self-help, third-sector groups, and local authority-funded libraries, were also asked to host leaflets and posters as well as to add these materials to their self-help sections.

Presentations were made by members of the research team to a range of GPs and primary care staff to raise awareness of the study across the county. These presentations were complemented by posters, cards, and leaflets that were displayed in every primary care waiting room in Nottinghamshire. Community pharmacists were targeted through their health promotion work and asked to promote the study through displaying the leaflets and posters, and when they considered it appropriate, verbally informing people who might be collecting medication for their mental health that a trial was being conducted. We targeted other health and social care workers, including educational establishments, such as universities, further education colleges, and those in contact with socially isolated groups, for example, social workers, health visitors, or those who work with mental health problems such as the Improving Access to Psychological Treatment program providing psychological treatments for depression and anxiety, private counselors and wellness in mind, and an NHS-funded public mental health signposting service.

Sample and Eligibility

Potential participants from the county of Nottinghamshire self-referred to the study, and their eligibility was assessed by an automated digital program on the study website. The study website requested the GP's contact details when the person was ineligible for the study.

Inclusion criteria were as follows: patients (1) aged ≥16 years; (2) reside in the county of Nottinghamshire; (3) scored between 10 and 20 on the 9-item Patient Health Questionnaire (PHQ-9) [25] or 10 or more on the 7-item Generalized Anxiety Disorder questionnaire (GAD-7) [26], indicating probable caseness for depression and anxiety, respectively, but not a definite diagnosis of depression or anxiety disorder; (4) had access to the internet through a computer, tablet, or smartphone (Windows, iOS, or Android) device and email address; and (5) were able and willing to give informed consent (through electronic consent).

Exclusion criteria were as follows: patients (1) scored ≥21 on the PHQ-9 (severe depression); (2) scored 2 or 3 on PHQ-9 item

"thoughts that you would be better off dead or of hurting yourself in some way"; and (3) scored ≤10 on PHQ-9 and GAD-7.

BWW and MZ are only available in the English language. Therefore, the website recommended nonparticipation for those who believed they were insufficiently proficient in the use of the English language. There was no test of proficiency in English or information technology literacy.

Participants were ineligible for the trial because they scored in the severe range on the PHQ-9 or scored 2 or 3 on the suicide item of the PHQ-9. In line with other digital studies [27], a national research committee did not allow us to recruit these potential participants because, in their opinion, research into people with severe depression requires a greater duty of care than could be offered over the internet. These excluded participants were provided with an opportunity to request that the study team inform their GP, mental health care team, or caregiver of their current mood state. If the request was not completed, the study team followed up via email, asking if they would like the team to inform their GP or care team. We followed up the excluded participants on one occasion.

Information on the participants and the associated consent forms were provided electronically within the study website. Participants who wished to discuss the study could email and telephone the study team if they had any further questions before consenting to the study. An email confirming consent was sent to each participant once they had fully enrolled.

Interventions

Randomization: Arm 1—BWW

Participants allocated to receive 6 months of free access to the BWW website [8] were invited to create a user profile using a pseudonym that was linked to the trial identification to which they had been assigned within the study website. They had to create a profile within 14 days of being randomized. Participants were able to access any part of the BWW site (apart from the option of personalized therapy or counseling sessions that have to be prescribed by a clinician, that is, not offered directly to the general public) and interact with other users within the boundaries of the site's house rules. Anonymized records of log-ins, time on site, interactions, and page categories were recorded by BWW on behalf of the study team.

Randomization: Arm 2—Participants Allocated to MZ

Participants were directed to the MZ area of the NHS Choices website [9]. Participants were able to access all available materials on mental health, including depression and anxiety. We did not have records of time on site or use of the site. NHS MZ access was used as the control digital resource, so all participants were offered some help for their problems with depression or anxiety, but this control group did not have access to moderated, anonymized peer social support.

Outcome Measures

Once consented, participants were asked to complete self-rated questionnaires to measure well-being, depression, anxiety, work and social adjustment, receipt of services (for economic analysis), social support, and personality dysfunction at baseline. These were completed on the web (though the study website) for approximately 20 to 30 minutes. All data were stored on the website and downloaded and anonymized by the clinical trial manager.

Participation in the study lasted for 6 months. Participants received electronic follow-up invitations at 3, 6, 12, and 26 weeks after randomization to be completed on the website. Each participant was reminded to log onto the study website and complete follow-up measures by email 24 hours before each follow-up and at the follow-up time point. If follow-up was not completed, they received another reminder 48 hours later. Participants were emailed motivational statements encouraging follow-up as well as the offer of entry into a prize draw at the end of the study if they completed at least the primary outcome measure in all follow-up assessments. There were no other attempts to follow up participants using any form of digital, telephone, or face-to-face contact.

Primary Outcome Measure

The primary outcome measure is change in self-rated well-being from baseline to 6 weeks after baseline using the 14-item Warwick-Edinburgh Mental Well-being Scale (WEMWBS) [28].

Secondary Outcomes Measures

The secondary outcome measures are as follows:

- Well-being was measured at 3, 12, and 26 weeks using the WEMWBS.
- The GAD-7 [25] was completed as part of eligibility at baseline and at 3, 6, 12, and 26 weeks, as a measure of anxiety severity.
- The PHQ-9 [26] was completed as part of eligibility at baseline and at 3, 6, 12, and 26 weeks, as a measure of depression severity.
- Social function on the 8-item Work and Social Adjustment Scale [29], a measure of function, was completed at baseline and at 3, 6, 12, and 26 weeks.

Baseline Measures

At baseline, basic sociodemographic characteristics were collected along with measures of health and social care resource use over the 3 months before study entry [30], social support [31], life events over the previous 3 months [32], and personality dysfunction [33].

Modifications to the Original Protocol Conducted in Real Time Based on Participant Feedback

Feedback left by the first 50 participants suggested that they disliked the intrusiveness and length of some of the measures and assessments at baseline. One participant withdrew from the study for this reason. Therefore, compared with our protocol [24], we omitted the 12-item medical outcomes study short-form health survey version 2.0 (SF-12) [34] at all time points and only carried out the economic resource proforma [31] at baseline. At baseline, the number of questions asked fell from 92 to 80 and at each follow-up time point from 50 to 38.

Sample Size

The sample size calculation and justification is outlined in detail in our protocol paper [24]. A total of 676 patients were needed to detect a 3-point (SD 12), minimal clinically important difference for adults on the 14-item WEMWBS [35] at a significance level of .05 with 90% power. After adjusting for a 50% attrition rate at 6 weeks [36], a total of 1352 participants were required for our RCT.

Randomization and Monitoring

The treatment to which a participant was assigned was determined by a computer-generated pseudorandom code using random permuted blocks of varying sizes by a randomization system embedded within the website. No stratification or minimization was performed. Treatment assignment was relayed by the computer program to the participant and opened to the trial manager (CK) who monitored recruitment, data completion, and technical problems with the website.

Statistical Analysis

Feasibility and acceptability was assessed by recruitment and retention during follow-up using descriptive statistics. All analyses were performed on an intention-to-treat basis by a trial statistician blinded to treatment allocation using STATA 16 (StataCorp LLC). As all outcome scores were repeatedly measured at baseline and at 3, 6, 12, and 26 weeks, multilevel modeling was performed to quantify the treatment effect with participants as a level 2 unit and baseline, treatment arm, follow-up time, and interaction of arm×time as a covariate. Missing outcome values were investigated and imputed for all outcomes under the missing at random assumption with 100 data sets imputed for data analysis. REALCOME and STATA 16 were used to impute missingness. Similar models were conducted on observed values to check the robustness of the treatment effect estimates sensitive to the influence of missingness.

Health Economics

We electronically administered the Client Service Receipt Inventory [30] to participants at baseline, which collected data on NHS service use and other costing variables [37-44]. Owing to the inherent comorbidity of mental and physical health, these questions pertained to all service use and all health-related absenteeism in place of condition-attributable service use, as we wished to capture possible changes in service use and service-seeking behaviors. The withdrawal of the SF-12 instrument meant that we were unable to examine the health state utilities associated with mild-to-moderate depressive episodes and anxiety disorders.

The costs of health-related time taken off work (absenteeism) were estimated using the lost wages approach [45]. We adopted a median team multiplier, as although wages are a suitable estimate of marginal productivity losses to businesses, this measure tends to be an underestimation for individuals working in team environments [46]. We assigned population-level gross weekly salaries to individuals by full-time or part-time employment status and gender. We designated participants as part time if they were employed or self-employed and worked less than 30 hours per week and as full time if they were employed or self-employed and worked for more than 30 hours. We note that this does not attribute any value to health-related presenteeism or those who are unemployed owing to ill health.

The prevalence of mild-to-moderate depression and anxiety was derived using the Adult Psychiatric Morbidity Survey [42] by combining the severity of symptoms of common mental disorders, where a score between 12 and 17 represents a diagnosable mild-to-moderate condition, with common mental disorder in the past week using the Clinical Interview Schedule Revised score. We extrapolated productivity losses using disease prevalence by gender to control for observed self-selection and the number of individuals between 18 and 64 years of age active in the labor market (employed or self-employed) in the United Kingdom. Our estimates of direct-to-NHS costs used a larger population, including those who are inactive in the labor market. The data sources of NHS unit costs and the resources used to estimate productivity losses are displayed in Multimedia Appendix 2 (Table S1).

To control for missingness, we assumed the item response was missing at random. Multiple imputation was run following best practices [47,48] for a total of 50 imputed sets (m50) [49]. The final model specification included variables for gender, WEMWBS, PHQ-9, age, education, and employment status alongside our outcomes of interest. Multiple imputation was inclusive of both trial arms to increase the sample size because neither arm had received treatment at baseline. Models for direct-to-NHS costs and productivity losses were conducted separately, at the item response level, because of the inherent subsampling of productivity losses to only those in employment. Models were run multiple times, and distributions were visually inspected to confirm the robustness and stability of our imputations. The 95% bias-corrected CIs were derived from 1000-iteration bootstraps, and all health economics analyses were conducted in Stata/SE 16.1. Pounds sterling were converted to US dollars using the conversion rate published by the Federal Reserve as of March 26, 2021: £1 to US $1.38.

Data on Barriers and Facilitators

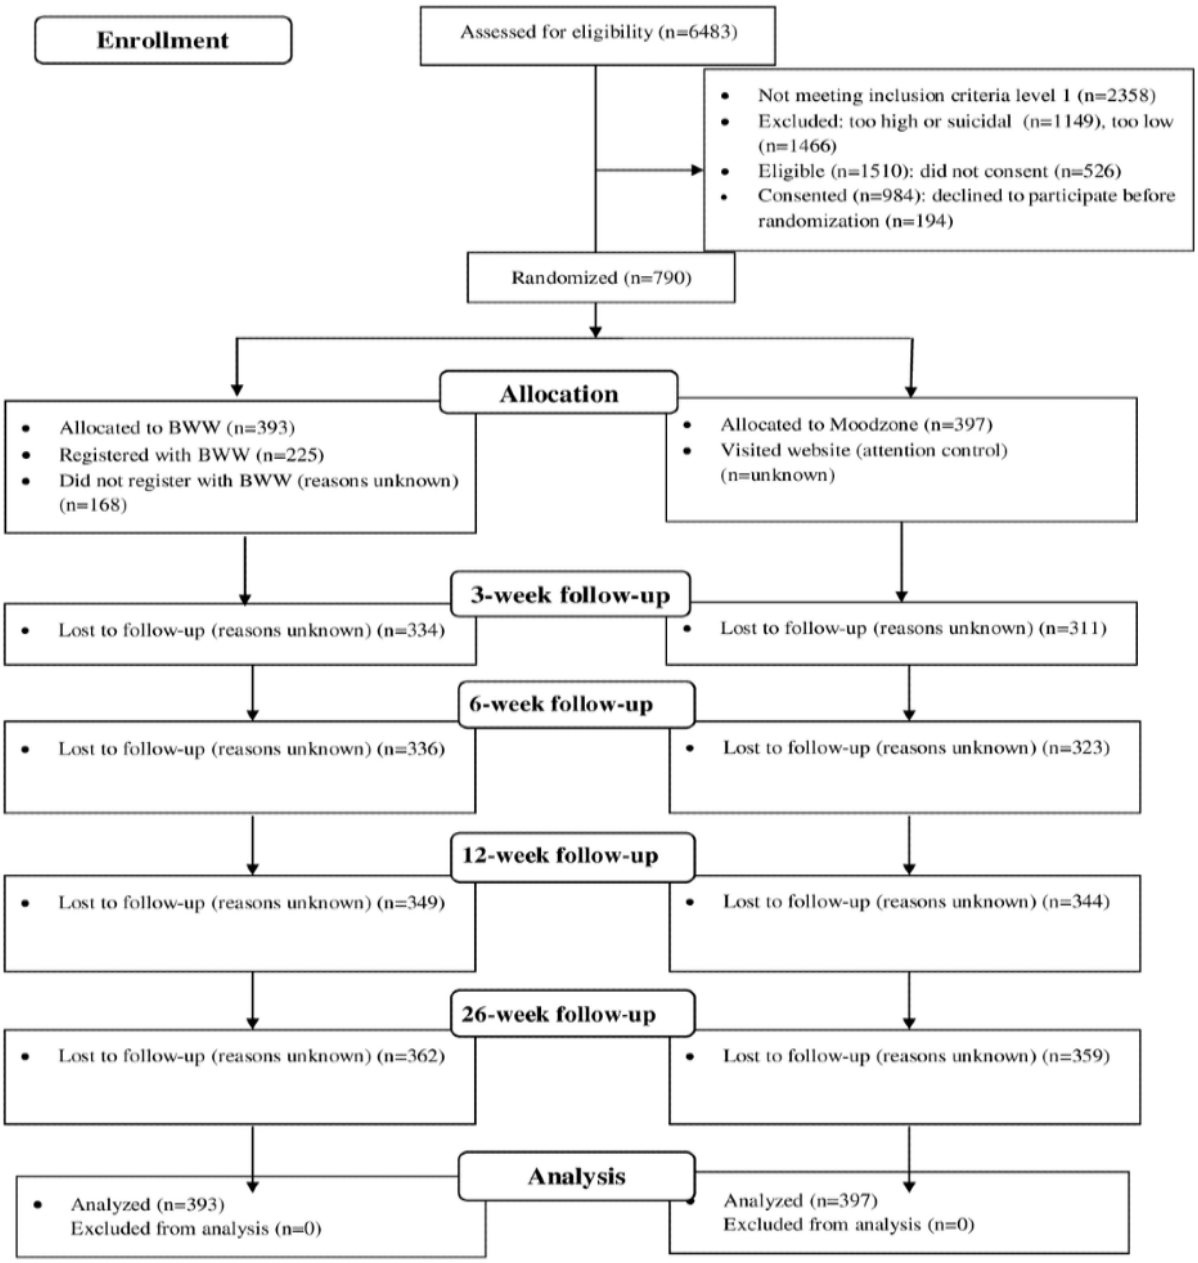
We asked for open-ended survey feedback at baseline and every follow-up and also received email and telephone feedback when participants wished to contact the research team. We then analyzed this feedback thematically.

Results

Overview

Figure 1 shows that there were 6483 visitors to the study website (14 per day) over 18 months of recruitment from September 16, 2016, to May 30, 2018. Of these, 4125 were from Nottinghamshire, aged >16 years, and had continued access to the internet. We excluded a further 1149 participants because their PHQ-9 scores were above 20 or because they scored 2 or 3 on the suicide item of the PHQ-9 and excluded 1466 participants who scored below 10 on both the PHQ-9 and GAD-7. Of the 1510 eligible participants, 790 consented and were randomized, 393 to MZ and 397 to BWW.

Figure 1. Flow of participants through the study.



Methods of Recruitment

Table 1 shows that the 6 most successful ways of recruiting visits to the website were through a university counseling service, direct contact with the research team at presentations, leaflets, pharmacies, and health visitors. However, the 6 most successful enrollment methods to the study (randomization) were through GPs, Facebook, trams, internet and social media, NHS acute hospitals, and leaflet door drop. In relation to primary care, 22,408 registered patients received a text message from their GP endorsing the study, and 180 people were consented and randomized into the study via this route. The efforts directed at raising awareness of this study are listed in Table S2 (Multimedia Appendix 2). Figures S2 and S3 (Multimedia Appendix 2) show recruitment by the geography of Nottinghamshire and in relation to the proximity of tram routes in the county, suggesting that proximity to tram routes in the City of Nottingham was associated with study enrollment.

Table 1. Number of people visiting the study website and those converted to randomized study participants according to their self-reported referral source.

Trial Results

Table 2 shows that randomized study participants had a mean age of 38.0 (SD 13.8) years, 81.0% (640/790) were female, 93.4% (738/790) were White, everyone had educational qualifications with 45.0% (354/787) having a university degree, 4.3% (34/790) were retired, and 8.9% (70/790) were unemployed. The mean scores showed moderate levels of depression and anxiety and moderate impairments in function and well-being. Of the 393 participants randomized to BWW, 225 (57.3%) registered to access BWW and 165 (42.5%) accessed it on more than one occasion. No participation data are available for the MZ website.

Of the 790 participants enrolled in the study, 572 (72.4%) provided complete case (CC) data on health care service use at baseline. The discussed results correspond to the reported participant service use in the preceding 3 months to baseline (Table 3). Of the 572 patients, no contact with any health service was reported by 271 (47.4%) patients of the CC sample. Out of the 572 patients, only 66 (11.5%) had any contact with mental health services, 228 (39.9%) had contact with their GP and 9 (1.6%) had out-of-hours care. Multimedia Appendix 2 (Tables S1 and S3) shows unit costs, productivity resources, disease prevalence, and CCs of intensity of service use.

Table 3. Baseline self-reported service use in the 3 months before study entry.

[a]Other use consisted of other specific National Health Service care, that is, phlebotomist or private health care, that is, physiotherapy and podiatry. Designations of the community psychiatrist were included as outpatient psychiatrist for the 4 participants who double counted by listing psychiatrists within other service use. Binary variables for inpatient or outpatient or primary and community aggregate service use were amended to 1 or 0 if missing and participants specified individual service contact or no individual service use, respectively. If binary variables declared no aggregate service use, individual service use binary variables were set to 0 if missing, and no other individual service use was observed.

[b]GP: general practitioner.

We report the direct-to-NHS costs and productivity losses in Table 4. Participants in employment took a mean 10.93 (95% CI 9.51-12.36) days of health-related time off work during the 3 months, which corresponded to a productivity loss of £1001.01 (95% CI 868.75-1133.27; US $1380.79, 95% CI 1198.35-1563.23), compared with £156.46 (95% CI 114.08-198.84; US $215.82, 95% CI 157.36-274.28) in direct-to-NHS costs per participant. The small variation between the CC and multiply imputed costs suggests that the observed characteristics are poor predictors of response missingness.

Table 4. Direct-to-National Health Service costs and productivity losses in the 3 months before study entry.

Variable	Population, n (%)	Mean (95% CI)	Total annual burden, £ (US $)
Complete case			
Absentee days[a] (n=494)	257 (52)	11.01 (8.62-13.80)	N/A[b]
Productivity losses (n=494)	257 (52)	£995.74 (775.27-1251.21; US $1373.52 [1069.41-1725.92])	2,336,113,572 (3,222,435,061)
Direct-to-NHS[c] costs (n=790)	483 (61)	£158.75 (119.23-209.13; US $218.98 [164.47-288.47])	505,479,259 (697,258,089)
Multiple imputation			
Absentee days (n=494)	494 (100)	10.93 (9.51-12.36)	N/A
Productivity losses (n=494)	494 (100)	£1001.01 (868.75-1133.27; US $1380.79 [1198.35-1563.23])	2,348,477,561 (3,239,489,947)
Direct-to-NHS costs (n=790)	790 (100)	£156.46 (114.08-198.84; US$ 215.82 [157.36-274.28])	498,187,621 (687,200,004)

[a]Days taken off work because of ill health of those employed or self-employed.

[b]N/A: not applicable.

[c]NHS: National Health Service.

Table 5 shows that follow-up assessment rates were very low at each time point. At baseline, 93.5% (739/790) participants completed the WEMWBS, but only 18.4% (145/790) completed it at 3 weeks, 16.6% (131/790) completed it at 6 weeks (the primary outcome), 12.3% (97/790) completed it at 12 weeks, and 8.7% (69/790) completed it at 26 weeks. Proportions of participants completing the primary outcome measure were 14.5% (57/393) in the BWW intervention group and 18.6% (74/397) in the MZ control group. There were no statistically significant differences in the primary outcome WEMWBS at 6 weeks between the 2 treatment groups nor were there any differences at other time points or in the PHQ-9, GAD-7, or Work and Social Adjustment Scale in the imputed or observed results.

Table 5. Modeled mean changes in well-being and mental health scores (95% CIs) at each study follow-up time.

Outcome and follow-up time	Randomized to Moodzone (n=397)		Randomized to Big White Wall (n=393)		Difference

[a]Participants with available scores at each time point.

[b]Primary outcome of randomized controlled trial.

Barriers to Participation and Retention in the Study

We collected the following feedback organized into 3 themes on barriers to participation and retention in the study from randomized participants, those who had considered participating, and those who refused to participate but left comments for the research team by email, text, or survey.

Lack of Personal Interaction With the Research Team

The study was set up to be automated so that a member of the public could participate in the trial, as they might do with other web-based applications, only seeking technical support if and when they needed it. However, this meant a lack of personal connection and engagement with the research team. Participants described this as contributing to a lack of obligation to complete the study measures and participate in follow-up time points. They viewed the interventions as similar information-giving interventions that were impersonal, with many participants not understanding how the interventions might be tailored to their needs.

Turning Away People With Severe Depression

Potential participants with more severe depression who were trying to take part but were turned away by the automated eligibility criteria on the REBOOT website expressed disappointment, frustration, and a sense of exclusion made apparent through a number of complaints to the study's email account.

Lack of Technical Support

Although people contacted the research team over technical problems, contact with the research team usually led to greater engagement by those participants during follow-up. The study experienced technical issues, such as website downtime, problems with progression through the site, and errors within the measures, which may have deterred the completion of some measures and retention in the study.

Discussion

Principal Findings

Overall, we found that running a fully automated, web-based intervention trial was challenging. Exclusion criteria were exclusive web-based enrollment and measurement, restricted

full enrollment, and retention during follow-up. We recruited and randomized only 790 of 1510 (52.3%) of those who expressed interest and were eligible, despite a considerable amount of effort by the research team using traditional advertising, internet and social media, health services, other public services, and third-sector contacts. Only 16.6% (131/790) of the patients completed the primary outcome at 6 weeks. As a result, the trial lacked the power to demonstrate any differences in outcome between BWW and MZ. The primary reasons for the lack of recruitment and poor retention in this automated RCT are discussed.

There was a demand for web-based information and peer support for the sort offered by the study intervention from people with severe depression and those who were actively suicidal. Far more of these visitors to the website were willing to participate in the study (1149/4125, 27.85%) than those with mild-to-moderate depression and anxiety who were enrolled (790/4125, 19.15%). We were not allowed to recruit these participants by a research ethics committee because of the opinion that research on people with severe depression requires a greater duty of care than could be offered over the internet. However, such patients access digital services on an everyday basis outside the research environment. A restrictive approach to research ethics may have an undesirable effect in that research into digital interventions is not carried out in the most vulnerable manner, where there is arguably more room for beneficial effects and greater safety concerns [50,51].

Participants were most successfully enrolled through GPs (directly and through texting from the practice), pharmacies, internet resources such as Facebook and social media, public transport advertising, and door-drop–posted information in more deprived communities. We recruited a largely female, White, and educated sample who were mostly currently in work or education. Approximately half of those enrolled were not in contact with any health service in the preceding 3 months. A core aim of providing digital mental health approaches to reach people who are not in contact with health services was achieved. Younger females are a part of the population with increasing rates of depression and anxiety in the United Kingdom [2], suggesting that such people might be reached through digital direct-to-public services. However, we failed to recruit enough males, older participants, people from BAME backgrounds, people without any educational qualifications, and people in more rural areas, each of whom may require a combination of different strategies for enrollment.

Compared with the UK average of 4.1 sickness absence days of the general working population, our employed participants took a mean of 43.72 (95% CI 38.04-49.44) days off work per annum, with many individuals undergoing prolonged absences of illness from work. Individuals with mild-to-moderate depression or anxiety may represent a conservative annual burden of approximately £498 million (US $687 million) to the NHS and an additional £1.42 billion (US $1.96 billion) in productivity losses. Our extrapolation to a 1-year time horizon may underestimate or overestimate this burden. There exists a significant value for treating these individuals outside of the standard measures of health gain.

From feedback to the study, the decision to take part in the study was made very quickly by participants, many of whom were not necessarily committed to completing it. Participants found all contact with the study remote and therefore not engaging. Our research group has published a systematic review and meta-synthesis of qualitative data on enrollment and retention in the study or treatment from 24 trials of digital interventions with varying degrees of human engagement in enrollment, follow-up, or treatment of people with depression and anxiety. It identified that enrollment and retention to studies were determined by the participants' initial beliefs about digital health interventions, the offer of personal support, and the enablement of personalization of care [52]. Taking our results together with this meta-synthesis, the public health campaign and automated enrollment only provided a superficial understanding of what was being offered by the trial. The opportunities provided by BWW and MZ to use novel approaches to making choices about obtaining personal support and personalized care, particularly through BWW, which is designed to enable such choices to be made and provided almost immediately, were not made explicit and might have been explained better through initial human or virtual human contact. Those trials that have been automated and yet recruited and retained a high proportion of participants offered well-established treatments for depression and anxiety (cognitive behavioral therapy) to populations that could not otherwise access such help [20-22]. The concept of building a program of tailored personal support and formal psychoeducation through interaction with peers and trained guides that BWW offers was not well-known in the county of Nottinghamshire at this time. Better recruitment and retention rates were obtained in another trial of BWW in mental health service users involving more human support [10]. Therefore, our data suggest that a process of interaction with a human or possibly a virtual human is required to ensure a full understanding of what the trial offered, fully informed consent, and commitment to the study, particularly when the digital interventions are not already well understood in the population being studied.

Participants commented on how burdensome they had found the length of the questionnaires, and longer assessments in digital studies may deter participation [53]. Therefore, during the recruitment of the first 50 participants, we decided to stop collecting questionnaires, namely the SF-12. However, this change did not improve either recruitment or retention in the study.

In this study, participants were routed to 2 other websites, BWW and MZ, which each had the option of completing questionnaires examining their mental state similar to our follow-up measures. These may have confused or deterred participants from completing follow-up measures in the study. We only used email reminders of follow-up and did not use reminders through social media, telephone, or arranged face-to-face contact. More persistent follow-up using a variety of different methods might have improved follow-up rates and provided greater clarity that mental state questionnaires on BWW were independent of follow-up questionnaires in the study. We employed motivational statements and the opportunity to take part in a raffle to win store vouchers at the end of the study. Although

these potential intrinsic and extrinsic rewards may sometimes improve retention and follow-up assessment rates in RCTs [54], they are insufficient.

Conclusions

This study shows that the offer directed to the public of a trial of peer support and information-providing interventions for people with probable mild-to-moderate depression and/or anxiety backed by a public campaign was successful in reaching some parts of the population not in contact with primary care or secondary care mental health services. Most of these were White, educated women who were working and studying below the age of 50 years, who were costly in terms of loss of productivity. However, the public health campaign was not successful in enrolling a large number of high-risk groups for depression or anxiety: men, BAME communities, older people, poorly educated people, and people living in rural communities with poor access to traditional services. This fully automated trial was not successful in engaging or retaining participants because it did not recruit people with severe depression who most wanted these interventions and did not adequately explain how the digital interventions could provide personalized care and support.

Abstract

Background: Schizophrenia is a severe mental illness that burdens both patients and caregivers.

Objective: The aim of this study is to examine the feasibility of a web-based psychoeducation course targeted at caregivers of persons with schizophrenia spectrum disorders (SSDs) and to describe their experiences of living with a person with SSD based on the material caregivers produced during the web-based course.

Methods: A convergent, parallel, mixed methods study design was used. First, caregivers' engagement in the course was evaluated quantitatively. Second, the overview of the course feedback was evaluated using quantitative and qualitative methods. Third, the experiences of being a caregiver to a person with SSD were analyzed qualitatively with the thematic analysis of the writings caregivers produced during the web-based course.

Results: A total of 30 caregivers participated in the study and a web-based psychoeducation course. Less than two-thirds (18/30, 60%) completed the course. Content was most often logged for the first module, *Orientation* (3465 log-ins), and the lowest number of log-ins was recorded for the *Daily life* module (1061 log-ins). Feedback on the course varied; over half (10/17, 59%) of the caregivers considered the content to be very good or good, about half (9/17, 53%) considered the website layout to be good, only 6% (1/17) felt that the usability of the website was poor, and no one felt that it was very poor. From the reported experiences of being a caregiver to a person with SSD, 3 themes were formed: the caregiver's own well-being, relationship with the person with SSD, and experience of health care services.

Conclusions: The web-based psychoeducation course for caregivers living with a person with SSD seems to be especially suitable for those who have little experience as a caregiver. In the future, more planning and the consideration of aspects related to the needs of specific target groups, course content, practical arrangements, and scheduling should be taken into account. In addition, although caregivers can improve their own well-being in different ways, they need regular support and cooperation from health care professionals.

Introduction

Background

Schizophrenia spectrum disorders (SSDs) [1] are severe mental health disorders that affect informal caregivers (later caregivers) [2-5]. Over half of the caregivers of patients with schizophrenia experience burden [2,3], often conceptualized as an increased level of stress [6], financial concerns [7], heavy responsibilities [8], and stigmatized experiences [6]. Caregivers also tend to have health problems such as psychological distress [9,10], anxiety [11], or depression [11,12]. In contrast, caring for a person with schizophrenia can also offer positive experiences for family members [13]. Shiraishi and Reilly [13] found in their systematic review of qualitative studies that caregivers may experience family solidarity, admiration, self-confidence, personal growth, and appreciation in their role. These positive impacts on caregivers are individual and related to each caregiver's coping methods [14]. Mackey and Pakenham [15] also found in their study that coping resources were the most important predictor to better adjustment among caregivers of persons with mental disorders.

Psychoeducation has been found to be effective in reducing relapses and rehospitalization, shortening hospital stays, and increasing adherence in patients with SSD [16]. On the basis of a Cochrane review by Xia et al [16], the results of psychoeducation were better when caregivers were involved. Psychoeducation is recommended as part of treatment in several care guidelines for patients with SSD [17,18]. It can be realized in groups or individually with different kinds of materials, such as written leaflets, videos [16], or web-based materials [19]. During psychoeducation, individuals gain knowledge about the disorder with which they were diagnosed. This increases their understanding of the disorder and helps them to cope with it [16]. In their review of 32 randomized controlled trials with 2858 caregivers, Sin et al [20] found that psychoeducation for caregivers of patients with psychosis reduces caregivers' global morbidities, negative caregiving experiences, and negative expressed emotions. However, time restraints create an obstacle in face-to-face psychoeducation, as health care professionals need to integrate psychoeducation with other duties [21].

The increased use of digital technologies in health care can strengthen the accessibility of health services [22], and digital technologies offer new opportunities for web-based psychoeducation. A recent review of 46 studies [23] found good acceptance of web-based interventions targeted at caregivers of persons with mental health disorders, neurological disorders, or brain injuries. Web-based psychoeducation interventions have been developed for various caregiver groups, including those with a family member with SSD [24-28]. Web-based psychoeducation has several advantages over face-to-face interventions. Access to web-based psychoeducation is easier because participants can join from home, for example. Web-based psychoeducation also has lower costs [29,30]. The possibility of returning to web-based information when needed can support learning [30], and anonymous participation may reduce stigma [29]. Although access to web-based psychoeducation is easy, it requires an internet connection and a digital device, such as a computer or smartphone. In web-based psychoeducation, participants cannot receive the same level of support from health care professionals as they do with face-to-face interventions, and they must take more direct responsibility for their work. Security issues, such as personal information being shared on the internet, can raise ethical concerns [29].

In previous literature, a variety of web-based psychoeducation programs have been found to have a positive impact on caregivers. Rotondi et al [27] targeted their programs at caregivers and patients with SSD. The program included reading materials with information related to schizophrenia, 3 therapy groups (1 for patients, 1 for caregivers, and 1 for patients and caregivers), the possibility of asking questions from professionals, a library of previously asked questions with their answers, and news and activities in the community. Patients and caregivers used the program independently; however, the sessions were run by a therapist and moderated in therapy forums. During a 14-month period, caregivers used the program for an average of 14 hours, whereas patients used it for an average of 46 hours. Furthermore, another study by Rotondi et al [26] found that the use of the program decreased significantly after the first month. Chan et al [24] described a program that included information related to psychosis in reading materials and videos, information about local mental health services, local and international news, and an interactive discussion forum. In their study, caregivers were satisfied with the program; they visited the website 2-5 times for 5-30 minutes each time. Caregivers reported that the website increased their knowledge about psychosis (85%) and their understanding of local resources (78%). In addition, 84% of caregivers agreed or strongly agreed that they would recommend the website to others. Sin et al [25] studied an intervention for caregivers that included 12 sections. One section was a home page with an introduction and instructions for navigation. Information related to psychosis and caring was divided into 8 sections. Of the 8 sections, 2 sections were for web-based forums, 1 was for experts, and 1 was for peer discussion. In their study, 13 out of 14 caregivers would definitely (72%) or probably (21%) recommend the program to others.

Objectives

Despite the wide range of existing literature on psychoeducation courses, more research is needed to identify optimal ways of using web-based interventions to support caregivers of people with mental illness [31] and to find solutions to enable their psychoeducation. To our knowledge, research combining a web-based psychoeducation course and the use of its content to evaluate caregivers' experiences, especially those with a family member with SSD, is sparse [20]. Therefore, in this study, we examined the feasibility of the web-based course targeted at caregivers and described their experiences of being a caregiver for a person with SSD, based on the web-based material caregivers produced during the course. First, we assessed caregivers' engagement in the web-based course. Second, we collected caregivers' feedback of the web-based course. Third, we investigated the experiences of being a caregiver to a person with SSD, portrayed in writings produced during the web-based course.

In this study, we use the term *SSD* to refer to *schizophrenia spectrum disorder* based on the 10th version of International Classification of Disorders (ICD-10) categorization F20-29 [1]. The term *caregiver* refers to a patient's informal caregiver, such as a family member, close friend, or another person close to the patient who takes care of the patient in their daily life [32].

Methods

Design

A convergent, parallel mixed methods study design [33] was used to evaluate the use of a web-based psychoeducation course. Both quantitative and qualitative data collection and analysis methods were used to provide a broad view of the topic [34]. First, to evaluate engagement, quantitative methods were used to collect and analyze caregivers' log records from the web-based psychoeducation course. Second, a combination of quantitative and qualitative methods was used to collect and evaluate caregivers' numeral and written feedback about the course. Third, qualitative methods were used to collect data portrayed in writings and explore experiences of caregivers caring for a person with SSD. The convergent, parallel design [33] was appropriate, as data were collected at different points in time throughout the course. The study was reported according to Good Reporting of a Mixed Methods Study [35].

Setting

The study was conducted within FinFami (Finnish Central Association of Families With People With Mental Illness), which is a central organization of 18 local associations based throughout Finland. The target group of the organization is caregivers of people who are recovering from mental illness. The mission is to promote well-being by providing information, support, and hope. With its local associations, FinFami organizes group activities, courses, and events for caregivers [36]. For convenience purposes, 5 local family associations in Southern Finland were invited to participate in the study.

Eligibility Criteria

Participants were eligible to participate in the study if they met the following inclusion criteria: a caregiver of a person with SSD (ICD-10, F20-F29 [1]), were closely related (eg, parent, spouse, or child) to a person with SSD, were aged 18 years or more, could read and write in Finnish, and were willing to participate in the study. Caregivers were excluded if they were not able to read and write in Finnish, were unable to give informed consent, or the mental illness of their relative was something other than SSD.

Ethical Issues

This study was approved by the Ethics Committee of the Hospital District of Southwest Finland (ETMK 56/2015). Research permission for data collection was granted by each local family association participating in this study. Consent was not requested from persons with SSD as recruitment occurred in caregiver associations.

During the course, tutors of the course contacted caregivers via phone if there was any concern over the health of the caregiver. Phone calls were also made if topics were too confidential to talk about in the discussion forum or too sensitive to address via email. Tutors were ethically responsible [37] for identifying if a caregiver was in need of professional help, and if they were, the tutors would validate the caregiver's situation, support them in getting help, and provide more information on the services available for caregivers.

Sampling and Recruitment

The consecutive sampling method was used to minimize sampling bias by reaching all potential participants during the recruitment phase [38]. First, the researchers approached a volunteer contact person in each local family association. Second, an information session was held for the contact persons to introduce the study and the practical arrangements of the data collection. Third, contact persons were informed about the study in each local association, and caregivers were tentatively invited to participate if they met the inclusion criteria. A total of 3 information meetings for potentially interested participants were arranged for caregivers, during which a short introduction of the study was conducted. The caregivers had an opportunity to introduce themselves and their role as a caregiver. Caregivers were informed about the study aim, methods, possible advantages and disadvantages, ethical issues (voluntariness, privacy, and confidentiality), and practical arrangements [39] of the web-based psychoeducation course and the use of its content to evaluate caregivers' experiences. Caregivers were also informed in oral and written formats about their right to refuse or withdraw at any phase of the study [39,40].

Caregivers who decided to participate in the study signed an informed consent form after an information session. If they needed more time to think about their participation, they took the consent material home and returned it via post. If a caregiver was willing to participate in the study but was not able to join the information session, written information about the study and a consent form for them to sign was sent to them by post, along with a stamped envelope. Caregivers were able to register for the course after providing consent.

Web-Based Psychoeducation Course

The web-based psychoeducation course was designed to offer information and peer support to caregivers of persons with SSD. The web-based method was selected because the internet is already used for seeking help and information related to health problems [41], and there is a need to increase the use of web-based methods in health care [22]. The course consisted of papers and written tasks on the Moodle learning platform and an information package on MentalNet, which is a psychoeducation website providing information related to SSD (eg, etiology, symptoms, treatment, daily living, and patients' rights; ICD-10 codes F20-F29 [1]). The content of MentalNet is based on a literature review; it was designed in cooperation with health care professionals, patients, and caregivers and originally aimed to support patients' self-management [42]. Nurses have recommended MentalNet as useful for family members, making the website a suitable structure for the course [43]. Anonymity was secured with personal user accounts and passwords on the learning platform. More detailed information about MentalNet is available in other publications [42,43].

The web-based psychoeducation course was hosted by the University of Turku. The length of the course was 8 weeks, and it comprised 6 modules consisting of 6 themes: (1) orientation, (2) mental illness, (3) treatment, (4) daily life, (5) well-being, and (6) patient and caregiver rights. Each module lasted 1 week, except *Orientation*, which lasted 2 weeks. Finally, there were concluding remarks and the opportunity to provide feedback. The deadlines of tasks assigned to caregivers were flexible in case the caregivers needed more time to complete the tasks (Table 1).

Table 1. Description of the structure and content of the web-based psychoeducation course.

Module and length	Content	Task of the week
Module 1: Orientation; 2 weeks	• Welcome • Description of the course • Schedule of the course • Introduction of course leaders and tutors • Service promise • News • Information and instructions about the learning platform • Security and net etiquette • Discussion forum	Please read the orientation material and write your expectations from the course. Introduce yourself shortly and anonymously. Describe the well-being of the person you care for and of yourself by answering the following questions: (1) How does the person you care for act, what do they think, and what do they "look like" when they are in poor condition? (2) What does the person you care for look like when they are doing well? (3) What should the person you care for avoid to maintain a good state of mind and a sense of hope? (4) How can you help make this happen? (5) What do you do to maintain your positive state of mind and a sense of hope? (6) What things should you avoid to maintain a positive state of mind and a sense of hope? Voluntary written task: Draw a line on the paper to mark the most important turning points in your life (joys and sorrows). Describe and write what you marked on the paper.
Module 2: Mental illness; 1 week	• Information about the origin of SSDs[a] and its symptoms • Additional information about how caregivers can help themselves and their relatives with the illness in different stages of the disorder	Please read the theme "Mental illness" and answer the following questions in writing: (1) What kind of difficult situations have you experienced related to your relative's disorder? (2) What things have not worked well in getting through difficult situations? (3) What things have worked well in difficult situations that you would like to share with other caregivers? (4) Please comment on other caregivers' writings in this module.
Module 3: Treatment of the illness; 1 week	• Information about the content of care and rehabilitation for SSD • Additional information about research concerning the care of SSD and different types of care and restrictive treatment methods	Please read the theme "Treatment" and answer the following questions in writing: (1) What is the meaning of a written treatment plan for your relative? (2) What does it mean for your relative if they are treated in inpatient or outpatient care? (3) What does it mean for you if your relative is treated in inpatient or outpatient care?
Module 4: Daily life; 1 week	• Information about support from caregivers • Information about different types of support and benefits that might help in managing daily life	Please read the theme "Daily life" and answer the following questions in writing: (1) What kind of things support your relative's daily life? (2) What kind of things support your own daily life? (3) In what kind of situations is there an increased risk that your relative would not take their medication? (4) What kind of things support your relative in taking their medicine properly?
Module 5: Well-being; 1 week	• Information about mental and physical well-being in relationships	Please read the theme "Well-being," do a writing, and answer and share the following questions in writing with other caregivers: (1) How can you affect your own well-being? (2) How can you decrease the burden caused by the care of your relative?
Module 6: Patient and caregiver rights; 1 week	• Information about patients' rights for sufficient and necessary treatment, self-determination, and their rights to be informed about their treatment and to keep their information confidential • Information about compulsory treatment • Information about caregivers' rights in a relative's treatment	Please read the theme "Patient and caregiver rights" and answer the following questions in writing: (1) How have you acted in situations where a relative with the disorder has not allowed you to take part in their treatment even if you are worried and want to take part? (2) What is good or bad about dealing with health care in your opinion? (3) How would you change practices related to compulsory treatment?

[a]SSD: schizophrenia spectrum disorder.

The caregivers participated in the course at home on their own computers using pseudonyms. For psychoeducation to be truly empowering, it should provide versatile information covering a wide variety of topics (eg, financial help and ethical aspects) in addition to subjects related to the disorder itself [44]. The themes and tasks in the course were structured to provide caregivers with a comprehensive program that would help them identify any problems in their daily lives and explore solutions to the problems. The layout of the course was predesigned [42,43]. However, each participant could tailor the specific content of the 6 modules based on their own needs. Each participant reflected on their own situation and sought answers to their questions using the web-based material available on the course website. The courses were designed to support caregivers' self-management and well-being and help them recognize their own resources. In addition, caregivers were encouraged to share their thoughts in a discussion forum using a peer support approach. The specific content of the course

material in each module was based on a variety of evidence-based sources on the MentalNet website [45,46].

A total of 3 trained professional tutors specialized in mental health provided feedback after each completed module and answered any emerging questions. Of the 3 trained professional tutors, 2 were psychiatric nurses—one was a registered nurse, a family psychotherapist, and a master's student in nursing science and the other was a doctoral student (a registered nurse with extensive experience in psychiatric nursing). The third tutor had a PhD. Via emails or text messages, the tutors encouraged caregivers to continue in the course, share their worries, and use the psychoeducation website for support. Moreover, a course coordinator answered practical questions related to the study or course and informed the caregivers about the phases of the course.

Data Collection

Summary of Data Collection

Data were collected between November 2015 and January 2016. Sociodemographic information was obtained with a paper questionnaire, either filled out at the end of the information session or returned by post. The quantitative data related to caregivers' engagement in the web-based course, which was based on the course's access log, were collected during the course. Quantitative and qualitative feedback of the course was collected after the course (by January 3, 2016) using a web-based questionnaire as part of the course tasks. Finally, caregivers' experiences were gathered qualitatively from the learning platform after the course. The researcher copied all caregivers' writings into one Microsoft Word document, which comprised 156 pages (font: Arial 11; spacing: 1.5).

Data Collection Methods

Feasibility of the Web-Based Psychoeducation Course

Engagement in the Course

Caregivers' engagement in the course was assessed by calculating their activity on the learning platform. Caregivers' log-ins for each module were automatically recorded on the learning platform. The number of caregivers visiting every module and the number of finalized module tasks (writings) were calculated manually.

Feedback on the Course

A questionnaire designed by the research group was used for feedback. The questionnaire included three 5-point Likert scale questions (eg, "My feedback about the content of the psychoeducation course"; 1=very poor; 2=poor; 3=neither good nor poor; 4=good; 5=very good) with items about content, layout, and usability of the course [47,48]. The participants were also invited to provide written feedback about the course and the website.

Caregivers' Experiences of Caring for a Person With SSD

The qualitative data concerning experiences of being a caregiver for a person with SSD were portrayed in writings [49] designed primarily for the psychoeducation course. Caregivers were instructed to read specific course material assigned for each week, complete writing tasks based on their experiences and guided with open-ended questions related to each theme, and return their tasks via the web-based platform (Table 1).

Sociodemographic Information

Caregivers were asked to provide background information on a form regarding their age, gender, marital status, educational level, employment status, housing situation, and relationship with the person with SSD. They were also asked to provide some information about the person with SSD (the duration of mental illness and duration of using mental health services). In addition, caregivers were asked about any possible chronic illnesses they might have and their skills and attitudes regarding computers and the internet.

Data Analysis

An evaluation of the use of the course was based on an analysis of data collected at different time points. Caregivers' engagement in the course was evaluated using descriptive analysis methods. The frequencies of the log-ins to each module were calculated. The number of caregivers visiting each module and completing the tasks over the duration of the course was calculated. Participants' feedback on the course was then evaluated using descriptive statistics (frequencies and percentages).

For written feedback, data were categorized and analyzed using qualitative content analysis [50]. The written feedback was collected into one document and read through so that the researchers could familiarize themselves with the data. Similarities were identified and classified into categories.

To investigate caregivers' experiences of being a caregiver to a person with SSD, the writings produced during the course were analyzed using thematic analysis. Thematic analysis was chosen because it can be used to identify, analyze, organize, describe, and report themes found in the qualitative data [51]. First, the first author (AL) read all writings several times to become familiar with the data and to get an idea of the experiences of these caregivers. Second, initial codes such as *individual hobby* and *social relations* were generated. During coding, sections of the text were marked, indicating the code or subject. Third, potential subthemes were generated inductively from the initial codes. The marked sections were copied and collected into separate files. Fourth, the coded data and potential subthemes were reviewed and refined by collapsing and separating them to ensure that they were in a coherent pattern. An example of a coding tree is presented in Table 2. The data were reread to confirm that the themes were related to the data set and that nothing had been overlooked. Fifth, the themes were defined and named after identifying what each theme contained and considering an appropriate name [51]. One researcher (AL) conducted the coding process. Two researchers (AL and MA) defined the subthemes and themes.

Table 2. Example from a coding tree of caregivers' well-being.

Phrase in the text	Initial code	Subtheme	Theme
Reading a book	Individual hobby	Hobbies	Caregivers' experiences of factors supporting well-being
Jogging	Individual hobby	Hobbies	Caregivers' experiences of factors supporting well-being
Friends	Social relations	Support from other people	Caregivers' experiences of factors supporting well-being
Family	Social relations	Support from other people	Caregivers' experiences of factors supporting well-being

Results

Participants

The participant flow and the sociodemographic information about participants are presented in Figure 1 and Table 3, respectively.

Figure 1. Flow diagram of the participants.

[b]SSD: schizophrenia spectrum disorder.

Feasibility of the Web-Based Course

Regarding engagement in the web-based psychoeducation course, the highest number of log-ins was recorded for the *Orientation* module (3465 log-ins), and the lowest number of log-ins was recorded for module 6, *Daily life* (1061 log-ins; Multimedia Appendix 1). A total of 30 (100%) caregivers visited the modules, 25 (83%) caregivers completed at least one of the main modules besides *Orientation*, and 18 (60%) caregivers completed all the 6 modules. The numbers of caregivers who visited and completed the modules are presented in more detail in Multimedia Appendix 2.

Feedback on the Web-Based Psychoeducation Course

Feedback Characteristics

More than half (10/17, 59%) of the caregivers evaluated the content of the psychoeducation as very good or good, about half (9/17, 53%) evaluated the website layout to be good, only 6% (1/17) considered the usability of the website to be poor, and no one felt it was very poor (Table 4).

Table 4. Feedback about content, layout, and usability (n=17).

Dimension of the feedback	Caregiver, n (%)
Content of the website	
Very good	2 (12)
Good	8 (47)
Neither good nor poor	7 (41)
Poor	0 (0)
Very poor	0 (0)
Layout of the website	
Very good	0 (0)
Good	9 (53)
Neither good nor poor	6 (35)
Poor	2 (12)
Very poor	0 (0)
Usability of the website in psychoeducation	
Very good	2 (12)
Good	5 (29)
Neither good nor poor	9 (53)
Poor	1 (6)
Very poor	0 (0)

Caregivers' written feedback about the course was divided into 2 categories: (1) content of the course and (2) course arrangements.

Content of the Course

The caregivers found the content of the course to be interesting. The theoretical information was considered good, and caregivers

used it in conversations with professionals. In addition, the tasks were found to be good. Caregivers found the writings of other participants valuable because they could compare their own situation with others' situation and read how others had survived. However, they were of the opinion that the content of the course did not provide new information for long-time caregivers. They did not find peer support when there were no similar situations or there was only limited conversation between the caregivers. In addition, they found it depressing to read others' stories.

Course Arrangements

The caregivers found that the course was well constructed. Caregivers learned how to use the learning platform during the course. There were, however, some technical problems, especially at the beginning of the course. The caregivers felt that the end of the year was not a good time to take part in the course. They found that there was too little time allocated for each module. In addition, the information meeting at the beginning could have been a web-based conversation instead of a face-to-face meeting.

Experiences of Caregivers Caring for Persons With SSD

Themes and Subthemes

An overview of the themes and subthemes is presented in Textbox 1.

Textbox 1. Themes and subthemes.

Influence on caregivers' lives

- Experiences of the impact of illness on the caregivers themselves
  - Physical well-being
  - Mental well-being
- Factors supporting the caregivers themselves
  - Positive mood
  - Hobbies
  - Everyday routines
  - Support from other people and the health care system

Relationship with the person with schizophrenia spectrum disorder

- Caregivers' experiences of a good relationship
  - Help in everyday life
  - Mental support
  - Help related to the illness
- Caregivers' experiences of challenges in a relationship
  - Physical distance
  - Challenges related to schedules
  - Difficulties in communication
  - Challenges related to stage of the illness

Experience of health care services

- Caregivers' positive experiences in the treatment of the illness
  - A sense of security created by hospital care
  - Benefits of outpatient care
  - Good cooperation with health care
- Challenges faced by caregivers in the treatment of the illness
  - Inadequacy of outpatient care
  - Challenges of multiple diagnosis
  - Challenges in cooperation between caregivers and health care
  - Challenges related to commitment in care
  - Challenges related to legislation

Influence on Caregivers' Lives

The influence on caregivers' lives was divided into 2 themes: (1) experiences of the impact of illness on the caregivers themselves and (2) factors supporting the caregivers themselves. Living with a person with SSD has an impact on caregivers themselves. Caregivers expressed signs of depression with feelings of sadness, tiredness, and dejection. Burdening feelings appeared when caregivers were worried about the management of the person with SSD and other family members. They also described a link between the well-being of the caregiver and that of a person with SSD. For example, caregivers found that their own well-being worsened when the state of illness of the person they cared for deteriorated:

> *After all, the camel's back was broken because I was and lived alone. In addition to physical disorders, depression hit as it hits many other caregivers.*
>
> *During the illness, the fear of mine has been related to coping of other family members.*
>
> *I notice that my own mood depends on my son's situation.*

Caregivers described events or occasions that supported them. These included positive mood, everyday routines, hobbies, and

support from other people. Caregivers tried to keep themselves positive by using humor to get through hard moments and tried to avoid energy-consuming people and events. Maintaining regular routines, such as maintaining proper nutrition and regular rest, helped to manage daily activities. Hobbies, including exercise, cultural activities, societal activities, voluntary work, and traveling, gave meaning to their lives. Caregivers received support from other people, such as family members and friends, who helped in difficult times. Colleagues also showed support, as they helped caregivers focus on work. Support from the official social and health service sector included discussions with professionals when the relative was in hospital. Support from the service sector consisted of peer support and family association meetings. Caregivers understood that the passage of time supported their well-being and that they needed to take care of themselves to support others and live their own life:

> *Focusing on "normal things," sense of humour and friends are what carries me if it otherwise goes against the walls.*
>
> *I try to do things I like: I meet people, I have hobbies like studying and exercise, theatre and travelling.*
>
> *When I feel particularly difficult and hopeless, I talk to a friend. I go and talk with a professional about my situation.*

Relationship With the Person With SSD

Caregivers described good relationships with the persons with SSD they cared for. They provided practical daily support for the persons with SSD, such as assistance in shopping or household chores. They encouraged people with SSD to keep up their routines and stay away from substance abuse. For example, they participated in public events together without being ashamed. Caregivers discussed general topics that the person with SSD was interested in, introduced easy-to-discuss topics, and tried to get the person to think more positively. They also paid attention to whether they were showing symptoms or not. Caregivers supported the person with the illness in seeking help, even if it was a hard decision. They were involved in planning and monitoring care and attended meetings organized with mental health professionals:

> *I visit the city about once a week with my mother. At that time, we go banking, shops and other places.*
>
> *I try to encourage her and talk about her good sides and what she is good at. The illness is not usually seen but can sometimes be, so I have decided not to be ashamed of her anywhere.*
>
> *We go to public events and we have done trips together abroad.*
>
> *Fortunately, at least for now I have had an opportunity to join the care meetings and my wife has wanted me to be there.*

Caregivers described challenging relationships with the persons with SSD. These challenges were related to physical distance, timetables, the stage of illness, and challenges in communication. Sometimes, the physical distance between the caregiver and the person with SSD was too great for them to meet each other often. Schedules were sometimes difficult to coordinate, or there was only a short amount of time to see each other. Sometimes, in a bad stage of the illness, the person with SSD might not want to be in touch or want the caregiver to be involved if they were in hospital. The person with SSD could also be threatening toward the caregiver. Communication with the person with SSD was challenging when that person lacked insight, and caregivers had to be careful about what topics could be discussed without triggering anxiety or anger:

> *She lives with her partner in another city, so we are mainly in contact by phone, in the summertime we meet more.*
>
> *I try to visit her weekly, but we often have scheduling conflicts, so our meetings do not always succeed. Many times, I have needed to withdraw, change the subject and let it be, because arguing with a man with lack of insight is somewhat hopeless.*
>
> *Once he picked up a scythe. I looked at the exits and didn't stay long that time.*

Experience of Health Care Services

Positive experiences related to care included the feeling of safety created by hospital care, good cooperation with health care services and support from professionals, and advantages of outpatient care. Caregivers were relieved when the person with SSD was safe in a hospital when they needed it. The cooperation with health care services was good when the person with SSD had had a long relationship with the same professionals, and caregivers were familiar with them and were able to contact them easily. Caregivers received concrete support from professionals, such as nurses and police, when they needed help getting the person with SSD into hospital care. Outpatient care supported the person, enabled them to be out of hospital, and enabled caregivers to see the person and how they were coping;

> *I was able to sleep a bit longer at night when she was in the hospital, and during the day I didn't have to worry about what was waiting at home when I came back from work.*
>
> *Outpatient care is also the best option for me. I can keep my husband at home and I see him every day. Likewise, I know when he goes to see his therapist and in what condition he comes home from there.*
>
> *As the departments and staff became more familiar, cooperation began to work better in every way.*

On the contrary, the challenges faced by caregivers included insufficient care, problems in cooperation between the caregiver and the health care service, and legislative issues. Caregivers described how physical symptoms and side effects of medicine were not taken seriously or were not appropriately dealt with, and there were challenges with substance abuse problems. Sometimes, it took long to get help for the person with SSD, and outpatient care seemed powerless. Caregivers had witnessed inappropriate behavior, such as verbal mocking and excessive use of force by the police when they had taken the person to a hospital. The person with SSD sometimes denied caregivers access to information, and the opinions or experiences of caregivers might have been ignored when professionals had contradictory views about the need for inpatient care.

Furthermore, caregivers and health care professionals did not understand each other, especially if a doctor was not a native Finn. Legislation related to self-determination was a barrier to care if the patient wanted to stop their medication or treatment. Examples of the phrases are provided below:

> *Of outpatient care, I often stated that it was not treatment at all, but indeed neglect. If the patient does not come to the appointment once a month, no one from healthcare services goes home to see what the situation is.*
>
> *The first thing that comes to mind is the physical illnesses of a mental patient. It seems to me that one doesn't believe they exist.*
>
> *They may have decades of experience about the person with illness. One would expect that cooperation would be more beneficial than detrimental.*
>
> *For a long time, I tried to keep my husband to stay even in outpatient care, go to doctor's appointments and take his medicine.*
>
> *Even if the denial of information is standing, one should listen to relatives.*

Discussion

Principal Findings

The goal of this study is 2-fold. We first evaluated the feasibility of the web-based course with caregivers who participated in a psychoeducation course by analyzing engagement and feedback on the course. Second, participants' experiences of being a caregiver to a person with SSD were portrayed in writings produced during the web-based course. These 2 goals complemented each other by providing valuable information to both caregivers and professionals. It has already been shown that psychoeducational interventions for family caregivers of people with psychosis are effective [20]. It is therefore important to consider how web-based methods can be used to support family members, especially those who lack daily support [52]. At the same time, web-based courses could provide insights into caregivers' daily concerns and how support from professionals could more efficiently meet the individual needs of caregivers. It has been shown that web-based methods are sometimes preferable to face-to-face methods, as some caregivers are less likely to share their inner thoughts in face-to-face counseling sessions [53,54].

Out of 34 caregivers providing informed consent, 30 caregivers started the web-based course. Engagement with the modules decreased as the course proceeded. The number of log-ins similarly decreased in a study by Rotondi et al [26]. This may be because caregivers lack the strength to continue [2,3]. Some web-based programs with different target groups have shown a similar decrease in log-ins and an increase in withdrawals during the program [55]. In our study, of the 30 caregivers, 60% (18/30) completed all the 6 modules, which is a fairly good result compared with similar studies [28].

The question of how feasible web-based psychoeducation courses are for caregivers still remains if 53% (9/17) of the participants are unsure of its usability. Therefore, we need to discuss what might have been the reason for the lower ratings in our study. First, it is possible that, considering participants' extensive experience in caregiving, the course content did not offer new or valuable information for them, although the content of the course seemed to be interesting to the participants. Therefore, this kind of course might be more topical for people new to their role as a family caregiver. It has already been recommended that low-intensity interventions could be used as a first step of service for illnesses of milder severity before stepping up to treatments with higher intensities if needed [56].

Second, we offered opportunities for peer support via a web-based course platform. However, only a limited number of conversations between caregivers can be identified. Caregivers in our study may have been less active users of web-based discussion forums, which could have limited their willingness to have discussions via the internet. Furthermore, some participants may have been worried about the privacy issues of web-based services [57]. Third, our professional tutors offered individual support to each participant and actively contacted them if any worries could be recognized based on their writings. Caregivers might not have been used to remote support if they were familiar with face-to-face contact with professionals. On the other hand, acceptance of web-based interventions has been found to be high even if contact with professionals is limited [58]. In general, support provided by professionals seems to increase attrition [59,60]. Therefore, in practice, the preferences for psychoeducation courses and the presence of tutors or other professionals should be clearly indicated by the caregivers before the intervention. During these exceptional times in health services, we need to be able to provide web-based services effectively to those who are not able to travel to seek help or are not motivated to use web-based services.

Fourth, we may also ask whether these web-based courses should be targeted only to participants who are fully engaged and facilitated to use web-based methods or if more individual support should be offered to participants with a lack of engagement and skills. On the basis of a previous study, available technical support is important when participants lack technical skills [61]. The caregivers in our study had the possibility of asking questions via the internet [62]. Chat functions, video meetings, and video-recorded instructions could also be added to the course platform to help caregivers with any technical problems. Although these solutions may help technically oriented participants, they may not be useful to those who are less technically literate.

Fifth, the findings of this study indicate that a successful web-based psychoeducation intervention for caregivers demands that participants are supported during the course so that they will likely be engaged in the entire course. Ensuring that participants are motivated, have the necessary technology skills, and get help when needed is crucial. Engagement in the course could be supported by adding professional guidance and discussing the timing of the course and how much time should be allotted for each task of the course. On the other hand, keeping in mind refusals and dropout rates, we need to consider whom web-based psychoeducation courses should

target—should only those who are familiar with web-based methods be the focus, or should everyone, even those with fewer skills in digital technology, be targeted? To answer this fundamental question, more empirical studies are still needed. In any case, researchers should be clearly aware of the challenges of tailoring the web-based method to the needs and requirements of the target group.

Caregivers reflected on their own experiences of being a family member of a person with SSD. Their writings show that caregivers have problems with their own physical and mental well-being, which is similar to earlier findings [9-11,63]. Compared with the results of the study by Pollio et al [5], who identified 355 problems caregivers faced in managing mental illness in their relatives, our study focused on positive methods and how to manage daily life. We found that, in addition to burdening experiences, caregivers had versatile methods for supporting their own well-being and they received support from people around them. This is contrary to previous studies, in which caregivers of persons with schizophrenia lacked social support [64]. This is a positive result, as social support is associated with a lower level of burden [65]. Caregivers also described their relationship with the person with SSD they cared for, including both good and challenging experiences. Caregivers were able to modify their communication, social relationships, and daily activities based on the patient's mood and mental status. This flexible communication style would also be welcome in interactions with professionals.

Indeed, cooperation with professionals was seen as challenging, especially if they had different views of the patient's needs in inpatient care. As found in earlier studies [66,67], caregivers had contradictory feelings when a person with SSD was admitted to a hospital. They were relieved that the person was getting help; however, they also felt that they did not receive information and that they were ignored as a resource in care. The legislation in Finland [68] determines that information contained in patient documents is confidential, and professionals are not allowed to give out information to anyone about a patient's care without written consent from the patient. In general, confidentiality is highly respected in health care services. However, it has been found to be problematic in psychiatric services [66]. Even so, it is still possible for health care professionals to listen to the worries of caregivers, give them general information about treatment, and show empathy without breaking any confidentiality rules in patient care. Web-based psychoeducation programs could serve as a tool for understanding caregivers' situations and offering support and knowledge in a neutral way.

Limitations and Strengths

Our study has a number of limitations. First, because of the small sample size, the results cannot be generalized to a wider context. Second, most participants in our study were women aged around 60 years [24,25,27,28] who had been caregivers for quite a long time [28]. This means that most of them were *experienced* caregivers with long histories of being support persons for someone close to them with SSD. It may be that our target group would have benefited more from the involvement of a therapist in the support process, and therefore, our intervention might not have been properly suited to our target audience.

Third, we used the convenience sampling method, and potential participants were invited to participate in the study in the local associations. As the recruitment of this study was realized via the local family associations, caregivers in our study might have had more social support than caregivers generally have, which might have biased the results. Fourth, not all caregivers gave their feedback about the web-based course, although the option to do so was offered in quantitative and qualitative formats. It is also possible that the most critical caregivers dropped out in the early study phase, and therefore, the feedback was biased. We could have also used validated scales to collect feedback data [69], and the results could have been used to improve the course and its content in the future. Fifth, the length of each module could have been longer to allow more time to complete all the tasks. This might have decreased the dropout rate during the course. Sixth, the individual writing tasks were guided with questions, which may have focused on the content of the writings. Finally, some caregivers had technical problems at the beginning of the course, which may have discouraged their participation later in the course.

One strength of this study is that the data collection method was innovative. We used web-based methods for data collection, which have been found to be particularly useful in conducting a qualitative study with vulnerable study groups [70] and with stigmatized topics [4,71]. Typically, caregivers' experiences of dealing with mental health disorders have often been studied using quantitative methods and questionnaires (eg, Zarit Burden Interview [72] and Camberwell Family Interview [73]). Qualitative methods using individual interviews [74], focus groups [75], and a combination of these [76] have also been used. With caregivers' writings, we were given access to caregivers' uninhibited thoughts and feelings based on their stories, experiences, and insight, instead of extra pressure caused by face-to-face interviews with researchers.

Although not conclusive, our descriptive, small-scale study can contribute to improving the feasibility of web-based psychosocial interventions. In addition, having regular meetings with the local family associations allowed us to develop good relationships with them and deepen our collaboration with caregivers. Flexible tailoring and support, good monitoring, and good topics should allow us to continue our studies with larger sample sizes in the future.

Conclusions

Our study relates to the feasibility of a web-based psychoeducation course and the exploration of experiences of being a family caregiver. These focuses complement each other in that the study offers valuable information about usability and insights into the lives of caregivers. On the basis of the results, we can conclude that web-based psychoeducation may not be an optimal method for all caregivers of persons with SSD. However, it might be suitable for those who are quite new in their situation and those familiar with technological devices and social media platforms. To be successful, the use of web-based methods requires detailed planning related to content, practical arrangements, and the scheduling of the intervention. Carefully

matching the target group and the web-based methods is especially key in meeting the participants' needs and expectations. Effort should also be put into course participant selection. In addition, we can confirm that web-based courses are a usable method for obtaining rich, informative, qualitative data from writings that can increase professionals' understanding of caregivers' experiences and current needs. The next step is to run a larger study with sufficient power to obtain more rigorous information on the topic. We can conclude that although caregivers have versatile ways to improve their own well-being, they still need regular support and cooperation with health care professionals.

Acknowledgments

This study was funded by the University of Turku. The authors thank FinFami for their cooperation and the caregivers for their participation in the study. The authors would like to thank the course coordinator, VP, from the University of Turku for her dedicated work in running the web-based course.

Authors' Contributions

MV initiated the study. MV, MA, and HH designed the study. HH and MA were responsible for acquiring the data. AL was responsible for analyzing the data and drafting the manuscript. AL, MV, and MA wrote the manuscript, and HH participated in manuscript revision. All authors approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Growing evidence supports the benefits of eHealth interventions to increase patient engagement and improve outcomes for a range of conditions. However, ineffective program delivery and usage attrition limit exposure to these interventions and may reduce their effectiveness.

Objective: This study aims to evaluate the delivery fidelity of an eHealth intervention, describe use patterns, compare outcomes between low and high users, and identify mediating factors on intervention delivery and receipt.

Methods: This is a mixed methods study of an internet-based intervention being evaluated for effectiveness in a randomized controlled trial (RCT). The intervention comprised medication and cardiovascular disease (CVD) risk data uploaded from the primary care electronic health record (EHR); interactive, personalized CVD risk score estimation; goal setting and self-monitoring; an interactive social forum; and optional receipt of heart health messages. Fidelity was assessed over 12 months. Trial outcomes were compared between low and high users. Data sources included program delivery records, web log data, trial data, and thematic analysis of communication records.

Results: Most participants in the intervention group (451/486, 93%) had an initial training session conducted by telephone (413/447, 92.4% of participants trained), with a mean duration of 44 minutes (range 10-90 minutes). Staff conducted 98.45% (1776/1804) of the expected follow-ups, mostly by telephone or email. Of the 451 participants who commenced log-ins, 46.8% (211) were categorized as low users (defined as at least one log-in in 3 or fewer months of follow-up), 40.4% (182) were categorized as high users (at least one log-in in more than 3 months of follow-up), and 12.8% (58) were nonadopters (no log-ins after their training session). The mean log-in frequency was 3-4 per month in ongoing users. There was no significant difference between the groups in the primary trial outcome of adherence to guideline-recommended medications (P=.44). In unadjusted analyses, high users had significantly greater eHealth literacy scores (P=.003) and were more likely to meet recommended weekly targets for fruit (P=.03) and fish (P=.004) servings; however, the adjusted findings were not significant. Interactive screen use was highest for goal tracking and lowest for the chat forum. Screens with EHR-derived data held only an early interest for most users. Fidelity measures (reach, content, dose delivered, and dose received) were influenced by the facilitation strategies used by staff, *invisible* qualities of staff-participant communication, and participants' responsiveness to intervention attributes.

Conclusions: A multifeature internet-based intervention was delivered with high fidelity to the RCT protocol and was regularly used by 40.4% (182/451) of users over 12 months. Higher log-in frequency as an indicator of greater intervention exposure was not associated with statistically significant improvements in eHealth literacy scores, lifestyle changes, or clinical outcomes. Attributes of the intervention and individualized support influenced initial and ongoing use.

Introduction

Background

Cardiovascular disease (CVD) accounts for approximately one-third of deaths globally [1], and effective prevention remains the cornerstone of efforts to reduce disease morbidity and mortality. Emphasis is on improving modifiable lifestyle factors, such as tobacco smoking, obesity, unhealthy diet, low physical activity, and alcohol consumption, and controlling high-risk conditions such as hyperglycemia, hypertension, and hyperlipidemia [2]. Technology-based approaches have the potential to support self-care, self-monitoring, and adoption of CVD prevention recommendations and more active interactions between patients and health care providers for managing chronic conditions [3-5]. Evidence for the effectiveness of internet-based strategies for CVD risk factor control is promising [6,7] but considered inconclusive [8].

Studies of internet-based interventions to support lifestyle behavior modification identify attrition of web use among the key reasons for suboptimal exposure or participation, which in turn influences uptake, adherence, and potential effectiveness [9-12]. The reasons are likely multifactorial: interventions targeting behavior change often consist of many interactive components and functions for voluntary use by recipients in home-based or nonclinical settings—attributes of intervention complexity [13]. Engagement with such interventions is characterized not only by subjective user qualities, such as interest, motivation, and sensory and intellectual satisfaction [14], but also by how these intersect with website use or behavior [15]. However, self-reported use of internet-based health resources generally does not objectively describe actual website interactions over time. This presents a gap in the fuller understanding of the activities undertaken at such websites [16]. Information about user activities has important implications for design and functionality decisions that can influence initial adoption and ongoing use [17].

Within a process evaluation, it is therefore useful to examine the fidelity of intervention delivery and receipt in terms of actual use behavior and a fuller understanding of the content that most influences user interaction. Intervention fidelity encapsulates both the implementation and delivery by providers and the treatment receipt and interaction with the intervention by the intended target audience [18]. Both dimensions can influence future program adaptation and scale-up [19]. Other proposed benefits of measuring or evaluating fidelity include ensuring internal program validity [20] and identifying which intervention elements affected participant responsiveness or reaction [21]. It is further recommended that these analyses precede trial outcome assessments to avoid bias in their interpretation [13,22].

Objectives

Using data from a cohort of participants at moderate to high risk for CVD within a randomized controlled trial (RCT), this study aims to (1) evaluate the delivery fidelity of a consumer-focused web application with integration of data from primary health care electronic health records (EHRs), (2) describe objectively measured patterns of website usage and compare RCT outcomes between low and high users, and (3) identify mediating factors on delivery and receipt of the intervention that may explain the engagement and interaction patterns observed.

Methods

Design

A mixed methods study was nested within a process evaluation of the Consumer Navigation of Electronic Cardiovascular Tools (CONNECT) RCT (Australian New Zealand Clinical Trials Registry ID: 12613000715774). Protocols detailing the RCT and process evaluation have been previously reported [23,24]. The process evaluation is multifactorial. The focus of this study was delivery fidelity; other aspects of the overall evaluation that have been previously reported [25,26] are not part of this study. Ethics approval was obtained from the University of Sydney (reference 2013/716) and the New South Wales Aboriginal Health and Medical Research Council (reference 959/13).

Participants

Adults with or at increased risk for CVD who had access to an internet-enabled device at least once per month and who could provide written informed consent were eligible to participate in the RCT. It was not a condition of enrollment that participants met any specific threshold of digital literacy or skill. Interest and willingness to use their device for study participation were required, but the extent of dependency on others to use their device for study purposes was not formally assessed at enrollment. Therefore, the digital support needs of individual participants were initially unknown to the staff who delivered the intervention. eHealth literacy scores were among the baseline data obtained from all those recruited but were not analyzed until completion of the RCT. Recruitment was conducted from 24 primary health care services in Sydney, Australia. Of the 934 participants who enrolled, 52.0% (486) were allocated to the intervention group and 48.0% (448) were allocated to the

control group. The control group received usual care from their primary health care provider; the intervention group received their usual care plus access to the eHealth intervention. This evaluation addresses the fidelity of intervention delivery in the latter group of participants.

Trial Outcomes

Briefly, the RCT tested the effectiveness of an eHealth intervention integrated with the primary care EHR for improving CVD risk factor control through better adherence to prescribed medications and lifestyle recommendations. The main trial results have been published elsewhere [27]. In summary, there was no significant difference between the control and intervention groups in the primary outcome of adherence to guideline-recommended medications, as defined by the proportion of days covered by guideline-recommended medications using pharmacy dispensing data (29.9% vs 32.8%; *P*=.48). There was little heterogeneity in the outcomes observed for prespecified subgroups, such as those with and without established CVD. However, the intervention was associated with improvements in 2 secondary outcomes: higher eHealth literacy scores (*P*<.001) and increased self-reported physical activity (87.0% vs 79.7%; *P*=.02).

Intervention

Participants in the intervention group received access to a purpose-built, multi-feature web application securely linked to data within their primary care EHR. The extensive, systematic process by which the application was co-designed and evaluated for usability in patients with CVD is detailed elsewhere [28]. The logic model linking program inputs to expected user uptake activities within the CONNECT RCT has been described previously [24]. Briefly, software to enable EHR data transfer (RecordConnect, Extensia Pty Ltd) was installed into the clinical software systems of participating primary care providers. After each medical encounter, changes or additions made within selected data fields of the EHR were uploaded to the consumer-facing website by the provider. Concurrently, participants could enter and track measurements in charts displaying trends, targets, and current results for personal biometric and pathology data related to vascular risk factors. Other personalized interactive features included absolute CVD risk score and heart age estimation, goal setting and tracking for healthy eating, physical activity, smoking cessation and emotional well-being, and updateable display of diagnoses and prescription medications with accompanying consumer information resources from national peak health bodies. Participants could also read and contribute to a closed chat forum page and could opt to receive semipersonalized heart health messages via email and/or text message format. Participants could receive an alert when their portal was updated from the EHR and could select their preferences for the heart health messages content from topics such as healthy lifestyle, goal reminders, and medication knowledge. The text message content was adapted from messages that our colleagues initially developed and tested for use with patients with CVD [29]. In this study of patients with similar demography and diagnoses to the earlier study, the multidisciplinary research team further reviewed and expanded the messages to ensure alignment with current Australian guidelines for primary and secondary prevention of CVD. The intervention was intended to take place in real life; it was home-based and without mandatory task completion, data entry, or counselor supervision. As a self-directed intervention, the frequency and extent of use were entirely controlled by the participants, although the study staff encouraged them to interact with and revisit the information and features.

Staff Support

Project staff consisting of registered nurses, dietitians, and pharmacists provided support for patients throughout the intervention period. Although these staff encouraged participants to interact with and revisit the information and features, they were not expected to formally counsel participants about risk factor management pertaining to their health circumstances.

During the initial one-to-one telephone-based or face-to-face training session, study staff provided participants with their *go-live* log-in information and orientation to the website features and navigation, and they answered initial technical and clinical questions. In terms of the quality of the intervention presented to participants, portals were checked before each participant's go-live session to ensure that data uploads from the EHR to the portal were current and that any identified screen errors were rectified before go-live. Thereafter, follow-up contact occurred at 4 scheduled time points (weeks 2, 6, 12, and 26) to answer questions and encourage website interaction and return visits. All scheduled and ad hoc contacts were documented on a standard form and included comments made by the participants and/or notes made by the staff. Participants who did not perform the initial training session with staff were sent self-directed materials; if they initiated log-ins, staff then made the required scheduled contacts.

Scheduled follow-up contact was by telephone unless the participant indicated a preference for email communication. Wherever possible, the staff member who conducted the go-live training conducted the scheduled follow-up with the participant and responded to their email and telephone communication. At each follow-up time point, the staff made at least two attempts to contact participants by telephone; if unsuccessful, an email was sent. To conduct the training sessions and scheduled follow-ups, standard operating procedures were developed, refined, and adopted throughout the RCT to optimize implementation consistency. A separate group of staff, blinded to the intervention allocation, conducted study outcome assessments and did not participate in the delivery of the intervention.

Data Sources

A total of five core measures of intervention delivery fidelity derived from concepts in digital health engagement [15] and guidance on process evaluation and implementation research, [30] were evaluated before knowledge of the RCT outcomes: reach, content fidelity, dose delivered, frequency and duration, and exposure (Table 1).

Table 1. Fidelity measures.

Fidelity measure	Description [15,30]	Data sources
Reach	Proportion of the intended target audience that participates in all or part of the intervention	Program delivery records
Content fidelity	The intervention content is delivered in the intended manner and quality	Program delivery records
Dose delivered	The amount of the intervention components that were provided to participants	Program delivery records
Frequency and duration	How long the intervention was implemented as intended in the trial design and how often participants made contact with the intervention	Program delivery records
Dose received or exposure	How much of the activities or components was read, viewed, or used for the intended duration	Web log files

Program delivery records regarding go-live training, and scheduled and ad hoc communication with participants, were reviewed. Participant factors affecting intervention delivery and exposure were gathered from textual data within the email and telephone records. These 2 fidelity measures closely relate to the 2 stages of a program's logic model: the intervention inputs and the intervention uptake [20].

Website use was central to the *dose* of intervention the participants received. Web log data were used to quantify use in terms of frequency and intensity over the 12 months of study follow-up. Go-live and subsequent session or log-in numbers and screens viewed per month were available for each participant. Session or page view duration and the number of daily interactions were not available. To further characterize exposure, participants were categorized as nonadopters, low (lower) users, or high (higher) users. The number of months in which a participant logged into the application at least once was counted during the 12-month follow-up period to categorize use. Nonadopters were defined as those who logged into the application only once. Low users were defined as those who logged into the application at least once per month in 3 or fewer months (eg, 12 log-ins in month 4 and 5 log-ins in month 7 of follow-up would be categorized as low use). High users were defined as those who logged into the application at least once per month in more than 3 months (eg, 12 log-ins in month 4, 5 log-ins in month 7, 3 log-ins in month 8, and 1 log-in in month 11 of follow-up would be categorized as high use). Hence, the definitions prioritized returning or ongoing log-in activity, often in nonconsecutive months, over the absolute number of log-ins. The log-in frequency data were skewed. Three months was chosen as the cutoff based on the median number of monthly log-ins over 12 months of follow-up. In the absence of an agreed standard for low versus high use of such interventions, the criteria used in this study resulted from an exploratory analysis of the log-in data at the completion of the RCT rather than from definitions set a priori. Optional email and/or SMS text messaging receipt was compared with website use to quantify the combination of passive and active content exposure.

Data Analysis

Descriptive statistics were used to describe and compare the format, the time required, and the content of all staff-participant contact episodes during the go-live and study follow-up periods, thus indicating resource needs for implementing the intervention content as planned. Textual data in the participant contact records were coded for similarities in ideas, and themes were identified inductively to describe the broader issues surrounding implementation needs and participant responsiveness [31]. The themes identified as influencing delivery and uptake were then merged with the original program logic model to indicate where they affect assumptions about program function and could be important implementation considerations for future similar interventions.

The demographic and clinical characteristics of the 3 user subgroups (nonadopters, low users, and high users) were compared using baseline data from the RCT database. The use patterns and characteristics of different types of user groups may be important for the future design of portal functions to optimize adoption. Subanalyses of RCT outcomes were also performed according to the 3 subgroups. For the subanalyses, the nonadopters and low users were combined into 1 group because of the small numbers in the former group. For the primary outcome subanalysis, adherence to guideline-recommended medication was calculated using the proportion of days covered from national pharmaceutical dispensing data. If a participant had a proportion of days covered of ≥80%, the participant was considered adherent to the guideline-recommended medication. Adherence (yes or no) was analyzed using a logistic regression model with treatment as an independent variable. Relative risk with 95% CIs was estimated by comparing high and low users. The primary subanalysis was adjusted for age, sex, and diabetes status.

In the secondary and tertiary outcome subanalyses, for categorical variables where a difference in proportions between high and low users at 12 months was calculated, a chi-square test of independence was used. If cell counts were too small, Fisher exact test was used. For continuous variables where a difference in mean value between high and low users at 12 months was calculated, an independent samples *t* test was used. Statistical significance was set at $P<.05$. The tertiary outcome subanalysis was adjusted for baseline values and analyzed using the ANCOVA (analysis of covariance) model. Analyses were conducted using Excel (Microsoft Office Professional Plus 2016) and SAS version 9.4.

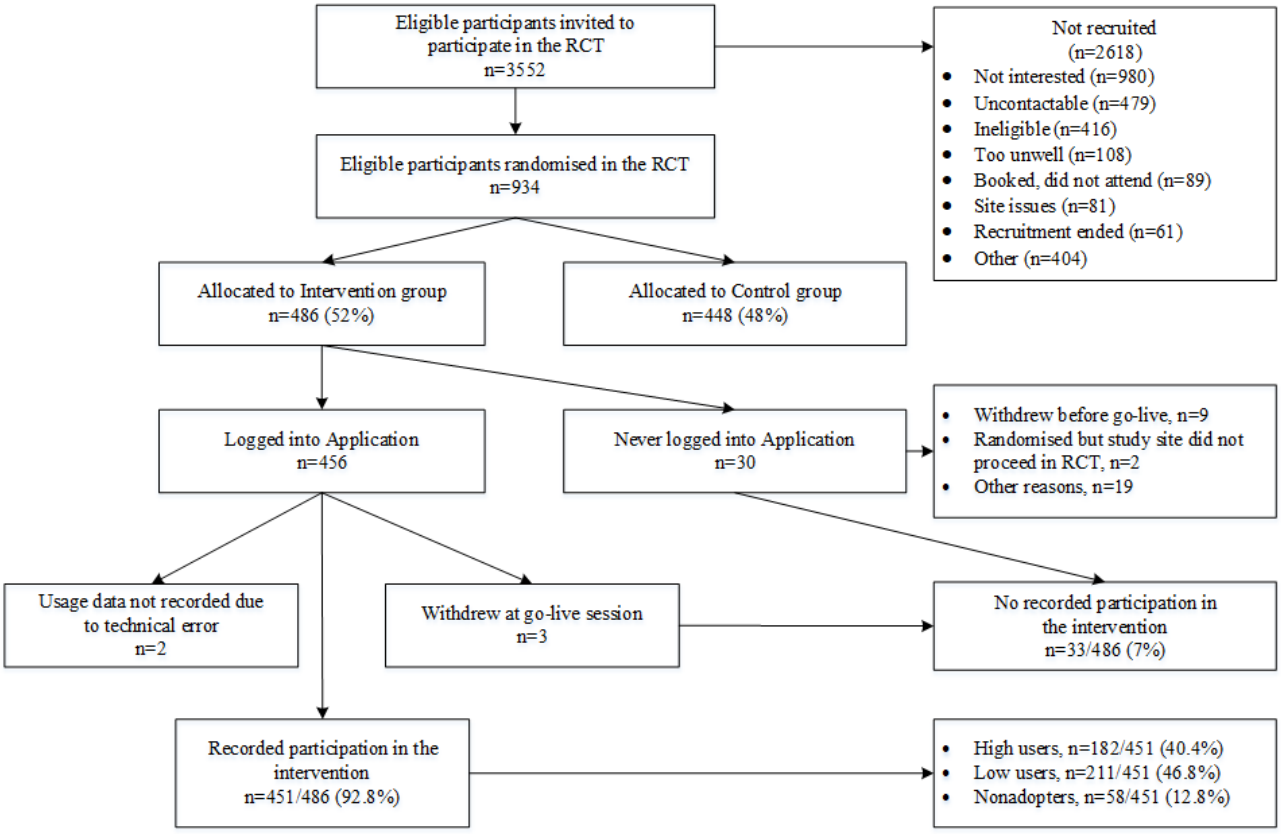
Results

Intervention Reach

Between November 2014 and May 2017, 934 eligible patients were enrolled in the RCT. Of these, 486 (52.0%) were allocated to the intervention group. The flow of the participants in the

intervention group is shown in Figure 1. Participants exposed to all or part of the intervention (451/486, 92.8%) were defined as being registered in the shared record software (RecordPoint) *and* logged into the app *and* used at least one feature or component at least once. Reasons for part-participation were (1) participants opting out of system-generated SMS text messaging or email content (although they could still access the website or rejoin system-generated content at any time), (2) participants stopping log-ins to the website but remaining opted in to system-generated SMS text messaging and/or email content, and (3) participants withdrawing from the study after go-live but before completion of the follow-up period.

Figure 1. Intervention reach. RCT: randomized controlled trial.



Intervention Content Delivery

Of the 486 participants allocated to the RCT intervention group, 99.6% (484/486) had a personalized, secure website populated with data from their EHRs. A study site that discontinued participation left 2 enrolled participants without access to the intended intervention.

In total, 2.7% (13/486) of the cohort withdrew at or before go-live training, leaving 97.3% (473/486) to undergo training. Of these, 94.5% (447/473) received the training session with staff as intended, and 6% (26/473) who could not keep either their telephone or their in-person appointment were mailed the self-directed materials, enabling them to log in and orient themselves to the application and receive staff assistance if they chose to do so. Of the 451 participants with a recorded go-live, most (447, 99.1%) received data uploads from their EHR for a full follow-up period of 12 months. Four participants from a primary health care site that closed within the course of the study did not have EHR-sourced data updated in their portal for their full follow-up period. Most log-in sessions by participants occurred on laptops, desktop computers, and tablets, and a minority of the log-in sessions occurred on smartphones.

An automated system sent messages at a preset, tapering frequency, commencing at the go-live session. Each month, 20% of the message delivery records were randomly selected and reviewed for compliance with the intended delivery schedule. Across both formats, delivery accuracy ranged from 86% to 100%. A severe disruption to weekly volumes of SMS text message delivery was identified by staff in March 2017. Program records indicated the text messages that were queued to be sent but did not indicate the actual message receipt; hence, nonreceipt would go unnoticed unless participants reported the problem. Once notified, programmers traced and rectified the source of the problem within the notification system; however, in the interim, a small number of participants did not receive the heart health content delivered via SMS text messaging.

Scheduled and Ad Hoc Participant Contact

Intervention training occurred over the telephone (413/447, 92.4%) or in-person (34/447, 7.6%). The mean training time for each format was 44 minutes (range 17-120 minutes) and 38 minutes (range 10-90 minutes), respectively. The characteristics of the scheduled participant support after training are summarized in Table 2.

Overall, 1804 follow-up calls were predicted based on 4 calls to each of the 451 participants, and 98.45% (1776/1804) were achieved. Of those, 80.29% (1426/1776) were verbal conversations and 19.71% (350/1776) were communications

via email or voicemail messages. No contact was attempted with participants who, in the time since the previous scheduled contact, requested no further calls from the study staff. Overall, the median time required for follow-up communication was 5 minutes. Technical problems or *how to* questions comprised most of the reported problems, and although they reduced over the 4 contact time points, forgotten passwords and SMS text messaging or email faults or preferences together accounted for approximately half of the technical assistance at week 26.

Unlike the scheduled contact, most of the ad hoc contact was initiated by participants (286/483 episodes, 59.2%) and involved 285 unique participants, representing 63.2% (285/451) of the participants. Ad hoc contact was more frequent by email (363/557, 65.2%) than by telephone (158/557, 28.4%) and required an average of 8.5 (SD 7.5) minutes of staff time (range 1-80 minutes; median 5 minutes). Most of the contact was for resolution of technical problems such as log-in or password problems (244/483, 50.5%), turning message receipt on or off (66/244, 27.0%), or discussing tracking or self-monitoring measurements (53/244, 21.7%). General feedback and miscellaneous administrative issues accounted for 26.3% (127/483). Content data were incomplete in 23.2% (112/483) of the contact logs.

Table 2. Characteristics of scheduled intervention participant support during study follow-up.

Characteristic	Scheduled follow-up after go-live training session				
	Week 2	Week 6	Week 12	Week 26	All weeks
Contact episodes initiated by project staff (n)	451	446	442	437	1776

Turning automated heart health message tip receipt on or off; faulty email delivery	19 (33.33)	11 (33.33)	7 (23.33)	11 (47.83)	48 (33.57)
Tracking or self-monitoring measurements	12 (21.05)	10 (30.30)	6 (20.00)	2 (8.70)	30 (20.98)
Request to withdraw or change study participation status	3 (0.67)	2 (0.45)	2 (0.45)	1 (0.23)	8 (0.45)

[a]Q1: first quartile.

[b]Q3: third quartile.

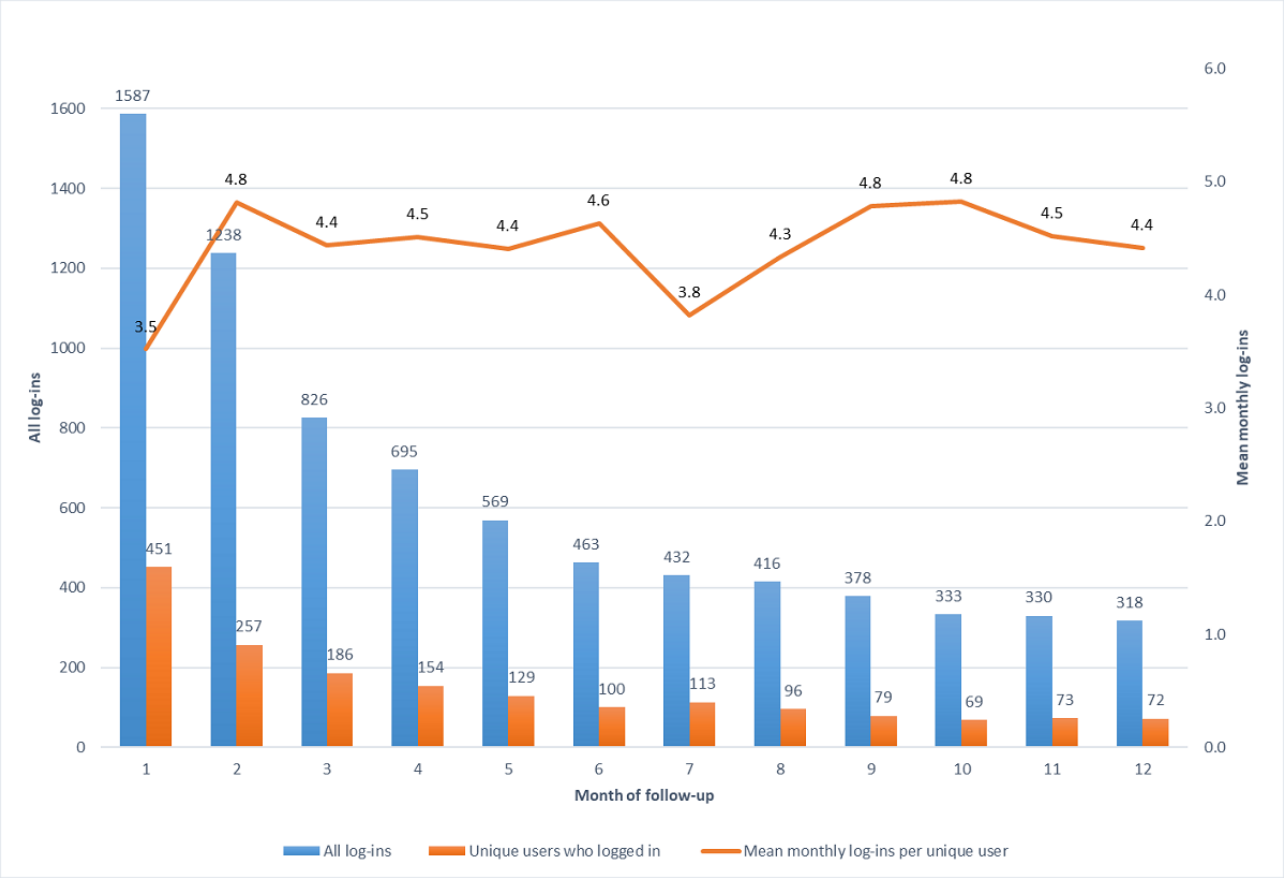
[c]The denominator includes telephone and email communication.

[d]The denominator is contact episodes in which staff directly spoke to the participant.

Intervention Log-In Frequency and Duration

The overall log-in activity pattern was used to indicate the frequency with which participants made contact with the intervention. The highest number of log-ins (n=1587) occurred in month 1 of participation, with subsequent monthly log-ins decreasing steeply by month 6 (n=463) and then remaining relatively stable from months 7 to 12 (Figure 2). Log-in activity by unique users began with all users (n=451) logging in at least to go-live. Unique user log-ins declined markedly in month 2 (257/451, 56.9%) and thereafter were made by up to 50.9% (200/393) of those who made any use of the intervention (after nonadopters were excluded). The mean log-in frequency among ongoing unique users was 3 to 4 times per month over 12 months. The median monthly log-in frequency was 4.5 (Q1, Q3: 4.4, 4.7) among ongoing users.

Figure 2. Characteristics of log-in activity.



Intervention Exposure

Excluding the nonadopters (58/451), monthly unique users dropped below 200 from month 3 among participants who continued to make any use of the intervention (393/451) and below 100 from month 8 (Figure 3). Only goals tracking was accessed by more than 50 unique users per month for 12 months. In terms of goal setting, 86.0% (388/451) of all users set goals for healthier lifestyle behavior, and most goals were for healthier eating and physical activity. More people set goals than returned to track their goal achievements. Overall, the social media or chat forum feature was the least subscribed, being visited by 12.7% (50/393) of unique users per month beyond month 4. Contributions to the forum by participants ranged from 0 to 12 postings each month.

In terms of the intensity of screen visits over time by unique users, visits to track goal progress markedly exceeded visits to all other screens over each of the 12 months, even though fewer unique users were logging in (Figure 4). By month 12, for example, 18.3% (72/393) of unique users made approximately 500 visits to the goal-tracking screen. In comparison, in the same month, there were fewer than 100 visits to each of the other interactive features, suggesting that electronic goal tracking was a valued feature determining returning log-ins. Overall, personal goal setting, risk factor monitoring, and CVD risk score estimation were accessed more than the chat forum and medicine features, with the highest interest in the earlier months.

Figure 3. Number of unique users who log in and access interactive screens per month of follow-up. CVD: cardiovascular disease.

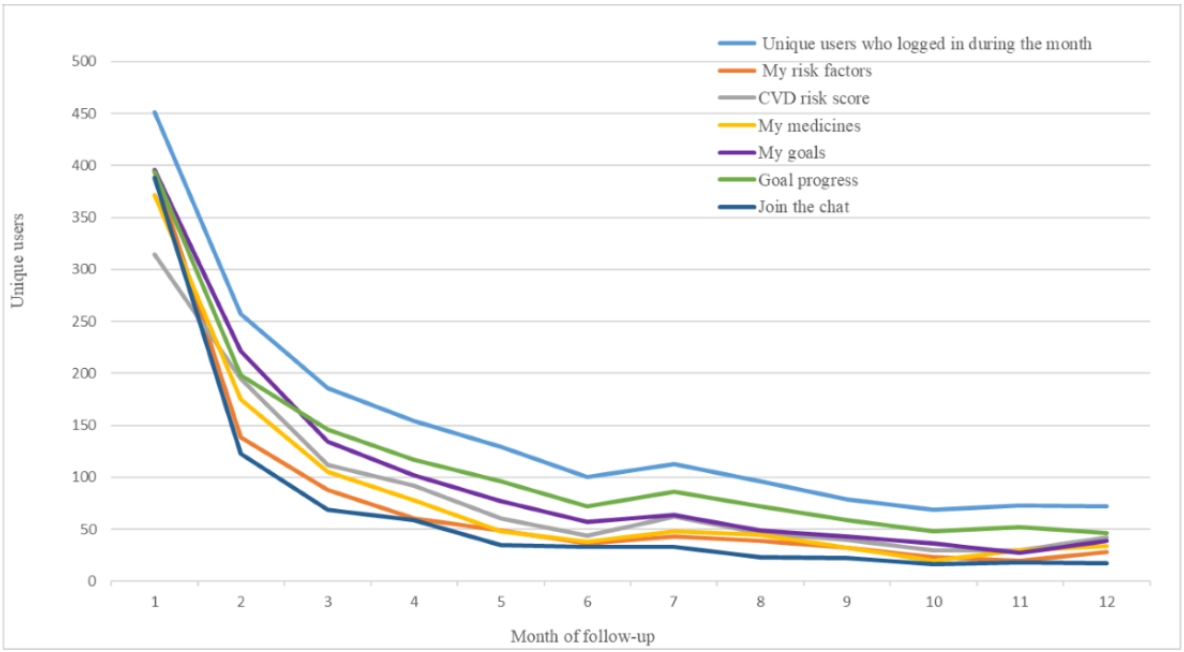


Figure 4. Intensity of screen visits over 12 months of follow-up. CVD: cardiovascular disease.

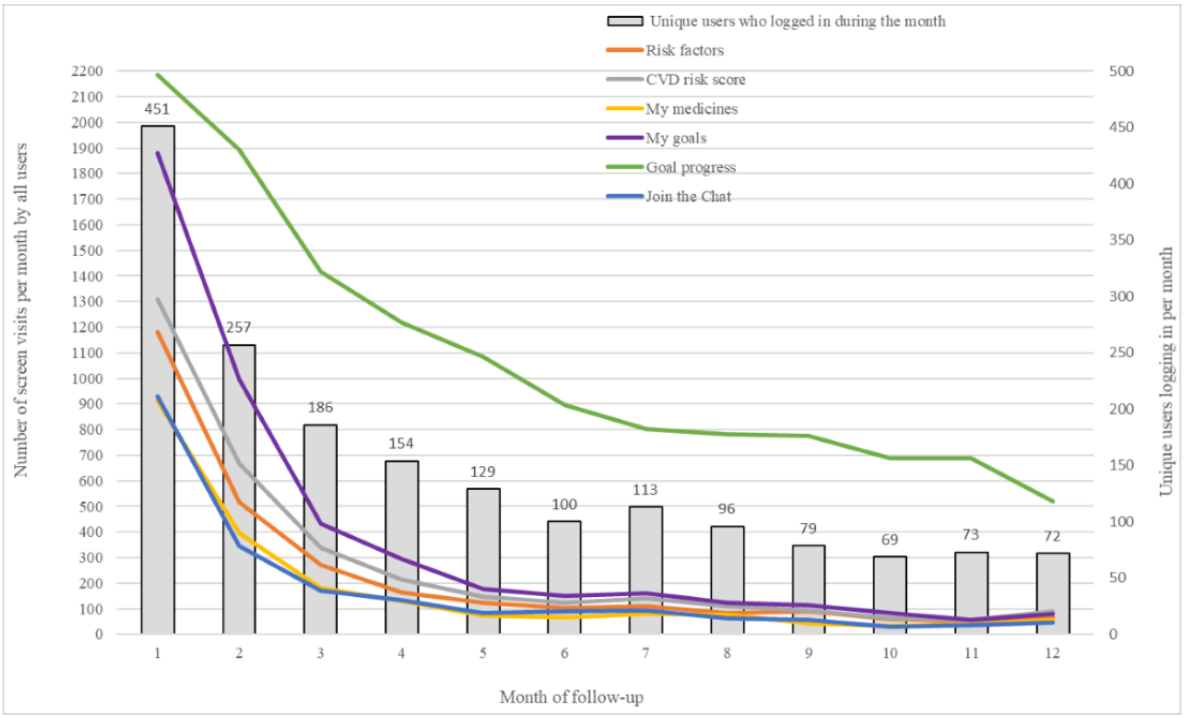

Subanalysis of High Versus Low Intervention Users

Baseline Characteristics

Of the 451 participants with usage records, 12.8% (58/451) were nonadopters, 46.8% (211/451) were low users, and 40.4% (182/451) were high users (Table 3). There were no major baseline differences between these groups in terms of demographic and biometric data, CVD risk status, or other health conditions. The characteristics of all intervention group participants in this evaluation study mirrored those of the overall RCT cohort [27], although the proportion of Aboriginal and Torres Strait Islander Australians was higher than in the RCT (4.9% compared with 4.0%) and slightly higher than the proportion of Aboriginal and Torres Strait Islander representation in the general Australian population in the most recent census (3.3%) [32]. The mean difference in eHealth literacy scale (eHEALS) scores between low and high users was significant (1.13; 95% CI 0.53-1.72; P<.001). Most of the nonadopters (32/58, 55%) received school education only, whereas postschool education was more frequent in the low (150/211, 71.1%) and high (142/180, 78.9%) users.

eHEALS[n] mean (SD)	24.6 (7.7)	26.7 (6.3)	28.5 (5.7)	27.1 (6.4)

[a]Nonadopter is defined as a participant who logged into the app only once in total.

[b]Low user is defined as a participant who logged into the app at least once in 3 or fewer months of follow-up.

[c]High user is defined as a participant who logged into the app at least once in more than 3 months of follow-up.

[d]CVD: cardiovascular disease.

[e]SBP: systolic blood pressure.

[f]DBP: diastolic blood pressure.

[g]Eight participants with missing carbon monoxide breath test results.

[h]LDL: low-density lipoprotein.

[i]HDL: high-density lipoprotein.

[j]HbA_{1c}: hemoglobin A_{1c}.

[k]COPD: chronic obstructive pulmonary disease.

[l]PBS: pharmaceutical benefits scheme.

[m]Forty-three participants withdrew consent for the use of their pharmaceutical benefits scheme data.

[n]eHEALS: eHealth literacy scale. Maximum score is 40.

RCT Outcomes

There was no significant difference in the primary outcome of adherence to guideline-recommended medication between the low- and high-user groups (*P*=.44), although the proportion of participants that was adherent increased by 5.7% in the high-user group but only by 3.1% in the low-user group. In the unadjusted analyses, compared with the low-user group, the high-user group had significantly higher eHEALS scores and mean numbers of fruit and fish serves per week; however, these differences were not significant after adjustment for baseline scores. Compared with low users, high users also had nonsignificant higher adherence rates to blood pressure–lowering therapy and statin medications, meeting Australian guideline targets for both blood pressure and low-density lipoprotein cholesterol, and doing at least one thing to control their salt intake.

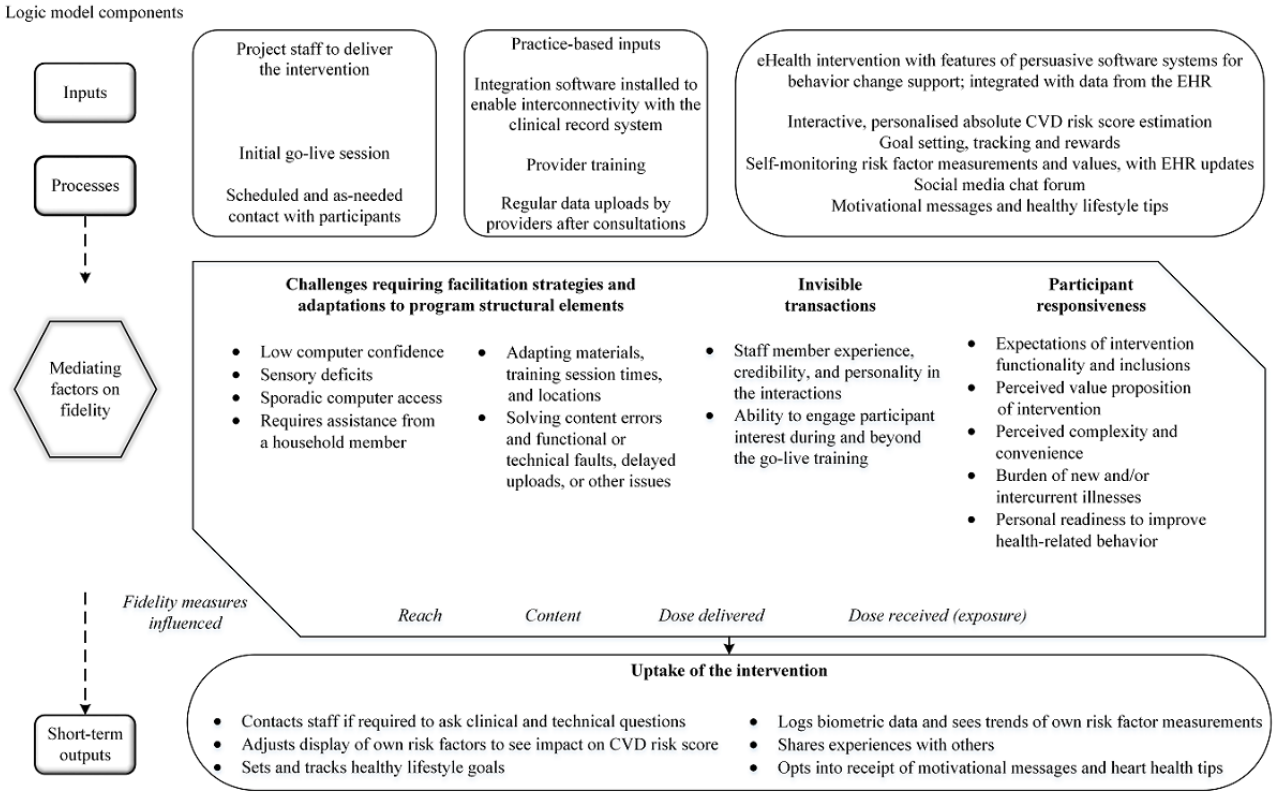
Exposure to Email and SMS Content

Most participants in each of the subgroups opted to receive messages for more than 3 months of follow-up: 96.2% (175/182) of high users, 86.9% (166/191) of low users (data missing for 20/211, 9.5% of low users), and 90% (52/58) of nonadopters.

Factors Mediating Intervention Delivery and Receipt or Early Adoption

At the completion of the RCT, 3 factors were identified from the review of program delivery and participant communication records as having influenced intervention dose delivery and receipt, in relation to the stages of the program logic model (Figure 5).

Figure 5. Modified logic model showing mediating factors on the relationship between the intervention processes and outputs. CVD: cardiovascular disease; EHR: electronic health record.



Facilitation Strategies by Staff and Adaptation of Structural Elements of Program Delivery

Standardized intervention delivery was subject to some variation and adaptation, as different participant needs were identified by staff conducting the go-live training and follow-up communication. After reviewing the communication records with participants, a range of facilitating strategies emerged as having been important to intervention receipt; they are summarized in Textbox 1. The conduct of go-live training was always adapted to enable those with hearing or speech impairments, or less computer confidence, to take part. A paper-based reference guide was provided to those who found website navigation and functions difficult to recall. Telephone-based training with participants with low skills or memory impairment extended the time requirements and underscored the need for clear, simple instructions with less technical jargon; setting up website shortcuts and browser bookmarks to simplify return log-ins; allowing time to practice on interactive screens; and split-session training. Some participants needed a family or household member to be present or required their training appointment outside business hours.

Textbox 1. Facilitation strategies required to support intervention delivery and receipt.

Facilitating strategies identified from communication records:

- Face-to-face go-live training offered to those unwilling to do so by telephone
- Go-live scheduling outside business hours (eg, evenings or Saturday mornings)
- Inclusion of a carer or family member in go-live training or ongoing communication to facilitate use of the intervention
- A self-directed paper guide for participants who
  - required a nonelectronic reference to improve confidence with navigation of the website and its features
  - had hearing or speech impairments that would make telephone-based go-live training unsuitable
  - did not participate in go-live training with staff
- Retraining of website navigation skills at any time in the follow-up period
- Resolution of technical questions that could reasonably be done by the participant without staff assistance (eg, changing preferences or settings within the app)
- Trouble-shooting delayed upload of recent measurements or pathology test results from the electronic health record, which may have revealed a fault with the data integration software at the health service
- Sending a courtesy email to a participant when an error or technical problem within their application had been corrected or if a required correction was delayed
- Removing or correcting erroneous biometric data entry within screens or charts that were not editable by the participant

Invisible Transactions

Staff member experience and personality as a mediating factor on the quality of professional communication and interaction with participants and the ability to engage their interest during and beyond *go-live* training were not formally measured. It is uncertain if, and how much, the staff members' credibility, trustworthiness, skill, and friendliness affected participants' initial and ongoing willingness to engage with the intervention. Regardless, program delivery and communication records revealed that these qualitative influences were likely at play, although they could not be quantified. Staff notes about personal health topics raised by participants in calls and emails and several elements of the study design underscored the value of staff attributes, namely, (1) the personalized nature of EHR-derived data that often required clear, accurate explanations by telephone or email, without complex medical or technical jargon; (2) the remote intervention delivery and support arrangements that increased anonymity between parties and prevented face-to-face communication cues; and (3) the wide variation in participant ages, education, and digital literacy that necessitated more supportive approaches for some. During a call at week 26, a participant stated that she always felt more energized after calls with staff, suggesting that human contact may still be valued even after 6 months using a self-directed resource.

Participant Responsiveness

Four concepts appeared to influence participant responsiveness to the intervention, and hence log-in frequency and exposure, given that all components and content were available.

First, participants' preferences for intervention functionality and inclusion influenced their reactions. The concept and presentation were appealing, but some participants' expectations were not met. Comments included:

> *...I would like to see log space for blood sugar levels measured at home.* [Go-live phone call]
>
> *Simply adding data and reading all the information is not enough* [Week 2 phone call]
>
> *...I wish I had this when I had my heart attack. I am doing more walking and eating more vegetables than I ever have before. It keeps me on track all the time.* [Week 6 phone call]

A second and related expectation was the perceived value offered by the intervention. Some viewed it as minimally useful compared with their existing resources or habits for managing their health, suggesting the need for strong personal relevance of content or functions. Others gained motivation for their healthier lifestyle efforts and were prompted to log in. The descriptive comments included the following:

> *...After my angioplasty...the information was largely what had been covered in the hospital rehab program and did not really provide any additional motivation to me.* [Email from a participant]
>
> *...It's been a big help...tracking goals has become my routine now. Email and SMS tips are reinforcing, it makes me want to go back into my app to update the tracker.* [Week 26 phone call]
>
> *Setting goals gave me an incentive to log on.* [Email from a participant]

Interestingly, the EHR data integration was of less value to participants who felt a close rapport with their care provider or for whom new data uploads would be infrequent:

> *...The tie-in with the [doctor] was good but not useful for me because I don't go that often.* [Week 26 phone call]

> *...A lot of the Program I found was not useful to a person like me who has a good relationship with their GP and practice.* [Email from a participant]

A third issue affecting log-ins was perceived convenience compared with other digital health apps or devices. The intervention was useful for monitoring and assessing risk but not for fitness tracking, for example, which was a priority for some users. For example, participants described the concurrent use of commercial phone-based apps or a wearable device on which they could readily track their physical activity and dietary behaviors. Others were satisfied with the content from the automated messages and, therefore, logged in less often:

> *...I haven't logged onto the app very often; however, I like receiving the tips, they remind me to be good.* [Week 12 phone call]

> *I use other apps to count calories and steps.* [Week 26 phone call]

> *...I am not much on the app; I prefer to access an app quickly on the phone with few clicks to see the essential info.* [Week 6 phone call]

Fourth, timing relative to other personal priorities affected intervention exposure. Participants described infrequent log-ins because they (or their spouse, for example) had a new or existing intercurrent illness with immediate priority. Examples included new diagnoses of cancer or other long-term conditions, unforeseen surgery, the demands of a new treatment or therapy, and frequent clinic appointments.

These responsibilities lowered engagement with the intervention. For others, study enrollment coincided with their readiness to improve their health-related behavior. A participant commented that his participation was "a wake-up call" that helped him to succeed with weight loss goals. Another stated after 6 months that "This is the catalyst that made me get stuck in." Thus, the timing of participation was both a constraint and an enabler of intervention exposure.

Discussion

Principal Findings

This mixed methods evaluation examined the intervention delivery fidelity of a consumer-focused web application with data integration from the primary health care EHR and optional health message receipt. No single or uniform measure defines or quantifies fidelity [20,33], but core evaluation metrics of reach, content fidelity, and dose delivered [19,30] overall were fulfilled as intended. Adaptations to routine implementation, known as structural adaptations [34], were made to overcome individual barriers to intervention reach and receipt. Initial high-user log-ins dropped early in the follow-up period, a trend noted across such interventions more generally [35,36], and the unique user log-in rate tapered to a mean frequency of 3 to 4 per month. Progress tracking had the highest screen visit intensity for the longest duration. Screens with EHR-derived data generally held stronger interest in the early follow-up period. Email and SMS text message receipt augmented active participation by high users and strengthened content exposure in low users and nonadopters. Intervention nonadopters, low users, and high users were similar across a wide range of characteristics, suggesting that the website was amenable to use in general but not which characteristics were important for log-in frequency. The association of patient-level factors and log-in behavior would thus be of further research interest for improving design or excluding content [37]. More frequent intervention use was associated with nonsignificant differences in clinical measures and health-related lifestyle behaviors after 12 months. It is possible that the study was insufficiently powered to fully elucidate the impact of higher intervention exposure; however, in any event, the differences were small in absolute effect size and may not be clinically important. Further research could ascertain if the higher eHEALS scores noted at baseline in the high-user group are an important precursor to using digital health interventions and if more frequent use raises self-reported eHealth skills. Prescribed log-in activity in relation to the adoption of desired offline behaviors may be an area of further inquiry, particularly as website engagement has been shown to benefit physical activity and eating behaviors, even when not significantly associated with biological outcomes [38]. Qualitative data revealed important influencing factors on intervention delivery and receipt, a noted advantage of mixed methods inquiry in process evaluations [13], and a strength of this study. The original program logic model was used as not only a representation of the causal assumptions within the intervention [13] but also as a scaffold on which to show where the identified factors impacted intervention delivery and uptake [20].

Engagement with technology has been defined as a 4-stage cyclical process consisting of an initial point of engagement, the period of engagement, disengagement, and reengagement, with the stages having both shared and exclusive sensory-emotional and spatiotemporal attributes [39]. For example, the system's novelty and esthetic attributes, combined with user emotions of motivation and interest, are especially important to initiation; attributes such as customization, feedback, and control that promote positive affect appear important to ongoing and return visits; and low-level interaction, boredom, or other negative emotions influence disengagement [39]. A recent systematic review found that changes to health status caused disruption or drop out, as did user perception of the technology's compatibility with their routine, their own digital literacy, and relevance to their symptoms or (dis)abilities [40]. In the diffusion of innovations theory, individuals look to reduce their uncertainty about the consequences of adopting an innovation and to perceive a relative advantage if they do so [41]. Factors such as personal convenience, satisfaction, and suitability for needs are proposed to matter more than the intervention's objective advantage. Notably, for this study, reliance on what the participants themselves chose to undertake was an important contextual factor for adoption [42], underscoring the significance of user-perceived relevance and value.

A more recent framework calls the desirability of the technology to the user its value proposition, and more complex interventions may be less likely to reach this threshold for adoption [43]. Personal relevance, program expectations, current health behavior, convenience, and so on, as identified in this study,

concur with engagement factors for digital health interventions previously identified, particularly the themes of personal agency and motivation, personal life and values, and perceived quality of the intervention [44]. Notably, in a multidomain model for engagement with web-based interventions [14], the authors point out the utility of these determinants in any framework of assumptions about intervention use. The relevant framework in this study was the program logic model, in which the determinants derived from the qualitative data analysis were merged to help explain program uptake and what the intervention delivery required in practice (Figure 5). The perception of advantage from using such interventions may have an upstream influence on recruitment to the RCT; of the eligible invited participants who were not recruited, 37.43% (980/2618) gave their reason as *not interested* (Figure 1). Although reasons for disinterest among the RCT nonparticipants were outside the scope of this evaluation, we recommend that further studies be conducted to explore and define a value proposition for similar interventions targeting the primary health care context. Furthermore, the overall generalizability of findings may be improved with greater participation of primary care attendees in studies of digital interventions. The number of participants randomized represented 26.29% (934/3552) of those invited to participate in the RCT. Hence, there may be barriers and enablers of engagement and uptake that would be further understood with higher study participation in this setting.

Patient engagement with portals directly linked to an EHR has inconsistent definitions of both adoption [17] and active use, ranging from at least one use, [45] to more than 1 log-in every 4 months, [37] and at least two log-ins in 12 months [16]. Other studies of web-based lifestyle and disease management interventions have noted that 46% of participants abandon the program after a single log-in [46] and high-frequency use of progress-tracking features by returning users [38]. In general, interventions in which information is tailored hold more user interest and show less attrition than those with generic information design [47], an inflexible or static website [48], or ones that give virtual rather than human feedback [38]. A study in which participants with diabetes and/or CVD accessed a web-based portal to view and track information within their EHR noted that those who used data-tracking functions only comprised between 4% and 11% of users and were among the most frequent and consistent users [16]. Clearly, not all EHR-integrated functions will attract all users, and a range of administrative functions may hold value for many patients over clinically oriented functions.

However, within this study, intervention features with EHR-derived data, such as CVD risk score estimation, medications, and risk factor status, were visited more frequently in the early follow-up period than in the later follow-up period. Overall log-in attrition contrasted with comparatively high average monthly log-ins by ongoing users, suggesting that they derived some personal value. The constant appeal of tailored progress tracking was perhaps because of more immediate visual feedback for everyday healthier lifestyle behavior. The informational nature of CVD risk estimation and risk factor status may benefit an initial call to action but not persistent revisits if few updates occur in the shorter term, or it may have entirely disinterested some users. Furthermore, few outcome measures were associated with greater log-in frequency. Further research could explore whether ongoing exposure impacts important but less quantifiable cognitive and emotional stages and processes of health behavior change, [49] as this information becomes increasingly important to design of technologies with this intent [50]. Direct interaction with the primary care provider was not designed into this intervention, so its value to EHR-linked innovations in the local context requires further inquiry. In provider-linked portals with disease self-management intent, more frequent contact from a clinician may nudge website engagement rates [51] although other user differences may be important, such as their primary care providers' *buy-in*, their baseline self-efficacy, or having a new versus long-term diagnosis [47]. Provider endorsement of a digital application as an extrinsic motivator of engagement is hypothesized but requires investigation [41,52].

High delivery fidelity raises the resource-related question of the optimal support requirements for ongoing website engagement. The type of intervention support appears to benefit different exposure measures. Peer and counselor support facilitate longer session length, for example, when offered in interventions for weight, alcohol, and smoking reduction, whereas updated website content and email and/or telephone contact appear important for site revisits [35]. Other triggers of staff-initiated phone contact could prompt website revisits, for example, a defined number of consecutive days without log-in activity, in addition to scheduled follow-up [44]. Patients are receptive to automated revisit reminders via telephone or email but prefer personal feedback from, for example, a nurse about their disease self-monitoring and health behavior activities [36]. Variations in the intended intervention delivery are generally more likely with complex interventions [21] and with foreseeable differences in provider experience and skill [45]. In this study, the characteristics of study personnel were important contextual and quality factors because the study relied largely on non-face-to-face communication to deliver and support the intervention. In such a context, personality, attitude, and perceived expertise may influence user interest and the reliability of program delivery [21,34]. In addition, contact initiated by participants yielded more app-related problem solving, suggesting that ad hoc support is important to be able to access on the participants' own timeline of website interaction. Flexible rather than fixed staff facilitation may, therefore, be a worthwhile design consideration because different types of users prefer the option of more human involvement for guidance or accountability, whereas others may choose less or require less over time [46].

Limitations

First, although typical fidelity measures were chosen, quantified, and described to suit the intervention, it is acknowledged that fidelity research requires systematic scoring practices to better enable comparison and replication of like interventions [53]. Furthermore, there were no prescribed usage or adherence goals with which to compare participant subgroups, but it is acknowledged that uniform concepts of adherence in eHealth would assist in understanding which elements and in what dose, are associated with the intended outcomes of the intervention.

[54]. Second, the duration of session and screen visits would have enabled further quantification of use intensity and the relative appeal of features and website components. Third, this study intentionally focused on process rather than outcomes and excluded any assessment of participants' offline lifestyle behavior for CVD risk factor control. For this reason, other types of engagement with the overall program content may have been underestimated [52]. Fourth, this study excludes cost-effectiveness measures that are important when balancing user uptake with the required facilitator resources, software application oversight and maintenance, and health service support of the EHR linkage software. Furthermore, this study was a summative evaluation. Although intervention delivery and monitoring were dynamic and adaptable throughout the RCT, it is acknowledged that formal evaluations at interim time points can be useful if it is possible to make regular or ad hoc modifications to the program.

Conclusions

A complex eHealth intervention designed for overall self-directed use can be implemented with high delivery fidelity. Personal progress tracking was consistently used; EHR-derived data features were early but not persistent triggers of revisits. This design intent may reflect how consumers use web-based resources in everyday life but makes usage frequency and thus exposure more unpredictable. Hence, mediating influences and support intensity should be factored into future program planning as drivers of reach and uptake. Despite high delivery fidelity, more frequent intervention use was only associated with small, nonstatistically significant improvements in medication adherence; some clinical measures; and lifestyle behaviors after 12 months. In recognition of multifactorial drivers of engagement, a more explicit personal value proposition should target broad user variables, such as motivation, personal relevance, the context of health care provider use, the timing of program exposure, digital literacy, and preference for log-in adherence accountability. In future research, outcomes related to intervention exposure and reach are important to report so as to expand the evidence about the user and system attributes that promote the uptake of health records with disease self-management functions.

Acknowledgments

The authors would like to thank the patients and general practitioners from the primary health care services that participated in the CONNECT RCT. The authors thank the following project staff for their assistance with the setup, maintenance, delivery, and support of the EHR-integrated intervention: S Parker, C Pitt, J Forbes, and F Bampi. The authors would like to acknowledge Professor Mark Harris, Professor Noel Hayman, Professor Anthony Rodgers, Professor Anushka Patel, Associate Professor Kathryn Panaretto, Professor Clara Chow, Dr Annie Lau, and Dr Emma Heeley for their contributions to the design of the CONNECT RCT and process evaluation protocols. GC was supported by a Health Professional Scholarship (ID 101544) from the National Heart Foundation of Australia. The CONNECT RCT was funded by the Australian National Health and Medical Research Council (ID 1047508). JR is funded by the National Health and Medical Research Council Career Development Fellowship (APP1143538). The funders had no role in the review and approval of the manuscript for publication.

Abstract

Background: Outdoor risky play, such as climbing, racing, and independent exploration, is an important part of childhood and is associated with various positive physical, mental, and developmental outcomes for children. Parental attitudes and fears, particularly mothers', are a major deterrent to children's opportunities for outdoor risky play.

Objective: The aim of this study was to evaluate the efficacy of 2 versions of an intervention to reframe mothers' perceptions of risk and change parenting behaviors: a web-based intervention or an in-person workshop, compared with the control condition.

Methods: The Go Play Outside! randomized controlled trial was conducted in Canada from 2017 to 2018. Participants were recruited through social media, snowball sampling, and community notices. Mothers of children aged 6-12 years were self-assessed through eligibility questions, and those eligible and consented to participate in the study were randomized into a fully automated web-based intervention, the in-person workshop, or the control condition. The intervention was underpinned by social cognitive theory, incorporating behavior change techniques. Participants progressed through a series of self-reflection exercises and developed a goal for change. Control participants received the Position Statement on Active Outdoor Play. The primary outcome was increase in tolerance of risky play and the secondary outcome was goal attainment. Data were collected online via REDCap at baseline, 1 week, and 3 months after the intervention. Randomization was conducted using sealed envelope. Allocations were concealed to researchers at assignment and data analysis. We conducted mediation analyses to examine whether the intervention influenced elements of social cognitive theory, as hypothesized.

Results: A total of 451 mothers were randomized and completed baseline sociodemographic assessments: 150 in the web-based intervention, 153 in the in-person workshop, and 148 in the control condition. Among these, a total of 351 mothers completed the intervention. At 1 week after the intervention, 113, 85, and 135 mothers completed assessments for each condition, respectively, and at 3 months after the intervention, 105, 84, and 123 completed the assessments, respectively. Compared with mothers in the

control condition, mothers in the web-based intervention had significantly higher tolerance of risky play at 1 week (*P*=.004) and 3 months after the intervention (*P*=.007); and mothers in the in-person workshop had significantly higher tolerance of risky play at 1 week after the intervention (*P*=.02). No other significant outcomes were found. None of the potential mediators were found to significantly mediate the outcomes.

Conclusions: The trial demonstrates that the web-based intervention was effective in increasing mothers' tolerance for risk in play.

KEYWORDS

outdoor play; mothering; independent mobility; physical activity; risk perception; risky play; risk reframing

Introduction

Evidence is growing regarding the importance of outdoor play for children's health and well-being, as are efforts to improve children's access to these opportunities [1]. Outdoor play includes inherent risks, including those explicitly sought out by children as they explore their bodies and environments. Risky play, such as climbing trees, building dens, or even walking home from school without an adult, is an inherent and important part of outdoor play [2], and has been associated with increases in physical activity, decreases in sedentary behavior, and positive influences on physical, social, and cognitive development [3,4]. Parental attitudes and fears, particularly mothers', are a primary barrier to children's outdoor risky play opportunities [5-7]. They include fear of serious injury, traffic, abduction, or even the belief that time spent in outdoor play has little value in contrast to academic or other pursuits. Efforts to shift parent attitudes are a frequent focus of practitioners wanting to promote high-quality play opportunities [8], and policy makers wanting to improve rates of children walking to and from school [9,10].

Previous attempts to influence parent attitudes and practices toward risky play have been limited to in-person workshops and have not been rigorously evaluated [11]. We sought to develop and evaluate a risk reframing intervention for parents, particularly mothers as they may be typically the more limiting parent [12,13], that would be accessible through either an in-person workshop or on a web-based platform. A web-based intervention that was freely available would facilitate parents' access, as well as the ease with which practitioners could incorporate the intervention into their existing practice by, for example, encouraging the parents in their network to complete the intervention prior to children's enrollment in activities.

This paper reports the results of a randomized controlled trial (RCT) evaluating the efficacy of a risk reframing intervention to increase mothers' tolerance for risky play and attain a behavior change goal related to providing risky play opportunities for their 6-12-year-old children. The intervention development, content, and theoretical framework were previously published [14]. We tested 2 versions of the intervention: a web-based and an in-person workshop. We hypothesized that participants in either intervention condition would have significantly greater increase of tolerance for risky play than those in the control condition at 1 week and 3 months after the intervention. We also hypothesized that a greater proportion of participants in either intervention condition would attain their behavior change goal than those in the control condition.

We further examined whether social cognitive theory (SCT), the behavior change model that underpinned the development of the intervention, produced the hypothesized effect on the outcome variables. Specifically, we hypothesized that self-efficacy, outcome expectations, and knowledge of risky play would mediate the relationship between the risk reframing intervention and the outcomes: tolerance for risky play and goal attainment.

Methods

Study Design

A description of the protocol for this study has been published [14]. Briefly, the study was a single-blind (researchers and outcome assessors), 3-parallel condition RCT. The trial was conducted between December 2017 and September 2018 in the Metro Vancouver area of British Columbia, Canada. Measures were collected at baseline, 1 week, and 3 months after the intervention. The primary outcome was increase in tolerance of risk in play at either follow-up time point. The secondary outcome was mothers' goal attainment at either follow-up time point.

The trial was registered with the United States National Institutes of Health's Protocol Registration and Results System (NCT03374683) and approved by the University of British Columbia/Children's and Women's Health Centre of British Columbia Research Ethics Board (H15-03271). No change was made to methods after trial commencement. We followed the CONSORT-EHEALTH guidelines in reporting this study [15]. The completed checklist is presented in Multimedia Appendix 1.

Participant Recruitment and Eligibility Criteria

Participants were recruited through advertising on online forums and social media, distributing notices through our networks, snowball sampling, and posting notices in community centers. Interested participants visited the study home page in the REDCap electronic data capture tool hosted at the British

Columbia Children's Hospital Research Institute [16]. There they were provided with a description of study procedures and information that completing the survey questions indicated consent. Potential participants were self-assessed through eligibility questions establishing that they were a mother with primary custody of a child/children aged 6-12 years; residing in the Metro Vancouver Regional District; and able to speak, read, and understand English. Computer/internet access and literacy were implicit eligibility criteria because accessing the study home page and completing the eligibility questionnaire would be otherwise impossible. Enrolled participants were emailed a unique link to the baseline questionnaire package in REDCap.

Randomization and Blinding

Enrolled participants were automatically assigned to 1 of the 3 conditions by REDCap: control, web-based, or in-person workshop. Participants had equal likelihood of being assigned to each condition (33%, ie, nearly 170). The randomization schedule was generated beforehand via sealed envelope [17] using randomized permuted blocks of size 3, 6, and 9. The list was then transferred to REDCap. Unbeknownst to participants, randomized allocation occurred in the background before participants completed the baseline questionnaire. This had to be done because REDCap limited capabilities for real-time, streamlined randomized allocation. The nature of the intervention did not permit participant blinding, but they were informed of their allocated treatment after completing the baseline questionnaires. The in-person workshop facilitator could not be blinded to allocation as the other 2 arms did not have a facilitator. Likewise, research staff who coordinated in-person workshop schedules could not be blinded to allocation of the in-person workshop. In-person workshop participant information (name and email address) was only used to coordinate the workshop. This information was encrypted, password protected, and stored in a password-protected folder in a secured network at the British Columbia Children's Hospital Research. However, allocations were concealed to the researchers at participant assignment and data analysis.

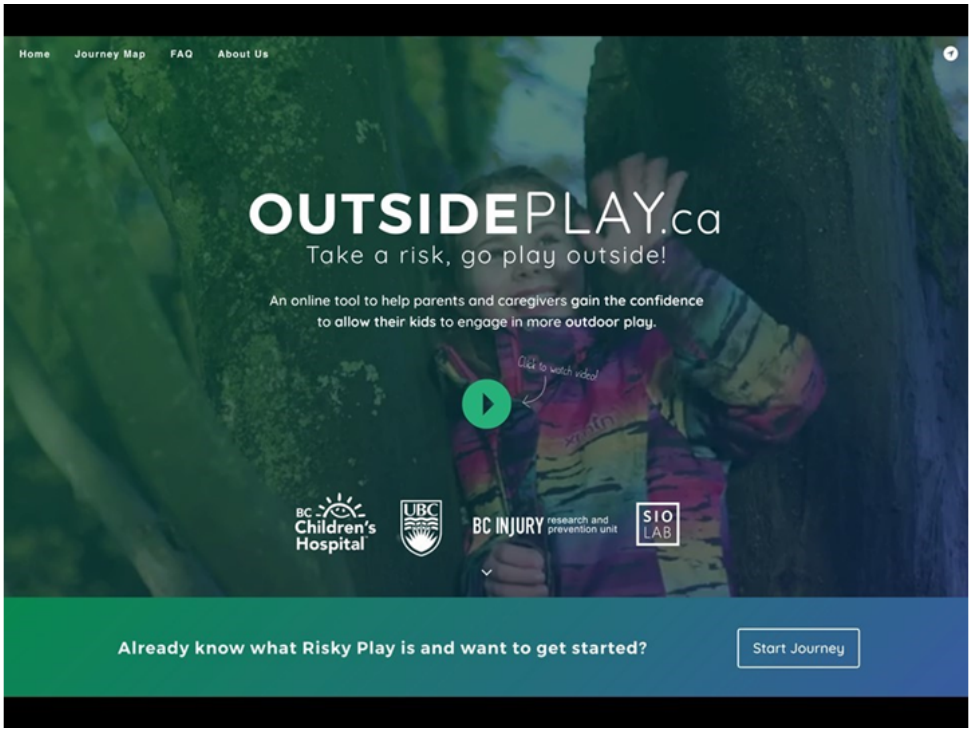
Risk Reframing Intervention

Participants in the web-based intervention were provided with a link to the fully automated web-based intervention [18] which they need to complete within 1 week. A reminder was sent via email if participants did not complete the web-based intervention within 24 hours. The final reminder was sent 48 hours after their baseline entry via email. Contact information (ie, email, phone) was provided for participants to contact the research coordinator if they had any feedback or questions. Participants in the in-person workshop were scheduled to attend the in-person workshop. Briefly, the risk reframing intervention was adapted from an in-person workshop for parents and teachers developed by Bundy and colleagues [8,19] using SCT [20] to incorporate health behavior change techniques (BCTs) as per Michie et al's taxonomy [21]. The published study protocol outlines each intervention task with the corresponding SCT construct and BCTs [14]. We sought to address common concerns about risky play and engage participants in self-reflection tasks to consider how these concepts applied to their parenting approach. The home page included a 2-minute video introduction to the topic and the tool, text defining outdoor and risky play, and outlining why they are important, as well as a brief description of the journey participants would follow in the tool. The logos of the British Columbia Children's Hospital, the University of British Columbia, British Columbia Injury Research and Prevention Unit, and the Digital Lab were prominently displayed on the home page. As per SCT, the home page focused on building knowledge and influencing outcome expectations. BCTs included credible source, and information about health, social, and emotional consequences. Participants then proceeded through 3 chapters. Chapter 1, *Reflection*, involved considering the values and traits they most desired for their child in adulthood, their child's favorite activities, their own favorite play activities at the same age, and what they got out of these childhood activities. As above, this chapter also focused on knowledge and outcome expectations. BCTs included framing/reframing and incompatible beliefs. Chapter 2, *What Would You Do?*, presented participants with 3 interactive video segments (climbing a tree, walking home from school, and building a den) and gave them the choice to allow or not allow the child to engage in the activity. If the participant chose to allow the activity, the child displayed excitement at the opportunity and a sense of achievement upon completion. If the participant chose to not allow the activity, the child displayed disappointment and dejection. Once the choice was made, the rest of the video played with the outcome of that choice. Participants were also asked to reflect on fears that influenced their choice, and things that helped them let go. In addition to the above SCT constructs (knowledge and outcome expectations), this chapter provided opportunities for observational learning, building self-efficacy, and identifying barriers and opportunities. BCTs included information about health, social and environmental, and emotional consequences; problem solving; demonstration of behavior; comparative imagining of future outcomes, framing/reframing; and focus on past success. Chapter 3, *Creating Your Plan*, allowed participants to review their journey and set a realistic goal as well as the timeline and steps to attain it. Participants could enter their own goal in a text box, or select from a list of suggested goals that included steps to attain it; for example, "letting my child play out in the yard without supervision" with the following steps: "Let your child play outside for a few minutes while you watch from the window. Gradually extend this time. Then try not watching out the window." This chapter reinforced the above SCT constructs, and also encouraged building self-efficacy and outlining intentions. BCTs included goal setting (behavior and outcome), problem solving, action planning, demonstration of behavior, prompts/cues, graded tasks, comparative imagining of future outcomes, framing/reframing, and incompatible beliefs.

The intervention was developed by the study authors. Once the web-based platform was complete, the in-person workshop presentation (prepared in Microsoft PowerPoint) and facilitator and participant manuals were developed using images from the web-based platform. Intervention content was frozen during the trial. The web-based intervention is available online [18]. Screenshot of the landing page can be seen in Figure 1 and the complete screenshots of the web-based intervention can be

accessed in Multimedia Appendix 2. The in-person workshop materials can also be accessed in Multimedia Appendix 3.

Figure 1. Intervention landing page.



Participants using the web-based intervention took between 15 and 45 minutes to complete it, depending on their movement through each task. The in-person workshops lasted approximately 45 minutes to 1.5 hours, depending on participant discussion. Participants in the control condition took 15-20 minutes to complete.

Comparison Condition

Participants in the control condition were asked to review an online version of the Position Statement on Active Outdoor Play, which includes information on research and recommendations for action in addressing barriers to outdoor play [1,22].

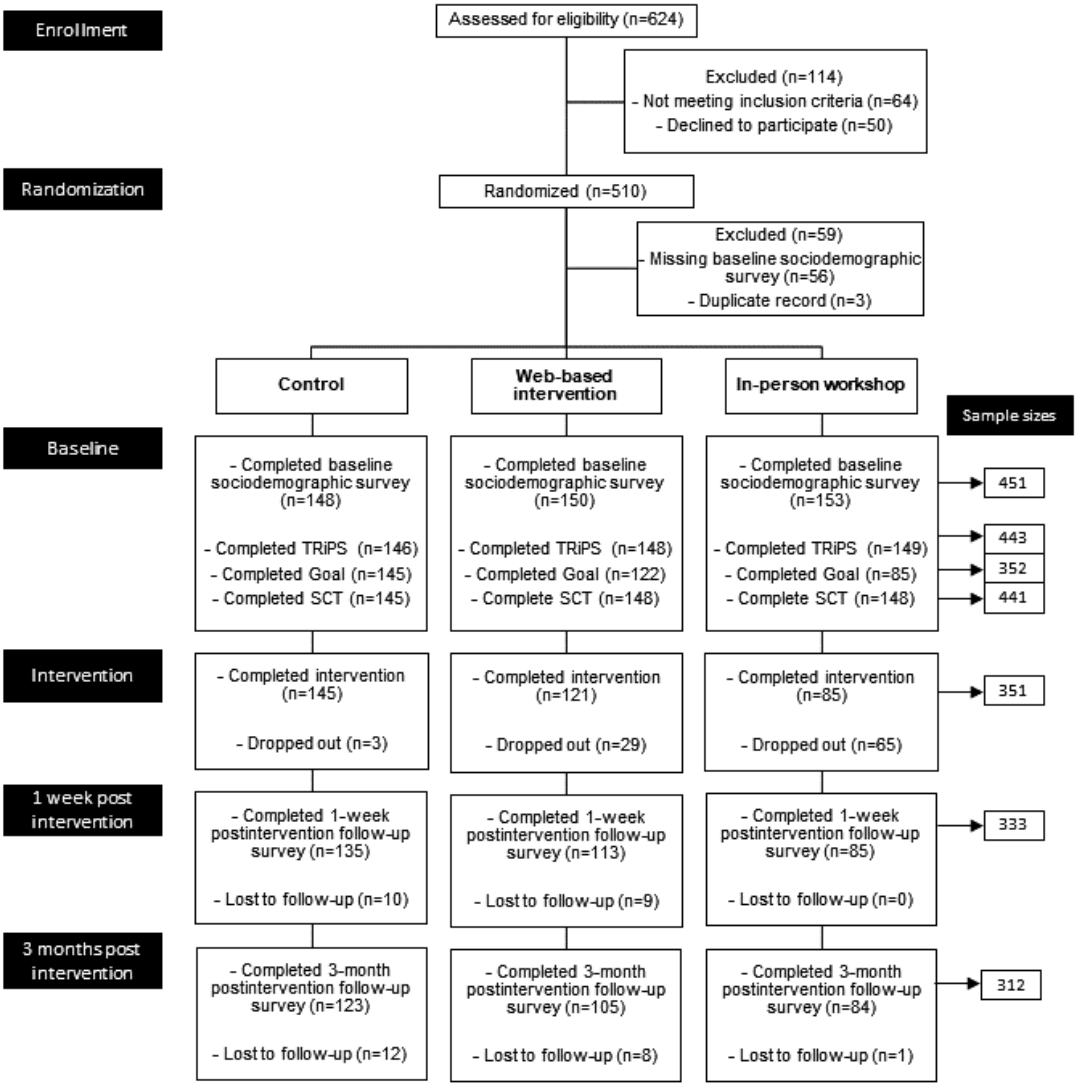
Outcome Measures

Measurements were taken at baseline, 1 week, and 3 months after the intervention. Participants in all conditions received an honorarium of Can $30 (US $24) at baseline and Can $15 (US $12) at each follow-up as a compensation for participation. Nonrespondents received 2 email reminders to complete survey data. Participants attending in-person workshops were provided with an additional honorarium of Can $30 (US $24) to compensate for expenses incurred in attending, such as travel or childcare.

The primary outcome measure was increase in the total score on the Tolerance for Risk in Play Scale (TRiPS), a 31-item measure examining adults' tolerance of risk during children's play, based on Sandseter's 6-category model of risky play [23]. An earlier version of the TRiPS scale has been validated [24]. We obtained the scale from the author AB and assessed its psychometric properties in our sample using Rasch analysis. This analysis was conducted using mirt package in R software [25]. Rasch analysis of the baseline data (N=443 completed TRiPS; Figure 2) resulted in dropping 1 item (Do you allow this child to play-fight, testing who is strongest?) due to local dependence. The remaining 30 items resulted in the following model fit: root mean square error of approximation (RMSEA)=0.051 (90% CI 0.047-0.056), standardized root mean square residual (SRMSR)=0.089, Tucker–Lewis index (TLI)=0.874, comparative fit index (CFI)=0.874, and empirical reliability=0.789. Theta standardized scores from the Rasch analysis of the final 30-item TRiPS scale ranged from –3.372 to 1.975, with a mean of 0.000 (SD 0.974). A higher standardized score indicates higher tolerance of risky outdoor play.

The secondary outcome measure was self-reported behavior change, measured by participants' self-reported progress on attaining the goal they set for themselves within the risk reframing intervention. At each follow-up, participants were reminded of their goal and asked "Did you accomplish your goal?" with "Yes" and "No" response options.

Figure 2. CONSORT flowchart.



Behavior Change Model

To assess whether the effect of the intervention was mediated by SCT as we had theorized [14], we developed measures for self-efficacy, outcome expectations, and knowledge of risky play. All measures were previously published [14]. Confirmatory factor analyses were performed on the baseline data (n=441 completed all SCT construct measures; Figure 2) to test the psychometric properties of the 3 measures, resulting in the following: (1) 4-item self-efficacy, RMSEA=0.075 (90% CI 0.020-0.139), CFI=0.987, and SRMSR=0.023; (2) 7-item outcome expectations, RMSEA=0.107 (90% CI 0.085-0.129), CFI=0.975, and SRMSR=0.023 (2 items were dropped: "promote MY CHILD's self-confidence" and "help MY CHILD become more imaginative" due to high modification indices); and (3) 7-item knowledge of risky play: RMSEA=0.129 (90% CI 0.108-0.151), CFI=0.965, and SRMSR=0.026 (2 items were dropped: "promote A CHILD's self-confidence" and "help A CHILD become more imaginative" due to high modification indices). Average scores of all remaining items were calculated for each SCT construct, respectively.

Statistical Analyses

All statistical analyses were conducted in Stata 15 (StataCorp) [26].

Power

The TRiPS is scored on a logit scale and previous research indicated that scores on the TRiPS for a sample of parents of children aged 5-13 range from 0.20 to about 1.95 with SDs in the range of 1.78-1.82 [24]. With a sample size of at least 81 mothers in each condition, a test that averaged the differences in TRiPS score from baseline to the first assessment would have 80% power at a .05 level of significance to detect a difference of 0.75 with the control condition when the SD is 1.82 and the correlation between repeated observations is 0.75.

Descriptive Analysis

To compare sociodemographic differences between conditions, for continuous variables, one-way ANOVA was used, or Kruskal–Wallis H test (if variance was not equal between conditions). For categorical variables, chi-square test was used, or Fisher exact test if single-cell numbers were small. One-way ANOVA was used to compare TRiPS scores between different

conditions at different time points. Significance level was set at $P<.05$.

Treatment Effect of the Intervention

Linear and generalized linear mixed effects models with random intercepts and unstructured covariance were fit to analyze the effects of the intervention on TRiPS scores and goal accomplishment, respectively. In other words, the mixed effects regression analysis examined (1) whether TRiPS scores changed 1 week and 3 months after the intervention, and (2) whether these changes were greater in either experimental condition (web-based intervention or in-person workshop) compared with the control condition. Intent-to-treat analysis of TRiPS scores used last-observation-carried forward as the method of imputation, because missing data were primarily in the in-person workshop condition. Because these participants only completed baseline measures and did not receive the intervention, it is reasonable to expect their scores to remain the same throughout the study. Unstandardized (ie, raw) beta coefficients (β) were reported, which are interpreted as the change of TRiPS scores when comparing the experimental conditions with the control groups at baseline.

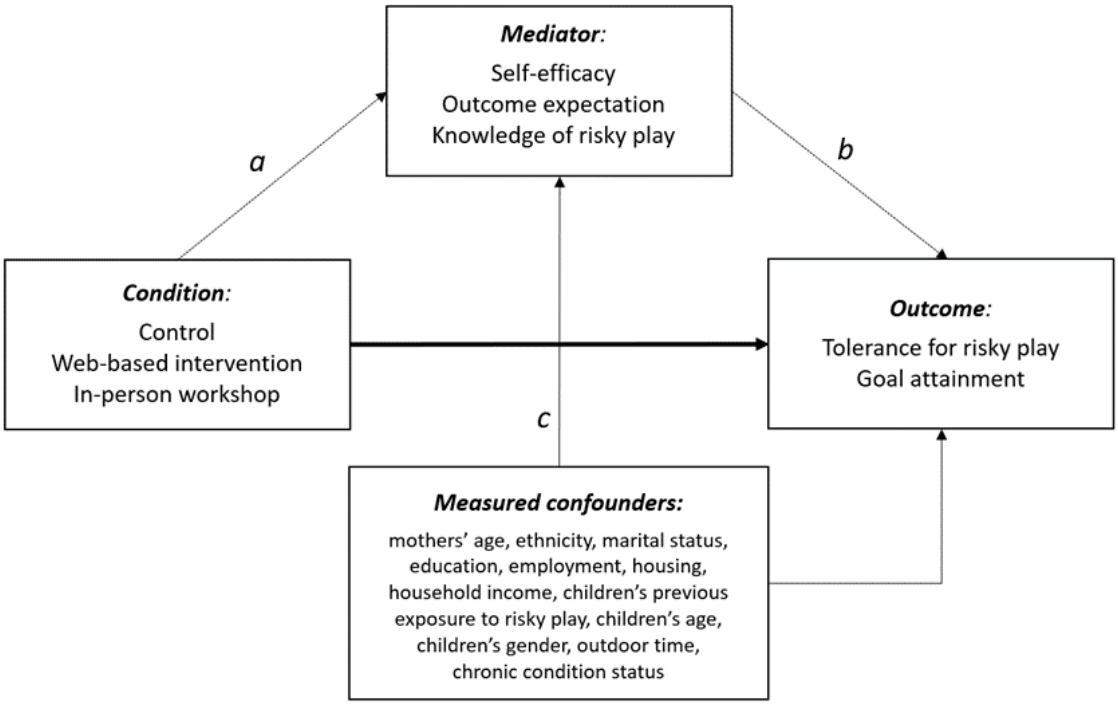
Similar to the TRiPS analyses, we conducted a generalized mixed effects regression analysis to examine the effect of the intervention on goal accomplishment, when comparing the control condition at 1 week with either of the experimental conditions at 3 months' follow-up. Intent-to-treat analysis of goal accomplishment was not performed due to the absence of baseline data. To establish a goal, participants had to complete either intervention. As a result, there was no basis to impute values of goal accomplishment. Odds ratios (ORs) were reported, which are interpreted as the odds of attaining goals for the experimental conditions at 3 months' follow-up, when comparing with the control conditions at 1 week after the intervention.

All models were adjusted by parents' age, ethnicity, marital status, education, employment, housing, and household income; and children's previous exposure to risky play, age, gender, weekday/weekend outdoor time, and chronic condition status.

Behavior Change Model Testing

To test whether SCT produced the hypothesized effect on the outcomes, we tested whether the effect of the intervention was mediated by self-efficacy, outcome expectations, and knowledge of risky play, as outlined in Figure 3. We followed the steps of mediation analysis for RCTs suggested by Whittle et al [27]. First, univariable linear regression models were fitted to the potential mediators to test whether there was an association between treatment and each mediator, respectively. Second, because a variable can only be a mediator of treatment, if there is a significant effect ($P<.05$) of treatment on the mediator (path *a*), a mediation analysis in the second step was only fitted to variables that were significantly associated with treatment. In the second step, the test of indirect (mediating) effect was performed by fitting regression models to the outcome, with treatment and the significant mediator found in step 1 included as covariates (path *ab*). This step of analysis controlled for baseline covariates, attempting to control for these as potential confounders in order to add robustness to our analyses. These confounders included mothers' age, ethnicity, marital status, education, employment, housing, household income; and children's previous exposure to risky play, children's age and gender, weekday/weekend outdoor time, and chronic condition status. Similar to the TRiPS analyses, intent-to-treat analysis was conducted using the last-observation-carried forward.

Figure 3. Mediation analysis.



Results

Overview

Figure 2 shows the study flow diagram. Recruitment began on December 1, 2017, and closed on June 18, 2018, once we had a minimum of 81 participants in each condition with complete data. A total of 510 mothers of a child between 6 and 12 years old residing in Metro Vancouver were automatically allocated to 1 of the 3 conditions by REDCap. Of these, 351 completed the intervention. While randomization produced roughly equal numbers of participants allocated to each condition, the in-person workshop condition experienced the most drop-outs (n=65). This condition involved the most time commitment for the participant and produced scheduling challenges. As such, despite the additional Can $30 (US $24) incentive to participate, it was most difficult to maintain participants in this condition. However, of the mothers attending the workshop, only 1 was lost to follow-up. We were able to ensure fidelity to the web-based intervention as we received a summary of all responses when a participant completed the intervention. These were reviewed to ensure full completion. Fidelity to the in-person workshop was established through attendance to the workshop.

Participant Characteristics

Baseline sociodemographic data from 451 mothers were included in our analyses. Participant demographics are displayed in Table 1. There were no statistically significant differences between conditions with respect to demographic characteristics at baseline (see the "*P* value column" in Table 1). There were statistically significant differences between conditions for child's disability/chronic condition at both 1 week (*P*=.03) and 3 months (*P*=.03) after the intervention, with the percentage of children having chronic conditions in the web-based intervention higher than that in the other 2 conditions (10/113 [8.8%] for 1 week after the intervention, and 9/105 [8.6%] for 3 months after the intervention, respectively). We also further compared the sociodemographic characteristics between those who completed the intervention (N=351) and those who did not complete the intervention (N=100), and found that employed mothers were more likely to complete the intervention (75.8% [266/351] versus 65.0% [65/100], respectively, *P*=.03). There were no statistical differences for other sociodemographic characteristics (see Multimedia Appendix 4).

[a]One parent reported age=7 years, which is not reasonable, so we treated that data as missing.

[b]Prefer not to answer, n=4 (n=2 for web-based intervention; n=2 for in-person workshop).

[c]Can $ 1=US $0.80.

[d]A total of four children did not have information regarding their sex (n=3 in the control group, n=1 in the in-person workshop).

[e]Fisher exact test due to small sample size in single cell.

[f]Kruskal–Wallis H test due to non-equal variance between conditions.

Primary Outcome: TRiPS

Table 2 presents the description of TRiPS scores by treatment conditions and time point, without accounting for treatment effects nor adjusting for sociodemographic characteristics. There were no statistical differences in TRiPS scores between different conditions at each time point. Table 3 describes findings of the mixed effects regression analysis. Mothers who completed the web-based intervention condition had significantly higher TRiPS scores than mothers who completed the control condition at 1 week (=.26, 95% CI 0.09-0.43; *P*=.003) and 3 months (=.24, 95% CI 0.06-0.42; *P*=.01) after the intervention, indicating sustained change. Mothers who completed the in-person workshop condition had significantly higher increases in TRiPS scores than those in the control condition at 1 week after the intervention (=.19, 95% CI 0.06-0.38; *P*=.04). No statistically significant differences were found when comparing mothers who completed the in-person workshop condition with those in the control condition at 3 months after the intervention (=.09, 95% CI –0.10 to 0.29; *P*=.33).

Results of the intention-to-treat analyses for the effects of the intervention on TRiPS score largely replicated the analyses described above, indicating that mothers in the web-based intervention condition were significantly more likely to increase their TRiPS scores at 1 week (=.25, 95% CI 0.08-0.42; *P*=.004) and 3 months (=.24, 95% CI 0.06-0.42; *P*=.007) after the intervention compared with those in the control condition. Mothers in the in-person workshop condition had significantly higher increases in TRiPS scores than those in the control condition at 1 week after the intervention (=.22, 95% CI 0.03-0.40; *P*=.02). No statistically significant differences were found when comparing mothers in the in-person workshop with those in the control condition at 3 months after the intervention (=.13, 95% CI –0.06 to 0.32; *P*=.17).

Table 2. Description of TRiPS[a] scores by treatment conditions and time points.

Evaluation period	Sample size, n	Control, mean (SD)	Web-based intervention, mean (SD)	In-person workshop, mean (SD)	*P* value for 1-way ANOVA
Baseline	443	0.05 (1.03)	–0.11 (0.94)	0.06 (0.94)	.24
Completed intervention	351	0.05 (1.03)	–0.14 (0.97)	0.18 (0.87)	.05
1 week after the intervention	333	–0.09 (1.03)	–0.06 (1.05)	0.22 (0.80)	.06
3 months after the intervention	312	–0.03 (0.92)	–0.09 (0.93)	0.15 (0.80)	.19

[a]TRiPS: Tolerance for Risk in Play Scale.

Table 3. Results of mixed effects regression analysis for change in TRiPS[a] scores by treatment condition and time point.

Regression and group comparisons	Coefficients (95% CI)	*P* value for coefficients	*P* value for joint test of main effects
Raw TRiPS theta scores (N=351, for those who completed the intervention)[b]			
Treatment effects			.21

In-person versus control by 1 week versus baseline	0.22 (0.03 to 0.40)	.02	
In-person versus control by 3 months versus baseline	0.13 (–0.06 to 0.32)	.17	

[a]TRiPS: Tolerance for Risk in Play Scale.

[b]Significant ($P<.10$) sociodemographic predictors include ethnicity, housing condition, previous exposure to risky play information, child's age, child's disability/chronic conditions, and weekend outdoor time.

[c]Significant ($P<.10$) sociodemographic predictors include ethnicity, parental employment status, housing condition, previous exposure to risky outdoor play information, child's age, child's disability/chronic conditions, and weekend outdoor time.

Secondary Outcome: Goal Attainment

Table 4 presents the results of the generalized mixed effects regression analysis. There was no statistical difference in goal attainment between mothers in the web-based intervention and the control condition at 3 months after the intervention as compared with 1 week after the intervention (OR 0.59, 95% CI 0.18-1.91; $P=.37$). There was also no statistical difference in goal attainment between mothers in the in-person workshop and the control condition at 3 months after the intervention as compared with 1 week after the intervention (OR 0.55, 95% CI 0.17-1.76; $P=.31$).

Table 4. Results of the mixed effects regression analysis for goal attainment by treatment condition and time.[a]

Regression and group comparisons	Odds ratios (95% CI)	*P* value for coefficients	*P* value for joint test of main effects
Treatment effects			.004
Web based versus control	3.36 (1.32-8.54)	.01	
In-person versus control	0.72 (0.28-1.85)	.49	
Time effects			<.001
3 months versus 1 week	7.27 (3.11-17.02)	<.001	
Treatment by time effects			.53
Web based versus control by 3 months versus 1 week	0.59 (0.18-1.91)	.37	
In-person versus control by 3 months versus 1 week	0.55 (0.17-1.76)	.31	

[a]Significant (*P*<.05) demographic predictors include ethnicity, child's disability/chronic conditions, and weekend outdoor time.

Behavior Change Model Mediation Analysis

Because only significant intervention effects were observed for TRiPS score and not goal attainment, mediation analyses were only conducted for TRiPS data. With regard to the direct effects of treatment conditions on the 3 SCT constructs, none of the 3 SCT constructs (self-efficacy, *P*=.16; outcome expectations, *P*=.24; and knowledge of risky play, *P*=.12) was associated with treatment exposures in the unadjusted models, neither for those who completed the intervention (N=351) nor for the intention-to-treat analysis sample (N=441, for those who completed baseline sociodemographic, TRiPS, and SCT survey; all *P* values were >.05). As there was no direct association between treatment and the SCT constructs (path *a*), further mediation analyses were not conducted because it was not possible for the SCT constructs to have an impact on the study outcome via mediation (ie, path *ab*). Therefore, none of the potential mediators were found to significantly mediate outcome.

Discussion

Principal Findings

Our hypotheses were partially supported. Mothers receiving both the web-based intervention and the in-person workshop intervention at 1 week after the intervention reported significantly higher increases in their tolerance for risky play than mothers in the control condition at baseline. These differences remained significant at 3 months after the intervention for mothers receiving the web-based intervention but not mothers receiving the in-person workshop intervention. There were no significant differences in goal attainment.

We did not have sufficient statistical power to test the difference in efficacy between the 2 versions of the intervention. In any case, the significant results for the web-based intervention and not for the in-person workshop at 3 months after the intervention are unexpected, as the in-person workshops provided arguably a higher intervention dose given the greater length required in participation and the more social aspect of the experience that could influence participant perceptions of social support, a construct of SCT [20]. Workshop participation required fitting into a set schedule and demanded significantly more time commitment and effort than the other conditions. Thus, it required a higher motivation level and had greater attrition. Those who ended up attending the in-person workshop might have already been fully aware of the benefits of children's outdoor play, which inadvertently left limited room for improvement. However, this possibility is not supported by baseline scores on the TRiPS, which did not differ between conditions. Another possible explanation could result from the fact that the number of participants attending each workshop varied considerably (2-12 participants), which could negatively impact the extent of discussion [28]. Further, workshops were facilitated by a professional facilitator, without content expertise in outdoor play and who was not a parent. SCT stresses the importance of relatable peers modeling behavior to encourage behavior change [28]. Thus, appropriate probing to foster discussion and participants' engagement with the topic may have been hampered.

It is not readily apparent why there was a null finding for goal attainment. It is possible that the binary yes/no outcome may have hampered participant responses in that participants may not have indicated they had attained their goal unless they perceived that all aspects were complete. In addition, goals may have been overly ambitious and did not have clear steps to attain them, such as "give my child more independence to enjoy freedom." Future iterations of the intervention should encourage users to set a more realistic and actionable goal. Sample actionable goals were provided in the tool but it is possible that these required further details on actions.

In sum, our findings indicate the efficacy of both versions of the risk reframing intervention for changing mothers' tolerance to risky play, with the web-based intervention displaying long-term effects.

Behavior Change Model

The hypothesized relationship between the constructs of SCT (self-efficacy, outcome expectation, and knowledge) and the intervention outcomes was not supported. We offer the following explanations for these findings. First, the intervention may have been of insufficient intensity or duration to influence these constructs. To reduce access and engagement barriers, we sought to develop an intervention that was efficient, would require limited time commitment, and would not necessitate repeat visits [14]. Therefore, future iterations may attempt to increase

the intervention dose to determine whether this would impact the mediators as we hypothesized. Second, it is possible that our SCT constructs were not sensitive enough to detect change over time. While we evaluated the psychometric properties of our measures, we do not know whether these measures are sensitive to change as they were developed for this study. Third, although we hypothesized that both self-efficacy and outcomes expectations would increase as a result of the intervention, it is possible that going through the intervention and attempting to change parenting practices proved more difficult than anticipated for some parents and might explain why no change was observed for the SCT constructs. We did not collect data on other potential factors that could influence parents' success, such as self-efficacy in overcoming barriers, thus limiting our insight on these results.

Strengths and Limitations

Our research is the first to use health behavior change theory and BCTs to develop an intervention to reframe mothers' perceptions and influence their parenting behaviors related to outdoor risky play. As recommended by published guidelines [29,30], we are also among the first to test the active ingredients of the intervention, examining the hypothesized relationships between SCT constructs and the outcomes. In addition, our use of RCT methods represents a gold-standard methodological evaluation technique. Previous research reported on but did not evaluate an in-person workshop intervention separately from a loose parts intervention in the playground [11]. Furthermore, our RCT evaluated 2 versions of the risk reframing intervention, providing insight into the efficacy of alternative delivery methods with important implications for practice.

There were several limitations to the study. Given the nature of the intervention, it was not possible to blind participants to their allocation, thus potentially introducing sources of bias. Furthermore, the intervention was developed based on research conducted in Western settings and was only available in English. As such, it may not reflect the perspectives and needs of other cultural and linguistic conditions and non-Western settings. Likewise, because one of our conditions necessitated in-person participation, we were only able to recruit participants within a limited geographic area, thus potentially limiting the applicability of our findings to other areas, such as rural communities.

Conclusions

Our findings provide confidence in encouraging use and broad dissemination of the web-based intervention. Given the ease of distribution, no cost to users, and low resource requirement for ongoing maintenance of the web-based tool, it is encouraging that this was an effective model and can provide the basis for further iterations and versions. Future research is necessary to examine the risk perceptions of parents from other cultural conditions and settings to facilitate the development of interventions that are applicable to their settings and realities.

Acknowledgments

This study was funded by the Lawson Foundation (Grant Nos GRT 2015-68 and GRT 2016-72). The Lawson Foundation was not involved in any aspect of study design or writing of the manuscript. MB and LM are supported by salary awards from the British Columbia Children's Hospital Research Institute. GF is supported by a Canadian Institutes of Health Research-Public Health Agency of Canada Chair in Applied Public Health. We thank Kathryn Soo and Jaspreet Dhillon, our research work study students who made the project possible. We also thank Juan Tellez, Kevin Quach, and Fahad Hasany from the Digital Lab at the University of British Columbia Department of Pediatrics for providing partnership and technical support in the development and programing of the web-based tool. We thank Dr Anita Niehues for her ideas and contributions to the development of the web-based intervention. We also thank Pam Fuselli, Heidi Campbell, Pierre Harrison, Brandy Tannenbaum, and Dr Guylaine Chabot for their review of and comments on an earlier version of the in-person workshop materials. We are further grateful to the Lawson Foundation for funding tool development and evaluation and to Christine Alden for her personal engagement in the project. Finally, we would like to express our gratitude to the participants for sharing their perspectives.

Authors' Contributions

MB conceived the study. AB and IP assisted MB with adaptation of the original risk reframing workshop for the purposes of the study. JJ led the development of the web-based platform. CH and MB developed the in-person workshop presentation and manuals. MB and LM led development of the study design, with contribution from GF, CH, and the remaining authors. MB wrote the first and subsequent drafts of this manuscript. LM and YL advised on statistical analysis. All authors read and approved the final manuscript.

Abstract

Background: Self-management strategies are regarded as highly prioritized in chronic obstructive pulmonary disease (COPD) treatment guidelines. However, individual and structural barriers lead to a staggering amount of people with COPD that are not offered support for such strategies, and new approaches are urgently needed to circumvent these barriers. A promising way of delivering health services such as support for self-management strategies is the use of eHealth tools. However, there is a lack of knowledge about the usage of, and factors affecting the use of, eHealth tools over time in people with COPD.

Objective: This study aimed, among people with COPD, to explore and describe the experiences of an eHealth tool over time and factors that might affect usage.

Methods: The eHealth tool included information on evidence-based self-management treatment for people with COPD, including texts, pictures, videos as well as interactive components such as a step registration function with automatized feedback. In addition to the latter, automated notifications of new content and pedometers were used as triggers to increase usage. After having access to the tool for 3 months, 16 individuals (12 women) with COPD were individually interviewed. At 12 months' access to the tool, 7 (5 women) of the previous 16 individuals accepted a second individual interview. Data were analyzed using qualitative content analysis. User frequency was considered in the analysis, and participants were divided into users and nonusers/seldom users depending on the number of logins and minutes of usage per month.

Results: Three main categories, namely, ambiguous impact, basic conditions for usage, and approaching capability emerged from the analysis, which, together with their subcategories, reflect the participants' experiences of using the eHealth tool. Nonusers/seldom users (median 1.5 logins and 1.78 minutes spent on the site per month) reported low motivation, a higher need for technical support, a negative view about the disease and self-management, and had problematic health literacy as measured by the Communicative and Critical Health Literacy Scale (median [range] 154 [5-2102]). Users (median 10 logins and 43 minutes per month) felt comfortable with information technology (IT) tools, had a positive view on triggers, and had sufficient health literacy (median [range] 5 [5-1400]). Benefits including behavior changes were mainly expressed after 12 months had passed and mainly among users.

Conclusions: Findings of this study indicate that the level of motivation, comfortability with IT tools, and the level of health literacy seem to affect usage of an eHealth tool over time. Besides, regarding behavioral changes, gaining benefits from the eHealth tool seems reserved for the users and specifically after 12 months, thus suggesting that eHealth tools can be suitable

media for supporting COPD-specific self-management skills, although not for everyone or at all times. These novel findings are of importance when designing new eHealth tools as well as when deciding on whether or not an eHealth tool might be appropriate to use if the goal is to support self-management among people with COPD.

KEYWORDS

COPD; qualitative content analysis; eHealth; self-management; primary care; chronic disease

Introduction

Chronic obstructive pulmonary disease (COPD) is a common, preventable, and treatable disease, listed as the third leading cause of death worldwide by the World Health Organization [1]. The disease most often presents with dyspnea of varying severity [2]. COPD is a complex disease with several pulmonary and extra-pulmonary manifestations, and leads to numerous negative clinical consequences such as exercise intolerance, decreased physical activity, decreased quality of life, as well as increased health care use [2,3].

Previous studies have shown that among people with COPD, those who use self-management strategies to manage their disease present with fewer symptoms and show reduced negative consequences of the disease [4-6]. Self-management strategies, such as exercise training, breathing strategies, and energy-conserving techniques during activities of daily life [7], have previously been found to reduce the need for hospitalization, increase physical activity and physical performance, as well as improve the quality of life [4-6,8,9].

Despite a high prioritization of self-management in COPD treatment guidelines [10], a staggering amount of people are not offered support for such strategies due to limitations of both individual and structural nature [10-12]. It is, therefore, crucial to find a way to circumvent this problem so that people with COPD are offered support to learn and use these COPD-specific self-management strategies.

eHealth tools, such as mobile apps and web-based platforms, represent a promising way of delivering health services such as support for self-management strategies to people with COPD. eHealth solutions are becoming increasingly common and are found to be feasible and effective within the COPD population [9,13-20]. eHealth tools have, for example, been used for educating and keeping track of a person's health and are thought to be a significant source of health-related information [14,15,19,20]. We previously found that access to the COPD Web for 3 months resulted in increased self-reported levels of physical activity among people with COPD [17]. Improved COPD-specific knowledge and altered self-management strategies were also found among the participants. However, the general use of the COPD Web varied profoundly among participants, and the vast majority of users mainly used the platform during the initial month [17]. To date, several research groups have investigated and provided valuable information on important factors to consider when designing eHealth tools [21-23], though less is known about user behavior over time. Specifically, knowledge of factors associated with the use of eHealth tools over time is sparse. The aim of this study was, therefore, to explore and describe the experiences of using an eHealth tool over time and factors that might affect usage among people with COPD.

Methods

Study Design

This exploratory qualitative study is presented in line with the Consolidated Criteria for Reporting Qualitative Research (COREQ) guidelines [24]. This qualitative study is part of a process evaluation in a parallel-group (1:1 allocation) controlled pragmatic pilot trial that was reported in line with the Consolidated Standards of Reporting Trials (CONSORT) statements for pragmatic trials and for pilot and feasibility trials [25,26]. The study was registered at ClinicalTrials.gov (NCT02696187) and ethical approval was given by the Regional Ethical Board, Umeå University, Umeå, Sweden (Dnr: 2014-319-31, 2015-457-32). Written informed consents were obtained from each participant before enrollment in the study. This study includes participants that were allocated to the intervention group and that had access to an eHealth tool, the COPD Web. To further ensure privacy of participants, all names were changed to pseudonyms during the start of the analysis, so that only interviewers (AN and MT) and SM knew their real names.

Setting and Sample

Five publicly funded primary health care units (2 situated in the north of Sweden and 3 in the middle of Sweden) were invited to participate as study sites in the pragmatic pilot trial [27]. In the main study 83 patients with COPD were included; of these, 43 were randomized to the intervention group and had access to the COPD Web. Of those randomized to the intervention group, a minimum of 3 participants at each of the 5 units were contacted and asked to participate in the individual interviews. We used purposeful sampling to ensure there is at least one male/female person with COPD at each primary health care unit. To be included in this trial, participants had to be able to read and understand Swedish or be assisted by someone with this capacity when using the eHealth tool.

The COPD Web

In brief, the COPD Web is an interactive webpage cocreated with users [16]. It consists of 2 main sections: one directed at health professionals, and another directed at people with COPD. Contents include videos, written information, images, and

helpful links. The COPD Web section aimed at people with COPD to support their self-management by increasing their knowledge about COPD and strategies to improve their health (eg, activities such as physical activity and exercise, breathing techniques, observing symptoms of exacerbations, and advice about making everyday activities less strenuous) [27]. In addition to the specific content of the COPD Web, there were a few things on the fringe of what was covered by the COPD Web that should be noted. The COPD Web also includes a function of registering physical activity (steps), for which participants received a pedometer with instructions on how to use it as well as an information leaflet on the importance of physical activity [27]. The COPD Web also had automated notifications of new publications on the website via email. It was first introduced to each participant by a health professional during a regular visit using a standardized procedure (designed to take a maximum of 10-15 minutes). During the introduction of the COPD Web, all participants were provided with a username and login. Further information about the eHealth tool is presented in the protocol [27].

Process of Data Generation

Overall, 16 participants (12 women), age range 48-86, accepted to participate in an individual face-to-face interview at 3 months after the intervention started. Follow-up interviews were done at 3 and 12 months, as both ranges of time are commonly used when investigating intervention-based effects in people with COPD [13,14]. At 3 months, 15 interviews were conducted in the participants' homes and 1 at a university (the worksite of the interviewer), according to the participant's wishes. Sociodemographic information including age, sex, civil status, occupation, physical activity, smoking habits, and educational level was obtained through a standardized questionnaire while information on lung function was obtained from medical records [27]. At the 12-month follow-up, the participants were contacted again over the telephone and 7 (5 women) of the previous 16 participants accepted a second individual interview—this time conducted over the telephone. The reason for declining a second interview was that they had not used the COPD Web at all between the 3- and 12-month follow-up period.

Experiences related to the usage of the COPD Web over time were collected through individual semistructured qualitative interviews. An interview guide was used as the framework for the interviews. It consisted of the following main areas: (1) user habits, (2) user experience, (3) accompanying parts (ie, introduction, pedometer, electronic newsletter), (4) potential effects, and (5) future use (Multimedia Appendix 1). Questions regarding all main areas were posed, albeit in varying order. The interviews at the 3-month follow-up ranged between 7 and 40 minutes (median 25 minutes) and interviews at 12 months ranged between 4 and 14 minutes (median 8 minutes).

In addition, data on characteristics of the individuals and thought to be important for their use of the COPD Web were collected. It included the impact of COPD on daily life measured with the COPD Assessment Test [28], dyspnea measured with the modified Medical Research Council Scale [29], and health literacy (ie, the degree to which individuals can find, understand, and use information and services to inform health-related decisions and actions for themselves and others) [30]. The latter was measured with the Communicative and Critical Health Literacy (CCHL) Scale questionnaire. A total score of less than 100 indicates a sufficient communicative and critical health literacy [30], a total score of more than 100 but less than 1000 indicates a problematic health literacy, and a total score of over 1000 indicates a lack in communicative and critical health literacy [30]. Data on the participants' use of the COPD Web were collected automatically from the website and included the number of visits (logins), pages used, and time spent on the website [27].

Research Team and Reflexivity

AN (PhD in physiotherapy, male, 32 years) and MT (PhD in physiotherapy, female, 43 years), conducted the interviews separately depending on geographic placement. Both interviewers were employed as postdoctoral researchers at Umeå University at the time. Prior to the study, AN had performed over 20 interviews (no specific training), and MT had performed over 30 interviews (supervision during postdoctoral employment). There was no relationship established between the researcher and the participant before the interviews.

In all of the interviews, only the researcher and the participant were present, and audio recordings were used. MT made short field notes for most of the interviews (used as a mean of recollection during analysis), AN did not take notes during or after the interviews. No immediate callbacks on the interviews were made (ie, for potential amendments or additional questions). Interesting or unexpected topics raised during the interviews were discussed and used to guide follow-up questions during the following interviews. Interview audio recordings were transcribed verbatim by an experienced third-party transcriber and verified by the authors by comparing with the audio records [31]. Transcripts were not returned to participants for comment or correction. Participants were not engaged to provide any feedback on the findings.

Analysis

Data were analyzed using an inductive approach of qualitative content analysis, as this method is useful when dealing with already gathered qualitative data where the goal is to increase the understanding of experiences of using an eHealth tool [32]. All interviews were read through several times (with the assistance of audio recordings for auditory cues). The interviews were then condensed, coded, and sorted into categories and subcategories [33]. MAXQDA 2018 software was used in the analysis process to facilitate administration of the interviews, codes, and quotes. SM was main responsible for the analysis, and researcher triangulation was used throughout the whole analysis phase to attain a higher level of credibility [16,33]. Continuous discussions among authors during the interviewing phase and making use of a semistructured interview guide were measures taken to enhance dependability [33].

To further explore usage over time, the participants were subgrouped based on their objective use of the COPD Web during the initial 3 months. *Users* were defined as those with more than 1 login/month or more than 20 minutes total spent time/month at 3 months. An individual that did not meet these

criteria were defined as a *nonuser/seldom user* at 3 months. Codes by users and nonusers/seldom users were then marked in the subcategories to analyze the data further. Furthermore, to explore usage during the initial 3-month period, we also compared responses between the 3- and 12-month interview in those accepting a follow-up interview at 12 months.

Results

Study Participants

Patients with COPD at each of the 5 included primary health care units were contacted with the goal of recruiting at least one female/male person with COPD at each unit. No male participant accepted an interview at one of the primary health care units. In total, we contacted 23 patients with COPD (12 female); of these, 7 declined (2 female), and 16 accepted participation in the interviews at 3 months. Furthermore, of those who accepted an interview at 12 months, 5 out of 7 were users at 3 months. When subgrouped based on their use of the COPD Web during the initial 3 months, users had, in median, sufficient communicative and critical health literacy. By contrast, nonusers/seldom users had problematic communicative and critical health literacy. No other apparent differences in absolute values were seen for any other participant characteristics between users and nonusers/seldom users at 3 months (Table 1).

Table 1. Participant characteristics.

[a]FVC: forced vital capacity.

[b]FEV_1: forced expiratory volume in 1 second.

[c]CAT: COPD assessment test (0-40, higher scores denote a more severe impact of COPD on patient's daily life).

[d]MRC: Medical Research Council Scale (1-5, higher score denote a higher degree of disability that breathlessness poses on day-to-day activities).

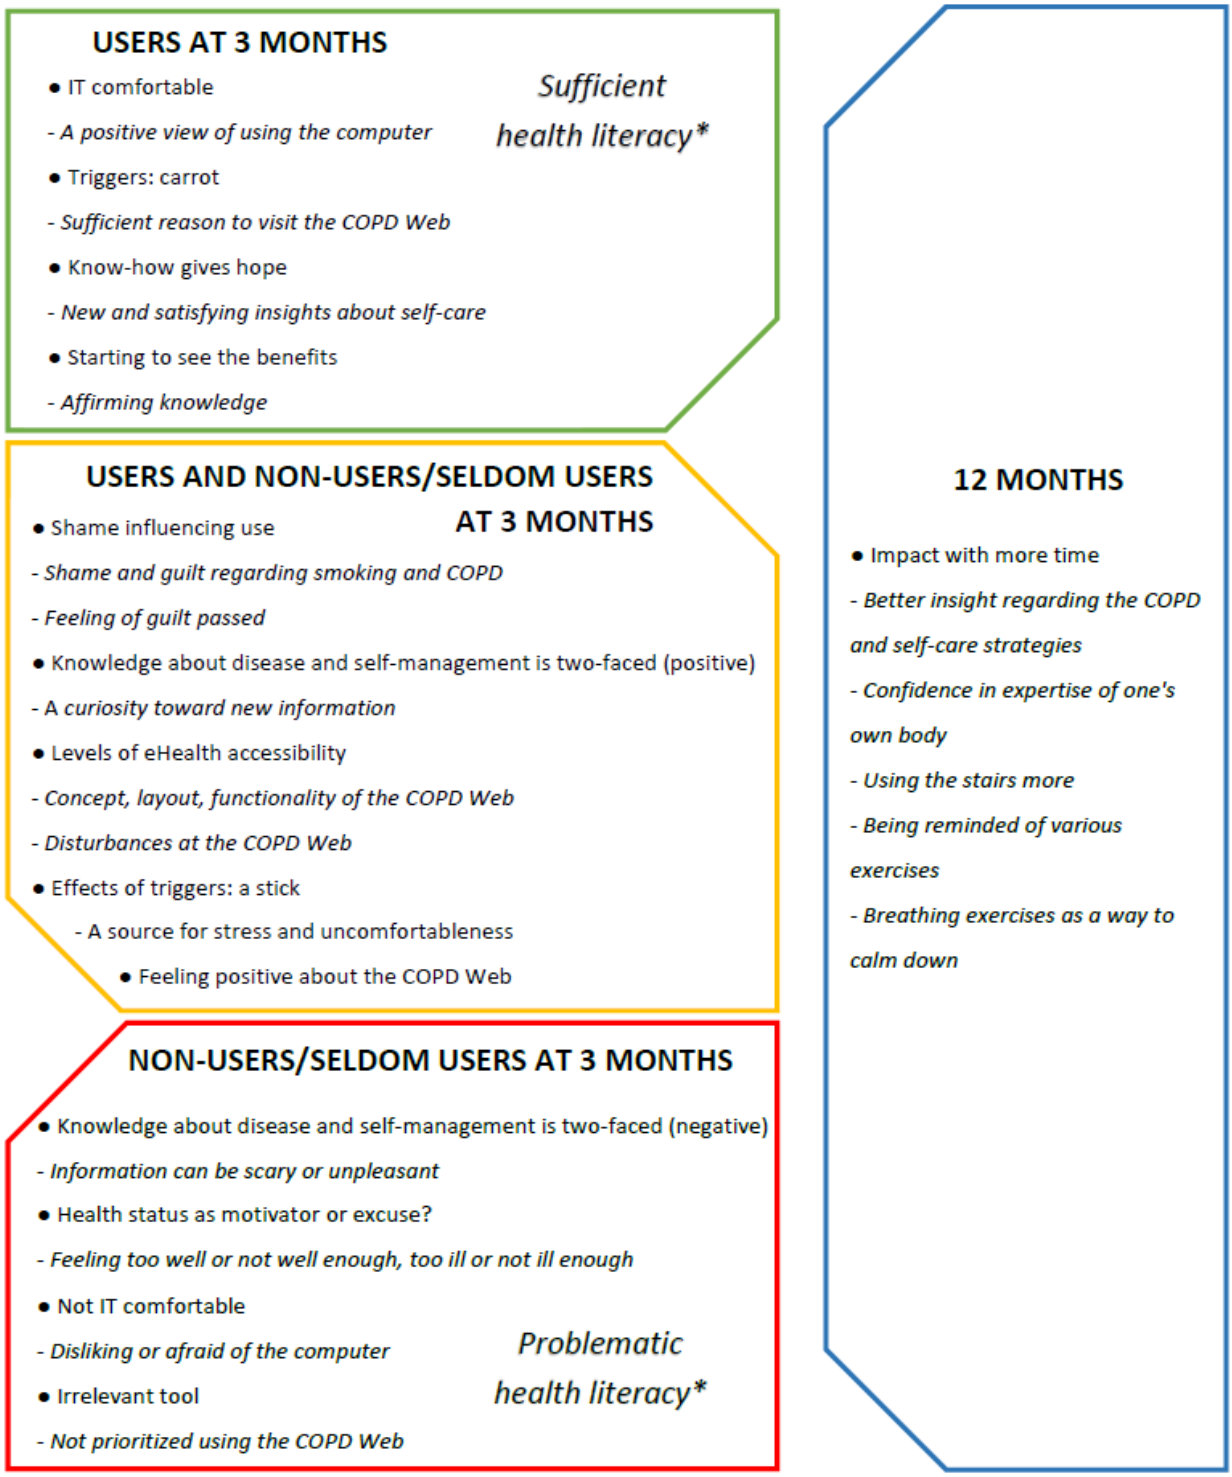
[e]COPD: chronic obstructive pulmonary disease.

[f]Data missing on 1 participant.

[g]CCHL: Communicative and Critical Health Literacy Scale, Swedish version (lower score = better health literacy).

The analysis resulted in 3 main categories, which, together with the subcategories, represent the participants' overall experiences regarding the use of the COPD Web over time and descriptions of factors that could affect the usage of the said tool (Textbox 1). An overview of the main results are seen in Figure 1.

Figure 1. Overview of user experience and factors affecting usage. "Users at three months" represent experiences mainly seen among those who used the COPD Web during the initial three months, "Non-user/seldom-users at three months" represent experiences mainly seen among those who did not use, or used at a limited extent, the COPD Web at three months, "Users and non-user/seldom-users at three months" represents experiences seen among both users and non-user/seldom-users at three months while "12 months" represents experiences mainly expressed at 12 months. *Based on the communicative and critical health literacy scale, Swedish version.



Textbox 1. Description of categories and subcategories. IT: information technology.

Ambiguous impact

- Shame influencing use
- Knowledge about disease and self-management is two-faced
- Health status as motivator or excuse?
- IT comfortable or not?

Basic conditions for usage

- Levels of eHealth accessibility
- Triggers: carrot or stick?
- Feeling positive about the COPD Web
- Irrelevant tool

Approaching capability

- Know-how gives hope
- Starting to see the benefits
- Impact with more time

Ambiguous Impact

Overview and Subcategories

In this category, participants expressed contradicting thoughts about seeking care due to, and specific information about, COPD. There were also some diverging thoughts on competence and motivation regarding the use of information technology (IT). The category includes the 4 subcategories "Shame influencing use," "Knowledge about disease and self-management is two-faced," "Health status as motivator or excuse?," and "IT comfortable or not."

Shame Influencing Use

Having COPD was sometimes experienced as something taboo, hushed up, or embarrassing which led to loneliness or isolation and prompted nonusers/seldom users to distance themselves from the eHealth tool, and users to try out the tool. A sense of not having anyone to talk to about their COPD, and feeling like COPD is rarely talked about, were mentioned as reasons for liking and welcoming the COPD Web.

> *Yes, but just talking about COPD, well...you just actually don't do that. That's why it's a good thing with this kind of page where you can get to know a little more.* [Charlotte, user, 3-month interview]

Among nonusers/seldom users experiences of shame and guilt regarding smoking and COPD were conveyed. A feeling of shame caused participants to withhold the diagnosis from family and friends and also hindered contacting health care. Having developed COPD was described as one's own fault (due to smoking), and therefore, something one should handle all by oneself. Hence using the COPD Web might be seen as getting undeserved assistance.

> *Well, this...I only have myself to blame. This is a result of my smoking. And that's how it is. I guess I'll have to battle this on my own.* [Gertrud, nonuser/seldom user, 3-month interview]

Knowledge About Disease and Self-Management Is Two Faced

Participants proclaimed a curiosity toward new information, a wish to know more, and indeed reported having actively searched for information and sources of information. Only nonusers/seldom users expressed that the urge to receive information about COPD and COPD-related subjects was not absolute. In addition, users mentioned the advantage of having access to a lot of information, whereas nonusers/seldom users felt that information could be scary or unpleasant, especially if it contradicted one's preconceptions. At the 12-month interview, participants (both users and nonusers/seldom users at 3 months) mentioned a desire to see if any new information had been posted or to refresh knowledge on something they had read about earlier as reasons for revisiting the COPD Web.

Health Status as Motivator or Excuse?

The own health status experienced was a prominent reason to visit or not to visit the COPD Web (ie, feeling good or poor made them more likely to use [or not use] the COPD Web). One view was that if one felt too well he/she would not be motivated to search for information, while another view was that one had to feel good to really be able to take in the advice and information. Besides, some thought themselves not ill enough while some proclaimed themselves not ill at all—either way, none of these conditions seemed to warrant visits to the COPD Web.

> *Well, of course, the better you feel…I believe it's more like you think it's more fun to just go in and read.* [Bella, nonuser/seldom user, 3-month interview]
>
> *[…] I kind of feel too healthy.* [Katarina, nonuser/seldom user, 3-month interview]

At 12 months it was still thought by former users to be more likely that one will use the eHealth tool if he/she feels sick.

IT Comfortable or Not?

Participants had different comfort levels regarding the use of computers and the internet. A positive view of using the computer and the internet was expressed among users. Users further mentioned the advantage of the COPD Web being accessible from anywhere (at home and any other place on the globe). Disliking or being unused to the computer or the internet was only mentioned by nonusers/seldom users as hinders for visiting the COPD Web and searching for information in general. Later, at 12 months, a nonuser/seldom user that previously stated her dislike and ignorance regarding both computers and the internet said that she was somewhat afraid of the computer:

> *Actually, I'm also a little afraid of the computer […] l am reluctant to have anything to do with it. Unfortunately. Sometimes I think that now I will…and then… "No, not now, not now, not now!"* [Penny, nonuser/seldom user at 3 months, 12-month interview]

Nonusers/seldom users also reported not prioritizing using the computer or the COPD Web, not having any interest in computers or the COPD Web, and preferring to read information as well as note (eg, step counts) on a paper instead of on the computer screen. Others explained their absence from the website as a result of being engaged in other activities or having forgotten about the computer or the COPD Web. Still, comments on lack of time for using the computer or COPD Web occurred among nonusers/seldom users. Disinterest for the eHealth tool was also reported at 12 months by both users and nonusers/seldom users.

Nonusers/seldom users expressed a need for their support system in the form of health professionals or close relatives. Support was used as a source of knowledge when it came to using the technology involved, as well as a motivational source for looking up information or learning new things and for allocating time for computer use.

> *I'm lucky to have a couple of lads I can call. "What the hell do I do now?"* [Kenneth, nonuser/seldom user, 3-month interview]

Basic Conditions for Usage

Overview and Subcategories

This category represents the technical aspects of the eHealth tool, covering both experiences of the functionality of the software and hardware and various attitudes using technical products in general. This category includes the 4 subcategories "Levels of eHealth accessibility," "Effects of triggers: a carrot or a stick?," "Feeling positive about the COPD Web," and "Irrelevant tool."

Levels of eHealth Accessibility

Generally, the concept, layout, and functionality of the COPD Web was appreciated at 3 as well as 12 months. Participants described disturbances, such as problems with their computer, frustrating and inconvenient. Sometimes strong feelings of being fed up with things not working were expressed, at both 3 and 12 months.

> *No, there's nothing else. There's my computer. I would be out on the web almost every other day looking, otherwise.* [Carol, nonuser/seldom user, 3-month interview]

> *Well, I've had a few problems with my computer, but I have been in and checked all [e-mail newsletters] that I've received.* [Cindy, user at 3 months, 12-month interview]

The COPD Web's low compatibility with smartphones was reported as a hindrance by some nonusers/seldom users at both 3 and 12 months.

Triggers: Carrot or Stick?

Overall, participants felt that the triggers (ie, automated notifications of new content, pedometer, and the step registration function) had a kind of gateway function and made using the COPD Web closer at hand. Users described themselves positively about using and subsequently revisiting the COPD Web when getting email newsletters from the eHealth tool.

The pedometer was reported to be a useful tool concerning physical activity; it was also perceived as a sufficient reason to visit the COPD Web to register steps on the site. Using the pedometer was recognized as a way to prove, in a concrete way, that you had done right (or done something at all) with regard to your level of physical activity. There was a drive, a motivation, expressed in registering steps on the COPD Web, and a pedometer helped in building this motivation.

> *My [pedometer] was my dangling carrot. All the time, I could see how much I walked … well, I thought that was really terrific.* [Patricia, user at 3 months, 12-month interview]

However, the pedometer was also recognized as a possible source for stress and uncomfortableness if you had not "done enough." Some nonusers/seldom users indeed felt like being monitored or watched when wearing it, which could be experienced as both a motivational push and something negative. Further, the pedometer was thought by some users to be of more use to someone worse off, health-wise, than oneself.

Overall, participants expressed that the introduction to the COPD Web had included a suitable type and amount of information and also that the health professionals had introduced the COPD Web well, both elements triggering interest for the COPD Web. Among nonusers/seldom users, getting valuable support during the introduction which inclined them to participate despite feeling insecure about computer use was expressed. Further, some users reported having participated due to a sense of duty. However, a somewhat contradictory experience was also conveyed, expressing that the introduction took too much time and was not relevant:

> *Because I'm not ill. So I shouldn't have to be there (at the introduction). And so I thought … good God, does this [introduction] never end?* [Gertrud, nonuser/seldom user, 3-month interview]

Feeling Positive About the COPD Web

Users of the COPD Web expressed that they were generally missing feedback from the health care provider/system regarding the actions of self-care they had already set in motion and were glad to be able to verify these with the help of the COPD Web. Possible prevention of deterioration was expressed as reason enough for using the COPD Web for some users. Users also mentioned that one can choose what to focus on, or do, on the COPD Web, and this was remarked as a very positive feature/function of the site. Further, users of the website reported liking how it can remind you about information, exercises, and other supportive tools for self-management. The COPD Web was also regarded as a source for positive extrinsic motivation by both users and nonusers/seldom users. Participants expressed curiosity for the COPD Web, as well as positive anticipatory feelings toward it. The COPD Web was described as a new concept that had not been introduced to them before and which spiked their interest.

> *[…] I thought … my God, that's great! This is about me. Naturally I needed to grip the chance. That's how it was. And the way in which [the COPD nurse] presented things and the way [the COPD nurse] described things caught my interest […]* [Kelly, user, 3-month interview]

While the thought of appreciating all help that you can get was mentioned, it did not ensure the usage of this eHealth tool. Participants mentioned that looking around in general and checking what the site was about as reasons for visiting the COPD Web.

Irrelevant Tool

Nonusers/seldom users felt that they did not have time for, had forgotten about, or had otherwise not prioritized using the COPD Web. Some users also expressed this feeling. A sense of having been "in the game" for too long, and thus already having heard all the information was expressed. This was also mentioned at 12 months. Some felt this was fine, and some were frustrated about not being able to find new information, but this ultimately seemed like a reason not to "bother" with the eHealth tool. Others felt that they were already doing what the COPD Web instructed them to do regarding self-care and so had less need for the website. Consequently, the website was expected to feel more relevant when you are newly diagnosed. In addition, visits on the website could be due to a sense of obligation (toward the study) as this former user stated at 12 months when asked how come they stopped their, formerly very active, step registration:

> *Yes, but then I asked you whether […]… should I continue registering my steps? You said, no, you do as you want to. […] So then I didn't bother with it.* [Cindy, user at 3 months, 12-month interview]

Approaching Capability

Category Overview

This category includes participants' experiences regarding getting access to COPD-specific knowledge and skills for self-management and the benefits experienced from using the COPD Web, as well as reports of actual behavioral changes within 12 months since starting to use the COPD Web. The 3 subcategories covered are "Know-how gives hope," "Starting to see the benefits," and "Impact with more time," wherein the for the last subcategory all codes are solely from the later (12-month) follow-up.

Know-How Gives Hope

The content of the COPD Web was perceived to be instructive in a concrete way, which gave new and satisfying knowledge about and insights into self-care. Users reported using the website as a sort of archive where they could search for information and tips, even regarding things that were not specific to COPD. Some users felt it was nice just to have access to this well of information, seemingly regardless of how much it was utilized. A remark on the power of habit was made where the use of the COPD Web felt helpful in changing or affecting habits in a good way because it could be revisited several times. Users also perceived that their view of COPD had become more hopeful because the COPD Web had informed them about the things that they were able to use to their advantage. Having heard depressing statements from people in one's vicinity, it felt positive to learn about actions to take and feelings of being fortified and boosted in your actions of self-care.

> *Well, do you want to know what is good? That there is … that you don't have to become worse and worse but there is something you can do about it yourself. I think that's positive* [Cindy, user, 3-month interview]

By contrast, some users conveyed a sense of no change at all in their view of the disease from having access to the COPD Web.

Starting to See the Benefits

To get an affirmation of what you had already heard or learned from other sources was an appreciated function of the COPD Web, and this is in line with the statement of some users that not all advice on the website is new news, but they can still help you. Otherwise, users felt they visited the website to improve their overall situation by learning more about the diagnosis, their body and treatments, and how to perform a specific exercise. Breathing techniques on the site were reported as helpful during, for example, travels and also as a helpful way to prepare before a particular trip.

> *I looked at this thing about going up steps. And so I went to Spain and I knew that we had to go up some steps a long way up to a church and so I actually practiced exhaling on the next step. You breathe in, take a step and then breathe out and take two steps and so on. I think this worked very well.* [Patricia, user, 3-month interview]

In addition, the COPD Web function of step registration was mentioned as a strong motivator for doing exercises.

Impact With More Time

In this subcategory, a little more time had passed, and all statements are from the 12-month follow-up. The content of the website was said to have led to a better insight regarding the COPD and the self-care strategies, as well as to essential changes in everyday life. Participants commented that the COPD Web

had helped them in understanding how vital actions such as contacting the health care in time and using the stairs were important. However, learning about COPD, in general, had also given some confidence in the expertise one holds about one's own body. Therefore, it was said, one could also feel more confident in asking for, or even demanding, care from their health care settings when something did not seem right.

> *Now, just like then when I was so wilted at Christmas time there, I was the one who stood up for myself and told them that this is the way I am and I now need to come in and perhaps get some help to stop all this. Yes. Not to say… and other times I've let things drag on more. That's just the way it is. But I do understand that it's more important to [seek care] quicker and not let things drag on.* [Kelly, user at 3 months, 12-month interview]

Others said that changes to everyday life were the actively changed patterns of body motions (eg, standing up without using one's hands), using the stairs more, and avoiding getting minor illnesses that might escalate to worse conditions due to COPD. Some felt that they had learned more from the website than from traditional health care meetings. The convenience of being reminded of various exercises and breathing exercises was especially mentioned as a way to calm down, to feel more at ease. By contrast, there were participants, including both former users and nonusers/seldom users, who after the 12 months still felt that their habits had not changed and that things were as they always had been—with or without the COPD Web.

Discussion

Principal Findings

This study aimed to, among people with COPD, explore and describe the experiences of using an eHealth tool over time and factors that might affect usage. The main results reflected study participants' experiences in the categories of *ambiguous impact*, *basic conditions for usage*, and *approaching capability*, and indicated that level of motivation, comfortability with IT tools, and the level of health literacy seem to affect usage of an eHealth tool over time. Furthermore, regarding behavioral changes**,** gaining benefits from the eHealth tool seems reserved for the users and specifically after 12 months, thus suggesting that eHealth tools can be suitable media for supporting COPD-specific self-management skills, although not for everyone or at all times. These findings support earlier qualitative studies noting that people with COPD are a heterogeneous group and that there is no one general way to reach all people with COPD [34]. Furthermore, even though technical difficulties are irritating, they do not seem to determine level of usage. Similarly, recognizing the usefulness of the eHealth tool, and even curiosity toward the tool do not seem to influence the level of usage.

Interpretation of Findings: User Experience and Factors Affecting Usage

In general, users shared positive comments about IT tools on the COPD Web, including receiving information, the electronic newsletters, and the contents on the eHealth tool. These findings are in line with previous studies in which those who used a mobile app, in general, had a positive view on eHealth tools [35,36]. Furthermore, as captured in the subcategory "Starting to see the benefits," users seemed to be able to incorporate the advice into their everyday life, and they felt that the eHealth tool helped them to improve their overall situation. This suggests that the eHealth tool provided participants with at least some of the tools needed to manage their condition [7].

As knowledge and skill on how to integrate the demands of the disease into the daily routine are crucial to enable behavior modification [7,37], findings from this study are of importance. Specifically, in a similar way, as previously reported after self-management interventions for people with COPD, users in our trial reported increased knowledge on how to perform specific exercises and use of breathing techniques in daily life [38]. Some users also mentioned that they gained a sense of hope, as the eHealth tool had informed them about their disease so that they were able to utilize this knowledge to their advantage. The latter is of importance as a person's belief in his or her ability to manage the disease is a powerful and well-recognized predictor of health-related behavior changes [7,39]. Our findings also suggest that the eHealth tool was beneficial as a self-management tool for the users, as it seemed to have resulted in more substantial confidence in their ability to manage their disease, which is an essential factor to influence specific health behaviors [40-43]. The sense of hope in itself could also be a reason for the continued use of the eHealth tool among users because the perception of a clear benefit has been highlighted as a critical facilitator for eHealth usage.

In addition to the positive view on information and IT tools, when exploring potential differences in baseline characteristics among users and nonusers/seldom users, we saw that users also had sufficient communicative and critical health literacy as measured by the CCHL Scale, Swedish version. Health literacy has been defined as "the degree to which individuals can obtain, process, and understand basic health information and services needed to make appropriate health decisions." [44]. It is, in other words, a set of fundamental skills for obtaining precisely the kind of information that is communicated with the help of eHealth tools, which might help explain some basic differences between those who used and did not use the COPD Web. By contrast, nonusers/seldom users of the eHealth tool had a problematic communicative and critical health literacy. Thus, the level of health literacy might be a contributing factor to our observed findings because this is important in taking in new information as well as highlighting a need for education and training. The latter has also been identified as a critical barrier to eHealth use in daily practice [30]. Limited health literacy toward eHealth was likewise the top mentioned barrier for implementing eHealth services in a recent systematic review and meta-analysis [36]. Low health literacy is also widespread among patients with COPD. For example, Puente-Maestu et al [45] found that more than 50% of their patients with COPD had low health literacy. Similarly, as evident among nonusers/seldom users in our trial, people with both COPD and low health literacy have previously also been reported to be more dependent on others and to be more concerned about their illness [45,46]. With this in mind, our findings further support previous views

that health literacy should be considered when designing self-management support programs for people with COPD [47] and, specifically, that low health literacy seems to be an important barrier to using eHealth tools over time and other strategies should be considered. Moreover, participants expressed that the COPD Web would have been especially relevant when they were newly diagnosed and that the COPD Web would have enabled them to circumvent underestimating the importance of self-care–related information. This observation is similar to the findings made by Ansari et al [48] who demonstrated that newly diagnosed patients with COPD had difficulty recognizing the impact of COPD on their health, mostly due to low awareness of the disease and its long-term implications.

Furthermore, nonusers/seldom users reported a problematic attitude toward IT tools or a completely nonfunctioning computer or internet connection at their disposal. However, even though nonusers/seldom users had access to and utilized help when needed, they still did not use the eHealth tool, which implies that their lower level of interest (low motivation) or faith in new information and technology had more to do with not using the tool more. Triggers, such as the automatic newsletters or pedometer, did not seem to affect usage in itself. The electronic newsletters, for example, did help in getting people to use the eHealth tool actively—but still, it only seemed to make a positive impact for those already more inclined to receive new information, use the computer/internet, and prioritizing an eHealth tool such as this. The same goes for the pedometer and the step registration function that were expressed as motivating and useful by users. These findings could be related to the Fogg Behavior Model (FBM) [37]. The FBM suggests that acquiring a targeted behavior, in our case, using the eHealth tool, requires sufficient motivation, ability, and triggers. Thus, the low motivation, the low ability to use IT tools, and the opposing view on used triggers help us understand why nonusers/seldom users did not use the tool.

Nevertheless, as reported above and captured in the subcategory "IT comfortable or not," the expressed need for assistance could also be linked to the low health literacy among our nonusers/seldom users [45,46,49]. Further, no apparent differences in disease severity or other sociodemographic characteristics such as age, sex, smoking history, living conditions, or basic educational level could be seen between users and nonusers/seldom users of the eHealth tool. This further indicates that our population either used their health status as an excuse for not using the eHealth tool or that their perceptions of their health status varied no matter the objective measurements. Our findings, however, still indicate that the nonusers/seldom users were in that group more due to insufficient self-competence and motivation, and a more negative general attitude toward getting informed. For example, in contrast to users that only expressed a positive attitude toward receiving new information, nonusers/seldom users also expressed that information could be scary or unpleasant. Again, these findings could be linked to the lower health literacy of nonusers/seldom users [45,46,49]. In this study, both users and nonusers/seldom users expressed that the eHealth tool was easy to use. This indicates that even though the ease of use has been stated as the most successful factor for implementing eHealth services [36], it was not a key factor explaining usage in our sample.

In the interviews performed at 12 months, we could see a shift in the type of information provided in the interviews, despite using the same interview guide as during the 3-month interviews. Specifically, as highlighted in the category "Assembling know-how," the reported changes in behavior (eg, standing up without using one's hands and using the stairs more) were mainly expressed at the 12-month interviews. Thus, knowledge from the eHealth tool was put into practice, and behavioral changes were underway at this time. Even though participants, mainly users, also expressed benefits since having access to the eHealth tool after the initial 3 months, these findings highlight that time might be an essential factor when evaluating the potential benefit of eHealth tools. These findings are in line with the results from a recent previous study suggesting that a continuous self-management program helps people with COPD to perform given self-health behaviors, thus indicating that achieving changes in health behavior takes time [38]. Further support for the latter is also seen in a qualitative systematic review from 2018 [34]. Other than this observation, no apparent differences were seen between the 3- and 12-month interviews, which also supports the consistency of our 3-month findings [31,50].

Strengths and Limitations

Strengths of this study are the direct comparison of users and nonusers/seldom users, as well as the design of the study following the COREQ guidelines, increasing the credibility of our findings [24]. Trustworthiness has been strived for by utilizing triangulation and recurrent discussions regarding the material through all phases [51]. Furthermore, interviews were conducted via both face-to-face meeting and telephone due to practical choices. The 2 interview methods are, however, equally credible according to Ward et al [52] who found that interviewees felt free to divulge sensitive information over the telephone and that the communicative cues were to be regarded as equal to those used within face-to-face interviews. Interview lengths are varying and at times, very short. However, a specific duration is not a guarantee for richness [51,53], and we interpreted our data to be rich enough for the analysis that was carried out. To counteract the potential loss of information by removing the researchers from this process by using a professional transcriber [54], the transcripts were then checked for deviations between audio and transcript [31]. Besides, knowledge and notes from the interviewers were utilized when needed during analysis. In addition, we continuously consulted the audio recordings when triangulation indicated risks of interpretational differences of a transcript [33]. Even though the number of interviews in itself is not a crucial criterion in qualitative methods, it should be noted that the number of informants, especially at 12-month interview, was relatively few. Besides, even though there was a variation in age, sex, education, stage of COPD, and living conditions, the vast majority of included participants were females, living alone, and with overall low disease severity as evident by low CAT and MRC scores, as well as moderate forced expiratory volume in 1 second (%FEV_1) of predicted values. It should also be noted

that the majority of the interviewees were women, highlighting a potential selection bias [55], as more men than women declined to participate in the interviews. Analyzing whether the results would have been similar if more men had participated was outside the scope of the study, but should be considered for future projects. In addition, of importance, the cut-offs used to define users and nonusers/seldom users were not predetermined and set by the researchers after having access to information about the usage of the COPD Web. However, these cut-offs were set by a researcher not involved in the primary analysis, and before codes were tracked back to individual informants. Lastly, objective data on the use of the eHealth tool were only available during the initial 3 months. Thus, we cannot elaborate on whether the users at 3 months also were users at 12 months.

Conclusions

To our knowledge, this study was among the first to explore experiences and factors that affect the usage of an eHealth tool aiming at improved self-management strategies in people with COPD over time. The novel findings of this study indicate that usage of an eHealth tool, to support self-management, is affected by the view on the information. That is, curiosity or fear for new information can influence whether to use an eHealth tool or not. In addition, a low motivation, a higher need for technical support, and a problematic health literacy were seen among nonusers/seldom users. By contrast, users were comfortable with IT tools, had a positive view on triggers, and had sufficient health literacy. Lastly, reaping benefits from an eHealth tool seems to be reserved for the users, and primarily after 12 months. These findings suggest that eHealth tools can be suitable media for supporting COPD-specific self-management skills, although they are not for everyone or at all times.

Furthermore, factors such as motivation, IT comfortability, and level of health literacy are important to consider when deciding on whether or not an eHealth tool might be appropriate to use if the goal is to support self-management among individuals with COPD. In addition, our findings highlight that time might be an essential factor when evaluating the potential benefit of eHealth tools aiming at behavioral changes regarding self-management strategies.

Abstract

Background: Despite increasing demand for treatment among cannabis users in many countries, most users are not in treatment. Internet-based self-help offers an alternative for those hesitant to seek face-to-face therapy, though low effectiveness and adherence issues often arise.

Objective: Through adherence-focused guidance enhancement, we aimed to increase adherence to and the effectiveness of internet-based self-help among cannabis users.

Methods: From July 2016 to May 2019, cannabis users (n=775; male: 406/575, 70.6%, female: 169/575, 29.4%; age: mean 28.3 years) not in treatment were recruited from the general population and were randomly assigned to (1) an adherence-focused guidance enhancement internet-based self-help intervention with social presence, (2) a similar intervention with an impersonal service team, and (3) access to internet as usual. Controls who were placed on a waiting list for the full intervention after 3 months underwent an assessment and had access to internet as usual. The primary outcome measurement was cannabis-use days over the preceding 30 days. Secondary outcomes included cannabis-dependence severity, changes in common mental disorder symptoms, and intervention adherence. Differences between the study arms in primary and secondary continuous outcome variables at baseline, posttreatment, and follow-up were tested using pooled linear models.

Results: All groups exhibited reduced cannabis-use days after 3 months (social presence: –8.2 days; service team: –9.8 days; internet as usual: –4.2 days). The participants in the service team group (P=.01, d=.60) reported significantly fewer cannabis-use days than those in the internet as usual group; the reduction of cannabis use in the social presence group was not significant (P=.07, d=.40). There was no significant difference between the 2 intervention groups regarding cannabis-use reduction. The service team group also exhibited superior improvements in cannabis-use disorder, cannabis-dependence severity, and general anxiety symptoms after 3 months to those in the internet as usual group.

Conclusions: The adherence-focused guidance enhancement internet-based self-help intervention with an impersonal service team significantly reduced cannabis use, cannabis-use disorder, dependence severity, and general anxiety symptoms.

Introduction

Cannabis is the most consumed illicit drug in Europe, having witnessed a steady increase in recent years, evidenced by roughly 24.7 million European users in 2019 [1]. The global number of cannabis users was estimated as 178 million people in 2017 [2]. As more and more countries consider decriminalization or outright legalization, it seems unlikely that the increase in cannabis users will stagnate soon [3]. However, only a minority of cannabis users seem to develop cannabis dependence; in general population surveys, the risk of becoming dependent on cannabis appears to be between 10% and 11% of all cannabis users [4,5]. However, for cannabis users who start at a young age, the risks of cannabis dependence [6] and cannabis use problems [7] are significantly higher. In addition, poorer mental and physical health, lower educational attainment, and reduced cognitive performance than non-cannabis users are common among daily cannabis users [8]. Numerous studies [9] also point to a broad range of often co-occurring mental health disorders, such as depression, anxiety, and posttraumatic stress disorder, during the treatment of problematic cannabis use.

Treatment demand in Europe for first-time admissions with cannabis listed as the main problem substance has been increasing steadily, having almost doubled from roughly 45,000 in 2006 to approximately 83,000 in 2017 [1]. However, it is clear that, although the number of clients seeking treatment has increased, they still account for just a small minority of cannabis users who could potentially benefit from treatment, with or without comorbid mental health problems [9]. Similarly, only a few consumers seek professional medical assistance [10], suggesting that a broader range of treatment options should be provided [11]. Various potential barriers prevent people from seeking treatment, including poor accessibility to treatment centers, the lack of awareness of negative health consequences, the wish to reduce cannabis use on their own [12], and fear of stigmatization as a drug addict, which seems to be a major factor [13,14]. Facilitators of treatment, on the other hand, include improving available information, increased access to cannabis-specific services, providing additional treatment options, and making admissions easier [15], all of which many internet-based interventions could provide.

Studies on web-based interventions for which participants were recruited from the general adult population (>18 years old) have been shown to draw a cannabis-using population that is different than those entering outpatient addiction treatment centers, not only in terms of having a higher level of education and being older, but also in terms of reporting more frequent cannabis use [14,16]. However, poor adherence to the intervention is often found in these studies [17,18]. Moreover, a recent meta-analysis [19] on internet-based treatments for cannabis users yielded significant but only small effect sizes for the reduction of cannabis use (mostly frequency) in the short term (15 comparisons, Hedges g=0.12) that could not be maintained longer term (12 months). The effects of multisession interventions, such as those combining cognitive behavioral therapy [20] with motivational interviewing [21], produced larger effect sizes (6 comparisons, Hedges g=0.18) than single-session interventions using approaches like brief interventions [22] and motivational interviewing (13 comparisons, Hedges g=0.09). Among the studies assessing multisession interventions, only 2 took symptoms of possible co-occurring mental health disorders into account [14,23].

In previous studies [13,14], called CANreduce 1.0, we were able to show that additional professional chat sessions increased the effectiveness of an internet-based self-help program designed to reduce cannabis use. The study [14] also found that participants who had the opportunity but did not participate in these chat sessions, nevertheless reduced their cannabis use more than those who only received internet-based self-help from the beginning. It seems that, on its own, having a professional therapist send chat invitations helped to reduce cannabis use in cannabis users. Since only a quarter of the participants in the treatment arm with chat took part in at least one chat appointment, we wondered whether the same effect could be achieved by replacing the professional therapist with a virtual eCoach. We also found that almost half (44.8%) of participants screened positive for clinically relevant depression symptoms at baseline [14]. Comorbidity of depressive symptoms and substance use and its hindrance on positive treatment outcomes has repeatedly been demonstrated [24].

CANreduce 2.0, a minimally guided internet-based self-help intervention for cannabis users, is designed to overcome the issues of low intervention adherence and effectiveness, as well as to address frequently co-occurring mental health disorders. This intervention is based on adherence-focused guidance which has, to date, never been tested as a component of an internet intervention for individuals with a substance use disorder but has been documented to be effective at increasing adherence to web-based self-help for the reduction of stress and depression symptoms [25,26]. The concept of adherence-focused guidance enhancement is primarily based on the supportive-accountability model of guidance in web-based interventions [27], which argues that adherence to internet-based interventions relies on an online coach (eCoach) who is seen as trustworthy, benevolent, and having expertise, and who has clear, process-oriented expectations in a reciprocal eCoach–participant relationship. In addition to an eCoach, we incorporated cognitive behavioral therapy–based approaches [28-31] into the program to target issues that potentially help to ameliorate overlapping common mental disorder symptoms, such as inactivity, depressed mood, excessive rumination, and difficulty relaxing.

The primary goal of this study was to investigate whether intervention effectiveness and program adherence can be increased by implementing adherence-focused guidance and

emphasizing the social presence factor of a personal eCoach when compared with a general support team implementation.

Methods

Study Design

This study was a 3-arm, randomized controlled trial that compared 2 versions of a minimally guided web-based self-help intervention for cannabis users based on adherence-focused guidance, cognitive behavioral therapy, motivational interviewing, and social presence factor—one combined with a personal eCoach (social presence), and one with a general support team (service team)—to a wait-list control group that underwent an assessment and had access to internet as usual (internet as usual) for the purpose of reducing cannabis use and associated mental health problems. The internet as usual group was able to use the internet to search for additional support and information regarding cannabis use from other online resources. Each intervention lasted for 6 weeks and was followed by a posttreatment survey and a follow-up survey 3 months postbaseline.

Participants were randomized, by computer, to the 3 conditions in a 1:1:1 ratio. Participants in the social presence and service team groups did not know to which program version they had been assigned, while participants in the internet as usual group knew they had been assigned to treatment as usual. The study was approved by the ethics committee of the Canton of Zurich on July 4, 2016 (BASEC 2016-00264) and registered (ISRCTN11086185). A detailed study protocol has been published [32].

Recruitment and Inclusion and Exclusion Criteria

We recruited participants from August 2016 through May 2019 with 2 websites, advertisements in relevant internet forums and newspapers (or online versions thereof), and search engine website advertisements. Study inclusion and exclusion criteria, and the rationale behind them, are summarized in Table 1.

Table 1. Inclusion and exclusion criteria and underlying rationale.

Criteria	Reasoning
Inclusion	
Informed consent via the web form	To ensure knowledge of procedures and the declaration of consent
Minimum age: 18 years	To ensure a minimum age of participation
Cannabis use at least once weekly over the last 30 days	To include participants with less than daily cannabis use, increase validity
At least once weekly internet access and a valid email address	To ensure at least some access to the intervention
Good command of the German language	To ensure that participants will be able to understand the information provided
Exclusion	
Participation in other psychosocial or pharmacological treatments for the reduction or cessation of cannabis use	To avoid confounding treatment effects
Current pharmacologically treated psychiatric disease or any history of psychosis, schizophrenia, bipolar type I disorder or significant current suicidal or homicidal thoughts	To avoid having participants with these problems enter the study

For compensation, all participants who completed the final follow-up evaluation were offered a choice of either an online voucher worth 30 € (approximately US $35.85) or donating that amount to charity.

Sample Size Calculation

We anticipated that a Cohen *d*=0.30 was appropriate, by employing previous internet-based studies in cannabis users [16,32] recruited from the general population, and adherence-focused guidance enhancement internet-based studies among individuals with stress or depression [25,26] to estimate effect-size differences between the adherence-focused guidance-enhanced version with (social presence) versus without (service team) a personal eCoach. This resulted in a sample size of 176 for each study arm (n=528 in total) to detect a small effect size with 80% power and an alpha error of 5% (2-tailed testing).

Treatment Arms

Both active interventions—social presence and service team—consisted of a dashboard and 8 self-help intervention modules that included stories of 6 fictional companions who appeared within the modules at key points, with the goal of encouraging reflection on potential questions raised by the modules. Table 2 provides an overview of the modules' contents and underlying therapeutic approaches. Both active interventions also incorporated a use and activity diary, weekly semiautomated motivational and adherence-focused guidance–based email feedback, and a section containing educational information on cannabis and health. The semiautomated motivational emails were triggered by a moderator, depending on how participants responded in exercises. These feedback emails also included module suggestions, dealing with high-risk situations, cravings, or the pros and cons of their use. Participants in both active intervention groups also were invited to ask questions of either their eCoach (social presence group) or support team (service team group) whenever they felt the need.

Table 2. Modules.

Module	Content	Therapeutic approach
Module 1: Introduction	• General overview • Introduction of fictional companions • Reflection on personal cannabis use	Based on motivational interviewing techniques [21]
Module 2 : Identifying risk situations	• Identifying personal high-risk situations • Recognizing seemingly irrelevant, but triggering decisions	Cognitive behavioral therapy approach to relapse Prevention [28]
Module 3: Working on needs	• Strengthening social contacts • Decreasing excessive ruminations • Developing healthier sleeping habits	Behavioral activation approach [29]
Module 4: Craving	• Concept of craving • Ways to deal with feelings of craving	Based on cognitive behavioral therapy [30]
Module 5: Dealing with relapses	• Relapse prevention • Dealing with relapses	Cognitive behavioral therapy approach to Relapse Prevention [28]
Module 6 : Working on problems	• Relationships between use, problems, and depressive symptoms • Skills to deal with solvable and unsolvable problems	Social problem-solving approach [31]
Module 7: Saying “no”; refusal skills	• Strengthening refusal skills for use in high-risk situations	Based on cognitive behavioral therapy [30]
Module 8: Preserving achievements	• Review of program • List of 5 personalized points to help secure achievements after the program is complete	Based on motivational interviewing techniques [21]

The only difference between the social presence and service team interventions was that, for the social presence group, a semiautomated eCoach, with short personal introduction videos (Multimedia Appendix 1) that preceded most of the modules and a picture of the female eCoach displayed on the dashboard, was used, while for the service team group, an anonymous semiautomated support team, with no pictures, videos, or any other kind of social presence, was used.

The control group had access to the internet as usual, since it was deemed impossible and unethical to prevent participants in this group from seeking out other internet support or face-to-face treatment options during the waiting period. A detailed description of the groups and their technical specifications is provided in the study protocol [32].

CANreduce 2.0 is regarded as a medical device and is CE (*Conformité Européenne*) certified.

Measurements

Table 3 provides an overview of the measurement instruments. The primary outcome of interest was the number of days of cannabis use over the preceding 30 days, in accordance with the timeline follow-back method [33,34]. Secondary outcomes included the severity of cannabis-use disorder assessed using the Cannabis Use Disorders Identification Test-Revised (CUDIT-R [35]); the Severity of Dependence Scale (SDS [36]); quantity of cannabis use over the previous 30 days using the timeline follow-back method, quantified in individually standardized cannabis joint sizes (detailed description in the study protocol [32]); the use of alcohol, tobacco, or other illicit drugs besides cannabis (with questions derived from the European Adaptation of a Multidimensional Assessment Instrument for Drug and Alcohol Dependence [37]); change in depression (Centre of Epidemiologic Studies of Depression, CES-D, scale [38], anxiety (Generalized Anxiety Disorder–7, GAD-7 [39]), and attention deficit and hyperactivity symptoms (adult Attention Deficit and Hyperactivity Self-Report Scale, ASRS, version 1.1) [40]; Short Screening Scale for lifetime Diagnostic and Statistical Manual of Mental Disorders, fourth edition, Posttraumatic Stress Disorder [41]; client satisfaction questionnaire [42]; Working Alliance Inventory adapted for web-based interventions [43], and treatment adherence (finished modules, time spent on modules). Furthermore, the occurrence of any negative intervention effects was identified using a questionnaire [44] at the 3-month follow-up assessment. We asked all participants if they had used any treatment other than CANreduce during the 3 months and, if so, to identify it from a predefined list of services. Details regarding study measures are reported in the study protocol [32].

Table 3. Assessment instruments.

Assessment instruments	Assessment
Sociodemographic data	Baseline
Center for Epidemiologic Studies Depression scale (range 0-60)	Baseline
Short Screening Scale for DSM-IV[a] Posttraumatic Stress Disorder (range 7-28)	Baseline
General Anxiety Disorder–7 (range 0-21)	Baseline
Adult ADHD[b] Self-Report Scale version 1.1 (range 0-24)	Baseline
Frequency of cannabis use (last 30 days)	Baseline, posttreatment, 3-months follow-up
Cannabis use according to the timeline follow-back method	Baseline, posttreatment, 3-months follow-up
Cannabis Use Disorder Identification Test-Revised (range 0-40)	Baseline, posttreatment, 3-months follow-up
Severity of Dependence Scale (range 0-15)	Baseline, posttreatment, 3-months follow-up
Fragebogen Substanzanamnese (substance use questionnaire)	Baseline, posttreatment, 3-months follow-up
Client Satisfaction Questionnaire-I (range 8-32)	Posttreatment
Intervention adherence (continuous assessment over 6-week treatment)	Posttreatment
WAI-TECH[c] (range 10-70)	Posttreatment
Negative effects [44]	3 months follow-up

[a]DSM-IV: Diagnostic and Statistical Manual of Mental Disorders, fourth edition.

[b]ADHD: attention deficit hyperactivity disorder.

[c]Working Alliance Inventory adapted for web-based interventions.

Statistical Analysis

Data were analyzed according to intention-to-treat (ITT). To address missing data for the ITT analyses, we applied multiple imputation procedures using the multivariate imputation by chained equations software package [45] in R (version 3.6.1; R Foundation for Statistical Computing), a minor deviation from the study protocol, which involves specifying a multivariate distribution for the missing data and drawing imputations from their conditional distributions using Markov chain Monte Carlo techniques. As recommended, 20 imputation sets were employed [45]. All sociodemographic, as well as primary and secondary outcome variables that had been assessed in all 3 groups, were included in the imputation. Reported outcomes use the ITT results from the imputed data sets, but complete case analysis results are also reported.

Cohen *d* effect size was used to compare change scores between the 3 treatment arms. As suggested elsewhere, Cohen d=0.2 indicates a small effect, Cohen d=0.5 indicates a medium effect, and Cohen d=0.8 indicates a large effect [46].

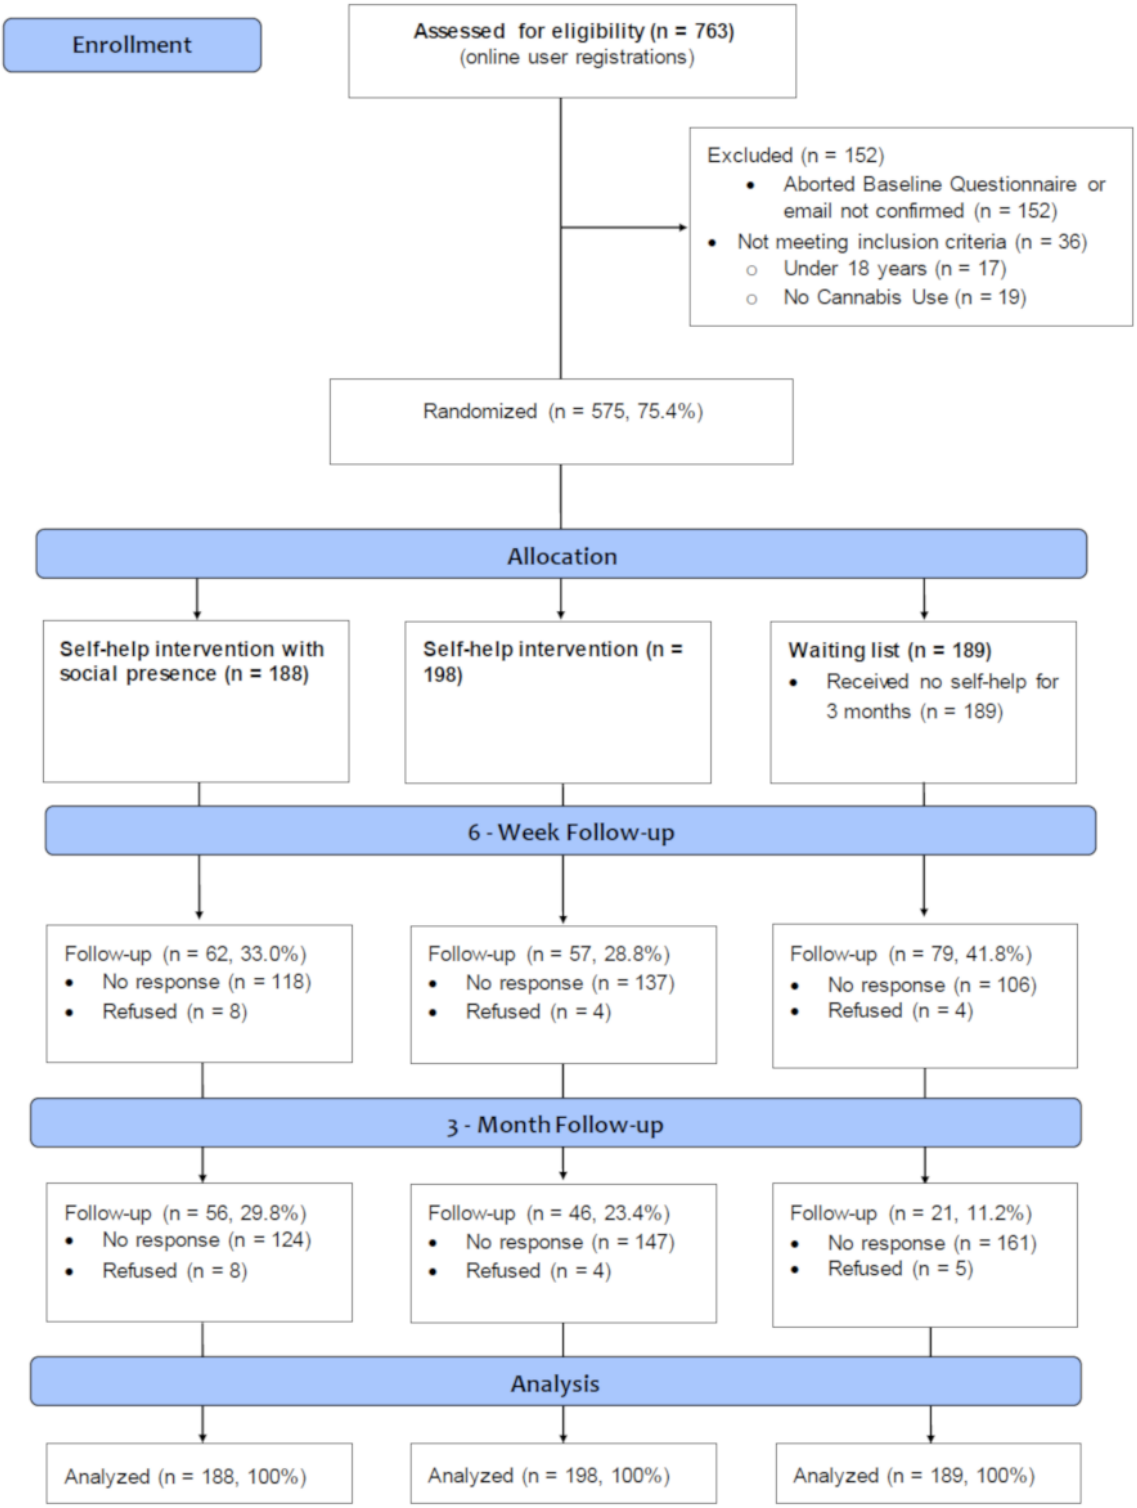
Differences between the study arms in primary and secondary continuous outcome variables at baseline, posttreatment, and follow-up were tested using pooled linear models. Change scores from baseline for primary and secondary outcomes were dependent variables, and study condition was the independent variable; all controlled for the baseline value of the respective outcome variable. Effect sizes were calculated for changes from baseline to follow-up (within-group effect size d_w) and between the 2 intervention groups (social presence, service team) and internet as usual. All P values are 2-sided with no adjustment made for multiple comparisons, which was deemed unnecessary based on CONSORT recommendations [47].

Results

Participation

Between July 2016 and May 2019, a total of 763 people registered online for the program, among whom 575 were randomized to the 3 study arms (Figure 1). All participants received email reminders for follow-ups and subsequent telephone calls if they did not complete the survey. We were able to reach 198 participants (34.4% of the initial sample) posttreatment, and this number dropped to 123 (21.4%) for the final assessment 3 months postbaseline. A coding bug arose within the email system which affected distribution of the final assessment questionnaire to the internet as usual group (only telephone follow-ups were performed). There were significant differences in follow-up rate between the study groups (χ^2=20.16, P<.001) that may have been caused by this bug.

Figure 1. Participation flowchart.



Baseline Characteristics

Of the 575 participants, 406 (70.6%) were male, and the average age was 28.3 (SD 7.9). Most (n=234, 40.7%) were from Switzerland, followed closely by 216 (37.6%) from Austria, and 121 (21.0%) from Germany. The average participant had used cannabis almost daily (25.7 days, SD 5.9) over the preceding 30 days. Complete case analyses of baseline data and study group comparisons are summarized in Table 4.

Table 4. Baseline participant data.

[a]Chi-square test (*df*).

[b]ADHD: attention deficit hyperactivity disorder.

[c]PTSD: posttraumatic stress disorder.

[d]Risky use is defined as 5 or more standard drinks per day on at least 3 days a week. A standard drink is defined as 50 mL spirits, 150-200 mL wine, or 330-450 mL beer.

Primary Outcome: Cannabis-Use Days

Immediately posttreatment, both intervention groups (social presence: mean 8.0, SD 9.3, d_w=.89; service team: mean 10.7 days, SD 9.5, d_w=1.18) reduced their cannabis use significantly more than internet as usual (mean 3.8, SD 8.1, d_w=.55) (social presence: B=–4.34, CI –7.21 to –1.47, *P*=.004, between-group effect size *d*=.48; service team: B=–6.43, CI –9.87 to –2.97, *P*<.001, *d*=.71). These effects persisted 3 months postbaseline, with participants in the service team (mean 9.8, SD 9.9, d_w=1.18) group still reducing their cannabis-use days significantly more (B=–5.70, CI –10.09 to –1.30, *P*=.01, *d*=.60) than in the control group (mean 4.2 days, SD 8.8, d_w=.55). Similarly, there was a significantly greater reduction in the social presence group (mean 8.2 days, SD 9.8, d_w=.93) than in the control group (B=–4.41, CI –9.19 to 0.37, *P*=.07, *d*=.40). There was no significant difference between the 2 intervention groups immediately posttreatment (*P*=.26) or 3 months postbaseline (*P*=.44) (Figure 2; Table 5).

Secondary Outcomes

At follow-up 3 months postbaseline, a significant difference was noted in the decrease in cannabis-use disorder severity between the service team group and controls (B=–3.39, CI –5.96 to –0.83, *P*=.01, *d*=.52), but no significant difference was detected between the social presence and the internet as usual group (*P*=.07). Additionally, there was a significantly greater reduction in the severity of dependence in the service team group compared to the internet as usual group (B=–2.16, CI –3.90 to –0.42, *P*=.02, *d*=.60). There were significantly greater reductions in general anxiety disorder symptoms in both groups (social presence: B=–2.70, CI –3.59 to –0.55, *P*=.001, *d*=.41; service team: B=–2.87, CI –4.43 to –1.31, *P*<.001, *d*=.51) compared to the internet as usual group. All groups decreased their mean ASRS score, but no significant intergroup differences were detected (social presence: mean 0.9, SD 3.9, *P*=.57; service team: mean 2.1, SD 4.2, *P*=.61; internet as usual: mean 1.6, SD 4.0). Similarly, mean CES-D scores decreased in all groups (social presence: mean 3.6, SD 9.6, *P*=.83; service team: mean 7.5, SD 10.3, *P*=.40; internet as usual: mean 4.7, SD 10.4) with no significant between-group differences (Table 6 and Table 7). Upon review, the number of standard joints was deemed unreliable as a measurement and was dropped from analysis.

Adherence and User Satisfaction

Participants in the social presence group completed an average of 2.6 (SD 2.6) modules versus 2.4 modules (SD 2.5) completed in the service team group (t_{374}=0.85, *P*=.20). Social presence group members (mean 46.9 minutes) spent significantly more time than service team users (37.5 minutes) on the program (t_{374}=2.04, *P*=.02). Social presence group members exhibited the highest retention rate (29.8% versus 23.4% in the service team group), but this difference was not significant (χ^2=1.81 *P*=.18).

There was no significant difference between the 2 intervention groups in level of user satisfaction (*P*=.83), but there were significant differences between each of the 2 intervention groups and internet as usual (internet as usual: mean 12.9, SD 6.9; social presence: mean 24.6, SD 5.4, t_{139}=11.36, *P*<.001; service team: mean 25.5, SD 4.6, t_{133}=12.74, *P*<.001).

Participants in the social presence group (mean 52.7, SD 13.6) scored significantly lower (t_{114}=–2.81, *P*=.005) on the Working Alliance Inventory than those in the service team group (mean 59.6, SD 13.0).

Adverse Effects

Among the 123 participants who completed the final follow-up assessment, 82 completed the questionnaire on adverse intervention effects (social presence: n=44, service team: n=24, internet as usual: n=14). Of these, 66 (80.5%) reported no negative effects during the study, while 10 (12.2%) answered that an adverse effect had affected them “somewhat negatively,” 4 (4.9%) answered that an adverse effect had affected them

"quite negatively," and 2 (2.4%) answered that an adverse effect had affected them "to a great extent." However, there was no significant difference between the 3 treatment arms (χ^2=1.33, *P*=.27).

Dropout Analysis

Participants who dropped out scored significantly higher on the CES-D scale (t_{197}=–2.21, *P*=.03), GAD-7 (t_{218}=–2.92, *P*=.004), and ASRS (t_{216}=–2.12, *P*=.04) scales; reported a greater number of risky alcohol use years (t_{211}=–2.37, *P*=.02); finished fewer modules (t_{140}=9.23, *P*<.001); and spent less time on the program (t_{145}=7.15, *P*<.001) than those who completed the final follow-up evaluation. Full dropout analysis is summarized in Multimedia Appendix 2.

Discussion

Principal Findings

In this study, participants in intervention group service team (*d*=.60; *P*=.01) reported significantly greater reductions in cannabis use than those in the internet as usual group immediately after treatment and 3 months postbaseline. A reduction in the social presence group that was significant immediately after treatment (*d*=.48; *P*=.004) was no longer significant (*d*=.40, *P*=.07) at follow-up. Additionally, there were reductions in cannabis-use days 3 months after baseline in all 3 groups. There was no significant difference between the 2 active interventions.

The intervention group service team clearly outperformed all the internet-based interventions previously studied (Cohen *d* between 0 and 0.37 at follow-up 3 months from the start of treatment [19]), in terms of reducing cannabis use in general population samples, and the effects achieved were maintained 3 months after baseline. This persistence of effects aligns with the results of 2 previously published studies: one, an evaluation of video-based self-help [16], and the other, our own previous CANreduce 1.0 [14] study, in which we compared the efficacy of internet-based self-help with and without professional chat sessions to a control group. Within-group effect sizes for reducing cannabis use frequency (social presence: d_w=.93; service team d_w=.1.18) were better than those found in our previous study (d_w=.75) [14] and similar to those found by Rooke et al (d_w=1.08) [16]. Interestingly, the intervention group in the study [16] involved extended videos with an eCoach that, in our opinion, represents, apart from the reciprocal eCoach-participant relationship, the most important component of adherence-focused guidance. Thus, it appears that adherence-focused guidance also makes a difference during internet-based self-help, in terms of reducing cannabis use in cannabis users, which may allow findings from studies on stress and depression symptom reduction [25,26] to be expanded to the web-based cannabis interventions.

Our new programs also performed better than web-based interventions for brief personalized feedback (d_w=.85) and extended personalized feedback (d_w=.89) [48]; however, the study did not use a control group. Two recent meta-analyses [49,50] on brief interventions for cannabis reduction found little to no evidence of significant reductions in use or frequency. Even though some in-person brief interventions yielded small effects, the evidence consistently favored more intense, longer interventions [51]. There is evidence that brief interventions are beneficial for mild to moderate cases [52], while our program generated good effects in more severe cases. Current literature seems to indicate that more rather than less comprehensive interventions fare better in treating cannabis-use disorders. A combined stepped-care model with a range of varied intense treatment options could reach more users than a one-size-fits-all approach, as the majority of users are not in treatment [10].

Our a priori hypothesis that the social presence of a personal eCoach would outperform an impersonal study team was not confirmed. To the contrary, participants in the impersonal study team group had a significantly higher working alliance score with significant cannabis-use days reduction at 3 months (after baseline), indicating a stronger bond with the impersonal study team. We suspect that this is because the 2 adherence-focused guidance enhancement versions differed only slightly—the only differences being the presence versus absence of introduction videos and eCoach picture—and because support-team group participants may have perceived that there was an entire team being there to help them. Nevertheless, participants with access to an eCoach exhibited significantly greater adherence (in time spent, *P*=.02) and nonsignificantly greater retention (*P*=.18) than those with a support team, besides users in the latter group performing better overall in the primary outcome. Additionally, participants in the 2 intervention groups differed in their baseline scores for severity of dependence and depression. Thus, our findings did not support the existence of a linear relationship between adherence and treatment success. We found that greater adherence led to better retention and, with this, to greater data availability, and thus, more robust results to guide future research. A number of participants dropped out immediately after the start of the program, with 27% (102/386) not finishing a single module. This may stem from a discrepancy between what participants expected and what the program actually offered. Future programs should provide more information (eg, pictures or videos) to interested participants, so that they have a better idea of what to expect.

Our implementation of a single eCoach did not seem to achieve the level of social presence that was intended, even though it led to greater engagement. There may have been different intrapersonal aspects that could have affected how the participants perceived the eCoach or the study team. As we develop this program further, we intend to increase the program's social presence and offer a variety of eCoaches to foster more personal freedom and choice. We nonetheless note that, in both intervention groups, the program was well received by users.

Among secondary outcomes, we found significant differences between the service team group and internet as usual were detected, in terms of reducing the severity of cannabis dependence (*P*=.02) and reducing cannabis-use disorder severity (*P*=.01). To our knowledge, this finding has only been reported once before, in a study [16] in which a similar program was evaluated.

We expected that the active interventions would significantly alleviate the symptoms of common comorbid mental health disorders more than internet access as usual was only partially correct, with greater reductions observed for general anxiety disorder.

In a meta-analysis [53], Kedzior and Laeber identified a positive association between both cannabis use and cannabis-use disorders, and anxiety disorders. Our findings that decreased cannabis use was accompanied by decreased anxiety symptoms were consistent with those of the meta-analysis [53]. It appears that cannabis has a bidirectional effect on anxiety [54]. On one hand, some individuals with anxiety may experience a degree of acute relief from their symptoms if they use cannabis infrequently and in low doses. On the other hand, regular and heavier use could lead to a cannabis-use disorder, thereby worsening anxiety symptoms. Interestingly, the acute effects of cannabis use, such as panic attacks, resemble the symptoms of anxiety disorders [55], which could have increased the anxiety score in our sample. This said, attributing anxiety to either an anxiety disorder or cannabis use does not make much of a difference to the person suffering from anxiety.

Measuring the success of the program in cannabis-use days may be not as specific as number of joints but corresponding results from CUDIT and the severity of cannabis dependence scale support the effectiveness of the program. Future usage quantity measures should also account for cannabidiol, as well as the potency of the tetrahydrocannabinol consumed. Measuring potency is difficult, as it requires either regulated products or toxicological testing, both of which seem unlikely to be feasible in Switzerland, Austria, or Germany for the foreseeable future. Future studies on adherence-focused guidance among cannabis users need to also start investigating long-term intervention effects (12 months or longer).

Strengths and Limitations

CANreduce 2.0 was associated with comparable rates of adherence and retention but greater effect sizes than either the chat-enhanced or self-help only versions of CANreduce 1.0 [13], while being fully automated and requiring little to no human support, which in turn decreased the intervention's complexity and costs of widespread implementation. Additionally, the program reached almost twice as many women (29.4% vs 17.4%), an older population (mean age 28.3, SD 7.9 vs 21.6 years, SD 8.4), and more severe users (daily use: 74.7% vs 31.2%) than Swiss outpatient treatment monitoring statistics [56]. These differences also were observed with the previous CANreduce 1.0 program [13], supporting our belief that such programs reach a different population of cannabis users than that reached by traditional outpatient treatment facilities.

This study has several limitations. First, technical difficulties decreased the number of participants who could be successfully followed up in the internet as usual group, which likely contributed to the overall high attrition rate (452/575, 70%), though this rate is common in these types of intervention [14,16]. To reduce any bias created by dropouts, multiple imputations were used, but large variances that decreased the chance of finding smaller effects still existed. Second, the introduction and rising popularity of low tetrahydrocannabinol (less than 1%) and high cannabidiol joints in the market may have caused some confusion in our study, as it is not clear how these were counted by participants; consequently, we had to drop our personalized standard joint measurement, in which participants chose from a range of different predefined joints to match their own consumed joints [32]. Third, all measures were self-reported and could not be validated externally, though there is evidence that the internet enables people to be more open and honest and to offer more accurate self-evaluations regarding their problems [57]. Last, the study only followed patients for a relatively short time period (3 months) meaning that we can make no claims of long-term treatment success; this said, beneficial effects were maintained for at least 3 months after the baseline was completed.

Conclusions

The internet-based self-help interventions with an impersonal service team based upon adherence-focused guidance enhancement reduced cannabis use, severity of dependence, and general anxiety symptoms. The program reached a different group of treatment seekers in the general population than that reached by typical outpatient treatment options. The program is fully automated and requires little human support, which may render such programs cost-effective additions to the general health care system.

Acknowledgments

The study was funded by the Swiss National Science Foundation (grant 10001C_192301) and internal funds from the Swiss Research Institute for Public Health and Addiction. The funding sources had no role in the writing of the manuscript or the decision to submit for publication. Content is solely the responsibility of the authors and does not necessarily represent the official views of the Swiss National Science Foundation or the Swiss Research Institute for Public Health and Addiction.

Authors' Contributions

MS had the initial idea for this study. CB prepared the first draft of the paper and final manuscript. AW, DE, LS, and MS developed the interventions for study arms 1 and 2. AW and CB programmed and implemented the CANreduce 2.0 study websites. DM helped to develop and adapt the Austrian version of the website. DE, DM, LS, MA, MW, MK, SH, and TB provided continuous feedback on the development of the interventions and the manuscript. CB performed statistical analysis. CB, MA, MK, MS, and SH thoroughly revised the first version of the manuscript. All authors approved the final version of the manuscript. CB is the guarantor.

Conflicts of Interest

DE has served as a consultant to/on the scientific advisory boards of Sanofi, Novartis, Minddistrict, Lantern, Schoen Kliniken, Ideamed and German health insurance companies (BARMER, Techniker Krankenkasse) and a number of federal chambers for psychotherapy. He is also stakeholder of the Institute for health training online (formerly GET.ON/ nowHelloBetter), which aims to implement scientific findings related to digital health interventions into routine care.

Abstract

Background: A decrease in the level of pulse oxygen saturation as measured by pulse oximetry (SpO_2) is an indicator of hypoxemia that may occur in various respiratory diseases, such as chronic obstructive pulmonary disease (COPD), sleep apnea syndrome, and COVID-19. Currently, no mass-market wrist-worn SpO_2 monitor meets the medical standards for pulse oximeters.

Objective: The main objective of this monocentric and prospective clinical study with single-blind analysis was to test and validate the accuracy of the reflective pulse oximeter function of the Withings ScanWatch to measure SpO_2 levels at different stages of hypoxia. The secondary objective was to confirm the safety of this device when used as intended.

Methods: To achieve these objectives, we included 14 healthy participants aged 23-39 years in the study, and we induced several stable plateaus of arterial oxygen saturation (SaO_2) ranging from 100%-70% to mimic nonhypoxic conditions and then mild, moderate, and severe hypoxic conditions. We measured the SpO_2 level with a Withings ScanWatch on each participant's wrist and the SaO_2 from blood samples with a co-oximeter, the ABL90 hemoximeter (Radiometer Medical ApS).

Results: After removal of the inconclusive measurements, we obtained 275 and 244 conclusive measurements with the two ScanWatches on the participants' right and left wrists, respectively, evenly distributed among the 3 predetermined SpO_2 groups: $SpO_2 \leq 80\%$, $80\% < SpO_2 \leq 90\%$, and $90\% < SpO_2$. We found a strong association and a high level of agreement between the measurements collected from the devices, with high Pearson correlation coefficients of r=0.944 and r=0.954 on the correlation plots, low Pearson correlation coefficients of r=0.083 (P=.17) and r=0.23 (P=.001) on Bland-Altman plots, biases of 0.98% (95% CI 0.65-1.32) and 1.56% (95% CI 1.24-1.87), and root mean square errors of 2.97% and 3.00% from the participants' right and left hands, respectively.

Conclusions: In conclusion, the Withings ScanWatch is able to measure SpO_2 levels with adequate accuracy at a clinical grade. No undesirable effects or adverse events were reported during the study.

Introduction

Prevalence of Respiratory Diseases

According to the World Health Organization, respiratory diseases are medical conditions affecting the airways and other structures of the lungs. Three of these include chronic obstructive pulmonary disease (COPD), sleep apnea syndrome (SAS), [1] and COVID-19 [2]. COPD is a chronic inflammatory lung disease that causes persistent and progressive airflow limitation [3,4]. Patients with COPD often experience dyspnea,

cough, sputum production, and exacerbation, defined as a worsening of the previously cited symptoms. The global prevalence of COPD in 1990 was 10.7% of persons aged at least 30 years, with 227.3 million cases, and it rose to 11.7% in 2010, with 384 million reported cases. By 2030, COPD is predicted to be one of the most common specific causes of death worldwide [5]. COPD is generally caused by tobacco smoke and exposure to outdoor and indoor pollution [3]. COPD is not a life-threatening condition but is associated with multiple comorbidities, such as cardiovascular diseases, hypertension, diabetes mellitus, and osteoporosis, all of which increase the risk of mortality [4,6]. SAS is a sleep disorder in which pauses in breathing or periods of shallow breathing during sleep occur more often than normal [1]. Each pause can last for a few seconds to a few minutes, and this occurs many times per night [1]. SAS affects 1%-6% of adults and 2% of children [7]. It affects males approximately twice as often as females [7]. Although people can be affected at any age, SAS occurs most commonly among those aged 55-60 years [7]. The prevalence of SAS is highly underestimated, as 80% of patients are undiagnosed [8]. SAS increases risks of hypertension and cardiovascular and cerebrovascular diseases. SAS also negatively affects patients' quality of life by causing daytime sleepiness and impairing cognitive function, which can lead to accidents [8,9]. COVID-19 is a contagious coronavirus disease that was first detected in 2019, caused by SARS-CoV-2, and has led to an ongoing pandemic. As of December 23, 2020, 76 million cases and 1.7 million deaths linked to COVID-19 had been confirmed, straining health care systems throughout the world [3].

Oxygen Saturation as a Detection and Monitoring Tool

Detecting SAS, COPD, and COVID-19 earlier in people can help reduce potential damage from these diseases, and accomplishing this requires a more thorough examination of oxygen levels. Oxygen saturation, defined as the fraction of oxygen-saturated hemoglobin relative to total blood hemoglobin, is measured either through an invasive method by sampling arterial blood to analyze the arterial oxygen saturation (SaO_2) via a co-oximeter or with readings collected noninvasively using a pulse oximeter to measure the peripheral or pulse oxygen saturation (SpO_2) level [10]. A pulse oximeter measures oxygen saturation in peripheral arterial blood by illuminating the skin and measuring the light absorption of oxygenated (oxyhemoglobin) and deoxygenated (reduced hemoglobin) blood using two light wavelengths: 660 nm (red) and 940 nm (infrared). The ratio of light absorbance between oxyhemoglobin and the sum of oxyhemoglobin plus deoxyhemoglobin is calculated and compared with previously calibrated direct measurements of SaO_2 to establish an estimated measure of SpO_2 [11,12]. Physiologically, oxygen saturation levels range from 95%-100% in a healthy person, and a decrease, also referred to as oxygen desaturation, can be suggestive of a respiratory disease [12]. Indeed, SpO_2 levels drop to less than 90% in patients with COPD and COVID-19 as they experience extensive periods of hypoxemia and in patients with SAS when they endure repetitive oxygen desaturation events [12-14]. Although spirometry and polysomnography (PSG) are the gold standards for diagnosing COPD and SAS, respectively, these medical devices are intrusive and are not suitable for long-term monitoring and mass screening because of their high cost and lack of accessibility [15]. In the case of COVID-19, it has been observed that some patients experience oxygen levels below 90% without dyspnea, a condition termed "silent hypoxemia;" therefore, the detection of low SpO_2 levels is even more useful for early detection and monitoring of COVID-19 [16]. Furthermore, during a pandemic that has caused a worldwide health crisis, pulse oximeters are a low-cost and easy-to-use solution to identify problems at an early stage and monitor patients at home after hospitalization [17].

Benefits of Connected Devices

Smartwatches exhibit a high degree of satisfaction and growing popularity among the general population for health monitoring [18]. These wrist-worn devices provide a wide range of personalized health features for users, such as heart rate monitoring, sleep quality control, and oxygen saturation measurements, which can assist the prevention and long-term monitoring of diseases [19]. The Withings ScanWatch is a high-end watch with an embedded heart rate sensor that uses a reflective pulse oximeter on its caseback. The device is worn as a regular watch and is connected to a smartphone through the Withings Health Mate application. Its software, the Withings Scan Monitor, measures, transfers, records, and displays the wearer's functional SpO_2 level. The Withings ScanWatch is intended for intermittent measurements and can be used in hospital, sleep laboratory, long-term care, and home use environments. Therefore, the Withings ScanWatch is an alternative option to finger pulse oximeters and offers several advantages to users. It enables the user to avoid the discomfort of wearing a finger pulse oximeter (especially during sleep), and it is more firmly attached to the user's wrist than the finger pulse oximeter, which can slip on the finger. Therefore, the Withings ScanWatch has the potential to ensure better compliance than a finger oximeter.

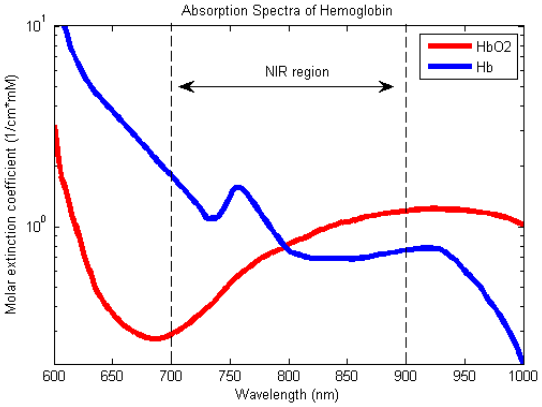
Sleep Apnea

In particular, because the ScanWatch is a wrist-worn watch that can measure SpO_2 continuously along with heart rate and, potentially, breathing rate [20,21], it could provide a less costly and time-consuming alternative to PSG. More specifically, due to the high cost of and lack of access to PSG, a subject cannot be monitored by PSG over the long term, although night-to-night variability of the apnea-hypopnea index has been found [22]. ScanWatch would enable physicians to follow patients over several weeks, at home, and in a way that does not disturb their sleep, as can occur with intrusive PSG devices. Withings ScanWatch may therefore be an alternative for screening, diagnosing, and monitoring SAS.

Biophysics of Pulse Oximetry

Pulse oximetry relies on the differential absorption by blood of red and infrared light. Figure 1 shows the absorption spectra of these two dominant forms of hemoglobin, namely oxygenated (HbO_2) and deoxygenated (Hb).

Figure 1. Absorption spectra of oxygenated and deoxygenated hemoglobin. Licensed from Adrian Curtin/CC BY-SA. Hb: deoxygenated hemoglobin; HbO_2: oxygenated hemoglobin.



Two wavelengths are chosen so that the ratios of the absorption rates of Hb and HbO_2 are respectively maximal and minimal. Thus, customary choices are red light (at 660 nm) and infrared light (at 940 nm). From the intensities of the transmitted or reflected light at these two wavelengths, one can deduce the concentrations of both forms of hemoglobin, [HbO_2] and [Hb], and the functional oxygen saturation of arterial blood (neglecting carboxyhemoglobin and methemoglobin).

In practice, a ratio of ratios (also called modulation ratio), R, is computed as follows [23]:

Alternating current (AC) refers to the amplitude of the pulsatile component of the PPG signal, and direct current (DC) refers to the value of its baseline. The ratio of AC/DC is commonly called the perfusion ratio.

An analytical relationship between the perfusion index R and the fraction of oxygenated hemoglobin SpO_2 can be obtained with a model based on the Beer-Lambert law and a simplified model for the light path taken by both wavelengths. This simple model, which neglects the multiple scattering events of light in the skin, applies to some extent to pulse oximeters operating in transmission where tissues are located between the light-emitting diode (LED) and photodiode (PD). However, the model is unable to explain how reflective pulse oximeters operate, where the LED and PD are on the same side. Therefore, an experimental calibration of R to SpO_2 during a hypoxia study is necessary.

Reflective PPG on the Wrist and Its Challenges

Measuring SpO_2 with a reflective sensor is more challenging on the wrist than on the fingertip. Due to the thickness of the wrist and the presence of bones, it is impossible to measure SpO_2 in transmission. In reflectance mode, the signal-to-noise ratio (SNR) is smaller than typically found in transmission-mode finger pulse oximeters for two reasons. First, the light emitted by the LEDs penetrates the various layers of the skin, but only a small fraction will find its way back (upward) to the PD adjacent to the LED after multiple scattering events inside the skin. Second, blood perfusion is dramatically lower on the back of the wrist than on the finger. During our calibration studies, we compared blood perfusion on the wrist and on the finger using ScanWatch sensors, and we found empirically that the SNR for the measurements taken at the finger was approximately 10 times as high as the SNR for the measurements taken at the wrist.

A second challenge is that optical measurements on the wrist are more prone to artifacts. Motion artifacts are much more frequent than on the fingertip because of the presence of tendons and bones. Light-skin coupling of finger pulse oximeters is robust due to the clamp design. In the absence of a clamp, the optical sensor can lose contact with the skin more easily, both breaking the optical coupling and letting ambient light in; this tends to unpredictably modify the DC levels.

Objectives

The main objective of this study was to clinically test and validate the accuracy of the reflective pulse oximeter function of the Withings ScanWatch to measure SpO_2 levels during mild, moderate, and severe hypoxia compared to a co-oximeter, the ABL90 hemoximeter (Radiometer Medical ApS), in accordance with the ISO 80601-2-61:2017 standard and US Food & Drug Administration (FDA) guidance. The secondary objective was to confirm the safety of the device when used as intended.

Methods

Recruitment

This monocentric and prospective clinical study with a double-blind analysis was conducted on 14 healthy participants in a hypoxia laboratory at the University of California San Francisco in March 2020 at an altitude of 122 m and at a room temperature of 25 °C. Inclusion criteria were being between the ages of 18 and 50 years, having a healthy status with no evidence of any medical problems, and having both wrist circumferences between 14 and 22 cm. Current smokers, women who were pregnant, lactating, or trying to get pregnant, and participants with obesity (BMI >30 kg/m^2) or who had an injury, deformity, or abnormality at the sensor sites and piercings that might cause air leaks during the test were excluded from the study. Participants with a known history of heart, lung, kidney, or liver disease; diabetes; clotting disorder; hemoglobinopathy or history

of anemia; sensitivity to local anesthesia; or fainting or vasovagal response or any other serious systemic illness were also excluded, as well as those diagnosed with asthma, sleep apnea and Raynaud disease. Exclusion criteria also included participants with a resting heart rate of over 120 beats per minute, a systolic blood pressure over 150 mm Hg, a diastolic blood pressure over 90 mm Hg, a room air SpO_2 under 94%, and a carboxyhemoglobin level over 3%.

Study Design

All selected participants in the study met the inclusion criteria. Before starting the study, two Withings ScanWatch units were placed on each participant's wrist to measure their SpO_2, while a 22-gauge catheter was placed in their left radial artery to measure their SaO_2. In addition, two reference finger pulse oximeters were placed on each participant to facilitate the identification of plateaus and any discrepancies between the hands. Each participant was then asked to lie in a semisupine position, to remain still, and to breathe a mixture of gas through a mouthpiece while a nose clip blocked their nose. After a 5-minute rest period, they were instructed to hyperventilate 2-3 times deeper and faster than normal during the runs to speed alveolar gas equilibration. The target SpO_2 at each run was chosen to be evenly balanced over the 70%-100% SpO_2 range. On the initial step of the run, two blood samples of 1-2 mL were first collected 30 seconds apart from the participant at the same oxygen saturation level as the room air. Then, approximately 10 seconds later, the inspired oxygen was abruptly changed to reduce oxygen saturation to the next SpO_2 target level. On the next steps of the run, two blood samples were collected 30 seconds apart from the participant when the reference finger pulse oximeters both measured a stabilized level of oxygen saturation, with less than 1% of difference for 35 seconds. Note that the second sampling was not performed if the oxygen saturation level was destabilized between measurements. Then, approximately 10 seconds later, inspired oxygen was abruptly changed again to reach the next SpO_2 target level. Overall, these 75-second periods of stable oxygen saturation were defined as "plateaus," and every participant was subjected to 5 plateaus (typically 92%, 87%, 82%, 77%, and 70%) before being brought back to a high oxygen saturation level (100% O_2) by breathing oxygen-enriched air for 2 minutes. After this run was repeated a second time, the collected blood samples (approximately 20-25 samples per participant) were immediately analyzed with the co-oximeter (ABL90 multiwavelength hemoximeter), then compared to the data recorded with the Withings ScanWatches (Figure 2).

Registration

The study was registered at ClinicalTrials.gov (NCT04380389).

Materials

General Description of the Withings ScanWatch

The Withings ScanWatch is an analog battery-operated watch consisting of (1) a metal case with a connected movement, (2) three hands, with two hands indicating the time and one hand indicating a cumulated activity level, (3) an adjustable silicone band to fit any user's wrist between 14 and 22 cm, and (4) a reflective pulse oximeter composed of three LEDs (red, infrared, and green), one broadband photodiode, and one infrared-cut photodiode (Figure 3). It includes all the necessary hardware to record and transmit SpO_2 measurements via Bluetooth to the Health Mate application (available on Android version 6 or later and iOS version 10 or later). For the purposes of this clinical study, instead of using the original software, which displays only a single value of SpO_2 after a 30-second measurement, we used a derived version of the Withings Scan Monitor to continuously compute, display, and record SpO_2 levels. All the other aspects of the Withings Scan Monitor, such as its algorithm and averaging window, remained identical to its original version.

Figure 3. Front view (left) and back view (right) of the Withings ScanWatch.

Design of the ScanWatch Pulse Oximeter Sensor

In a reflective design, the positions of the emitters and receptors must be carefully chosen to maximize the SNR for both wavelengths. This is achieved with optical simulations using Monte Carlo methods [24]. On average, rays detected by the photodiode follow a banana-shaped path, the depth of which depends on the wavelength [25]. On the one hand, simulations show that for a given wavelength, a higher PD-LED spacing will enable the light to pass through deeper tissues, which are more likely to be pulsatile than the superficial skin. Therefore, a longer and deeper path should increase the pulsatile modulation (or perfusion ratio) of the light signal and therefore improve the SNR.

On the other hand, increasing the LED-PD distance also comes with disadvantages. Because only a small fraction of the total light emitted by the LEDs actually reaches the photodiode, increasing this distance requires a higher light intensity, which consumes more energy. In addition, LEDs have a maximum current they can sustain without damage, so it becomes counterproductive to increase the LED-PD spacing above a certain value at which too little light would be received by the photodiode to provide a usable signal. Based on this trade-off, we found that spacings between 7 and 9 mm were optimal.

Algorithm

The Withings ScanWatch embeds a real-time self-contained algorithm implemented in C language designed to estimate SpO_2. The machine learning components of the algorithm (the neural network and linear regressions) were trained using two hypoxia calibration studies, totaling 34 subjects. This algorithm comprises three parts, as described below.

First, a signal processing part estimates AC and DC for each wavelength as well as the modulation ratio. DC levels are obtained by applying a moving average filter on the raw signals, and AC levels are obtained by filtering the raw signals with a bandpass filter centered around 1 Hz and computing the moving standard deviation on the resulting signals. Thus, the perfusions (AC/DC ratios) can be computed for each wavelength, and the modulation ratio (perfusion in the red divided by the perfusion in the infrared) can be estimated. This modulation ratio is supposed to be linearly correlated with SpO_2; however, in the case of wrist-worn oximeters, the frequent occurrence of movement and respiratory artefacts often cause that ratio to be unreliable.

To counteract the problem of the modulation ratio not being linearly correlated with SpO_2, a second SpO_2 estimator is used independently from the first part using a 1D convolutional neural network [26]. The network takes as an input an 8-second window over the three LED signals and outputs a direct SpO_2 estimation. The green LED signal is provided to the network to help the network denoise the red and infrared channels. The advantage of this method over the standard one is that the advanced filter bank built inside the network can be trained to better handle movement and respiratory artefacts present on the signals, which are particularly present in reflective PPG measurements.

Finally, the modulation ratio computed in the first part and the SpO_2 estimation calculated in the second part are merged via a linear regression to obtain a final SpO_2 estimation.

Several indicators were used to determine whether a SpO_2 measurement was conclusive or inconclusive. First, two algorithms use the PPG and accelerometer signals to assess if the watch is worn and if the user is still. These algorithms are heuristics that rely on simple filtering and thresholding, and they were calibrated on separate data sets acquired specifically for this purpose. The stillness of the user was derived from the absence of variation in the accelerometer signal, and the presence of a pulse on the PPG signal was the main factor to determine that the watch was worn.

In parallel, a second neural network with the same topology (8-second window over the three LED signals) detected and eliminated signals of poor quality. The calibration hypoxia studies were manually annotated to provide labels on which to train the neural network.

An SpO_2 measurement was considered to be inconclusive if the watch was not worn, the user was moving, or the measurement was classified as being of poor signal quality.

Statistical Analysis

A statistical analysis of the collected data was performed with the software Python 3.6.9 on a frozen database. A separate analysis was conducted for each wrist. The bias (mean error) and root mean square error (RMSE) between the SpO_2 and SaO_2 values were calculated for each range of SpO_2 values ($SpO_2 \leq 80\%$, $80\% < SpO_2 \leq 90\%$, and $90\% < SpO_2$) and for the whole range of 70%-100%. We used the Pearson correlation coefficient to determine the strength of the association between

the SpO_2 values collected from the Withings ScanWatch and the ABL90 hemoximeter. We used Bland-Altman plots to measure the agreement between the Withings ScanWatch and the ABL-90 hemoximeter.

Because a time offset exists between the Withings ScanWatch and the blood sample measured by the co-oximeter, due in part to physiological considerations (eg, distance between the arms, the wrists, and the depth of the arteries) and in part to the delay inherent to the Withings ScanWatch algorithm, we applied a plateau-matching algorithm in accordance with the recommendations of the ISO 80601-2-61:2017 standard before comparing the readings. We used a cross-correlation method to determine the delay between the measurements collected by the devices on each patient's wrists and the blood samples. Table 1 provides an overview of the mean, median, and standard deviation values of the time offsets applied on the Withings ScanWatch measurements for plateau matching.

Table 1. Time offsets applied on the Withings ScanWatch for plateau matching. A negative offset indicates that Withings ScanWatch lags behind the co-oximeter.

Offset	Mean (s)	Median (s)	SD (s)
Right hand	–4.2	–4.5	9.5
Left hand	–5.2	–6.5	10.9

Results

User Statistics

The 14 participants in our study included 8 men and 6 women aged 23-39 years with various skin tones: fair, medium, and dark skin (Table 2). Their body mass index and blood pressure values before and after the study are also reported in this table.

Table 2. Demographic data of the study participants.

Subject	Age (years)	Gender	Skin pigmentation	BMI (kg/m^2)	BP1[a] (mm Hg)	BP2[b] (mm Hg)
1	25	Male	Dark	22.2	91/73	111/72
2	26	Male	Medium	22.0	119/63	112/67
3	23	Female	Dark	20.8	125/63	112/67
4	23	Female	Medium	23.0	112/57	-
5	26	Female	Light	21.7	123/61	126/74
6	26	Male	Medium	28.1	113/67	120/65
7	25	Male	Medium	22.7	117/57	121/73
8	39	Male	Light	28.1	106/71	112/81
9	28	Female	Light	22.7	107/63	101/67
10	26	Male	Medium	22.4	108/64	110/55
11	28	Female	Medium	25.4	127/70	111/67
12	30	Male	Medium	20.8	138/91	132/88
13	28	Male	Dark	23.5	128/70	120/68
14	26	Female	Light	25.4	109/60	107/70

[a]BP1: blood pressure before the study.

[b]BP2 : blood pressure after the study.

Signal Quality

Of the 322 oxygen saturation measurements collected by the Withings ScanWatches placed on the participants' right and left wrists, 275 (85.4%) and 244 (75.8%) samples, respectively, were classified as conclusive measurements and were subsequently included for further data analysis. The remaining samples, 47/322 (14.6%) and 78/322 (24.2%) taken from the participants' right and left wrists, respectively, were classified as inconclusive measurements (poor signal quality, motion detected, or watch not worn) and were excluded.

Oxygen Saturation

The SpO_2 levels collected from the conclusive measurements ranged from 70% to 100% and were evenly distributed into 3 groups: $SpO_2 \leq 80\%$, $80\% < SpO_2 \leq 90\%$, and $90\% < SpO_2$ (Table 3). In the $SpO_2 \leq 80\%$, $80\% < SpO_2 \leq 90\%$, and $90\% < SpO_2$ groups, we found biases of 0.75%, 2.02%, and 0.14% and RMSEs of 3.29%, 3.24%, and 2.41%, respectively, when the Withings ScanWatch was placed on the participants' right wrists, and biases of 2.25%, 2.41%, and 0.31% and RMSEs of 3.74%, 3.21%, and 1.90%, respectively, when the Withings ScanWatch was placed on the participants' left wrists. Overall, we found

RMSEs of 3.00% and 2.97% and a bias of 0.98% (95% CI 0.65-1.32) and 1.56% (95% CI 1.24-1.87) from the participants' right and left wrists, respectively (Table 4).

The correlation plots show a positive strong correlation between the SpO_2 values collected from the participants' right and left hands, with high Pearson correlation coefficients of r=0.944 and r=0.954, respectively (Figure 4). The Bland-Altman plots show a high level of agreement, with Pearson correlation coefficients of r=0.083 (P=.17) and r=0.23 (P=.001) for the devices on the right and left wrists, respectively, and 95% lower and upper limits of agreement of –4.66% to 6.62% and –3.46% to 6.58%, respectively (Figure 5).

Table 3. Distribution among the SpO_2 groups of the conclusive measurements collected by the Withings ScanWatch. The corresponding distribution of SaO_2 values given by the ABL90 hemoximeter are also reported.

Group	Values, n (%)		
	Withings ScanWatch (SpO_2[a])		ABL90 hemoximeter (SaO_2[b])
	Right wrist (n=275)	Left wrist (n=244)	Blood samples (n=322)
$SpO_2 \leq 80\%$	87 (31.6)	72 (29.5)	103 (32.0)
$80\% < SpO_2 \leq 90\%$	95 (34.5)	78 (32.0)	109 (33.9)
$90\% < SpO_2$	93 (33.8)	94 (38.5)	110 (34.2)

Safety

No undesirable effects or adverse events were reported during the study.

Discussion

Principal Results

Since 2014, the popularity of smartwatches has grown considerably, particularly in the health care and biomedical industries [18]. With their integrated biosensors, these wrist-worn devices have the potential to provide valuable health care data to users, thus opening new opportunities for clinical applications. Indeed, instead of going to medical facilities, which is time-consuming, costly, and requires highly trained personnel, users can now monitor their physiological conditions themselves and report any abnormalities to physicians [18,19]. The Withings Scan Monitor is the software embedded in the Withings ScanWatch, a smartwatch that displays a reflective pulse oximeter function to measure, transfer, record, and display SpO_2 levels. Here, we tested this functionality according to the ISO 80601-2-61:2017 standard and FDA guidelines to validate its accuracy in measuring SpO_2 levels at a clinical-grade level [27,28]. To this end, we compared the performance of the Withings ScanWatch with that of the ABL90 hemoximeter, a co-oximeter routinely used in the medical field for measuring SaO_2 levels in blood samples, to measure the SpO_2 levels of 14 participants who underwent plateaus of oxygen desaturation in the laboratory.

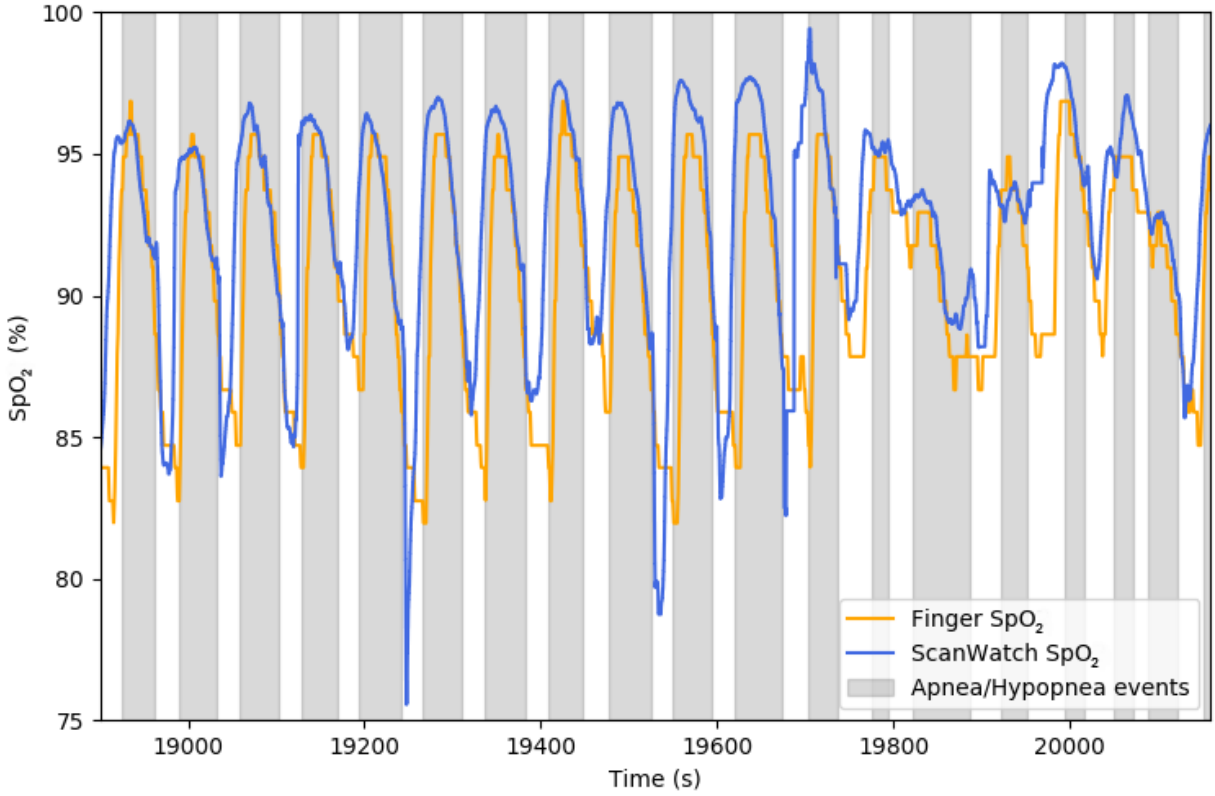
In this study, we observed an inequality in the distribution of the 325 measurements collected, with a higher rate of inconclusive measurements taken from the participants' left wrists (78/322, 24.2%) than from their right wrists (47/322, 14.6%). This imbalance was mainly caused by unwanted movements when taking blood from the participants' left arms. We also observed that the interactions between the catheter and the device on the left wrist interfered with the collection of the conclusive measurements when SpO_2 levels were below 90% (Table 3). Indeed, the distribution of the samples was slightly unbalanced, with 38% of measurements collected in the 90%<SpO_2 group. However, this difference was not significant. Thus, the ratio between the measurements distributed among the three SpO_2 groups is acceptable. Overall, we obtained sufficient conclusive measurements to meet one of the requirements set by the ISO 80601-2-61:2017 standard and FDA guidelines, which requires at least 200 paired samples from 10 participants to validate the reflective pulse oximeter function of a device.

Next, we examined the strength of the association and the agreement between the conclusive measurements taken from the reflective pulse oximeter function of the Withings ScanWatch and the ABL90 hemoximeter. We found high Pearson correlation coefficients of r=0.944 and r=0.954 on the correlation plots and r=0.083 (P=.17) and r=0.23 (P=.001) on the Bland-Altman plots, as well as RMSEs of 2.97% and 3.00% on the participants' right and left hands, respectively (Figure 4 and Figure 5). Taken together, these results indicate a strong association and a high level of agreement between the measurements collected from the devices. Therefore, we have demonstrated that the reflective pulse oximeter function of the Withings ScanWatch is adequate to measure the SpO_2 levels at different stages of hypoxia.

Detection of Sleep Apneas

In addition to the accuracy of 3% found in the hypoxia study, the ScanWatch SpO_2 algorithm possesses adequate resolution and dynamics to identify apnea and hypopnea events when worn during sleep (Figure 6). Indeed, when used in a continuous monitoring mode, the ScanWatch can detect short SpO_2 variations that occur in apneic patients, paving the way for automatic sleep apnea detection for patients at home without using intrusive and costly polysomnography setups.

Figure 6. SpO_2 measured by ScanWatch and a finger pulse oximeter during apnea/hypopnea events.



Limitations

The clinical study was conducted in a controlled environment with a well-established protocol and methodology to collect SpO_2 measurements during stable plateaus of SpO_2 in healthy participants aged 23-39 years. Its design may limit the generalizability of the results to real-world situations. Indeed, the ability of the Withings ScanWatch reflective pulse oximeter to dynamically monitor the evolution of SpO_2 in a subject is unknown in the real world because participants were exposed to stable plateaus of SpO_2 between 70% and 100% in this study. Finally, given the risks induced by hypoxia on older subjects or patients with respiratory conditions, we were unable to test the ability of the Withings ScanWatch to measure SpO_2 in these populations. In future work, the accuracy of the Withings ScanWatch reflective pulse oximeter should therefore be tested in real-life conditions (including in the home, at a hospital ward, and during rehabilitation), on a specific population such as patients with COPD or obstructive sleep apnea, or to diagnose and monitor patients with respiratory diseases.

Conclusions

FDA guidance and the ISO 80601-2-61:2017 standard require RMSEs below 3.5% and 4% for reflectance pulse oximeter approval, respectively [27,28]. These criteria were recently fulfilled by a wrist-sensor pulse oximeter, the Oxitone 1000, in a study in which its precision and accuracy were tested and an RMSE of 3% was reported [29]. Here, out of the conclusive measurements collected from the 14 participants, we have shown that the Withings ScanWatch exhibited acceptable RMSE levels for SpO_2 that were below the thresholds defined by these authorities. According to our data, we have thereby demonstrated that the Withings ScanWatch fulfills the requirements set by both the FDA guidelines and the ISO 80601-2-61 standard. The reflective pulse oximeter function of the Withings ScanWatch is thus validated and is accurate in measuring SpO_2 levels at a clinical-grade level. No undesirable effects or adverse events were reported during the study.

Abstract

Background: Internet gaming disorder has been a controversial topic for nearly a decade. Although internet addiction has been studied in medical students, there is a paucity of evidence regarding internet gaming disorder. Previous studies in Indonesia explored only the prevalence rate and characteristics.

Objective: This study aimed to determine the prevalence rate of internet gaming disorder and correlations between internet gaming disorder, temperament, and psychopathology among Indonesian medical students.

Methods: A cross-sectional study was performed from August 2019 to September 2019 using total and convenience sampling at a private university and a public university, respectively. The study variables were measured using the Indonesian version of the 10-item Internet Gaming Disorder Test, the Temperament and Character Inventory, and the Symptoms Checklist 90. Chi-square and logistic regression analyses were conducted to examine the relationships between demographic factors, temperament, psychopathology, and the presence of internet gaming disorder.

Results: Among the 639 respondents, the prevalence rate of internet gaming disorder was 2.03% (n=13), with a mean age of 20.23 (SD 0.13) years and an average gaming duration of 19.0 (SD 0.96) hours/week. Up to 71.2% respondents played using their mobile phones, and respondents with internet gaming disorder reported experiencing all psychopathologies assessed, except phobic anxiety. Bivariate analysis demonstrated that internet gaming disorder was associated with gender, gaming duration, gaming community affiliation, and 9 out of 10 domains of psychopathology. In a logistic regression model, internet gaming disorder was correlated with weekly gaming hours ≥20 hours (odds ratio [OR] 4.21, 95% CI 1.08-16.38, *P*=.04).

Conclusions: These findings suggest that the prevalence of internet gaming disorder among medical students in Jakarta, Indonesia is similar to that in other populations of Asian countries. The predisposing factor for internet gaming disorder was weekly gaming duration, while other demographic, temperament, and psychopathology variables acted as probable moderators. Strategies should, therefore, be developed and integrated into medical curriculum to screen and aid individuals with these predisposing factors.

KEYWORDS

internet gaming disorder; medical students; psychopathology; temperament; risk factors

Introduction

In this globalized era, the internet has become a necessity for people. It offers many benefits, especially for gamers, by connecting them digitally with others worldwide. Unfortunately, the internet bears its own negative effects when used excessively, which may lead to internet gaming disorder. Between 1995 and 2015, the percentage of internet users escalated (from 0%-14% to 45%-99% in 29 countries [1]). For internet gaming disorder, the prevalence globally varies from 0.7% to 15.6% among adults [2] and ranged from 0.6% to 19.9% among adolescents [3]. Specifically, a study in the US noted 8.5% of surveyed teenagers fulfilled criteria of internet gaming disorder [4], while German researchers revealed a prevalence of 1.2% [5]. Among Asian adolescents, a Taiwanese study discovered an internet gaming disorder rate of 3.1% [6], and a Japanese study demonstrated a prevalence 1.8% [7].

In Indonesia, internet usage rose from 0.9% in 2000 to 17.1% in 2014. Approximately 80% of the teenagers in Indonesia are on the internet daily [8]; consequently, the rate of internet gaming disorder among Indonesian teenagers is estimated at 10.15% [9] A systematic review [10] noted the high pooled prevalence of internet addiction (30.1%) among medical students [10], which is not surprising as this is a highly stressed group who are vulnerable to psychopathologies [11]. As such, they are at risk of adopting passive coping mechanisms. However, limited studies [10] have reported the more specific form of internet addiction (ie, internet gaming disorder) among medical students.

The varying prevalence of internet gaming disorder is due to the absence of consensus in diagnosing internet gaming disorder. Past studies [12] have looked at internet addiction as a generalized construct which encompasses all digital activities, and others, such as internet gaming, as a specific entity; however, the Diagnostic and Statistical Manual of Mental Disorders Fifth edition (DSM-5) and International Classification of Diseases 11 (ICD-11) have provided guidelines to identify affected individuals. According to the DSM-5, internet gaming disorder is defined as the persistent and recurrent use of the internet to play games that causes clinically significant impairment or distress. The patient must exhibit at least 5 out of 9 diagnostic criteria—preoccupation, withdrawal, tolerance, loss of control, giving up on other activities, continuation, deception, escape, and negative consequences—within a 12-month period [13]. Meanwhile, ICD-11 describes gaming disorder as a persistent or recurrent gaming behavior, either online or offline. The ICD-11 mentions 3 symptoms of gaming disorder, namely, impaired control over gaming, gaming being prioritized over daily activities and life interests, and its continuation or escalation, even after a negative impact has arisen [14]. Both internet gaming disorder (DSM-5) and internet gaming disorder (ICD-11) cover offline and online games [13], and accumulating evidence since the inclusion of internet gaming disorder within the section 3 of DSM-5 has led to international consensus for formal categorization of the disorder within ICD-11, which includes the internet as a specific identifier of the disorder [15]. As research and understanding of the disorders across populations grow, the nosology will require updates [15].

Researchers have developed numerous instruments to screen individuals afflicted with internet gaming disorder; however, there is no agreement regarding either screening tools or which clinical guidelines to adopt while diagnosing internet gaming disorder because there are limited studies on the diagnostic pathway, terminology definitions are arguable, and the diagnostic category is rather novel [16]. There are no definite indications yet for internet gaming disorder screening, and further research is required to define the risk and protective factors in order to narrow the specific population appropriate for screening [17].

Several studies in Indonesia have already described the prevalence, characteristics, and impacts of internet gaming disorder [9,18]. However, none of these studies focused on the relationship between internet gaming disorder and temperament, and internet gaming disorder and psychopathology. The main purpose of this study, hence, was to assess the correlations between internet gaming disorder, temperament, and psychopathology among medical students in Indonesia, given the prevalence of internet gaming disorder among Indonesian young adults and thus allowing for the ratification of preventive modules in medical schools.

Methods

Design

A cross-sectional study was conducted in private and public universities in Jakarta. The capital city of Indonesia was believed to be a representative sample base due to its dense and diverse population from across the archipelago. Total sampling in the private university and convenience sampling in the public university were performed from August to September 2019. This study was approved by Mochtar Riady Institute for Nanotechnology Ethics Committee (protocol number 1906010-02). Written consent was obtained from each respondent. Respondents who were screened with internet gaming disorder or other psychopathologies were invited for further psychiatric therapy sessions.

Respondents

The target population of this study was medical students in Indonesia, represented by the medical students in Jakarta. The sample consisted of medical students from private and public universities who had fulfilled the inclusion from respective and exclusion criteria (absence of severe psychotic disorders and substance use) by means of self-report and brief semistructured interviews with the research team. Criteria were chosen to ensure that the associations that generated were specific to internet gaming disorder. The respondents were briefed about the study in a specific session; respondents were required to give informed consent in order to participate. The minimal sample size was tabulated using the cross-sectional and hypothesis confirmation studies formula, with a type I error of 1.96, type II error of 0.84, and an absolute precision of .05 [19].

Measurements

The respondents completed a questionnaire providing demographic data and gaming-related characteristics (duration, affiliation to gaming community, and genre, whereby examples were provided). The game genres, which were adapted from prior studies [20-22], were divided into massive multiplayer role-playing games, multiplayer online battle arena, first-person shooting, multiplayer battle royale, real-time strategy, turn-based strategy, simulation, puzzle, or music/sports/platform. In addition, respondents answered 3 self-rated questionnaires.

The Indonesian version of the 10-item Internet Gaming Disorder Test (IGDT-10) consists of 10 statements about online gaming disorder similar to those of the original version. A 3-point Likert scale was used for response options (never, sometimes, and often). Scoring was then dichotomized (often=1; never or sometimes=0) to mirror the dichotomous nature of DSM-5 criteria. Items 9 and 10 represented the same construct and thus only a single score was used (ie, a response of "often" on either item scored only 1 point). The cut-off for internet gaming disorder, in accordance with DSM-5 criteria, specified a minimum of 5 out of 9 criteria [23]. In this study, we adopted the definition "persistent and recurrent use of the Internet to engage in games, often with other players, leading to clinically significant impairment or distress" for internet gaming disorder, and despite the terminology, internet gaming disorder encompassed individuals exhibiting problematic gaming symptoms in both offline and online settings [24]. For succinctness, respondents meeting the IGDT-10 cut-off were classified herein as having internet gaming disorder as IGDT-10 was found to cover clinical criteria of both DSM-5 and ICD-11 [25], though it should be cautioned that the instrument is a screening tool.

The Indonesian version of the modified Temperament and Character Inventory (TCI) was used to measure temperament. The questionnaire consists of 23 questions assessing the 3 domains of temperament (novelty seeking, reward dependence, and harm avoidance), and 16 questions that assess character (self-directedness and self-transcendence). However, this study only employed the former, and the partial instrument reliability was 52%. The answers were either "yes" (2 points) or "no" (1 point), and the points were summed up according to each domain. Each domain was divided into "low," if the total score was lower than average, and "high," if the total score was higher than average [26,27].

The Indonesian version of Symptoms Checklist 90 (SCL-90) has 82.9% sensitivity and 83.0% specificity. Respondents were asked if they had experienced any of the symptoms (90 statements) during the previous 7 days (1 week) using a 5-point Likert scale (0=never and 4=always). The points were summed based on somatization, obsessive-compulsiveness, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, psychoticism, and additional symptoms. Respondents were then divided into a *No* group if the total score was <61, and a *Yes* group if the total T-score was ≥61 [28,29].

Statistical Analysis

The data were analyzed using statistical software (Statistical Package for Social Sciences for Windows version 25, IBM Corp). The characteristics of respondents are reported descriptively. The relationships of characteristics, temperament, and psychopathology with internet gaming disorder were determined using chi-square and Fisher exact tests. Furthermore, stepwise binomial logistic regression analysis was applied to examine the multivariate relationship between internet gaming disorder, the respondents' characteristics, their temperaments, and psychopathologies (mean raw score and standard deviation are presented). Nine variables were chosen between respondents' characteristics and SCL -90, results of the TCI were not included as none were significant; the criteria set was $P<.25$ [30] and relevance was based on prior studies [31,32] in the field.

Results

Respondent Characteristics

In total, there were 639 respondents (mean age 19.9 years), of whom 59.6% were late adolescents (381/639); 64.2% were female (410/639; mean age 19.7 years), and 35.8% were male (229/639; mean age 20.2 years). Respondents started gaming at a mean age of 11.31 years (SD 0.14) and had mean weekly gaming duration of 15.34 hours (SD 0.57; male: mean 19.00 hours, SD 0.96; female: mean 13.29 hours, SD 0.69); 55.2% of the respondents (353/639) lived independently, and 85.8% played games before 8 years of age (548/639). The age cut-off was based on a previous study [33]. Twice as many males (75/229, 32.8%) played more than 20 hours a week compared to females (68/410, 16.6%). Approximately 22.3% of males (51/229) joined a gaming community, compared to 12.0% of females (49/410). Device-wise, both genders preferred smartphones for playing games (455/639, 71.2%) (Table 1).

Table 1. Respondent demographics.

Characteristic	Male (n=229), n (%)	Female (n=410), n (%)	All (N=639), n (%)
Age			
Early adolescence	0 (0.0)	1 (0.2)	1 (0.2)
Mid-adolescence	10 (4.4)	39 (9.5)	49 (7.7)
Late adolescence	130 (56.8)	251 (61.2)	381 (59.6)

Internet gaming disorder			
Yes	9 (3.9)	4 (1.0)	13 (2.0)
No	220 (96.1)	406 (99.0)	626 (98.0)

Respondents With Internet Gaming Disorder

Of the 639 respondents, 13 respondents were identified with internet gaming disorder (2.03%). The 13 respondents on average scored 5.56 (SD 0.53) on IGDT-10, compared to a mean score of 0.37 (SD 0.76) among the rest of the respondents. There was a statistically significant difference between gender, with males being 4 times more likely than females to have internet gaming disorder (odds ratio [OR] 4.15, 95% CI 1.26-13.64; *P*=.02). In addition, respondents playing >20 hours per week were 6 times more likely to be screened with internet gaming disorder (OR 5.82, 95% CI 1.87-18.08; *P*=.002). Attachment to a gaming community also displayed a statistical significance (OR 8.08, 95% CI 2.12-30.81; *P*=.04). No significant relationship was observed for age (*P*=.74), onset of gaming (*P*>.99), type of residence (*P*=.51), and device of choice (*P*=.57) with gaming disorder (Table 2). Among respondents with internet gaming disorder, 6 respondents (46.2%) mainly played multiplayer online battle royale, 4 respondents (30.8%) primarily enjoyed multiplayer online battle arena, 2 respondents (15.4%) focused on puzzle games, and 1 respondent (7.7%) chiefly played turn-based strategy games. Among respondents without internet gaming disorder, the most popular game genre was multiplayer online battle arena (190/626, 30.4%), second-most popular was multiplayer online battle royale (118/626, 18.9%), followed by real-time strategy (72/626, 11.5%), puzzle genre (69/626, 11.0%), and simulation (33/626, 5.3%).

Table 2. Comparison of demographics between respondents with and without internet gaming disorder.

Category	Internet gaming disorder		Comparison

TCI and Internet Gaming Disorder

Of the 3 TCI domains, none was found to have a significant relationship with internet gaming disorder (novelty seeking: *P*=.13; reward dependence: *P*=.35; harm avoidance: *P*=.18). Eight out of 13 respondents with internet gaming disorder exhibited high novelty seeking behavior; similarly, 67% of respondents (10/13) also had high harm avoidance, and approximately only 33% of respondents (2/13) displayed high reward dependence (Table 3).

Association Between Internet Gaming Disorder and Psychopathology

The Symptoms Checklist 90 (SCL-90) has 9 domains with supplementary Global Symptoms Index (GSI) and an additional domain in the Indonesian version. Overall, respondents with internet gaming disorder scored 2 to 3 times higher on all domains of SCL-90 than respondents without internet gaming disorder. Out of all the domains, only phobic anxiety (*P*>.99) and the additional domain (*P*=.20) were not statistically significant (Table 4). GSI and interpersonal sensitivity were found to be markedly significant (OR 12.87, 95% CI 3.96-41.78, *P*<.001; OR 23.18, 95% CI 5.35-100.46, *P*=.001) respectively. Two out of 13 respondents (15%) who scored highly on IGDT-10 presented with positive somatization, obsessive-compulsive disorder, depression, anxiety, hostility, and paranoid symptoms. Interpersonal sensitivity and psychoticism were reported by 3 respondents. Those with low IGDT-10 scores also reported similar psychopathologies; for instance, 6 respondents without problematic gaming also had positive somatization symptoms. Phobic anxiety symptoms were exclusively reported by 7 respondents without internet gaming disorder.

Multivariate Analysis of Internet Gaming Disorder, Respondent Characteristics, TCI, and SCL-90

Logistic regression analysis was performed to identify the factors that influenced risk of internet gaming disorder. The results are shown in Table 5. In the first model, when controlling for gender and community affiliation, weekly gaming duration of >20 hours per week remained statistically significant (OR 3.98, 95% CI 1.20-13.18, *P*=.02). The model explained 12.1% of the variance (R^2=0.121) and had acceptable goodness-of-fit with the Hosmer-Lemeshow test *P*=.74. When controlling for temperament and psychopathology, weekly gaming duration remained a significant factor associated with internet gaming disorder (OR 4.21, 95% CI 1.08-16.38, *P*=.04). The overall

model improved with pseudo R^2=0.301 and Hosmer-Lemeshow test P=.80.

Discussion

Prevalence and Demographics of Internet Gaming Disorder Among Medical Students

In a sample of Indonesian medical students, 2.03% (13/639) were suspected to suffer from internet gaming disorder, and a weekly gaming duration >20 hours was predictive of internet gaming disorder. Gender and participation in a gaming community did not increase the odds of internet gaming disorder. Subscales of the SCL-90, with the exception of phobic anxiety, were completed by respondents with internet gaming disorder, but none was found to increase susceptibility to internet gaming disorder in this study. The prevalence of internet gaming disorder has previously been found to range between 0.27% and 57.50% [34] and that of internet addiction has been found to range from 0.8% to 26.7% [35]. Notably, prior studies [5,36-41] indicated that internet addiction and video game addiction or problematic gaming prevalence dropped within the older age groups. Another study with young respondents (mean age 13 years), reported a higher prevalence of up to 4% [42] and up to 9% in primary school students [4]. Alternatively, a systematic review [43] estimated a pooled prevalence of 20.0% and 10.1% for internet addiction and internet gaming disorder, respectively, among the general population in Southeast Asia.

In addition, we found an association between gender and internet gaming disorder, with males constituting more than twice the number of respondents with internet gaming disorder than females, which was consistent with previous findings [36,39,40,44,45]. Furthermore, males played longer and were more likely to join a gaming community than females. In prior studies in pathological gambling, several theories have been suggested, such as differences in genetics and neurobiology between genders [46,47]. A functional magnetic resonance imaging study demonstrated that males exhibited amplified connectivity in their mesocorticolimbic pathway when playing video games compared to that exhibited by females [48]. This pathway is known for its pivotal role in reward assessment, motivated behavior, and cognitive regulation through dopaminergic modulation [49,50]. On a larger scope, gender differences have already been observed in multitudes of addictions, although many studies were culturally and politically biased [51,52]. A review [53] argued that although biological processes within the brain differ between males and females in certain areas, and there are variations in genetic expression, these are, nonetheless, further influenced at the phenotypic level by sociocultural factors and individual experiences. Gendered experiences, such as boys playing with robots and females with dolls, combined with sociocultural notions of gender-based activities, in which gambling and competitive activities are

perceived to be masculine, result in male and females tending to adopt opposite coping and escape mechanisms [53].

Internet Gaming Disorder and Gaming Characteristics Among Medical Students

Consistent with the findings of previous studies [5,45], the correlation between weekly hours spent gaming and internet gaming disorder was significant (*P*=.002), with approximately 22% of affected respondents spending more than 20 hours a week engaging in such activities. This relationship was maintained even after controlling for other significant sociodemographic factors, such as gender and community participation, temperament, and psychopathology (OR 4.21, 95% CI 1.08-13.68). A previous qualitative study [54] argued that although increased gaming time is associated with internet gaming disorder, it should not be considered a criterion for addiction when no negative consequence was observed. The study highlighted the essence of context when considering gaming time. This was revealed to be pertinent as the 2 cases identified demonstrated contrasting psychological and behavioral patterns, even though they both played over 14 hours a day [54]. Additionally, gamers may not accurately account for the duration spent on activities related to games, including strategizing, discussing, and fantasizing [55], as actual time spent gaming, thus camouflaged as seemingly short gaming duration. Another study [56] indicated that the effects of increased gaming time, particularly on weekdays, were more likely to develop into depressive, psychosomatic, and musculoskeletal symptoms. A probable explanation relates to the interaction with motive. Positive excessive gameplay might add to a person's life, in contrast to excessive play as a result of negative motivations, such as escapism. The time spent in gaming reduces the availability of time during which to perform other essential tasks, such as physical socializing, schoolwork, or work; thus, gameplay duration is a pivotal determinant when put together with gameplay motives [56-58]. Alternatively, serious gaming provided complementary avenue of training and education [59] and novel opportunities to socialize with individuals, from near and far. These generated social capitals, which are greatly influenced by physical and social proximity (familiarity) [60], more often than not spurred further indulgence in game activities [61] yet translate poorly to offline social support or provision of deep affective relationships [62,63].

Our study revealed a significant association between affiliation to a gaming community and internet gaming disorder (*P*=.04). Online gaming is an inherently social activity, particularly with the advent of massively massive multiplayer role-playing games, multiplayer online battle arena, and multiplayer online battle royale [20]. The majority of respondents with internet gaming disorder in our study favored multiplayer online battle royale and multiplayer online battle arena to other genres. Multiplayer online battle royale, as a survival game combined with scavenging and combat, presents gamers with unique scenarios and dynamic and competitive gameplay in each round [20,64]. Similarly, the game genre multiplayer online battle arena was also prevalent as it motivates gamers through nonrepetitive game style, array of in-game ranks and items, and emphasis on teamwork and clan [20]. The social factors in playing multiplayer online battle arena included making new friends, chatting, and working in a team. Social elements, such as developing reputation and admiration from the gaming community, were a central driving factor in obtaining enjoyment in playing these games [65]. Gamers with internet gaming disorder may have used online games as a substitute for establishing real-world relationships, as increasing internet gaming disorder symptoms are associated with social anxiety, and social motivations are associated with gaming addiction [66-69]. According to the social compensation hypothesis, the fleeting sense of social interaction in online games and the sense of escape from the physical world facilitates greater engagement in games [66,69]. This particular relationship was not explored in this study.

Temperament, Psychopathology, and Internet Gaming Disorder

Our study did not find an association between TCI domains and internet gaming disorder. This finding conformed with the results of a recent study [33], which argued that the 3 domains of TCI were neither protective nor risk factors for internet addiction. Individuals with high novelty-seeking supposedly modulate dopaminergic and heritable tendencies toward intense excitement, unpredictable and emotional behavior, and repeated exploratory activities in response to novelty [70]. The lack of association is partly explained as individuals with high novelty seeking are readily disinterested and lack persistence in doing a particular activity. The individuals then favor shifting their activities almost impulsively, and thus they are less likely to suffer internet addiction [33]. Our study showed a small distinction between high and low scores in all TCI domains. A previous study [71] in South Korea displayed a significant total score difference between problematic internet users and problematic drug users, although the subanalysis of the novelty seeking score difference was not statistically significant. The study [71] also showed an insignificant correlation between novelty seeking and internet gaming disorder, and a significant relationship with harm avoidance and reward dependence scores in the problematic internet user group, but not in the control group. This is in contrast with the findings of a similar study which proposed that novelty seeking and harm avoidance were strong predictors of internet gaming disorder compared to those for healthy individuals [72]. The contradictory evidence suggests that it is necessary to investigate personality factors more deeply, as novelty seeking, harm avoidance, and reward dependence have been found to be determined by a person's personality profile and their impulsivity [71].

Bivariate analysis revealed a correlation between respondents with internet gaming disorder and nearly all psychopathologies in the Indonesian version of SCL-90, except for phobia and the additional domains. This pattern may be an indication of the nonspecificity of psychological distress or a variety of clinical profiles presented by internet gaming disorder respondents. However, gender (*P*=.06), gaming community (*P*=.65), temperament (novelty seeking: *P*=.40; harm avoidance: *P*=.13), and psychopathological factors (GSI: *P*=.16; somatization: *P*=.53; obsessive compulsiveness: *P*=.26; interpersonal sensitivity: *P*=.68; depression: *P*=.73; anxiety: *P*=.68; hostility: *P*=.70; paranoia: *P*=.52; psychoticism: *P*=.34; additional: *P*=.16) lost significance in multivariate analysis. Nonetheless,

incorporating temperament and psychopathology enhanced the overall model pseudo R^2 from 0.12 to 0.30, suggesting that they may be important moderators. The complex interaction between online video game overuse and associated psychopathologies has persisted and is apparent in the ambiguous evidence available. Several cross-sectional [67,73,74] and cohort studies [4] described significant effects associated with social phobia, gaming, and addiction, while other studies failed to establish any association [75-77].

Our study had limited identification of the dysfunctions experienced by respondents at a single point in time; however, the directional causality between internet gaming disorder and psychopathology is of high importance. An elaborate cohort study [4] demonstrated that individuals who engaged in chronic persistent gaming developed depression, anxiety, and social phobia after 2 years. In addition, they had significantly lower grades and social functioning compared to those who recovered from internet gaming disorder or who did not develop internet gaming disorder [4]. Based on the proposed Escape Theory [78], a number of studies have depicted gaming as an escape strategy for patients dealing with depression [68,79]. Nonetheless, it has been argued that gaming addiction should not be viewed as merely an escape or defective coping mechanism because symptoms of other disorders are also evident [4]. Internet gaming disorder might worsen psychopathological distress, while the management of internet gaming disorder could alleviate these complaints [4]. It is uncertain, however, as to whether the psychopathologies were preexisting and then reinforced by internet gaming disorder, as previous longitudinal research has failed to establish significant causality between internet gaming disorder and symptoms of depression and anxiety [77].

Strengths and Limitations

This study is the first, to the knowledge of the authors, to investigate associations between temperament, psychopathologies, and internet gaming disorder in medical students in Indonesia. Additionally, our study was able to recruit a considerable number of respondents. Our study also distinguished online gaming by platform, from computers to mobile phones, given that an expanding number of people are occupied by digital games. Data from our study suggest that incorporating selective preventive measures among medical students targeted to proactively shift and shape gaming as positive and nurturing experiences within the medical education field is required. Prior research has demonstrated that serious games can be developed for the purpose of medical education and provided moderate effects in aiding transfer of knowledge or skills, with the additional benefit of generating a motivating and recreational learning experience [80]. Some have noted the lack of standard in pedagogical approaches of these game develops, but efforts are on-going to generate a structured framework [81] and advocate the use of serious games, which are disparate from commercial games, as prevention for gaming addiction [82].

One specific limitation of our study, apart from being cross-sectional, was that the samples were taken from medical students alone. Interpretations of correlations, or absence thereof, should be made with the sample scope in mind. Although the prevalence of internet gaming disorder among medical students fell within the range observed in the general population, the characteristics of the respondents differed largely from those of previous studies. For example, in our study, females comprised more than half of the respondents, whereas internet gaming disorder is more common in males, and past studies [35,39,75,83] have largely examined a male-dominant sample, This cross-sectional study utilized a convenience sample rather than randomized respondents, which introduced selection bias. Our study enrolled medical students to focus on an understudied population with respect to internet gaming disorder and which is presumed to have better health care access yet in reality most neglect to follow up on existing symptoms [10]; concurrently, the resources available limited how widespread sample recruitment could be. Further research should employ longitudinal design, wider population, randomized sampling, comparison to clinical psychiatric diagnoses, and investigate the development of potential interventions.

Conclusions

Our study demonstrated that the point-prevalence of medical students screened with internet gaming disorder in Indonesia is within the estimated global range. The weekly duration of gaming was the strongest determinant of internet gaming disorder. Additional research should explore the diversity of motives and negative life consequences in engaged gamers to fully contextualize the effect of gaming duration and internet gaming disorder. Therefore, strategies should be developed and incorporated into medical curriculum to screen and aid students with prolonged gaming duration and psychopathologies.

Acknowledgments

This work was supported by Hibah Insinas Dikti 2019 (KS, PW, AK, and RY). This funding source had no role in the study conception, design, analysis, interpretation, or decision to submit for publication.

Authors' Contributions

KS, PW, and AK designed the study. KS, EH, PW, AK, and RY collected the data. KS, EH, and LTS performed data analysis and wrote the first draft. All authors critically reviewed the manuscript and approved the final version.

Abstract

Background: As mental illness continues to affect 1 in 5 individuals, and the need for support has increased during the COVID-19 pandemic, the promise of digital mental health tools remains largely unrealized due to a lack of uptake by patients and providers. Currently, most efforts on supporting the uptake of digital mental health tools remain fragmented across organizations and geography. There is a critical need to synthesize these efforts in order to provide a coordinated strategy of supporting the adoption of digital mental health tools.

Objective: The specific aim of this project is to develop a web-based resource document to support the engagement of mental health providers and patients in the use of digital mental health tools.

Methods: The web-based resource was developed using a multimethod approach. A grey literature review was conducted in 2019 to identify relevant toolkits that are available in the public domain. This was supplemented with an environmental scan where individuals with expertise in the development, acquisition, implementation, and evaluation of digital mental health tools were invited to contribute additional tools or documents not identified in the grey literature search. An engagement workshop was held with stakeholders to explore how the resource document should be developed and delivered. These findings were collectively used to develop the final iteration of the resource document.

Results: Based on a gray literature review and environmental scan with 27 experts, 25 resources were identified and included in the resource guide. These resources were developed for patients and providers by organizations from 5 countries. An engagement workshop was held with 14 stakeholders, and barriers related to cultural sensitivity, sustainability, and accessibility of the toolkit were identified. The final iteration of the resource document was developed by the research team using findings from the gray literature review, environmental scan, and engagement workshop. The contents of the 45-page resource guide are directed at mental health care providers, administrators, and patients (inclusive of families and caregivers).

Conclusions: The use of a multimethod approach led to the development of a resource guide that builds on existing evidence on digital mental health tools and was co-designed with stakeholders and end-users. The resource guide is now publicly available online for free and is being promoted through digital health and mental health websites. Future work should explore how this document can be integrated into clinical care delivery and pathways.

Introduction

Mental illness continues to be a global challenge, particularly during the COVID-19 pandemic [1]. Even prior to the pandemic, mental illness affected 1 in 5 individuals in the United States [2]. Unfortunately, with fewer than 50% of individuals receiving treatment for their mental health issues, mental illness remains a top contributor of disability in many countries including the United States [3] and Canada [4]. This increasing and unprecedented demand has spurred great interest in the use of telehealth or other digital tools during the current pandemic, highlighting new opportunities for improving access to health care through digital technologies [5].

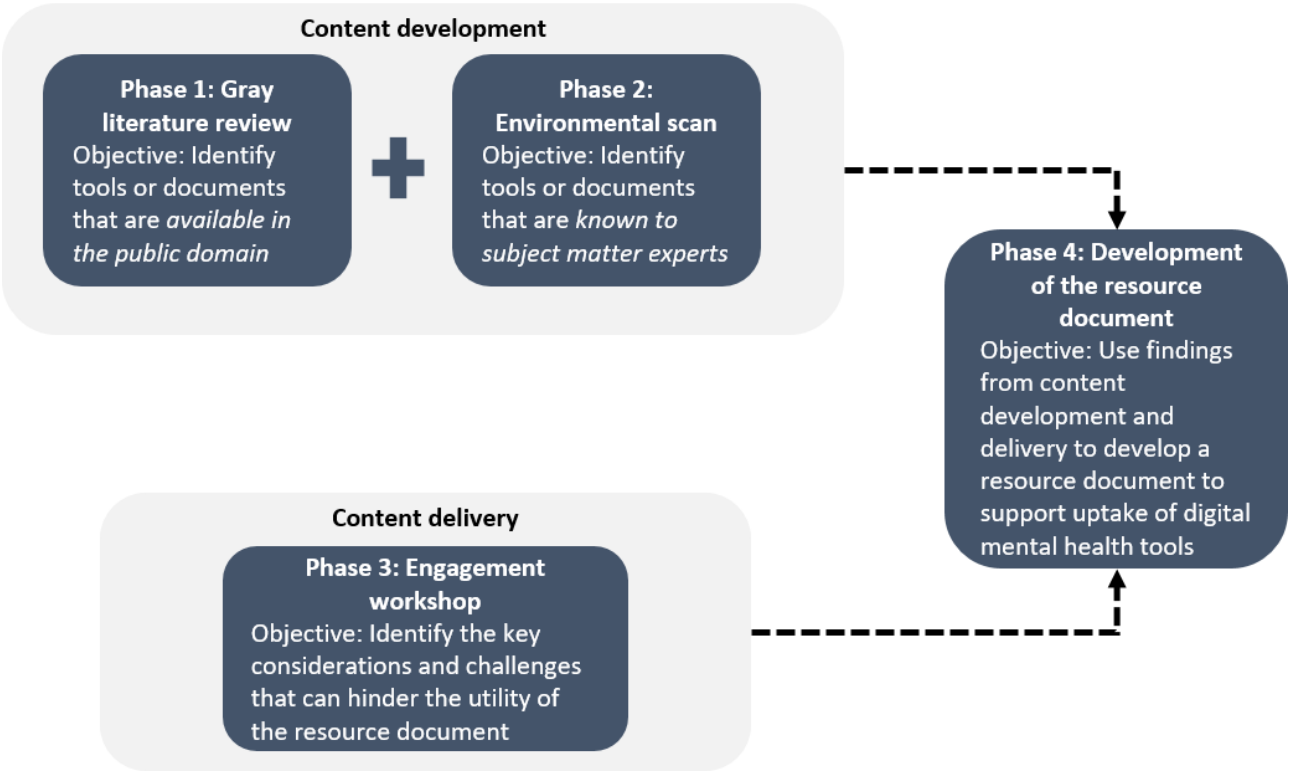
Digital mental health interventions, such as mobile apps, have been advocated by organizations, including the American Psychiatric Association (APA) [6] and the Health and Aging Department of Australia [7], as promising tools to support the current challenges in mental health service delivery. However, uptake of these tools by patients and providers remains poor [8]. In response, tools and resources for supporting the uptake of these tools into practice have recently been developed [9], yet these resources remain largely underused. Currently, most of the efforts and resources that are developed to support the adoption of digital mental health tools have been done in a piecewise effort across government organizations [10], hospitals, and mental health associations [11]. To our knowledge, there is no single source or repository where users can seek guidance on identifying relevant eHealth technologies for their needs. Given this, there is a critical need to collaborate with stakeholders and end-users in synthesizing a strong body of guidance and evidence to support digital health activities (eg, usability, user needs) and accelerate the adoption of digital tools for mental health contexts, especially during a global pandemic.

The objective of this project is to develop a comprehensive web-based resource guide to support mental health providers and patients in the selection and adoption of digital health tools through consideration of relevant factors (eg, demographics, clinical needs). The intended audiences of the guide are mental health care providers (eg, psychologists) and administrators (eg, implementation specialists) who are interested in integrating digital health tools into clinical practice, as well as people with lived experience and families or caregivers looking to use the resource to select helpful tools for their own needs. In this article, we share our approach and methodology for developing the resource document and outline how the main findings from each phase of the method informed the final development of the resource document. In addition, the implications of the resource document and challenges identified throughout the development process are discussed.

Methods

Following guidelines of the Agency for Healthcare Research and Quality [12], we used a multimethod approach (Figure 1) to develop the resource guide. The methods include a gray literature review, an environmental scan and engagement of experts in the field, and an engagement workshop with relevant stakeholders from a variety of backgrounds and interests. The findings from these 3 sources were then used to inform the development of the final version of the resource document (Multimedia Appendix 1). A multimethod approach [13] was selected to maximize the consolidation efforts of this work and deliver the findings in a meaningful and useful resources for a diverse audience. This work spanned across all provinces in Canada.

Figure 1. Overview of the multimethod approach for the development of the resource document.



Phase 1: Gray Literature Review

The objective of the gray literature review [14] was to identify relevant toolkits that are publicly available in the public domain. Following best practices on gray literature review [15], one of the authors (DM) conducted Google searches using key terms related to digital mental health tools, resources, and toolkits (Textbox 1). The first 10-20 pages of the Google Search results were reviewed, and tools or documents that met the inclusion criteria were identified and included. The inclusion criteria were as follows: available in English; technologies used or referred available in Canada; practical guidance for the use of digital mental health tools in clinical care provided; a target audience of providers, clients and caregivers, or both; and having relevance or being easily adaptable to the Canadian context (eg, health care system structure, processes).

Preference was given to Canadian sources and bilingual (French and English) resources. Relevant websites from mental health organizations (eg, Canadian Mental Health Association), medical organizations or hospitals (eg, British Medical Association), patient organizations (eg, The Mental Elf), and governmental organizations (eg, US Department of Health and Human Services) were also included. Tools of documents were excluded for one or more of the following reasons: they were more than 3 years old; they were digital mental health tools (eg, mental health apps, telemedicine portals); information was intended for policymakers, industry, or other audiences outside of providers, clients, or caregivers; they were academic or research articles; the tools had significant contextual information (eg, legal context or policy context) that rendered the information irrelevant for the Canadian context.

Blogposts or other lists (usually of apps) were also excluded due to a concern for the information being outdated. Included tools or documents were then catalogued using a Microsoft Excel spreadsheet for analysis. Relevant information related to the scope and utility was extracted from each tool or document. A content analysis [16] was used to understand the characteristics of the included tools and documents.

Textbox 1. Search strategy for gray literature review.

Gray literature search strings
• (electronic OR digital OR mobile) AND “mental health” AND (tool OR resource or e-tool OR e-resource OR toolkit OR app OR web)
• (electronic OR digital OR mobile) AND patient AND (tool OR resource OR e-tool OR e-resource OR toolkit OR app OR web)
• digital mental health tool
• digital tools to help my mental health

Phase 2: Environmental Scan

The purpose of the environmental scan was to identify relevant documents and tools that currently exist and are used in the field. To maximize the impact of the environmental scan and the number of documents and tools found, experts in Canada and the United States were identified using a snowball sampling approach through the professional networks of the project team and those who published, conducted research, or worked in the

field. Individuals who were knowledgeable across various digital health activities (eg, implementation, evaluation, design) were eligible to participate. Experts were contacted via email and telephone by the project team. Each expert was asked if they were aware of any tools or documents relevant to guide the uptake of mental health tools in the delivery of mental health care. These tools or documents were added to the list from the gray literature review (phase 1) and screened using the same inclusion and exclusion criteria. Content analysis [16] was also used to characterize the identified documents.

Phase 3: Engagement Workshop

We conducted an engagement workshop to increase the relevance and use of our research findings in practice [17]. Based on the environmental scan and literature review, a 1-day engagement workshop was held in January 2020 to gather information on the design and use of the resource guide. The engagement workshop was based on the Theory of Inventive Problem Solving (TRIZ) framework, which was developed in the 1960s to solve problems through the development of innovative and creative solutions [18]. Stemming from the principle of identifying the conceptual issue, it has become the basis for developing a conceptual solution that guides the arrival of the actual solution [18]. In contrast to traditional approaches, the TRIZ is said to guide the development of solutions by focusing on the contradictions that arise between the ideal and real system, and identifying solutions that close this gap [18]. Stakeholders, with diversity across roles, perspectives, geographies, and gender, were invited to participate in the engagement symposium. Individuals were eligible to participate if they had interest or experience with digital mental health tools. The inclusion criteria were kept broad to ensure we maximized the diversity among participating stakeholders. The structure of the workshop was completed using a World Café style [19], which is a structured approach to gather feedback from a large audience. The engagement workshop begins with asking participants to consider elements that would make the worst resource guide ever, and what approaches can be leveraged to prevent this from happening. Following this discussion, participants were invited to comment on what would be the critical elements that are relevant for an excellent resource. After each participant discussed these questions within the smaller group, a larger discussion was conducted before the engagement workshop was concluded. In the afternoon, participants were asked about current approaches for seeking information on digital mental health tools and how this resource document may be implemented to address current unmet needs. Challenges related to the uptake of the resource document were also discussed. Notes were taken by a member of the research team (JC) and were consolidated using a content analysis [16] approach.

Phase 4: Development of the Resource Guide

In order to develop the resource guide, the aforementioned efforts were consolidated by the research team. Foremost, after screening of the identified toolkits from the gray literature scan and environmental scan, a member of the research team (DM) consolidated and organized the list of resources based on the purpose and description provided by each toolkit. Each toolkit was also characterized by the intended audience, format, scope, language, and country of origin. The findings from the engagement workshop were then used by the research team to refine the draft of the resource document to a format and delivery that aligned with the need of stakeholders.

Results

The gray literature review and environmental scan led to the identification of 25 resources that were deemed relevant for the resource document. The engagement workshop, which was conducted with 14 participants, was used to inform the development of the resource document (Multimedia Appendix 1) [20]. A detailed description of the findings from each phase of the development (Figure 1) can be found in the next section.

Phase 1: Gray Literature Review

The gray literature review was conducted in September 2019, and a total of 19 resources were identified. Most of the identified resources from this phase of the project were websites or blog posts that contained a collection of apps (n=9). Other types of resources included app rating frameworks (n=3), implementation guides for clinicians (n=2), evaluation tools (n=1), electronic health record–related comic strips (n=2), and social media and info guides (n=2).

Of the 19 resources that were identified from the gray literature review, only 11 (60%) of the tools or documents met the inclusion criteria and were summarized for the final iteration of the toolkit. These included the HITEQ (Health Information Technology Evaluation, and Quality Center) Health App Decision Tree [21], the “e-Mental Health in Practice” document [22] from the Black Dog Institute, and patient information guides [23] from the National Health Service in the United Kingdom.

Phase 2: Environmental Scan

A total of 27 experts from Canada and the United States participated in the environmental scan. The demographics of the experts are outlined in Table 1. These experts have administrative, clinical, or research roles in mental health and either actively participate or have experience in activities (eg, development, implementation) related to digital mental health tools. There was representation across many provinces in Canada, with most participants being from Ontario (n=10). In terms of organization, most participants had affiliations with academic and government organizations. From the 42 tools or documents that were suggested by participants of the environmental scan, a total of 14 tools or documents met the inclusion criteria and were included in the final resource document.

Table 1. Demographic characteristics of participants in the environmental scan.

Characteristic	Number of participants (N=27), n (%)
Province/location	
British Columbia	1 (4%)
New Brunswick	2 (8%)
Nova Scotia	8 (30%)
Ontario	10 (37%)
Prince Edward Island	2 (8%)
Quebec	1 (4%)
Saskatchewan	1 (4%)
Outside of Canada	2 (8%)
Organizational affiliation	
Academic institution	10 (37%)
Government	9 (33%)
Hospital	3 (11%)
Nonprofit organization	5 (19%)

Characteristics of Resources

The gray literature review (phase 1) and environmental scan (phase 2) led to the identification of 25 resources in our web-based resource guide. Among the 25 resources, 9 resources (36%) provided ratings or reviews of digital mental health tools, and 3 resources (12%) provided guidance on the implementation of these technologies. Additionally, there were 4 resources (16%) that were tools for patients, 6 resources (24%) for clinicians, and 3 (12%) resources designed for both patients and clinicians.

In terms of the resources identified, most were developed in Canada (n= 10) and the United States (n=10), with other resources being from the United Kingdom (n=2), Australia (n=2), and New Zealand (n=1). Only resources developed in Canada were found to be available in French. In addition, only 60% of the resources (15/25) were developed or updated in 2018 and later. The latter resources do not have an updated date or were last updated before 2018. Most resources were developed collaboratively with private or not-for-profit organizations (n=15), academic groups (n=6), provider associations like Canadian Medical Association (n=5), health care organizations (n=2), and governments (n = 2). Likewise, funding for the development of the resource originated from not-for-profit organizations (eg, One Mind), health service organizations (eg, Ministry of Health of New Zealand), government-funded organizations (eg, Ontario Telemedicine Network), provider organizations (eg, British Medical Association), and academic institutions (eg, University of Chicago).

In terms of the audience, identified resources included content relevant to patients (n=10) and clinicians (n=20). In particular, 15 resources had clinician-specific resources, 5 resources contained patient-specific resources, and 5 resources had content for both populations. Some resources indicated a specific audience, such as primary care or general providers (n=2), frontline workers (n=2), physicians (n=1), medical school students (n=2), and researchers or app developers (n=1). Some resources targeted a specific mental health condition (eg, depression), while 13 resources focused broadly on mental health and e-mental health technologies.

As per the typology outlined by the Mental Health Commission of Canada (MHCC) [24], 5 resources reviewed and rated "computerized treatments, resources & apps," and 4 resources provided frameworks to conduct evaluations and reviews of these technologies. In addition, 3 resources provided implementation frameworks and guidance on integrating these technologies into clinical environments. These implementation frameworks were not limited to a single category within the typology.

The report from the MHCC [24] suggested that apps should disclose information related to the evidence base, cultural appropriateness, and gender responsiveness. For the 5 resources that provided app reviews, 4 of the sites included supporting evidence and 3 of the sites outlined privacy information about the apps. Although all tools are free to access, some tools reference apps that have a cost requirement, and these requirements are indicated in some tools (eg, Psyberguide). At last, only 2 of the sites provided data (eg, Practical Apps) about usability and user experience.

Phase 3: Engagement Workshop

A total of 14 participants from mental health organizations across Canada took part in the engagement workshop that was facilitated by 6 members (GS, DM, LC, HDS, AM, and JC) of the research team. The demographics of participants and facilitators in the engagement workshop are outlined in Table 2.

Table 2. Demographic characteristics of participants in the engagement workshop.

Category	Number of participants including facilitators (N=20), n (%)
Gender	
Female	16 (80%)
Male	4 (20%)
Province	
British Columbia	1 (5%)
New Brunswick	2 (10%)
Newfoundland	1 (5%)
Nova Scotia	2 (10%)
Ontario	13 (65%)
Quebec	1 (5%)
Role/contribution (multiselection)	
Clinician (eg, nurse, psychologist)	13 (65%)
Graduate trainee	4 (20%)
Indigenous perspective	1 (5%)
Person with lived experience	2 (10%)
Research personnel/expert	4 (20%)

In the first part of the exercise, the research team asked the participants, "What would make the worst toolkit ever?" Respondents suggested that accessibility barriers were an important consideration. Examples of accessibility barriers included a lack of "searchability" and poor user-friendliness of the resource guide itself. A document with too much text and use of jargon would make it difficult for the end-user to effectively integrate it into practice. In addition, respondents highlighted the need for making the resource a "living document" that does not contain outdated information and broken links. It was further noted that resources that are not culturally sensitive and not trauma-informed may also be dangerous for the end-user and can impede the value of the resource. Other factors discussed included a lack of a dissemination plan, discussion on privacy issues, and the absence of patients, families, or the community in the development of the resource guide.

The subsequent discussion aimed to address the challenges identified by exploring the questions "How could we prevent this from happening?" and "What would the best possible toolkit look like?" Participants made several suggestions including a focus on evidence-based development of the document, co-design with the audience, and development of a postdevelopment sustainability plan. It was indicated that the evidence-based development should be inclusive of the views and perspectives of intended end-users and include open-source links for readers to explore if they are interested. It was further suggested that the methodology of the resource guide be transparent in the resource document. Participants explained that the content of the resource document should also be inclusive of the different learning styles of individuals and manage the expectations of the reader (ie, relatively new field). With regard to the postdevelopment sustainability plan, participants suggested a "review cycle" where the materials would be revisited after a certain period of time to ensure up-to-date content. In addition, a follow-up/feedback loop with participants was encouraged to allow for continuous improvement of the resource document.

The afternoon session of the workshop focused on dissemination of the resource document. When participants were asked where they seek information on digital mental health tools, a variety of academic (eg, school) and professional (eg, regulatory college) organizations were listed. Other approaches included conferences, word of mouth, and the intranet of their employer. With regard to the challenges of implementing the resource document for uptake of digital mental health tools, there were concerns on the definition of the "toolkit" and who the target audience is. There was also discussion on how the scope of the toolkit may not be compatible with current structure of care systems. For example, some clinicians may not have a choice in deciding which tools would be made available to the patient, and the process would require engaging stakeholders across project management, clinical services, and privacy domains. It was also unclear if this resource document would be based on current principles of mental health care, such as the stepped care model [25]. Finally, some participants gave suggestions on delivering the contents of this document in other formats, such as a webpage as opposed to a static PDF document [20].

Phase 4: Development of the Resource Document

The findings from phases 1-3 of this project were used to develop the final iteration of the resource document (Multimedia Appendix 1) by the research team. The 45-page resource document [20] begins with background information on digital mental health tools and how various tools could be used to support the mental health needs of an individual. A set of questions were also developed to help guide a client's decision

on whether digital mental health tools are appropriate for their needs. The list of resources identified from phase 1 and 2 was then summarized in a chart by audience, format, language, country of origin, and whether the toolkit is specific to mental health. A summary of each of tool or document is subsequently provided. This summary includes additional information such as whether internet connection is required, if data is collected on the user, and the suitability of the resource for use during interaction with a client. The resource document concludes with a high-level overview of the project methodology.

Moreover, many suggestions and concerns from the engagement workshop (phase 3) were incorporated in the development of the final version of the resource guide. For example, the language used throughout the document was reflective of the suggestions of the stakeholders (eg, neutral, welcoming, and free of jargon) and brief instructions were provided at the beginning of the resource document to orient the end-user on usage of the document. The guide was also optimized for the search functionalities of the application.

Discussion

Principal Findings

Although digital mental health tools have gained significant traction and interest from patients, caregivers, family members, providers, and mental health organizations [26], uptake and integration of these technologies remain fairly poor across mental health care [8]. From the gray literature review (phase 1) and environmental scan (phase 2), a total of 25 resource guides that were relevant in supporting the uptake of digital mental health tools were identified. These resource guides were developed by various health care and mental health care organizations and targeted both patients and clinicians. Feedback on the delivery of these findings were identified from the engagement workshop with 14 participants. These findings collectively informed the development of the final resource document [20], which can be found in Multimedia Appendix 1.

In our experience, the use of a multimethod approach [13] provided a solid foundation for developing a document that aligns with the needs of the clients, caregivers, and end-users. Of the 25 resources that were identified, there was a relatively even spread of resources from the gray literature review (phase 1) and the environmental scan (phase 2). This demonstrates the importance and value of both sources as part of a comprehensive synthesis of tools or documents relevant to digital mental health tools. However, the absence of guidance on the delivery of the content can jeopardize the success of the project and lead to products that are not compatible with the needs of end-users [27]. Our engagement workshop (phase 3) was instrumental in engaging patients, clinicians and other relevant stakeholders in addressing this gap in guidance [27]. The application of the World Café [19] approach facilitated the consensus of opinions and perceptions throughout the workshop and provided great insight into how the resource document should be best delivered. Thus, the multimethod approach [13] is a valuable approach in consolidating the knowledge from each source to develop a relevant and timely resource document that is applicable for a variety of audiences.

This paper introduces a web-based resource guide [20] that our research team designed to foster the engagement of mental health patients and providers with digital mental health tools. This resource guide [20] is now publicly available for free and is expected to be used by both patients and practitioners in supporting the uptake of digital mental health tools. Patients and their caregivers may use this document to choose appropriate resources to guide the selection of a suitable app to meet their needs and requirements. In addition, using the questions that are listed on pages 9-11 of the resource document [20], individuals can also examine if digital mental health tools are appropriate and suitable for their needs, or if other (eg, in-person) interventions are necessary. Similarly, this resource guide will help providers and clinicians become acquainted and knowledgeable about the use of digital mental health technologies. In particular, providers may consider this resource document in speaking to patients and family members about the use of digital mental health tools as part of care [28]. Providers may also consider using this document as a means to guide the conversation and planning of which tools should be used and in what manner [29]. At a broader level, health care administrators may also use this newly developed resource to develop proper training and support for providers interested in using digital health tools in their practice.

During the development of the document, a number of evidence gaps were identified. Chiefly, the identified resources included in the resource guide fail to cover many of the technologies outlined in the MHCC typology [24]. As most of the published resources focused on mobile health apps, there is a lack of resources for other technologies such as virtual reality technology and robots [30-32]. Future work that focuses on the uptake of these emerging technologies would be useful [8]. Additionally, most of the resources are available in English only. Making the identified resources available in other languages, such as French, would be helpful [33], particularly given the abundance of French-speaking people in Canada. Similarly, none of the identified tools encompass other cultures, including indigenous perspectives, or address cultural appropriateness. Furthermore, given the emerging crisis of caregivers, future tools should explore the role of e-mental health technologies to support the needs of caregivers [34].

Although this resource document was developed prior to the COVID-19 pandemic, we expect that it will continue to be of value for supporting the ongoing mental health needs and demands during and beyond the pandemic. However, it is important to note that the pandemic has greatly accelerated the uptake of some digital mental health tools [35]. For example, many organizations have converted their delivery of outpatient or ambulatory care to telemental health visits (eg, using Zoom or Microsoft Teams) [28]. Some of these changes in practice have also led to the use of digital mental health tools, such as patient portals and mobile apps [36]. As part of the postdevelopment sustainability plan, it would be of value to synthesize the recent outputs from the use of digital mental health tools during the COVID-19 pandemic [37] to the current resource document.

Limitations

Although this resource guide has been developed with extensive input from gray literature and experts in the field, it has yet to be integrated into clinical workflows and refined by providers with experience using this resource with patients [8]. Additionally, the identification of relevant resources was limited to those available in the English language. Experts who participated in the engagement workshop and environmental scan were also all from North America. Exploring resources of other languages and consulting experts from other countries (eg, the United Kingdom) may provide insight into novel resources not identified here. Although, the findings from the engagement workshop were derived from a technique used to support consensus (World Café) [19], further validation of the findings (eg, member checking) [38] was not conducted with the participants of the group or with other participants. Moreover, the participants were not engaged during the review of the final iteration of the resource document. Thus, there is a need to evaluate the efficacy of the toolkit. Currently, it is unclear how the document may impact the uptake of digital mental health tools [8,26,39] (eg, patient–clinician relationship [40-44]), and examining the analytics and usage of these tools [45] may provide insights into this evidence gap.

Future Directions

This document is the product of a careful and meaningful synthesis of resources that encourage uptake of digital mental health tools, and future work should explore how these tools can be or have been integrated into clinical care pathways for mental health conditions (eg, depression). This may involve promoting and sharing the resource document across organizations that may be interested in the uptake of digital mental health tools. This may include the identified recommendations from the engagement workshop on expanding the delivery of the resource document to web-based approaches (eg, website, mobile app). It would also be useful to validate the findings from the resource document (eg, with other similar toolkits or documents) and to examine the efficacy of this resource document in addressing barriers and opportunities of digital mental health tools [38]. This can be conducted using a mixed methods approach [46] to incorporate both measurable outcomes and user experience. Moreover, at the solution level, identifying strategies to enhance uptake of emerging digital mental health tools is warranted. There remains a need to examine factors (eg, gamification [47]) that may relate to the engagement with digital mental health tools [8]. Finally, with regard to the recent events of the COVID-19 pandemic [35,37], it would also be useful to explore additional work and guidelines that are being developed during the pandemic and their impact on engagement with digital mental health tools, particularly concerning virtual care and telemental health [48,49].

Conclusions

This paper describes the development of a web-based resource guide that we designed to guide the uptake of digital mental health tools into the clinical environment through a multimethod approach. The document, which is available online for public use, includes a number of resources to guide the selection, implementation, and evaluation of digital mental health tools. Although these resources cover many objectives and audiences, there are disproportionately fewer resources available for emerging technologies like virtual reality. Moreover, the lack of resources designed for caregivers warrants further research. There is also a critical need to ensure that resources are inclusive of the needs of diverse cultures, including the First Nations, Inuit, and Métis people of Canada. Finally, future work should explore how this resource guide can be adopted and integrated into clinical environments.

Acknowledgments

Authors would like to sincerely thank all the stakeholders, participants, and topic experts who participated in the workshop and environmental scan during this project. This project was funded by Canada Health Infoway.

Authors' Contributions

GS contributed to the conceptualization of the study, methodology, formal analysis, investigation, supervision, project administration, and reviewing and editing of the manuscript. DM contributed to the conceptualization of the study, methodology, formal analysis, investigation, project administration, and the reviewing and editing of the manuscript. NT contributed to the conceptualization of the study and methodology. EM contributed to the conceptualization of the study and methodology. HDS contributed to the investigation, visualization, literature review, and the reviewing and editing of the manuscript. NS contributed to the conceptualization of the study and methodology. VS contributed to the literature review. JC contributed to the stakeholder workshop. BL contributed to methodology and the writing of the manuscript. LC contributed to the conceptualization of the study, methodology, and stakeholder workshop. AC contributed to the gap analysis, methodology, and stakeholder workshop. All authors gave final approval of the manuscript.

Conflicts of Interest

None declared.
